Maintenance Therapy, *Helicobacter pylori* Eradication, and Ulcer Recurrences Eradication of *H pylori* and maintenance therapy with H_2-receptor antagonists change the proportion of symptomatic to asymptomatic ulcer recurrences. Although the true incidence of asymptomatic ulcers in the general populace is unknown, 30% of endoscopically documented ulcer recurrences are asymptomatic in patients receiving placebo treatment. 644, 645 In contrast, 50% to 70% of ulcer recurrences are asymptomatic in patients receiving maintenance therapy with H_2-receptor antagonists. 638, 646, 647 Some reports indicate that many patients with duodenal ulcer have asymptomatic ulcer recurrences after eradication of *H pylori.* The risk of serious complications in patients with chronic PUD is 2% to 3% per year, with a lifetime risk that approaches 20%. 642, 648 Complications are the major cause of ulcer mortality. Most maintenance studies have been limited to 12 months or less and have had insignificant sample size for addressing whether long-term maintenance treatment reduces this complication rate significantly. Reviews of placebo-controlled maintenance trials demonstrate a low rate of complications in active-treatment and placebo-treatment groups, although complications are numerically higher in the latter. 638, 649, 650 Patients with prior ulcer complications have an twofold increased risk of subsequent complications. Retrospective assessment of long-term maintenance trials suggests that such patients have an extremely low complication rate on maintenance therapy. 638, 649, 650 In a prospective study of patients with a history of bleeding peptic ulcers, recurrent bleeding occurred in 3.5% of 28 patients who were deemed compliant with their maintenance regimen. Recurrent bleeding occurred in 26% of 39 patients deemed noncompliant with the maintenance treatment. 651 Studies suggest that eradication of *H pylori* may diminish the frequency of ulcer bleeding. Thus, the eradication of *H pylori* or maintenance treatment may decrease the long-term ulcer complication rate. The low rate of complications observed in placebo-treatment groups in maintenance therapy suggests that close patient follow-up may be important in decreasing ulcer complication rates, but more data are necessary to answer this important clinical question. The increased proportion of asymptomatic ulcers compared with symptomatic ulcers does not appear to pose an increased risk of silent ulcer complications. Asymptomatic ulcer recurrences discovered incidentally in maintenance trials are likely to undergo spontaneous healing without an increase in H_2-antagonist therapy, and they may have little clinical relevance. 645, 646 and 647 Because of the very low incidence of ulcer complications among patients receiving maintenance treatment, it is difficult to ascertain whether patients who develop complications are more likely to be asymptomatic.

Recommendations for Treatment of Recurrent Ulcers The appropriate management of recurrent PUD depends on the numerous factors outlined previously. Only broad, tentative recommendations are given here. First, *H pylori* should be eradicated, patients should be admonished to give up smoking, and, if possible, NSAIDs should be discontinued. Eradication of *H pylori* should be documented by endoscopic biopsy or breath testing 1 month after therapy has been discontinued. If patients are still *H pylori* positive, they should receive an additional course of anti– *H pylori* and ulcer therapy. The few patients with recurrent ulcer who are *H pylori* negative in the absence of NSAIDs and other cofactors should receive maintenance therapy for 2 years. Fasting serum gastrin levels should be obtained in patients with frequent relapses to exclude Zollinger-Ellison syndrome. Because of the amelioration of ulcer symptoms that occurs in some patients over time, maintenance therapy may be electively discontinued in patients without prior ulcer complications or serious medical illnesses after 1 to 2 years, and patients are then observed closely for ulcer recurrence. Patients who continue to have frequent recurrences despite *H pylori* eradication should continue maintenance treatment indefinitely. Proximal gastric vagotomy or other ulcer surgery should be performed in the patient with recurrent ulcer complications that occur despite continuous maintenance treatment or because of medical noncompliance. Otherwise healthy patients with frequent ulcer recurrences in the absence of *H pylori* who require high-dose H_2-antagonist or omeprazole for maintenance therapy with an annual cost of about $600 should be considered for proximal gastric vagotomy.

Management of Refractory Ulcers A small subset (5% to 10%) of ulcers remains unhealed despite conventional therapy; these are called *refractory ulcers.* Although the definition of refractory ulcers varies among investigators, it is defined for the purposes of this discussion as a duodenal ulcer that fails to heal after 8 weeks or a gastric ulcer that fails to heal after 12 weeks of therapy. These ulcers pose a significant management problem, because they are more difficult to heal and because they generally have a high rate of early relapse. They are the subject of several reviews. [652], [653]

Factors contributing to refractory ulcer. Several factors may be important in the development of refractory ulcers: noncompliance, inadequate suppression of gastric acid, *H pylori* infection, and incorrect diagnosis. In clinical practice, an actual cause of refractoriness is seldom identified. [653] The most important causes of delayed healing are discussed in this section. Patients commonly stop taking their medications after their pain is improved. All patients with nonhealing ulcers should be asked about medical compliance before proceeding with further medical workup. In a series of 35 patients with refractory ulcers, 100% of patients had detectable serum salicylate levels, although more than 50% denied aspirin ingestion. [654] In a more recent study, NSAID use was found in 40% of patients with refractory ulcers (out of 60 patients), with 43.7% of the cases being surreptitious. [655] The history of NSAID ingestion should be elicited from all patients with refractory ulcers. Surreptitious aspirin ingestion may be uncovered by questioning family members or by measuring serum salicylate levels. Although platelet COX inhibition may be a more sensitive assay for detecting NSAID ingestion, this is not available in most clinical settings. [656] Smoking is an important risk factor for refractory ulcers. Patients should be strongly counseled to discontinue tobacco use. [657] Gastric acid hypersecretion has been detected by some investigators in patients with refractory duodenal ulcers. [652], [653] In a prospective study by Collen and associates [658] of 75 patients with duodenal ulcer, the mean basal acid output was 20.0 mEq/h among 20 patients with nonhealing ulcers at 8 weeks, compared with 6.6 mEq/h among the healed ulcer patients. It is likely that acid hypersecretion contributes to refractory duodenal ulcers in a subset of patients. The overlap of gastric acid secretion between groups with and without refractory ulcers is so great that measurement of gastric acid secretion is seldom useful in evaluating refractory duodenal ulcers or guiding therapy. Acid hypersecretion resulting from Zollinger-Ellison syndrome is a rare cause of refractory duodenal ulcers but should be excluded with a fasting serum gastrin level or a secretin stimulation test. In studies of H_2-receptor antagonist therapy lasting as long as 4 weeks, some degree of tolerance appeared to develop to these agents. [656], [659], [660] The antisecretory effect of H_2-receptor antagonists demonstrated on the first day of therapy diminishes with time. Tolerance is not observed with PPIs. [661] The mechanisms by which tolerance may occur are unclear but may include up-regulation of the histamine H_2-receptor and secondary hypergastrinemia, which could lead to increased basal and meal-stimulated acid secretion. [662] Because of the outstanding efficacy of H_2-receptor antagonists in treating acute peptic ulcers, tolerance to these drugs appears to be of little clinical significance for most patients with ulcers. [659], [661] The importance of tolerance in patients with ulcers that are refractory to standard doses of H_2-receptor antagonist therapy has not been studied. Most patients with refractory duodenal and gastric ulcers are infected with *H pylori.* For patients who do not have evidence of *H pylori*–associated gastritis, attention should be directed to other causes of peptic ulceration, including NSAIDs and acid hypersecretory conditions. An underlying gastric malignant disease may masquerade as a chronic nonhealing ulcer, and biopsies should be performed from the ulcer margin of all nonhealing gastric ulcers. There are several reports of malignant gastric ulcers that have undergone complete healing with initial H_2-receptor antagonist therapy. [662], [663] Although such events are rare, physicians should not assume that partial or even complete healing is proof of the benign nature of an ulcer. Unusual causes of chronic ulceration include Crohn's disease, amyloidosis, sarcoidosis, eosinophilic gastroenteritis, lymphoma, ischemia, and infections such as tuberculosis, syphilis, and cytomegalovirus. Biopsies should be obtained from duodenal and gastric nonhealing ulcers to exclude these conditions.

Evaluation and treatment of refractory ulcers. In managing the patient with a refractory peptic ulcer, it is important to verify patient compliance with the medication regimen. All patients should be admonished to discontinue smoking, and a careful inquiry should be made into possible NSAID ingestion. Upper endoscopy should be performed to confirm a nonhealing ulcer. Biopsies of the duodenal or gastric ulcer should be performed to exclude malignancy and other nonpeptic causes of ulceration. Biopsies of the gastric antrum or breath tests need to be obtained to assess *H pylori* status. A serum gastrin level should be measured to exclude Zollinger-Ellison syndrome. Gastric acid secretory studies are occasionally required. Regardless of the underlying pathophysiological mechanism, other than the patient's harboring *H pylori,* a marked reduction in gastric acid secretion usually results in healing of most refractory duodenal ulcers. Of the ulcers that are unhealed after 8 weeks of standard H_2-receptor antagonist therapy, approximately 50% to 60% heal with an additional 8 weeks of H_2-receptor antagonist therapy. [652], [653] The PPIs omeprazole (40 mg/d) and lansoprazole (30 to 60 mg/d) produce healing in more than 90% of refractory duodenal ulcers after 8 weeks of therapy. [653], [664] There have been multiple controlled, prospective trials using patients with refractory duodenal ulcers to compare continued or high-dose H_2-receptor antagonist therapy with omeprazole treatment. These trials demonstrated convincingly the superiority of 40 mg of omeprazole each day over H_2-receptor antagonists for the treatment of refractory duodenal ulcers. However, 20 mg of omeprazole daily appears to be an inadequate dose for the treatment of many patients with refractory ulcers. There is a dearth of information regarding the efficacy of antisecretory regimens for refractory gastric ulcers, because nonhealing gastric ulcers have generally been regarded as an indication for elective surgery to exclude occult malignant disease. [665] The few available studies report healing in more than 90% of refractory gastric ulcers after 8 weeks of treatment with PPIs. Potent antisecretory therapy has decreased the number of truly refractory ulcers that require surgery. Several centers have reported a higher ulcer recurrence rate after proximal gastric vagotomy in patients with refractory duodenal ulcers. The responsiveness of these postsurgical ulcers to medical therapy may be poor. The role of this surgical procedure in refractory duodenal ulcers compared with other surgical procedures that carry higher associated morbidity rate requires clarification. [653], [666]

Recommendations. Almost all refractory ulcers can be healed with omeprazole (40 mg/d). Because of the outstanding efficacy and short-term safety of this drug, it is recommended as the drug of choice for refractory ulcers. Similar results may also be achieved with all PPIs. Alternative therapies are less effective. A larger problem in the treatment of refractory ulcers is frequent, early ulcer recurrence. For patients who are *H pylori* positive, eradication therapy should be given in an attempt to prevent ulcer recurrences. Some patients with refractory ulcers may be *H pylori* negative, and eradication therapy may be unsuccessful for others. Maintenance therapy with full-dose or half-dose nocturnal H_2-receptor antagonists yields a 1-year symptomatic recurrence rate of 50% to 70%, approximately double the rate for other patients with ulcers. Omeprazole (40 mg/d) appears to be extremely effective in maintaining remission in limited trials, but a dose of 20 mg/d is less effective. [667] The risks and benefits of long-term omeprazole with surgery must be carefully weighed for these patients.

CHAPTER 67

John Del Valle and James M. Scheiman

ZOLLINGER-ELLISON SYNDROME

“Fortunate indeed is the surgical service that does not have one or more problem cases of recurrent marginal ulceration despite the adequacy of the surgical attack,” noted the opening sentence of Zollinger and Ellison’s landmark description of the syndrome that today bears their names. [1] Benign ulceration of the upper jejunum associated with extremely high gastric acid secretion and the presence of a non–ß-cell adenoma of the pancreas was the triad of clinical findings described in two patients who eventually required total gastrectomy for relief of their severe ulcer disease. Although earlier reports [2], [3] described a similar clinical situation, it was Zollinger and Ellison who hypothesized that the components of this clinical triad were intimately related and were produced by a humoral agent that induced gastric acid hypersecretion and its sequelae. This hypothesis was confirmed by Gregory and colleagues, [4], [5] when they established that the tumor extract from a patient with Zollinger-Ellison syndrome contained a substance that was chemically and physiologically indistinguishable from the antral hormone gastrin.

Subsequent development of a sensitive and specific radioimmunoassay for gastrin [6], [7] facilitated the measurement of this peptide in the sera of patients with Zollinger-Ellison syndrome and confirmed that their circulating gastrin concentrations exceeded by severalfold the plasma levels found in a normal control population. This sensitive assay also permitted earlier tumor detection, a circumstance that has led to a steady increase in the number of patients described with gastrinoma. Potent inhibitors of gastric acid secretion and sophisticated preoperative and intraoperative diagnostic procedures have transformed Zollinger-Ellison syndrome from an illness for which total gastrectomy and tumor progression were the normal course to a condition for which a cure is feasible in many patients.

EPIDEMIOLOGY

The true incidence and prevalence of Zollinger-Ellison syndrome are unknown. The estimated incidence has ranged from 0.1% to 1% of patients who present with peptic ulcer disease in the United States. [8] The heterogeneous clinical manifestations, the widespread use of proton pump inhibitors (PPIs) for the treatment of acid peptic disease and its sequelae, [9] and the high incidence of silent pancreatic endocrine neoplasms [10] have all contributed to an underestimation of the incidence and prevalence of Zollinger-Ellison syndrome. The age range of affected persons has varied from 7 to 90 years, with the majority of patients diagnosed between the age of 30 and 50 years. Men with the disorder predominate over women by ratios varying from 2:1 to 3:2. [8], [11], [12]

Gastrinomas can be subdivided into tumors that are sporadic [13] and those that are genetically transmitted and associated with *multiple endocrine neoplasia type I* (MEN I). [14] Sporadic gastrinomas, the more common of the two, frequently behave as malignant tumors. Zollinger-Ellison tumors associated with MEN I occur at an earlier age than the sporadic tumors and have been characterized by some investigators to follow a more benign course. There are various distinguishing features between these two subtypes, as discussed later in this chapter.

PATHOPHYSIOLOGY

Gastric acid hypersecretion and severe peptic ulcer diathesis secondary to unbridled release of gastrin from a non–ß-cell endocrine neoplasm are the essential elements leading to Zollinger-Ellison syndrome. The neoplastic pancreatic cells secreting gastrin are thought to arise from the ductular epithelium and not from cells of the islets of Langerhans, despite the appellation of gastrinomas as “islet cell tumors.” [1] Normally, the adult pancreas does not secrete gastrin, but the fetal pancreas contains large quantities of this peptide. [15] After birth, the gastrin-secreting cells in the pancreas disappear and are not seen again, except as benign or malignant neoplasms in Zollinger-Ellison syndrome. The hypergastrinemia that results from the release of peptide from an endocrine neoplasm free of the usual regulatory restraints has two synergistic effects: overstimulation of gastric parietal cells to secrete acid and increased mass of parietal cells susceptible to overstimulation. The potentiated gastric acid hypersecretion that results is presumably the cause of the clinical manifestations (i.e., acid peptic disease and diarrhea) of the gastrinoma syndrome.

In contrast to many of the common malignant diseases, such as those originating in the pancreas, colon, or breast, gastrinomas are not associated with alterations in classic oncogenes such as *ras, myc, fos,* and *src* or with tumor suppressor genes such as *p53* or retinoblastoma susceptibility gene (*Rb*). [16] Despite this observation, studies reveal that 16% to 40% of sporadic gastrointestinal neuroendocrine tumors express mutations in the *MENI* gene, which is found to be defective in patients with MEN I. This is a 10-exon gene found in chromosome 11q13, [17], [18], [19] and [20] as further described later in this chapter.

Goebel and colleagues [21] attempted to correlate mutations of the *MENI* gene with clinical characteristics in 51 patients with sporadic gastrinoma. This study revealed that 31% of the tumors had a mutated *MENI* gene. Of interest, one mutation appeared to be clustered between a fairly narrow region (amino acids 61 to 166), a finding different from that seen in MEN I–related gastrinomas, in which the mutations occur throughout the gene. The presence of a mutation in the *MENI* gene did not appear to be useful as a marker for predicting patient outcome at an early stage of disease.

Additional studies have demonstrated a series of genetic alterations in gastrinomas including methylation and deletion of the *p16/MTS1* tumor suppressor gene, [22] amplification of the *HER-2/neu* protooncogene, [23] amplification of chromosome 9q, [24] and deletion of chromosome 1 [25], [26] or 3p. [24], [25], [26] and [27] More recently, Yu and colleagues [27] performed a detailed survey of genetic alterations in eight sporadic gastrinomas. Although the number of tumors was small, these investigators implied that important molecular features of gastrinomas include defects in chromosome 1, aneuploidy, and mismatch repair defects and deletions in the *MENI* gene. Serrano and colleagues [28] determined that alterations (hypermethylation of the promoter) in the tumor suppressor gene *p16INK4a/CDKN2A (p16INK4a)* was present in more than 50% of gastrinomas, independent of tumor extent. This genetic alteration is the most common one found in gastrinomas to date and suggests that changes in this gene may be an early event in its development. Although posttranslational processing variants of gastrin have been described in patients with gastrinoma, [29], [30], [31] and [32] the clinical relevance of this finding has not been established.

TUMOR DISTRIBUTION

More than 80% of gastrinomas have been localized in the anatomic area known as the *gastrinoma triangle.*[33] The boundaries of this triangle include the confluence of the cystic and common bile ducts superiorly, the junction of the second and third portions of the duodenum inferiorly, and the junction of the neck and body of the pancreas medially. The most common extrapancreatic site is the duodenum,[34] wherein up to 40% to 50% of gastrinomas arise.[35], [36] and [37] Other less common extrapancreatic sites include the stomach, bones, ovaries, liver, heart, and lymph nodes, which together account for fewer than 10% of gastrinomas.[38], [39] and [40] More than 50% of gastrinomas are considered to be malignant. Solitary pancreatic lesions were found in fewer than 30% of the earliest reported patients with gastrinoma.[11] With the trend toward earlier measurement of serum gastrin and exploratory surgery,[41] the incidence of metastatic disease at the time of operation has decreased. Nevertheless, multiple tumors or metastatic lesions are still observed in 30% to 55% of patients at the time of diagnosis.[35], [37]

The morphology of the neoplastic cells in gastrinomas is heterogeneous.[42], [43] The gastrin-producing cells are generally well differentiated and contain histological markers characteristic of endocrine neoplasms in general; that is, they contain chromogranin, neuron-specific enolase, and tyrosine hydroxylase. The degree of malignancy does not appear to correlate with a gastrinoma's histological appearance; however, this observation must be tempered by the knowledge that tumor aggressiveness is usually determined retrospectively.

As in the case with other endocrine neoplasms, gastrinomas have been found to express a variety of neuroendocrine peptides besides gastrin, including somatostatin, pancreatic polypeptide, adrenocorticotropic hormone, and vasoactive intestinal polypeptide. Although the clinical manifestations are generally associated with overproduction of one hormone, case reports illustrating combined syndromes have been described.[44], [45], [46], [47] and [48] Of these, Cushing syndrome in association with gastrinoma is the mixed syndrome most frequently described.[49], [50]

CLINICAL MANIFESTATIONS

More than 90% of patients with gastrinoma develop ulcers in the upper gastrointestinal tract at some point during the disease.[11], [12] and [13] Presenting ulcer symptoms are indistinguishable from those associated with benign peptic ulcer disease, but frequently they are less responsive to standard therapy. As in benign peptic ulcer disease, ulcers in patients with Zollinger-Ellison syndrome occur most frequently in the first portion of the duodenum (75%), and they are usually solitary. However, ulcers in patients with gastrinoma also may occur in the second, third, and fourth portions of the duodenum (14%), as well as in the jejunum (11%).[12] The ulcers are usually less than 1 cm in diameter but can occasionally present as giant lesions. Peptic ulcer disease refractory to standard medical therapy, recurrent ulcers after prior gastric surgery, diarrhea in patients with ulcers, or peptic disease presenting with complications such as obstruction, perforation, or bleeding suggest a possible diagnosis of Zollinger-Ellison syndrome. Esophageal symptoms caused by acid reflux are seen in as many as two thirds of patients with Zollinger-Ellison syndrome.[51], [52] The disease found in the esophagus may range from mild to severe esophagitis complicated by stricture formation and Barrett mucosa.

Diarrhea is the other common feature of Zollinger-Ellison syndrome; it can be present in more than half of patients, and it may precede the diagnosis by many years and occur in the absence of peptic ulcer symptoms.[11], [13], [53], [54] The pathogenesis of diarrhea is likely multifactorial, but its dependence on acid hypersecretion is demonstrated by amelioration of symptoms on continuous nasogastric suction or inhibition of acid secretion.[8], [55] Added features of the diarrhea are steatorrhea and maldigestion,[56], [57] which result from the inactivity of pancreatic enzymes at the low pH of the duodenum caused by the excessive acid load. The acidic pH of the small bowel also may lead to damage of the intestinal mucosa, resulting in a spruelike state with flattened intestinal villi and accompanying malabsorption.[58] Bile acids are poorly soluble in an acid milieu; thus, Zollinger-Ellison syndrome may result in decreased micelle formation and subsequent malabsorption of vitamin B 12 and other lipid-soluble nutrients and vitamins.[56] It is possible that in the presence of markedly high serum gastrin levels, gastrin itself may increase secretion of potassium and may reduce absorption of sodium and water by the small intestine,[59], [60] thus potentially leading to secretory diarrhea. Secretory diarrhea also may occur in Zollinger-Ellison syndrome in association with the secretion of another hormone besides gastrin, such as vasoactive intestinal polypeptide.

Twenty-five percent of patients with gastrinoma have MEN I syndrome.[14] The primary sites of organ involvement in this autosomal-dominant genetic disorder include the parathyroid, pancreas, pituitary, and, less commonly, adrenal cortex and thyroid. In a large series by Ballard and colleagues,[61] 87% of 85 patients with MEN I had involvement of the parathyroid glands, 81% had disorders of the endocrine pancreas, and 65% had pituitary involvement. Trump and colleagues[62] reported their findings in 220 patients with MEN I and observed different rates of organ system involvement, with 95%, 41%, and 30% of patients having parathyroid, pancreatic, and pituitary neoplasms, respectively. This later study also confirmed that parathyroid lesions were the first indication of this genetic disorder in 87% of patients. The clinical features of Zollinger-Ellison syndrome (ulcer complications, gastric or pancreatic surgery) account for the major morbidity and mortality related to MEN I.[63] The first clinical manifestation of MEN I may be Zollinger-Ellison syndrome in up to one third of patients, a finding suggesting that patients with the presumptive diagnosis of sporadic Zollinger-Ellison syndrome be monitored biochemically and, when feasible, genetically screened for evidence of MEN I.[64] Others recommend an oral calcium tolerance test to exclude early evidence of hyperparathyroidism and MEN I.[65]

The genetic defect in patients with MEN I has been mapped to the long arm of chromosome 11 (11q11-q13) by analysis of restriction fragment length polymorphism in affected families.[62], [63] As outlined earlier, the *MENI* gene consists of 10 exons and expresses the protein menin. Menin is a nuclear protein of 610 amino acids in length and is expressed widely throughout the body and functions as a tumor suppressor gene.[66] It interacts with Jun D an AP-1 transcription factor and with a protein involved in cell growth, SMAD-3.[67], [68]

Hyperparathyroidism and the associated hypercalcemia have direct bearing on the gastric acid hypersecretory state found in patients with Zollinger-Ellison syndrome and MEN I. Intravenous infusion of calcium in healthy human volunteers induces gastric acid hypersecretion, and calcium has been shown both in vivo[69] and in vitro[70] to stimulate gastrin release directly from gastrinomas. Moreover, gastrinomas express the calcium-sensing receptor,[71] thus explaining the mechanism by which calcium leads to gastrin release from these tumors. Indeed, previous reports[72], [73] have demonstrated that resolution of hypercalcemia by parathyroidectomy reduces basal acid output (BAO) and fasting serum gastrin concentrations in patients with gastrinoma with MEN I.

One consequence of prolonged hypergastrinemia in patients with Zollinger-Ellison syndrome with MEN I is the development of primary gastric carcinoid tumors. In a review of these data from the National Institutes of Health (NIH), Jensen[74] reported that 13% of patients with Zollinger-Ellison tumors with MEN I developed gastric carcinoids. Similar tumors have been noted previously in patients with achlorhydria and hypergastrinemia,[75] as well as in rats made hypochlorhydric and hypergastrinemic with potent antisecretory agents such as omeprazole. These findings presumably arise from the action of gastrin to induce cellular proliferation. However, gastrin may not be the only cause of the carcinoids, inasmuch as in Jensen's NIH series[74] only 0.6% of patients with sporadic Zollinger-Ellison tumors developed carcinoids. In support of the hypothesis that hypergastrinemia alone is not sufficient to promote enterochromaffin-like cell gastric carcinoid tumor development, it was observed that 75% (15 of 20 patients) of Zollinger-Ellison syndrome–related gastric carcinoid tumors had loss of heterozygosity at the *MENI* gene loci (11q13).[76] Therefore, it is postulated that the enterochromaffin-like cell carcinoid is an independent tumor type of MEN I, sharing a similar pathogenesis by inactivation of the *MENI* gene.

Once a secretory endocrine tumor is diagnosed, patients with MEN I should be evaluated carefully for the presence of other endocrinopathies. A thorough medical and family history must be obtained. Diagnostic studies should include evaluation of visual fields, fasting blood glucose, serum calcium, and prolactin levels. If there is suspicion of a pituitary lesion, a computed tomography (CT) or magnetic resonance imaging (MRI) scan of the head should be considered. MEN I is an autosomal-dominant disorder with a high degree of penetrance. Children of these patients have an approximately 50% risk of developing this disorder by 20 years of age[77]; thus, genetic counseling and screening of family members are imperative. In a study evaluating a large kindred (221 members) of patients with MEN I, elevated albumin-adjusted calcium, parathyroid hormone, gastrin, and prolactin (in girls and women) were the most frequently encountered laboratory abnormalities among presumed carriers of the *MENI* gene.[78] Trump and colleagues[62] evaluated 709 members of 62 families with MEN I and developed a screening program based on their observations (Fig. 67-1). The genetic defect in MEN I can be used to develop predictive testing for this syndrome[66], [79], [80] and can eventually serve as the basis for informed genetic counseling in families with MEN I.

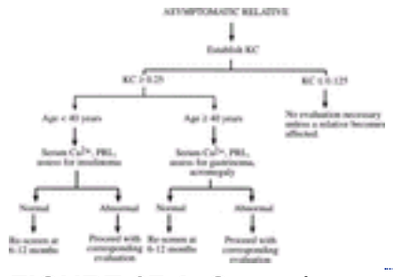

FIGURE 67-1. Screening protocol for relatives of patients with multiple endocrine neoplasia type I. *KC* refers to the coefficient of kinship, in which known affected individuals were assigned a KC of 1.0. Asymptomatic first-degree relatives (siblings, children) were assigned a KC of 0.5, and asymptomatic second-degree relatives (grandchildren, nephews, nieces) were assigned a KC of 0.25. Spouses were also screened and were assigned a KC of 0. (Adapted from ref. [62].)

A consensus statement for genetic screening and follow-up of patients with MEN I and their family members has been published. [81] These authors recommended that mutation analysis of the *MENI* gene be performed in patients meeting the following criteria: newly diagnosed neuroendocrine tumor typically found in MEN I (primary hyperparathyroidism, pancreatic endocrine tumor, or pituitary adenoma); age less than 40 years; positive family history; recurrent or multifocal neoplasia; or involvement of two or more organ systems. It is also recommended that genetic screening be performed in early adolescence of first-degree relatives of patients with MEN I. Persons carrying the *MENI* mutation should undergo annual biochemical screening, as outlined earlier.

DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC STUDIES

The various clinical circumstances in which a serum gastrin level should be obtained because of a suspected gastrinoma are outlined in Table 67-1. Fasting serum gastrin levels in healthy persons and in patients with routine peptic ulcer disease are usually less than 150 pg/mL. [82] The degree of hypergastrinemia in patients with Zollinger-Ellison syndrome varies greatly. Although occasional reports of normal levels, [83], [84] and values that vary from day to day, [85], [86] have been described, virtually all patients with gastrinoma have fasting levels greater than 150 pg/mL, with levels exceeding 100,000 pg/mL in some patients. A serum gastrin level greater than 1000 pg/mL in the right clinical setting is virtually diagnostic of Zollinger-Ellison syndrome; however, many patients do not have this level of hypergastrinemia. Elevated serum gastrin levels are seen in certain other clinical conditions as well (Table 67-2).

Multiple ulcers
Ulcers in unusual locations
Ulcers associated with severe esophagitis
Ulcers resistant to therapy, with frequent recurrences
Ulcer patients awaiting surgery
Extensive family history of peptic ulcer disease
Postoperative ulcer recurrence
Basal hyperchlorhydria
Unexplained diarrhea or steatorrhea
Hypercalcemia
Family history of pancreatic islet, pituitary, or parathyroid tumor
Prominent gastric or duodenal folds

TABLE 67-1 When to Obtain a Serum Gastrin Determination in Patients with Peptic Ulcer

Hypochlorhydria or achlorhydria with or without pernicious anemia
Retained gastric antrum
G-cell hyperplasia
Renal insufficiency
Massive small bowel resection
Gastric outlet obstruction
Other conditions (rheumatoid arthritis, vitiligo, diabetes, pheochromocytoma)

TABLE 67-2 Hypergastrinemia: Differential Diagnosis

Chromogranin A is a glycoprotein constituent of the secretory granules found in many neuroendocrine cells, [87] and as such it has been used as a histological and serologic marker for neuroendocrine tumors. [88], [89] and [90] Although serum gastrin and chromogranin A were found to be sensitive indicators for the presence of a gastrinoma, the latter had a relatively low specificity (67%). [90] Moreover, neither of the markers correlated with tumor growth or extent. However, it was observed in one patient that a rise in chromogranin A levels, which may reflect the extent of tumor and not enterochromaffin-like cell hyperplasia. This possibility requires further study.

With the ever-increasing use of potent antisecretory agents such as long-acting H_2 receptor antagonists and PPIs, drug-induced hypergastrinemia [91] must be excluded before proceeding with an extensive diagnostic evaluation for Zollinger-Ellison syndrome. The level of hypergastrinemia is reversible with drug cessation and is usually less than 1.5 to 2 times normal levels. Many patients with *Helicobacter pylori* infection and peptic disease develop hypergastrinemia and gastric acid hypersecretion, [92] which are reversible with eradication of the organism. The potential for *H pylori* infection to mimic the clinical and biochemical picture of Zollinger-Ellison syndrome was illustrated in a report [93]; thus, careful search and eradication of *H pylori* are mandatory in any patient with peptic ulcer disease before one considers a diagnosis of gastrinoma.

The most common cause of hypergastrinemia is gastric atrophy. [94] Gastric acid is the primary inhibitor of gastrin release; therefore, its absence leads to uninhibited secretion of the hormone with concomitant hyperplasia of antral G cells and hypergastrinemia as observed in pernicious anemia. [95], [96], [97], [98], [99], [100], [101] and [102] Up to 75% of patients with pernicious anemia have substantial hypergastrinemia. The gastrin levels in these patients can approximate those found in patients with gastrinoma, reaching values greater than 1000 pg/mL. Chronic atrophic gastritis and gastric carcinoma are two other conditions associated with hypochlorhydria or achlorhydria and hypergastrinemia. [98] Additional important causes of hypergastrinemia are outlined in Table 67-2.

To differentiate among the many causes of hypergastrinemia, various provocative tests [103], [104], [105], [106], [107], [108], [109], [110] and [111] have been developed (Table 67-3). The *secretin test,* initially developed by Isenberg and associates, [105] has proved to be the easiest and most reliable study to perform. Secretin can induce a significant early increase (albeit low) of serum gastrin levels in a few healthy persons and in patients with common duodenal ulcer disease, [110] but rarely in persons with achlorhydria. [111] The mechanism by which secretin stimulates release of gastrin from endocrine neoplasms is unclear. [70], [112], [113] and [114]

TABLE 67-3 Gastrin Provocative Testing

Unfortunately, naturally occurring purified porcine secretin is no longer available in the United States. Both porcine secretin and human synthetic secretin have been synthesized and are being considered by the United States Food and Drug Administration for clinical use. A randomized controlled crossover study of six patients with confirmed gastrinoma found that the synthetic secretin preparations could be used to confirm the presence of a gastrinoma. [115] Based on several studies composed of small numbers of patients, various criteria for establishing the positivity of a secretin provocative test have been proposed, including increases in serum gastrin of 100 pg/mL, 200 pg/mL, or 50% above basal levels. Frucht and colleagues [116] observed that the secretin test was found to be positive in 87% to 93% of all patients with

Zollinger-Ellison syndrome (80 patients) and proved to be more advantageous than the calcium infusion study (see later) because of its greater sensitivity, shorter sampling time, ease of performance, and lack of side effects. The parameter recommended by these authors for establishing a diagnosis of Zollinger-Ellison syndrome was an increase in serum gastrin of 200 pg/mL or greater. The false-positive secretin test results reported in other studies [116], [117] were not seen with these criteria. These same criteria may also apply to the synthetic secretin preparation, but this needs to be confirmed in a large-scale trial.

The less commonly employed provocative test is the *calcium infusion study.* More than 80% of patients with gastrinoma demonstrate an increase in gastrin levels of more than 400 pg/mL during the third hour of calcium infusion. As outlined earlier, lack of specificity, diminished sensitivity, and the potential adverse effects of administering intravenous calcium have made this provocative test less useful than the secretin test in diagnosing Zollinger-Ellison syndrome. It is usually reserved for patients with a negative secretin test in the presence of gastric acid hypersecretion and a strong clinical suspicion of gastrinoma. [116]

Standard meal studies have been employed to distinguish hypergastrinemia of gastric origin (as in G-cell hyperplasia or hyperfunction) from that of pancreatic origin (gastrinoma). Patients with Zollinger-Ellison syndrome may have less than a 50% increase in serum gastrin in response to a meal, and a postprandial increase in serum gastrin of more than 100% is characteristic of G-cell hyperplasia or hyperfunction. However, the studies of Frucht and associates [118] suggest that 50% of patients with Zollinger-Ellison syndrome have a greater than 50% postprandial increase in serum gastrin.

The net effect of hypergastrinemia is increased gastric acid secretion; thus, it is not surprising that a (BAO) of 15 mEq/h or greater is found in as many as 90% of patients with gastrinoma. [54], [86], [119], [120] and [121] However, 12% of patients with common duodenal ulcer disease can manifest similar levels of acid secretion. BAO of greater than 5 mEq/h is found in 55% of patients with Zollinger-Ellison syndrome, even after surgery. [119] The widespread use of potent anti secretory agents such as the PPIs further accentuates this problem. In fact, a study by Corleto and colleagues [9] suggests that the use of PPIs may mask Zollinger-Ellison syndrome, thus leading to delay in establishing this diagnosis. To enhance the sensitivity of the gastric secretory studies, *maximal acid output* (MAO) values may also be measured. Patients with gastrinoma are presumed to have near-maximal secretion of gastric acid even under basal conditions; thus, the acid secretory response to exogenously administered secretagogue (pentagastrin) is diminished. Accordingly, a ratio of BAO to MAO greater than 0.6 is highly suggestive of Zollinger-Ellison syndrome, [8] although a ratio of less than 0.6 does not exclude the diagnosis. [53], [86], [119] Unfortunately, pentagastrin is no longer available in the United States, making measurement of MAO virtually impossible. The other secretagogue used in gastric secretory studies was Histalog, which has been off the market for several years. Metz and Starr [122] observed that measurement of MAO had a small but significant benefit compared with measuring BAO alone.

There has been controversy over the utility of gastric analysis in view of the sensitivity and specificity of serum gastrin values with or without secretin stimulation. Investigators at the NIH performed the most exhaustive analysis to date of the role of gastric secretory studies in Zollinger-Ellison syndrome. [123] They prospectively examined 235 patients and reviewed 984 cases in the literature in an effort to delineate the potential role of gastric secretory studies in determining a diagnosis, clinical expression, and tumor extent. These authors observed that diarrhea, esophageal stricture, and pyloric scarring were associated with a higher BAO. It did not appear that the level of acid hypersecretion correlated with other clinical characteristics including tumor extent or size, primary tumor location, or other signs and symptoms in patients with gastrinoma. A summary of the recommendations made for measurement of gastric acid secretion in patients with Zollinger-Ellison syndrome is presented in Table 67-4. Under optimal circumstances, acid secretory studies should be part of the diagnostic evaluation in patients suspected of having gastrinomas. If the equipment needed for this test is not available, a simple basal gastric pH determination of greater than 3 essentially rules out the diagnosis of Zollinger-Ellison syndrome.

1. Secretory criteria for patients with no prior gastric acid–reducing surgery
   1.1. BAO ≥ 15 mEq/h
   1.2. BAO ≥ 18 mEq/h, in patients with known sporadic form
   1.3. No pH criterion useful for diagnosis
   1.4. BAC/MAC ratio ≥0.6
   1.5. Basal gastric volume >160 mL/h
   1.6. No MAO criterion useful
2. Patients with prior gastric acid–reducing surgery
   2.1 BAO ≥5 mEq/h
   2.2 No pH criteria useful for diagnosis
   2.3 BAC/MAC ratio ≥0.6
   2.4 BAO/MAO ratio >0.6
   2.5 Basal gastric volume >140 mL/h
   2.6 No MAO criterion alone useful
3. In hypergastrinemic patients, if pH >2, patient rarely has ZES
4. Acid measurements required only for 30 min

*All values refer to acid measurements made by nasogastric secretion with the patient not taking any gastric antisecretory medications (off proton pump inhibitors ≥1 wk; oral histamine H_2-receptor antagonists ≥48 h; intravenous histamine H_2-receptor antagonists ≥12 h).

BAC, basal acid H^+ concentration; BAO, basal acid output; MAC, maximal acid H^+ concentration; MAO, maximal acid output; ZES, Zollinger-Ellison syndrome.

Adapted from ref. 123.

TABLE 67-4 Recommendations for Measurement of Gastric Acid Secretion for the Diagnosis of Zollinger-Ellison Syndrome*

In summary, no single diagnostic test has a sensitivity or specificity of 100% in evaluating patients for Zollinger-Ellison syndrome. A fasting gastrin level greater than 1000 pg/mL and a BAO greater than 15 mEq/h in a patient with recalcitrant peptic ulcer is virtually diagnostic of Zollinger-Ellison syndrome. In the absence of this triad of findings, provocative testing may be required. Of these, the secretin stimulation test offers the greatest sensitivity and specificity.

TUMOR LOCALIZATION

Gastrinomas are notoriously difficult to localize. Case series of patients who eventually underwent surgery for Zollinger-Ellison syndrome before the 1990s noted the inability to identify the tumor in approximately 30% to 50% of patients, with more than 20% having metastatic disease at laparotomy. [35], [124], [125], [126], [127] and [128] More recent series, perhaps reflecting improvements in preoperative imaging modalities, have localized tumor in 85% of cases, although metastatic disease is frequently present (~50% of patients). Early intervention with resection of a localized tumor presents the only opportunity to cure this disease. [127], [128], [129] and [130] In addition, preoperative detection of metastatic disease will prevent unnecessary surgery. Accordingly, every effort should be made to localize the tumor preoperatively. A diagnostic plan for localizing gastrinomas in patients with Zollinger-Ellison syndrome is depicted in Figure 67-2.

FIGURE 67-2. Diagnostic plan for localizing gastrinomas in patients with Zollinger-Ellison syndrome. *CT,* computed tomography; *MRI,* magnetic resonance imaging;

EUS, endoscopic ultrasound; *EGD,* esophagogastroduodenoscopy; *R/O,* rule out; *SASI,* selective arterial secretin stimulation.

Many approaches have been used for the purpose of localizing gastrinomas. These include abdominal ultrasonography, [131], [132] CT scanning, [132], [133], [134], [135] and [136] abdominal arteriography, [137], [138], [139] and [140] selective portal venous sampling for gastrin, [139], [141], [142], [143] and [144] selective arterial stimulation of secretin (SASI), [145], [146], [147] and [148] endoscopic ultrasonography (EUS), [149], [150], [151], [152], [153], [154] and [155] and, most recently, somatostatin receptor scintigraphy (SRS) with the somatostatin analog octreotide. [156], [157], [158] and [159] The most recent additions to the imaging techniques, SRS and EUS, have emerged as the most useful in preoperative staging algorithms (see Fig. 67-2). The sensitivity of these modalities in localizing primary and metastatic gastrinomas is outlined in Table 67-5.

STUDY	SENSITIVITY (%)	
	Primary Gastrinoma	Metastatic Gastrinoma
Ultrasound	21–28	14
Computed tomography	35–59	35–72
Selective angiography	35–68	33–86
Portal venous sampling	70–90	N/A
Selective arterial stimulation of secretin	55–78	41
Magnetic resonance imaging	30–60	71
OctreoScan	67–86	80–100
Endoscopic ultrasound	80–100	N/A

TABLE 67-5 Sensitivity of Imaging Studies in Zollinger-Ellison Syndrome

Ultrasonography: Transcutaneous, Endoscopic, and Intraoperative

In general, transcutaneous abdominal ultrasonography is not considered useful for the diagnosis of gastrinomas. Most gastrinomas are small; therefore, sensitivity of this test is quite low, as demonstrated in a prospective study [160] in which transcutaneous ultrasonography was able to localize tumors in only 20% of patients later shown by surgery to have gastrinomas. Nevertheless, if a lesion is seen, it is likely to represent gastrinoma; thus, the specificity of ultrasonography was 90% to 100% in this prospective series.

EUS has facilitated high-resolution imaging of the pancreas, permitting delineation of structures smaller than 5 mm. Because the accuracy of this procedure in diagnosing small pancreatic carcinomas approaches 100%, [161], [162] it is not surprising that this diagnostic modality is useful in localizing small neuroendocrine tumors of the pancreas as well. [149], [150], [151], [152], [153], [154] and [155] Rösch and associates [152] examined 37 patients with surgically confirmed endocrine neoplasms of the pancreas (39 tumors), in whom preoperative ultrasonography and CT scan of the abdomen yielded negative findings. Thirty-two of the tumors were diagnosed by EUS (82% sensitivity), with a specificity of 95%. Tumors varied in diameter between 0.5 and 2.5 cm. However, all seven of the gastrinomas in this series were located in the pancreas, and none were located in extrapancreatic sites, such as the duodenum.

The University of Michigan group used EUS as a primary diagnostic tool to localize neuroendocrine tumors and evaluated more than 82 patients in a prospective study. [163] In their initial prospective study of 16 patients, Thompson and colleagues [154] observed that the sensitivity of a negative EUS result in predicting an extrapancreatic gastrinoma was 100%. Subsequently, their series was expanded to include 75 patients with neuroendocrine tumors with operative confirmation of the EUS findings. In 36 patients with suspected gastrinoma, these investigators confirmed a 100% accuracy to localize pancreatic lesions and to guide the surgeon to an extrapancreatic primary tumor, findings supporting the contention that EUS was invaluable in the preoperative evaluation of the patient with Zollinger-Ellison syndrome. [163] An early EUS localization strategy was found to be highly cost effective (and cost saving) when this group compared this approach with the one used before the introduction of EUS, which primarily used angiographic and venous sampling techniques. [164]

The sensitivity of EUS in detecting gastrinomas has been noted by other investigators. [155] In a study of 22 patients with Zollinger-Ellison syndrome, the sensitivity of EUS was 50% for duodenal wall tumors, 75% for pancreatic tumors, and 62.5% for tumor-bearing lymph nodes. These investigators observed that conventional endoscopy had a sensitivity of 40% for detecting duodenal wall lesions; thus, EUS has small incremental utility over endoscopy to localize duodenal wall lesions. Zimmer and colleagues [165] reported a similar experience, with EUS localizing 11 of 14 (79%) of all gastrinomas in 10 patients with Zollinger-Ellison syndrome. Of note, EUS localized 89% of the pancreatic lesions, and the results of conventional endoscopy are not reported. At the University of Michigan, a routine endoscopy (with a pediatric colonoscope) is performed to look for duodenal submucosal tumors, and EUS is primarily used to examine the pancreas.

Other centers without EUS experience have reported the utility of intraoperative ultrasonography, which appears to be useful in the localization of small gastrinomas. [166], [167] and [168] Tumors not detected by the surgeon through manual inspection may be imaged using this technique, with a sensitivity of 95% by experienced operators. [168]

Intraoperative Transillumination

Frucht and associates [169] prospectively examined the efficacy of intraoperative endoscopic transillumination for detecting duodenal gastrinomas in 26 patients. These investigators detected duodenal gastrinomas with 83% sensitivity, as compared with the sensitivity of the combined preoperative studies (25%) or intraoperative ultrasonography and surgical palpation (42%). This technique remains part of surgical protocols for the management of Zollinger-Ellison syndrome. [37]

Computed Tomography

The diagnostic accuracy of CT scanning reflects continued innovation in techniques and instrumentation. A prospective study [136] examined the value of CT in localizing tumors in 61 consecutive patients with gastrinoma. For extrahepatic gastrinoma, CT scanning with intravenous contrast had a specificity of 95%, a sensitivity of 59%, a positive predictive value of 96%, and a negative predictive value of 54%. For gastrinomas metastatic to liver, CT scanning had a specificity of 98%, a sensitivity of 72%, a positive predictive value of 93%, and a negative predictive value of 90%. Tumor size and location appear to be the key determinants in the successful diagnosis of gastrinoma by CT scanning. Approximately 80% of tumors in the pancreas and tumors larger than 3 cm are detected. Only 40% of extrapancreatic lesions and no tumors measuring less than 1 cm in diameter are detectable by CT scanning. The sensitivity and specificity of CT do not appear to be enhanced by performing dynamic studies. Whether helical techniques have led to improved sensitivity remains uncertain, although an initial report (requiring further comparative study) has reported 82% sensitivity for tumor localization. [170]

Angiography

Diagnostic innovations have limited angiography to selected patients without successful imaging by SRS or EUS. Maton and colleagues [140] prospectively examined the role of selective angiography in the diagnosis of 20 consecutive patients with gastrinoma. For hepatic gastrinoma, angiography had a specificity of 100% and a sensitivity of 86%, with a positive predictive value of 97% and a negative predictive value of 53%. In combination with CT scanning, 100% of the hepatic tumors were detected. Extrahepatic lesions were not as easily detected, inasmuch as CT scanning detected only 57%, angiography 70%, and the combination 73%, with a false-positive rate of 7%. This study suggests that after a CT scan, selective abdominal angiography will detect an additional 28% of patients with liver lesions and an incremental 16% of patients with extrahepatic tumors. Unfortunately, 24% of the extrahepatic lesions will be missed even when both tests are used. Nevertheless, angiography was found to be a useful adjunct to CT scanning in patients with Zollinger-Ellison syndrome who undergo surgery. This same group [171] subsequently reported less enthusiastic experience with CT (31% sensitivity for primary tumors, 42% for liver lesions) and angiography (28% and 62%, respectively). The reduced sensitivity likely reflects both increased numbers of patients referred with negative outside CT scans and angiograms and the ability of newer imaging modalities such as SRS to detect small lesions missed in the past.

Portal Venous Sampling

Before SRS and EUS, under the best circumstances the combination of ultrasonography, CT scanning, and angiography failed to localize tumors in up to 50% of the

patients with biochemical evidence of Zollinger-Ellison syndrome. Thus, percutaneous transhepatic selective portal venous sampling for gastrin was developed as a means to improve the diagnostic yield. [139], [141], [142], [143] and [144] There is general agreement with the relative sensitivity of this test in identifying the presence of gastrinomas (70% to 90%), but there is considerable debate over its specificity, with values ranging from 33% to 90%, depending on the series. Despite the potential usefulness of the selective venous sampling technique, its complexity and invasiveness limit its availability to only a few specialized centers, where it has largely been replaced by SASI; thus, it is not recommended for the evaluation of Zollinger-Ellison syndrome on a routine basis.

Selective Arterial Secretin Injection

SASI has been added to the growing list of modalities used for localizing gastrinomas. [145], [146], [147] and [148] For this study, initially described by Imamura and colleagues, [145] secretin (30 U) is injected selectively into the celiac, proximal splenic, gastroduodenal, proper hepatic, and superior mesenteric arteries, and blood samples for gastrin measurement are obtained simultaneously from the hepatic vein at short intervals (30, 60, 120, and 210 seconds). Given the result of emerging imaging modalities such as EUS and SRS, it appears that SASI will be employed infrequently and will be most helpful when imaging data are conflicting. [172]

Magnetic Resonance Imaging

MRI [173], [174] has been evaluated for the detection of both primary and metastatic gastrinoma, and initial results appear similar to those of CT scanning. In a prospective study, the NIH group found that MRI, using short-time inversion-inversion recovery sequences, was superior to CT for the detection of liver metastases (sensitivity, 71% versus 42%). MRI was equivalent to CT in detection of primary lesions, leading this group to suggest that it should replace CT as the cross-sectional imaging test of choice. The ability of SRS to localize occult liver metastases leaves the choice between CT and MRI a consideration of availability and local expertise.

Somatostatin Receptor Scintigraphy

Many gastrinomas express somatostatin receptors. Therefore, targeted nuclear scanning after injection of an isotopic analog of somatostatin—either iodine 123–Tyr3-octreotide or indium 111 (^{111}In)–diethylenetriamine pentaacetic acid–Dphe [1]-octreotide [156], [157], [158] and [159], [165], [171], [175]—has emerged as a readily available, noninvasive test to localize gastrinomas with a sensitivity and specificity of greater than 75%. The indium analog (^{111}In-pentetreotide) is marketed as OctreoScan 111 (Mallinckrodt, St. Louis, MO). In prospective studies, [174] the NIH group found that the scan was more sensitive than transcutaneous ultrasonography, CT, MRI, and angiography for localizing both primary and metastatic lesions, with sensitivities of 58% and 92%, respectively. The efficacy of EUS and SASI was not directly compared with SRS with regard to the ability to localize primary lesions. Consistent with these encouraging results, Cadiot and colleagues [175] observed that OctreoScan 111 scintigraphy was very useful in detecting small duodenal lesions (3 mm) and peripancreatic lymph nodes. In a review of 122 patients who underwent SRS to localize primary and metastatic gastrinoma lesions, the NIH group noted that SRS altered management in 47% of patients, with its greatest impact in the detection of liver metastases. [176] The investigators concluded that SRS should become the initial imaging modality of patients with gastrinoma. Among patients undergoing surgery for cure at the NIH, SRS was the most accurate preoperative imaging study, yet it still missed one third of all lesions found at surgery. [177] The ability of SRS to detect tumors was related to size, because only 30% of tumors 1.1 cm or smaller were imaged, compared with 64% of those 1.1 to 2.2 cm and 96% of those larger than 2 cm. Duodenal primary tumors were those most commonly missed by SRS. This same group also noted the limitations of SRS with regard to specificity; false positive results occurred in up to 10% of cases. [178] Knowledge of those clinical situations leading to false-positive results is essential for optimal interpretation of the OctreoScan 111, demonstrating the value of operator experience for all relevant diagnostic studies in the patient with Zollinger-Ellison syndrome.

In summary, surgical cure of Zollinger-Ellison syndrome requires accurate tumor localization. To avoid unnecessary laparotomy, OctreoScan 111 in combination with CT or MRI should exclude metastatic disease. If no metastatic disease is found, the approach to localize disease in the peripancreatic region is governed by local expertise and surgical experience. EUS (with upper gastrointestinal endoscopy to evaluate for duodenal tumors) appears to be the most cost-effective modality to evaluate the pancreas and duodenum, whereas SASI remains an alternative if EUS is not available. SASI also may detect occult metastasis and may assist in the interpretation of equivocal examinations. In other referral centers, the endocrine surgeon may go directly to exploration with intraoperative ultrasonography or transillumination. In the management of Zollinger-Ellison syndrome, it is clear that a team approach to localization and surgical exploration appears essential to ensure curative resection.

THERAPY

When considering the therapy of patients with Zollinger-Ellison syndrome, it is important to entertain two objectives: control of gastric acid hypersecretion and treatment of the malignant neoplasm. The emphasis placed on each of these objectives has shifted since the 1970s. Initially, total gastrectomy appeared to be the only alternative for effective treatment of the potentially lethal ulcer disease, and less attention was directed at tumor excision because many of these patients died of ulcer complications long before their tumors became problematic. The availability of highly effective antisecretory therapy such as histamine H_2 blockers and H^+, K^+-ATPase antagonists led to a significant reduction in mortality related to the complication of acid peptic disease. Under these circumstances, it has become increasingly apparent that the major cause of morbidity and mortality in Zollinger-Ellison syndrome is widespread metastatic disease [179]; thus, early tumor detection and excision have assumed primary importance.

Medical Therapy

The primary aim of medical therapy in Zollinger-Ellison syndrome is control of gastric acid hypersecretion. The development of histamine H_2-receptor antagonists was a major breakthrough toward this aim. Cimetidine, the first of these agents, proved very efficacious in controlling acid hypersecretion and prompted ulcer healing and symptom improvement in more than 80% of patients with Zollinger-Ellison syndrome treated on a short-term basis. [180] /SUP>, [181] and [182] However, over a longer term, these patients often required progressive increases in the frequency and dose of medication. Although H_2-receptor antagonists with greater potency and duration of action have been useful in treating patients with gastrinoma, [183], [184], [185], [186], [187], [188] and [189] an important newer class of drugs made available for the treatment of Zollinger-Ellison syndrome is the PPI, of which omeprazole was the first. [190], [191] The efficacy of these agents in inhibiting acid secretion, relieving dyspeptic symptoms, and promoting ulcer healing in patients with gastrinoma has been established. [192], [193], [194], [195] and [196]

Although earlier studies suggested that the doses of omeprazole required for effective inhibition of acid secretion in patients with gastrinoma were significantly higher than in patients with standard peptic ulcers (Table 67-6), a study by Metz and associates [197] suggests that the currently recommended maintenance dose of omeprazole (~60 mg/d) used in these patients is too high. Accordingly, a gradual reduction of omeprazole dose is recommended once the initial dose required for adequate control of gastric acid hypersecretion (as described earlier) has been achieved. More recently, the NIH group prospectively examined the effectiveness of low doses of omeprazole (20 mg/d) as initial therapy in patients with gastrinoma, [198] and based on their results, the investigators continue to recommend initiating omeprazole therapy at a dose of 60 mg/d. This dose allows rapid control of gastric acid secretion, thus minimizing complications related to peptic diathesis. Once an adequate maintenance dose is achieved, tapering the medication is then indicated while following symptoms and acid output. Lansoprazole has also been found to be safe and effective in the treatment of patients with gastrinoma for up to 10 years. [196] Tachyphylaxis is observed less frequently with PPIs than with H_2 blockers. One concern with long-term omeprazole therapy has been its potential for inducing enterochromaffin cell hyperplasia. A prospective study following 40 patients with Zollinger-Ellison syndrome who were treated with omeprazole for a mean of 29 months (6 to 51 months) reported no evidence of hematologic, biochemical, or gastric toxicity. [199], [200] Their marked potency, prolonged duration of action, and safety profile make PPIs the treatment of choice for peptic disease in patients with Zollinger-Ellison syndrome. The intravenous formulation of pantoprazole has become available and appears to be very effective in the treatment of patients with Zollinger-Ellison syndrome. [201]

AGENT	MEDIAN DOSES g/d (range)
H_2 Blockers	
Cimetidine	3.6 (1.2–12.6)
Ranitidine	1.2 (0.45–6)
Famotidine	0.25 (0.05–0.8)
H^+, K^+-ATPase Inhibitors	
Omeprazole	60 mg/d
Lansoprazole	60–90 mg/d

TABLE 67-6 Median Dose of Antisecretory Agents Used in Patients with Gastrinoma

Somatostatin is a known peptide inhibitor of gastric acid secretion [202] and gastrin release. [203] The biochemically stable analog of somatostatin, octreotide, has been used with varying success in patients with gastrinomas. [202], [203], [204], [205] and [206] At present, however, these compounds are available only in injectable form; thus, they are rarely used as first-line agents in the treatment of patients with Zollinger-Ellison syndrome. The long-acting depot formulation of octreotide has become available and shown in preliminary fashion to be beneficial in the treatment of neuroendocrine tumors of the gut. [207] Future studies will clarify the role of this compound in the therapy of patients with gastrinoma.

Surgical Therapy

Before the advent of potent antisecretory agents, total gastrectomy was the treatment of choice in patients with gastrinoma. Although initial operative mortality was very high (15% to 20%), [208] total gastrectomy offered better long-term survival than did more conservative approaches. [11] Increased experience and earlier diagnostic testing have reduced the operative mortality rate associated with total gastrectomy to less than 5%. [209] Nevertheless, the newer gastric antisecretory agents have obviated the need for total gastrectomy, and at present this procedure should be considered only in the rare patient with nonresectable gastrinoma in whom aggressive medical therapy has failed or in those patients who cannot take oral medications.

Another operation applied in the past as an adjunct to medical therapy in patients with Zollinger-Ellison syndrome is proximal gastric vagotomy. [210], [211] The rationale for this operation was the high failure rate with H_2 antagonists. The advent of PPIs may obviate the need for the routine use of this procedure.

As discussed earlier in this chapter, the hypercalcemia found in patients with MEN I may be associated with a gastric acid hypersecretory state that is refractory to medical therapy. A previous report [212] demonstrated that in addition to lowering both BAO and fasting hypergastrinemia in these patients, parathyroidectomy facilitates the management of peptic disease with H_2 antagonists. Although the availability of H^+,K^+-ATPase inhibitors may make this operation unnecessary, parathyroidectomy may be a surgical option for treatment of patients with gastrinoma with MEN I and hyperparathyroidism who are refractory to medical management.

Clearly, the appropriate surgical approach for therapy of Zollinger-Ellison syndrome today is curative resection of the neoplasm. Although initial series reported a cure rate of less than 10% after tumor resection, present data indicate that cure may be possible in as many as 30% of cases. Norton and colleagues [37] published the largest experience of surgical intervention in patients with gastrinoma. This group followed 151 consecutive patients (123 with sporadic cases, 28 with MEN I) who underwent surgery between 1981 and 1998. Thirty-four percent of patients with sporadic gastrinoma were free of disease at 10 years. Unfortunately, none of the patients with MEN I were disease free at the 10-year period. Moreover, the overall 10-year survival observed in these patients was 94%. These authors concluded that all patients with Zollinger-Ellison syndrome who do not have metastatic disease or MEN I should be offered surgical intervention for possible cure. Improved diagnostic capabilities have led not only to a reduction in unnecessary surgery on patients with metastatic disease, but also to the identification of extrapancreatic neoplasms with increasing frequency. [33], [34] and [35], [127], [128], [212], [213], [214] and [215] Studies have reported the incidence of extrapancreatic lesions to be as high as 66% and resection of these lesions to be associated with a high likelihood of long-term cure. [126], [216]

Patients with gastrinoma with MEN I represent a particularly difficult problem to the surgeon. Because of the multicentric nature and extrapancreatic location of tumors in MEN I syndrome, [217], [218], [219], [220], [221] and [222] curative resection is virtually impossible. [143], [187], [209], [223], [224] Some surgeons advocate an aggressive approach whereby all patients without evidence of hepatic metastasis are explored with removal of all duodenal lesions found by duodenotomy, enucleation of all tumors found in the head of the pancreas, and distal pancreatectomy. [219], [222] The rationale for this approach is to effect a potential cure and, failing that, to prevent the development of future pancreatic neoplasms. The value of such an aggressive approach remains to be established. If a single tumor is found during the preoperative evaluation, however, an attempt at surgical resection should be undertaken [225] because larger tumors may be associated with a higher likelihood of metastasis. The role of surgery in patients with gastrinoma and MEN I was explored in 81 consecutive patients. [226] All patients with limited disease (single tumor between 2.5 and 6 cm, $n = 17$) and advanced disease (two or more lesions >6 cm, $n = 31$) underwent exploratory laparotomy with tumor enucleation or resection. Patients with tumors smaller than 2.5 cm ($n = 17$) and those with liver metastases ($n = 8$) were observed. Approximately 40% of patients had advanced disease without metastases. Duodenal lesions were found in 80% of patients with Zollinger-Ellison syndrome and MEN I. The authors observed that tumors could be removed in patients with advanced disease with no mortality and a complication rate similar to that observed in patients with limited disease. An additional important observation was that patients with advanced tumor who underwent resection had the same survival rate as patients with limited disease and those without identifiable tumor. When looked at as a group (nonresected and resected), 15-year survival was between 89% and 100%, whereas for patients with metastatic disease, it was only 52%. The authors of this study concluded that surgical resection should be performed in patients with gastrinoma and MEN I with advanced localized disease. The ideal type of operation for this group of patients was not resolved by this study, but the authors did not recommend pancreaticoduodenectomy or distal pancreatectomy on a routine basis. Although a subgroup of patients with gastrinoma may have an aggressive course warranting a Whipple procedure, the tools to predict this subgroup of patients have not been developed (see later).

Operative management of Zollinger-Ellison syndrome requires careful and detailed mobilization and exploration of the entire pancreas duodenum (duodenotomy) and surrounding areas. [215], [219], [222] Any tumors that are found in the region of the pancreatic head should be enucleated, and tumors located elsewhere should be resected with great care. In the event that a tumor is not found at surgery, distal pancreatectomy should be avoided because more then 80% of the gastrinomas are located within the gastrinoma triangle. [33] If a lesion is found in the head of the pancreas, a Whipple procedure should be considered with great care because the mortality of this surgical procedure may outweigh its potential benefits. However, the decision may be facilitated if complete tumor excision is not possible by a less invasive procedure. [227]

Pisegna and colleagues [228] examined the effects of curative gastrinoma resection on gastric secretory function. They observed that the trophic effects of long-standing hypergastrinemia are largely reversible within a short period, with 50% and 75% decrease in MAO and BAO, respectively, within 3 to 6 months after curative resection. However, these observations also indicate that acid secretion must be monitored even after curative resection because as many as 55% of patients at 3 to 6 months and up to 67% at 4 years after gastrinoma resection remained mild hypersecretors requiring low doses of antisecretory drug.

Therapy for Metastatic Gastrinoma

Metastatic disease occurs in 25% to 40% of patients with gastrinoma and at present is the most common source of morbidity and mortality in this disease. One major difficulty in evaluating the effectiveness of the various therapeutic regimens is that most clinical trials have examined small numbers of patients. Antineoplastic chemotherapy has been of limited usefulness in Zollinger-Ellison syndrome. Combined treatment with streptozotocin, 5-fluorouracil (5FU), and doxorubicin (Adriamycin) has provided the most promising results. In one series of 42 patients with metastatic islet tumors of various types, [229] initial response rates of 63% and complete response rates of 33% were reported with this regimen. However, gastrinomas comprised a small percentage of the cases studied, and the response to chemotherapy may have varied according to the cell type of the tumor. In another study using a similar treatment regimen, Bonfils and colleagues [230] reported disappearance of the gastrinoma as assessed by imaging studies in 20% of their patients with Zollinger-Ellison syndrome with metastatic tumors.

A prospective study [231] by the investigators at the NIH provided a more sobering perspective on treatment of metastatic gastrinoma with chemotherapy. Ten consecutive patients with the disorder were treated with a regimen of streptozotocin, 5FU, and doxorubicin, and although a modest objective response was observed initially in four patients, the response lasted for less than 10 months. All the patients were considered as treatment failures thereafter, with no significant change in short-term survival, and many side effects of therapy, including nausea and vomiting (100%), alopecia (80%), proteinuria (40%), and leukemia (20%), were noted. At 10 months after initiation of therapy, all patients had evidence of tumor growth over the preceding 6 months. The question when to treat patients having metastatic gastrinoma with chemotherapy remains unanswered. Although an occasional patient with metastatic disease may survive up to 20 years, it appears that most will die within 5 years. Two approaches to treating these patients are to begin chemotherapy when the patient is symptomatic [229] or to reassess the patient 3 to 6 months after initial presentation and to use chemotherapy if the metastases are increasing in size. [232] Both approaches are based on studies including relatively small numbers of patients; thus, additional data are needed before firm recommendations can be given.

In view of the limited success of chemotherapy in the treatment of metastatic gastrinomas and neuroendocrine tumors of the pancreas in general (see Chapter 97), alternative therapeutic modalities

have been explored. As in the case of assessing the value of chemotherapy in patients with gastrinoma, the rarity of the disease coupled with the heterogenous group of patients studied and the variable natural history of these malignancies make the available data somewhat difficult to interpret.

Hormonal therapy with the stable somatostatin analog octreotide has been attempted in metastatic gastrinoma. [233], [234] Although early reports suggested a significant decrease in tumor size in response to octreotide, [235] subsequent studies have not been as encouraging. [236], [237] Tumor stabilization may be achievable, but this is unclear in the case of patients with gastrinoma. An interesting therapeutic alternative considered for treatment of neuroendocrine tumors has been octreotide radionucleotide therapy. [238] Although this option is in the very early stages of development, future studies may prove it beneficial for these patients.

Leukocyte interferon also has been used in the therapy of neuroendocrine tumors with reported success. [239], [240] and [241] Unfortunately, these encouraging results were not observed by Pisegna and associates [242] after examining the effect of human recombinant interferon-a in patients with Zollinger-Ellison syndrome. Smaller trials examining the efficacy of combining interferon with octreotide or 5FU have been published, [243], [244] but the limited number of patients evaluated makes these data difficult to interpret. In addition, there was a substantial increase in drug toxicity to interferon when this drug was combined with 5FU, making it a less desirable treatment option. [244]

Hepatic artery embolization is another treatment option considered for endocrine tumors that have metastasized to the liver. Ruszniewski and associates [245] examined the efficacy of chemoembolization with doxorubicin in 24 patients with metastatic tumors (5 patients with gastrinoma), and tumor stabilization was observed in 3 patients. More recently, Moertel and colleagues [246] treated 111 patients (with carcinoid and pancreatic endocrine tumors) with systemic chemotherapy in addition to chemoembolization and achieved an overall response rate of 80%. In view of the limited data available in patients with gastrinoma and the potential complications related to hepatic artery embolization, including abdominal pain, fever, nausea, and even death (<3%), [247], [248] this treatment should be reserved for treatment-refractory patients until further data are available.

Aggressive surgical resection (debulking) [249], [250], [251] and [252] has been performed successfully, with 5-year survival achieved in more than 75% of patients whose tumors were amenable to complete resection. [250] These data suggest a potential benefit of this surgical approach in patients who are experiencing severe refractory symptoms in which tumor distribution permits an attempt at resection (<10%).

Orthotopic liver transplantation also has been attempted as a therapeutic option in patients with hepatic metastases. The finding that these tumors are slow growing and are often unresponsive to aggressive medical management has served as the driving force behind this treatment modality. [253], [254] and [255] Unfortunately, the 4-year survival rate in patients with pancreatic neuroendocrine tumors was only 8% in the largest sample of patients examined. [255] Thus, orthotopic liver transplantation does not appear to provide an option for these unfortunate patients.

PROGNOSIS

Zollinger-Ellison tumors can be classified as either benign or malignant, [36], [256] based on a series of clinical characteristics. Of these characteristics, tumor extent and rate of tumor growth are the most important prognostic indicators for patients with gastrinoma. As reviewed by Maton and colleagues, [225] 5-year survival rates for all patients with gastrinoma vary between 62% and 75%, and 10-year survival rates vary between 47% and 53%. If one segregates the survival data according to extent of tumor present at the time of diagnosis, patients who have a negative laparotomy or who have all their tumor removed surgically have 5- and 10-year survival rates greater than 90%. In contrast, patients with tumors that were incompletely resected have 5- and 10-year survival rates of 43% and 25%, respectively. Weber and associates [36] critically evaluated 185 consecutive patients with Zollinger-Ellison syndrome and identified the criteria that determined metastatic rate and survival in these patients. These investigators confirmed that both benign and malignant categories of gastrinomas exist. The overall 10-year survival rates were 93% for patients with MEN I and 74% for patients without MEN I, somewhat better than rates reported previously, [225] but similar to results reported by Eriksson and colleagues. [257] It was also found by these investigators that there was no difference in survival for the following patients: those rendered disease free at surgery, those with tumor and persistent disease after surgery, and those with disease and negative exploratory laparotomy results. A poor clinical outcome is seen in female patients, in patients without MEN I, in patients with high serum gastrin levels, in patients with a large pancreatic tumor, and in patients with hepatic metastasis.

A detailed prospective analysis of the clinical course of 212 patients with Zollinger-Ellison syndrome [258] observed for a mean period of 15 years (range, 0.1 to 31 years) was published. Thirty-two percent of patients died (none of acid-related complications); 50% of them had gastrinoma-related causes of death. Gastrinoma-related causes of death are outlined in Table 67-7, with the most common being progressive cachexia associated with hepatic metastases (67%). Gastrinoma-related causes of death were more commonly observed in patients with the following characteristics: shorter disease duration; higher gastrin levels; pancreatic primary and large tumor; metastatic disease to lymph nodes, liver, or bones; and ectopic Cushing syndrome. When considering patients with hepatic metastases, tumor-related Cushing syndrome and development of metastases to bone were independent predictors of decreased survival time (Fig. 67-3). In addition to extent of hepatic metastases, the rate with which they developed was an independent indicator of poor prognosis. From this and other studies, [36] it appears that roughly 25% of patients with gastrinoma follow an aggressive pattern, with 10-year survival approaching 30%, whereas the remaining patients follow a more indolent course, with a 10-year survival of 95%.

CAUSE OF DEATH	NUMBER	PERCENTAGE (%)
Liver metastases with progressive inanition	22	67
Secondary PET syndrome	10	30
Liver metastases causing hepatic failure	4	12
Tumor-related embolism	2	6
Postoperative complications	1	3
Cardiac gastrinoma with arrhythmia	1	3

PET, pancreatic endocrine tumor.

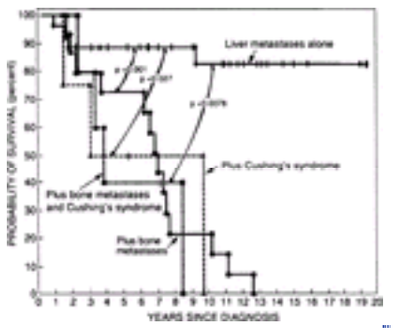

FIGURE 67-3. Impact of the presence of bone metastases, liver metastases, or ectopic Cushing syndrome, alone or in combination, on survival of patients with gastrinoma. (Adapted from ref. [258].)

Gibril and colleagues [259] performed a similar type of prospective study on the natural history of gastrinoma in 57 patients with MEN I. These patients were followed-up for a mean period of 8 years, with 23% having or developing liver metastases and 14% having a tumor with aggressive growth, defined as tumor growth of 25% volume increase or more per month or the appearance of any new lesion. In terms of survival, 5% of the study group, 23% of patients with hepatic metastases, and 38% of patients with aggressive tumor growth died during the study period. Factors predictive of aggressive gastrinoma growth were identified by the authors and are summarized in Table 67-8. Ultimately, further elucidation of the molecular determinants important in tumor development in MEN I coupled with recognition of clinical features predictive of poor outcome may allow earlier identification and intervention in patients prone to developing aggressive disease.

Clinical	
Age at MEN I diagnosis (y)	<35 ($P = 0.021$)
Age at ZES onset (y),	≤27 ($P = 0.043$)
Age at ZES diagnosis (y),	≤33 ($P = 0.032$)
Duration of ZES before diagnosis (y),	<2.1 ($P = 0.021$)
Laboratory	
Fasting gastrin levels,	≥10,000 pg/mL ($P < 0.0001$)
Tumor Characteristics	
Pancreatic tumor size,	>3 cm ($P < 0.0001$)*
Presence of liver metastases	($P < 0.00001$)
Presence of bone metastases	($P = 0.0019$)
Presence of gastric carcinoid	($P = 0.024$)

CHAPTER 68

Robert M. Genta

GASTRITIS AND GASTROPATHY

CLINICOPATHOLOGICAL APPROACH TO GASTRITIS

Gastritis, simply defined as the inflammation of the gastric mucosa, is a condition, not a disease. With rare exceptions (e.g., lymphocytic gastritis and the extremely rare phlegmonous gastritis), inflammation of the gastric mucosa per se does not produce signs or symptoms; its complications do. Thus, clinicians rarely search for gastritis. In dyspeptic patients with indications for endoscopy, biopsies from the stomach are often obtained to determine the patient’s *Helicobacter pylori* status. If an appropriate set of gastric mucosal specimens is collected and properly examined, valuable information in addition to the often implicit question “is there *H pylori*?” may be obtained: the type, severity, and distribution of gastritis and perhaps other causes of the gastric inflammation. This chapter is a discussion of useful strategies gastroenterologists and pathologists can use to optimize the diagnosis of gastric diseases.

Sydney System

The discovery of *H pylori* in 1982 coincided with a new trend in medicine: the birth of the expert group, whose task is to sift through the best available evidence (hence the term *evidence-based medicine*) and attempt to come to a consensus with regard to treatment strategies (*clinical guidelines*) or classifications of disease. Before the 1990 World Congress of Gastroenterology in Sydney, Australia, such a group of European gastroenterologists and pathologists set out to create a flexible matrix for the classification of gastritis. The resulting *Sydney System* had both endoscopic and histological divisions. [1] The former was met with general indifference and faded into oblivion. The latter unleashed passions that were distributed largely along geocultural lines: enthusiasm in Europe, where the system was conceived; indignation in the Americas and Asia, where investigators felt excluded both politically (none were asked to participate in the expert group) and nosologically (the types of gastritis commonly seen in Asia and South America received limited attention). In spite of these operational shortcomings, the Sydney System described a framework useful to generate diagnoses and flexible enough to incorporate new ideas as they emerged. Four years after its introduction, the Sydney System was reapprised by a group of pathologists including a wider geographic and disease representation. This group established a terminology of gastritis and identified, defined, and attempted to resolve some of the problems associated with the original Sydney System. The Houston workshop resulted in what is known as the Updated

Sydney System, which is currently the most widely used and cited method for the classification of gastritis. [2] Table 68-1 summarizes the different entities classified in the Updated Sydney System.

TYPE OF GASTRITIS	ETIOLOGIC FACTORS	GASTRITIS SYNONYMS
Nonatrophic	*Helicobacter pylori* ↑ Other factors	Superficial Diffuse antral gastritis Chronic antral gastritis Interstitial-follicular Hypersecretory Type B
Atrophic		
Autoimmune	Autoimmunity ↑ *H pylori*	Type A Diffuse corporal Pernicious anemia-associated
Multifocal atrophic	*H pylori* Environmental factors	Type B, type AB Environmental Metaplastic Atrophic pangastritis Progressive intestinalizing pangastritis
Special Forms		
Chemical	Chemical irritation Bile NSAIDs ↑ Other agents	Reactive Reflux
Radiation	Radiation injury	
Lymphocytic	↑ Idiopathic ↑ Autoimmune mechanisms ↑ Gluten Drugs (ticlopidine) ↑ *H pylori*	Varioliform Celiac disease-associated
Noninfectious granulomatous	Crohn's disease Sarcoidosis Wegener granulomatosis Foreign substances	
Eosinophilic	↑ Idiopathic Food sensitivity ↑ Other allergens	Isolated granulomatous Allergic
Other infectious gastritides	Bacteria (other than *H pylori*) Viruses Fungi Parasites	Phlegmonous, syphilitic, etc. Cytomegalovirus Mucormycosis

TABLE 68-1 Classification of Chronic Gastritis Based on Topography, Morphology, and Etiology

To create a report as suggested by the Sydney System, appropriate biopsy specimens should be methodically evaluated and the findings synthesized (Fig. 68-1). Whereas gastroenterologists in some institutions have made a habit of obtaining mapped specimens from each patient who undergoes gastroscopy, others continue to take few and often topographically unidentified specimens. These diagnostic guidelines can be best followed by those gastroenterologist-pathologist teams who work together and communicate effectively.

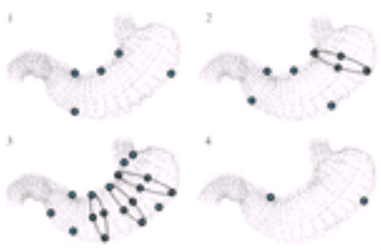

FIGURE 68-1. (**1**) The Updated Sydney System recommends a biopsy protocol that consists of five specimens, three on the lesser curvature and two on the greater curvature, from the antrum (*2*), the incisura angularis (*1*), and the corpus (*2*). (**2**) For protocols designed to assess the development of atrophy or endocrine cell hyperplasia, more extensive sampling from the corpus is required. (**3**) Extensive mapping protocols may be used for the detection of patchy conditions, such as the follow-up of mucosa-associated lymphoid tissue lymphomas. (**4**) In clinical practice, the most common sampling consists of one specimen from the antrum and one from the corpus. Although adequate to detect *Helicobacter pylori* gastritis, such a minimalist protocol does not permit the topographic definition of gastritis and is insufficient to establish the presence and extent of atrophy.

Biopsy Protocol

To obtain adequately representative samples for the classification of gastritis, the *biopsy protocol* depicted in Figure 68-1 is recommended. Biopsy specimens from the three compartments (antrum, incisura angularis, and corpus) should be separately identifiable when they are submitted to the laboratory. Proper orientation is indispensable for optimal histological evaluation; it may be accomplished either in the endoscopy suite when biopsy specimens are collected, or in the histopathology laboratory at the time of embedding. This latter option is generally preferable, unless endoscopy personnel are experienced and motivated to perform the precise and tedious work required to orientate minuscule fragments of fresh tissue properly.

To translate histopathological observations into well-defined topographic patterns, each feature is then graded using the standardized Visual Analogue Scale (Fig. 68-2). The final diagnosis issued should synthesize all individual evaluations, for example, " *H pylori* antrum-predominant gastritis" or "corpus-restricted atrophic gastritis without *H pylori* infection, suggestive of autoimmune gastritis."

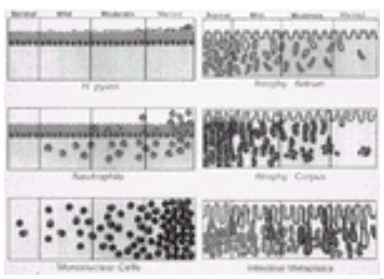

FIGURE 68-2. The Visual Analogue Scale is used to grade the five main components of gastritis (density of *Helicobacter pylori;* intensity of active and chronic inflammation; atrophy; and intestinal metaplasia).

The Updated Sydney System is also suitable for evaluating and diagnosing the special types of gastritis. A sample diagnosis might read "lymphocytic gastritis, corpus predominant, with *H pylori* infection." In the case of gastropathies, the Updated Sydney System is mainly useful for helping in the orderly assessment of the histopathological features of the mucosa. This applies even in the unlikely situation that the system's recommended set of five biopsy specimens is obtained from a patient with portal hypertension or watermelon stomach. However, in most such cases, attempting to grade each specimen individually is neither recommended nor necessary.

TOOLS TO DIAGNOSE AND CLASSIFY GASTRIC CONDITIONS

The different types of gastritides and gastropathies are characterized by various combinations of *histological changes,* many of which are expressions of immune, inflammatory, and adaptive responses common to several conditions. However, the presence, absence, and relative intensity of these responses provide important etiologic clues and are crucial in the categorization of the process. These histological changes can be viewed as the foundations for the terminology of gastritis, and some familiarity with them is indispensable to understand both the classification and the related manifestations of nonneoplastic gastric conditions.

Epithelial Degeneration

Surface epithelial degeneration is a nonspecific response to injury seen in all forms of gastritis. It is most conspicuous in chemical gastritis and *H pylori* gastritis. In *H pylori* gastritis, the intimate contact of bacteria with the surface cell membrane makes epithelial degeneration particularly prominent (Fig. 68-3). [3] Cell injury and necrosis can lead to erosions, which are seen endoscopically either as flat superficial lesions or as elevated lesions whose chronic nature is suggested by polypoid regenerative mucosa at the margins. The former are often the result of acute damage caused by drugs, bile reflux, or ischemia, whereas the latter are almost always associated with *H pylori* gastritis.

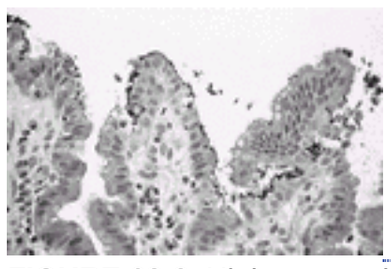

FIGURE 68-3. High-power view of antral epithelium with severe surface damage resulting from the adherence of large numbers of *Helicobacter pylori* organisms. Epithelial cells are depleted of mucin, flattened, and focally missing; the large hyperchromatic nuclei indicate increased regeneration.

Foveolar Hyperplasia

Elongation and increased tortuosity of gastric pits result from *hyperplasia of the foveolar cells,* a presumed adaptive response to increased cellular exfoliation from the surface epithelium. It can be viewed as a visual surrogate for increased epithelial cell turnover. Hyperplasia is accompanied by hyperchromatic nuclei and mitotic activity reaching an increased height of the pit and by other signs of cellular immaturity, such as mucin depletion and a high nucleocytoplasmic ratio. Marked foveolar hyperplasia is a prominent feature of chemical injury (Fig. 68-4A), [4] but lesser degrees are commonly seen in *H pylori* gastritis (Fig. 68-4B). [5]

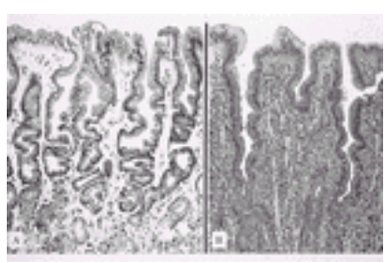

FIGURE 68-4. (**A**) Elongated, tortuous pits (foveolar hyperplasia) with minimal inflammation suggest chemical damage (bile or nonsteroidal antiinflammatory drug gastropathy). (**B**) In contrast, foveolar hyperplasia associated with inflammation of the lamina propria and surface epithelial damage is characteristic of *Helicobacter pylori* infection.

Hyperemia and Edema of the Lamina Propria

Mucosal hyperemia—often visible endoscopically—is considered to be an indicator of bile reflux gastritis, and a significant correlation has been found with the concentration of bilirubin in gastric juice. Histologically, marked edema of the lamina propria with minimal inflammation is a characteristic finding in bile gastritis. [4]

Neutrophilic Infiltration

The presence of *neutrophils* characterizes the “activity” in chronic gastritis (Fig. 68-5A). The cause is *H pylori* in most cases, but other infectious and inflammatory conditions (e.g., syphilis and Crohn’s disease [6]) may be responsible for the persistence of neutrophils, classically associated with “acute” inflammation. Neutrophils are found in virtually every patient with *H pylori* infection. [7], [8] The intensity of neutrophil infiltration may help to distinguish among the acute phase of infectious gastritis, *Helicobacter* gastritis with a particularly active component, and acute hemorrhagic gastritis resulting from chemical injuries (e.g., nonsteroidal antiinflammatory drugs [NSAIDs] or alcohol), in which inflammation is a minor component. Neutrophils disappear rapidly after successful eradication therapy; their persistence is a highly sensitive indicator of therapeutic failure. [7]

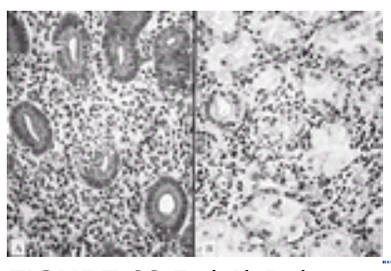

FIGURE 68-5. (**A**) Polymorphonuclear neutrophils in the lamina propria and infiltrating the foveolar epithelium are virtually pathognomonic of *Helicobacter pylori* gastritis. (**B**) A mixed infiltration of oxyntic glands may occur in *H pylori* gastritis, but also in autoimmune gastritis.

Eosinophilic Infiltration

Rare, scattered *eosinophils* may be present in the gastric lamina propria of healthy persons, particularly in underprivileged populations. Prominent eosinophilic infiltration of the gastric wall either may be part of the rare eosinophilic gastroenteritis or may represent a process confined to the stomach. In either case, the cause, suspected to have an allergic basis, is not known. Eosinophils are a major component in the responses to anisakiasis and may be a constituent of the granulomata that sometimes form around fragments of the helminths remaining in the gastric wall. [9] In adults with *H pylori* gastritis, there are usually small numbers of eosinophils. In contrast, children have been reported to have a greater eosinophilic component in the *H pylori*–infected gastric mucosa. [10] After eradication of the pathogen, eosinophils may increase for some time and then decline in parallel with mononuclear cells. [7]

Mononuclear Cell Inflammation

Infiltration of the lamina propria by lymphocytes, plasma cells, and small numbers of eosinophils and mast cells is a major feature of *H pylori* gastritis (Fig. 68-6A), except in areas of severe atrophy and metaplasia, in which the infiltrate tends to be sparse. When lymphocytes are seen infiltrating the surface or glandular epithelium, the possibility of lymphocytic gastritis should be considered. [11] In autoimmune gastritis, there is a diffuse infiltrate of mucosal plasma cells and

lymphocytes. [12] The latter are also present around and within oxyntic glands (Fig. 68-5B).

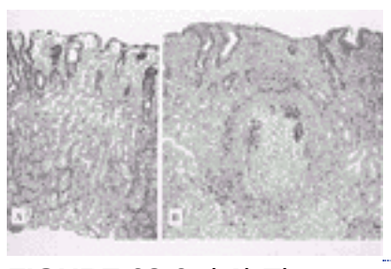

FIGURE 68-6. (**A**) The accumulation of mononuclear cells in the zone immediately subjacent to the surface epithelium pushes the oxyntic glands down, forming a thin band of inflammation limited to the upper portion of the mucosa, hence the term “superficial gastritis.” (**B**) Lymphoid follicles with germinal centers are found in almost all patients with *Helicobacter pylori* gastritis.

Lymphoid Follicles

Lymphoid follicles are rare in the stomach of healthy, *H pylori*–free adults. When an extensive biopsy protocol is used, lymphoid follicles or aggregates are found in virtually all patients with *H pylori* gastritis (see Fig. 68-6B). [13] In infected children and young adults, these entities may produce a distinctive nodularity in the gastric antrum, known endoscopically as *follicular gastritis.* [14] *H pylori* infection is the major determinant of gastric acquired mucosa-associated lymphoid tissue (MALT) and, therefore, a crucial factor in the origin of primary gastric B-cell lymphomas (MALT lymphoma). [15]

Atrophy

Gastric atrophy is defined as the loss of appropriate glands in a given gastric compartment [16]; that is, glands that are expected to be present in the portion of gastric mucosa under examination (e.g., oxyntic glands in the mucosa of the corpus) have been replaced by tissues not normally found there (Fig. 68-7). More recently, the narrower definition of *loss of specialized cells* has been proposed. [17] Whenever the gastric mucosa is damaged, irrespective of the mechanism or cause, it may either regenerate or return to normal (*restitutio ad integrum*), or it may undergo adaptive reparative processes leading to the replacement of the native mucosa with other structures. [18] Destroyed native glands may be replaced by fibroblasts and extracellular matrix, by glands of “pyloric” appearance (*pseudopyloric metaplasia*), or by an intestinal-type epithelium (*intestinal metaplasia*). During chronic *H pylori* infection, all these types of repair occur, the respective proportion of each probably modulated by environmental, genetic, and bacterial factors. [19] Widespread atrophy also occurs in autoimmune gastritis, as a consequence of the immune-mediated glandular destruction of the oxyntic mucosa. Atrophic foci found in stomachs with evidence of chemical gastropathy are probably the result of ulcer repair.

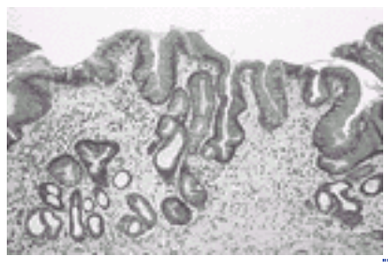

FIGURE 68-7. Biopsy specimen from the gastric corpus showing complete atrophy. No oxyntic glands are present, and the few foveae and mucous glands are widely separated by collagen.

Intestinal Metaplasia

Intestinal metaplasia is the replacement of the mucous cells that line the normal gastric mucosa with an epithelium similar to that of the small intestine (Fig. 68-8). The different types of intestinal metaplasia have been variously classified as follows: complete versus incomplete; types 1, 2a, and 2b; and types I, II, and III, based on their morphology and content in sulfomucins. [20] In general, the greater the extension of metaplasia in a stomach, the greater the proportion of the incomplete types. [21] Intestinal metaplasia is a virtually constant component of atrophic gastritis, and is found more frequently in the stomach of patients with *H pylori* gastritis. [22], [23] Small antral foci of intestinal metaplasia are also frequently found in bile reflux gastropathy, both in postoperative and in intact stomachs. [4], [24]

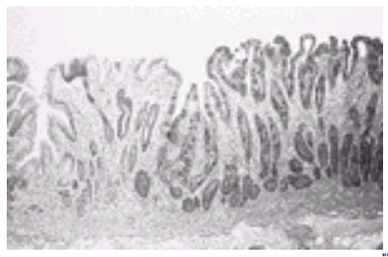

FIGURE 68-8. Corpus mucosa: the **left third** shows complete atrophy (i.e., absence of appropriate oxyntic glands) and moderate inflammation; the epithelium on the **right** consists of a small intestinal–type epithelium with goblet cells and a brush border (intestinal metaplasia).

Endocrine Cell Hyperplasia

Endocrine cell hyperplasia, a consequence of functional changes in chronic gastritis, is most prominent in autoimmune atrophic gastritis. In this condition, hypochlorhydria or achlorhydria lead to G-cell hyperplasia in the antral mucosa with an accompanying rise in serum gastrin levels. [25] This, in turn, induces the histamine-producing enterochromaffin-like cells in the oxyntic glands to undergo hyperplasia. [26] The type, number, and distribution of endocrine cells can now be established by using immunostaining techniques, which have replaced the less reliable classical argentaffin and argyrophil histochemical stains. Gastric endocrine cell proliferations are commonly classified according to the criteria proposed by Solcia and colleagues, [27] which distinguishes among hyperplasia, adenomatoid hyperplasia, dysplasia, and neoplasia.

Mild degrees of neuroendocrine proliferation may be seen, if they are searched for by immunoenzymatic methods, in many routine gastric biopsies: they represent an indirect and reversible effect of the widespread long-term use of proton pump inhibitors. [28] In this condition, hypertrophy occurs almost exclusively in enterochromaffin-like cells, the most common type of endocrine cell in the oxyntic mucosa, and is believed to depend on the trophic effect of the concomitant hypergastrinemia. [29]

Parietal Cell Alterations

Protrusions and pseudohypertrophy of oxyntic cells and glandular dilations are characteristic yet reversible responses to the long-term administration of proton pump inhibitors (Fig. 68-9). [29] These changes have also been described in patients with gastric ulcer disease, although the pathogenetic connection remains unclear. [30]

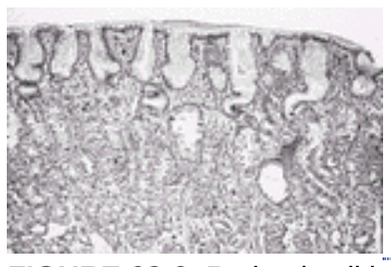

FIGURE 68-9. Parietal cell hyperplasia with protrusion into the lumen of dilated oxyntic glands is a distinctive effect of prolonged therapy with proton pump inhibitors.

HELICOBACTER PYLORI GASTRITIS

Chronic gastritis, one of the most common chronic conditions of humankind, is now known to be the result of specific and nonspecific responses mounted by the gastric mucosa against *H pylori* infection. [31], [32] *H pylori* infection is associated with most duodenal ulcer and gastric ulcers and with almost all primary gastric MALT lymphomas. In certain regions of the world, many infected persons develop metaplastic atrophic gastritis, a documented precursor of gastric carcinoma. Furthermore, certain extragastric conditions, including systemic autoimmune diseases, atherosclerosis, urticaria, and migraine, have been linked—albeit tenuously—to *H pylori* infection. [33] Thus, the importance of *H pylori* extends into the realm of numerous major diseases that may have gastritis as their common denominator.

Clinical Manifestations

The initial phases of *H pylori* infection elicit an acute mucosal inflammatory response whose clinical manifestations may include epigastric pain, nausea, and vomiting. Such symptoms are uncommon and are usually short-lived. Because patients rarely undergo endoscopic procedures in the early stages of *H pylori* infection, information regarding clinical aspects is limited. However, well-documented case reports allowed a glimpse into the early aspects of the infection [34] and of iatrogenic *H pylori* infection resulting from the use of inadequately disinfected endoscopes. [35] Most of these patients had multiple antral ulcers or erosions, whereas others had a predominance of hemorrhagic lesions; both their endoscopic and histopathological findings are virtually identical to those reported in subjects from human ingestion studies [36] and in patients with epidemic gastritis and achlorhydria, a condition described before *H pylori* was discovered and later found to be a manifestation of acute *H pylori* infection. [37]

In patients with uncomplicated chronic *H pylori* gastritis, the prevalence of dyspepsia is probably no greater than in uninfected persons, and among patients with nonulcer dyspepsia, the prevalence of infected and noninfected persons is similar. [38], [39] Furthermore, cure of *H pylori* in patients with nonulcer dyspepsia has not been shown conclusively to improve the dyspeptic symptoms, [40] although the reasons for this apparent lack of effect continue to be debated. [41] Even with its unclear relation to dyspepsia, *H pylori* infection has been estimated to be responsible for approximately 5% of gastrointestinal ailments in the community, [42] and patients with *H pylori* gastritis are at increased risk of duodenal and gastric ulcer, gastric cancer, and lymphoma.

Epidemiology

In many developing countries, the prevalence of *H pylori* in adults is close to 90%, with very high percentages of infected children, suggesting exposure to the bacteria early in life. In established industrialized countries (Western Europe, United States, Canada, and Australia), exposure occurs later, resulting in minimal percentages of infected children (<1% in Swedish and Danish schools in the year 2000) and low percentages of infected adults (~30% by age 50 years). Although the mechanisms of transmission remain poorly understood, improved socioeconomic conditions result in a decreased prevalence of *H pylori,* as vividly illustrated by historical data from Finland, [43] Sweden, [44] and Japan. [45] Furthermore, innumerable people receive amoxicillin, which, used alone, may cure approximately 10% of *H pylori* infections, [46] as well as other antibiotics for the treatment of respiratory and other infections. Among *H pylori*–infected patients undergoing such therapies, a small but cumulatively significant percentage is cured. Finally, it is likely that targeted anti–*H pylori* treatment in individual patients reduces transmission in the community and ultimately may contribute to the decreased prevalence of the infection in the population.

Endoscopic Appearance

Chronic *H pylori* gastritis has no distinct endoscopic pattern. Depending on the stage or distribution of gastritis, hyperemia, erosions, ulcerations, hypertrophy, and atrophy may coexist in various combinations in the same stomach, juxtaposed to one another and to apparently normal areas. Yet, none of these features is useful for predicting the presence or absence of chronic *H pylori.* Therefore, the diagnosis of *H pylori* gastritis requires histopathological analysis.

Histopathology

H pylori organisms are found in greatest numbers in the gastric mucous gel and attached to surface mucous cells (Fig. 68-10A). Bacteria are also present in the intercellular spaces and, particularly in patients receiving long-term antisecretory therapy with proton pump inhibitors, within the canaliculi of parietal cells. The difficulty of visualizing bacteria in these latter locations before the development of polyvalent staining techniques [47] may explain the misconception that *H pylori* is a strict gastric surface dweller.

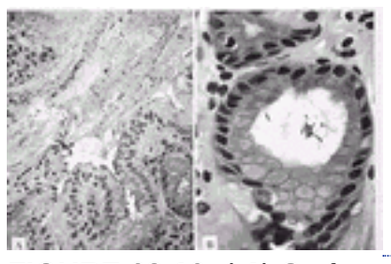

FIGURE 68-10. (**A**) Surface mucous layer containing innumerable *Helicobacter pylori* organisms. (**B**) *H heilmannii* at high magnification; these bacteria are more than twice as long as *H pylori,* and their spiral configuration is evident.

Antral, oxyntic, and cardiac mucosae are equally susceptible to infection and are colonized with similar frequencies. [8], [48] In patients with extensive antral intestinal metaplasia, a type of epithelium to which *H pylori* rarely adheres, [49] the infection is virtually confined to the nonmetaplastic areas of the corpus. This is also the case in many patients who regularly use proton pump inhibitors.

Infiltration of the gastric epithelium by polymorphonuclear neutrophils is the most distinctive feature of the gastric mucosa infected by *H pylori:* neutrophils are generally more abundant in the antrum and the cardia than in the corpus, where they may be rare or even completely absent in spite of visible bacterial colonization.

This distribution of inflammation characterizes *antrum-predominant gastritis,* the most common type of gastritis in Western populations. Neutrophils are usually the only inflammatory cells that infiltrate the gastric epithelium in *H pylori* infection, but in the lamina propria they are almost always mixed with lymphocytes, plasma cells, and variable amounts of eosinophils. Inflammation tends to be most intense in the superficial portions of the lamina propria (see Fig. 68-6A), hence the term *superficial gastritis,* still occasionally used as a synonym for nonatrophic gastritis.

Lymphoid follicles are virtually always found in infected stomachs (see Fig. 68-6B), and their presence is a reliable indication of active or recently treated *H pylori* gastritis. Their greatest density is in the region of the *incisura angularis,* and the lowest density is in the proximal greater curvature. [13]

"Disease-Specific" Virulence Factors

Since the discovery of the *H pylori* toxins VacA and CagA, which were linked to certain types of damage to the gastric mucosa, there have been continuous attempts to correlate them and other virulence factors with a specific manifestation or complication of *H pylori* gastritis. Although some of these factors can affect the intensity of inflammation and, perhaps through this mechanism, may ultimately influence the outcome of gastritis, [50] the virulence of *H pylori* seems to be largely host dependent, and none of these factors are disease specific. Thus, at present, there is no clinical application for tests that purport to determine the potential pathogenicity of an individual patient's *H pylori* strain. [51], [52] The best studied putative virulence factor is the cytotoxin-associated gene product (Cag) A, the product of one of the genes in the cag pathogenicity island. Subjects infected with *H pylori* with a functional cag pathogenicity island have elevated mucosal levels of interleukin-8, marked neutrophilic infiltration into the gastric mucosa, and an increased risk of developing a symptomatic outcome such as peptic ulcer or gastric cancer. However, the relationship between the presence of the cag pathogenicity island and outcome is not consistent in different geographic regions, especially in East Asia, where more than 90% of isolates possess the cag pathogenicity island. [53] In Western countries, where *H pylori* strains lacking the cag pathogenicity island are found in a higher percentage than in Asian countries, the increased likelihood of a symptomatic outcome can be seen. However, the presence of a functional cag pathogenicity island has no value in predicting current or future clinical presentation in individual patients. [54]

Other putative pathogenicity factors include the following: IceA (induced by contact with epithelium), a bacterial restriction enzyme for which no biologic or epidemiologic evidence as a virulence factor in *H pylori*–related disease has been confirmed; and VacA (vacuolating cytotoxin), which has been subtyped into an *s*1 genotype (presumably associated with duodenal ulcer disease) and an *s*2 genotype with reportedly low ulcerogenic potential. [55] A compilation of studies involving approximately 1500 isolates from Europe, the United States, and Asia has shown overwhelming that VacA genotyping is not useful to predict degree of inflammation, symptoms, presentation, or response to therapy.

The blood group antigen binding adhesin (BabA) is an outer membrane protein that appears to be involved in the adherence of *H pylori* to Lewis-b (Le^b) blood group antigens on gastric epithelial cells. [56] A small study suggested that infection with strains with the *babA*2 gene, *cagA* $^+$, and *vacA s*1 (triple-positive strains) may be correlated with duodenal ulcer, but a larger multinational study did not confirm the association. [52]

Diagnosis

The diagnosis of *H pylori* gastritis rests on the identification of *H pylori* in the gastric mucosa. When the search for *H pylori* relied exclusively on the availability of gastric biopsy specimens (for histopathology, rapid urease tests, or culture), only patients who required an endoscopic examination were tested. The development of increasingly accurate noninvasive tests allows the accurate diagnosis of *H pylori* gastritis based on indirect methods, that is, without necessarily visually identifying or culturing the organism. Furthermore, the availability and popularization of new, simple, and inexpensive tests have expanded the indications to a greater variety of patients and settings, including self-referring patients in the general practitioners' office.

Significant progress has been made also in our knowledge of factors that may influence the interpretation of the results and may interfere with the accuracy of each test. The prevalence of a condition in the population studied influences both the positive and negative predictive value of tests, even if a test's sensitivity and specificity are independent values inherent to the test itself. Therefore, clinicians should be familiar not only with the performance parameters of the tests they use, but also with their potential interpretative pitfalls as well as with the prevalence of *H pylori* in their patient population.

Invasive Tests

Histopathological examination of gastric biopsy specimens. *Helicobacter* spp. can be detected in histological preparations of gastric biopsy specimens stained with a variety of methods. Hematoxylin and eosin is a suboptimal choice of stains for the specific task of detecting *H pylori.* Reliable special stains include the Warthin-Starry and the Steiner silver stains, the Giemsa, Diff-Quick, and Gimenez stains, and a triple stain, [57] which, by combining modified Steiner staining, hematoxylin and eosin, and Alcian blue, allows the simultaneous visualization of the features of gastritis, including intestinal metaplasia, and the bacteria. Several modified versions of this stain have become available. [58] Anti– *H pylori* antibodies for the immunohistochemical detection of *H pylori* in paraffin-embedded biopsy specimens have high sensitivity and specificity; some laboratories use them for routine clinical diagnosis.

In situ hybridization and polymerase chain reaction. In situ hybridization may be used for the detection of *H pylori* in paraffin-embedded sections, but high cost and technical difficulties have relegated this procedure to the research laboratory. [59] Polymerase chain reaction for the detection of *H pylori* infection must also be considered a research tool because of its requirement for a sophisticated molecular biology laboratory, the availability of appropriate primers, and its high price.

Smear, brush, and touch preparations. Smears of gastric mucus and exfoliated epithelial cells, usually with Gram staining, may allow the detection of bacteria within minutes of the endoscopic procedure. Rapid urease tests have made cytologic assays obsolete.

Bacterial culture. *H pylori* is best cultured in a microaerophilic and humid atmosphere on culture media requiring fresh horse or sheep blood and antibiotics to suppress contaminants. [60] Cultures for *H pylori* are technically more complicated than those performed by the usual clinical microbiology laboratory. Because many clinical facilities are not equipped to perform the time-consuming procedures necessary to culture *H pylori,* several methods for transportation have been devised. [61]

Rapid urease tests. These assays exploit the high content of urease of *H pylori.* A fragment of gastric mucosa is placed into a broth or in agar containing various concentrations of urea. The urease produced by *H pylori* hydrolyzes the urea and releases ammonia, which raises the pH of the broth or agar, [62] and an appropriate indicator (e.g., phenol red) changes color as the pH increases. In the first commercially produced rapid urease test, the CLOtest, the original yellow gel capsule into which the specimen is placed becomes red within minutes to hours, depending on the quantity of bacteria present. Several rapid urease tests are now commercially available. Both their specificity and sensitivity, compared with histopathological examination, are extremely high, in most cases approaching 100%. [63], [64]

Noninvasive Tests

Serology. The development of new techniques has minimized the problems of cross-reactivity that plagued first-generation serologic tests. [65] Currently available tests are highly reliable. The large numbers of studies aimed at the discovery of an optimal diagnostic test for *H pylori* infection have also provided valuable information on the immune responses to this organism. For example, the selection of *H pylori* strains as sources of antigen is critical to the specificity and sensitivity of a test, and it is imperative to evaluate specific tests in the population to which it would be applied before selection of a test for use in specific settings. This population specificity highlights the importance of the many different geographic strains that infect different world populations.

Simplified "in-office" immunoenzymatic tests. Several in-office devices have been developed for the rapid detection of IgG anti– *H pylori* antibodies. Most of them consist of disposable kits that provide a yes/no answer within a few minutes of placing a drop of serum in a well that is preabsorbed with antigen and an immunoenzymatic detection system. Although some of these tests are accurate, results have been generally less than the minimum required sensitivity and specificity of 90%. [66], [67] Antibodies (mostly of the IgG class) against *H pylori* have been detected in the saliva and the urine of infected patients. The specificity and sensitivity of urine tests have been found to be satisfactory in several studies, particularly in Japan. [68]

Stool antigen assay. An enzymatic immunoassay (HpSA) that detects *H pylori* antigens in stools (thus providing information on the presence of current infection) has become available for the diagnosis of *H pylori* infection and for monitoring the response to therapy. The test is similar to an enzyme-linked immunosorbent assay, using polyclonal anti– *H pylori* antibody absorbed to microwells. A large European multicenter study has yielded encouraging results. [69], [70]

Urea breath tests. The urea breath tests are among the most important and innovative methods to detect *H pylori* infection. [71] These tests rest on the ability of *H pylori* to produce large quantities of urease. The ingestion of a solution containing urea is rapidly followed, in an infected patient, by the production of ammonia and carbon dioxide. The latter rapidly appears in the subject's breath. If the ingested urea is labeled either with the radioactive isotope ^{14}C or with the nonradioactive isotope ^{13}C, then the exhaled carbon dioxide will also be labeled and, therefore, measurable by an appropriate detection method. When ^{14}C-labeled urea is used, the general method consists of the ingestion of a solution or a capsule containing quantities between 0.5 and 10 µCi of the isotope-labeled urea. When ^{13}C-labeled urea is used, test subjects are given a solution of 125 g of 99.9% labeled urea followed by a meal aimed at increasing its permanence in the stomach. After a period of time, the subject inflates a balloon, which is immediately sealed and sent to a laboratory for the detection of the isotope-labeled carbon dioxide. Both types of tests are now well standardized and are approved by regulatory agencies in Europe and North America. The urea breath tests are extremely sensitive and specific and, in contrast to serologic tests, detect current active infection (not evidence of past infection). Their widespread use has made them more affordable, and they have

become the test of choice for a variety of populations, including children, pregnant women, and patients who cannot undergo an endoscopic procedure. [72], [73]

Helicobacter heilmannii Infection

More than 35 species of *Helicobacter* have been described, but only few other than *H pylori* have been shown to cause gastritis in humans: *H felis, H fennelliae, H cinaedi,* and *H heilmannii.* Among these, *H heilmanni*i (formerly known as *Gastrospirillum hominis*) is the most common, [74], [75] with an estimated prevalence of approximately 1% of all human *Helicobacter* infections. [75], [76] In some rural areas in Eastern Europe, this organism has been detected more commonly, leading to the hypothesis of zoonotic transmission. [75], [76] and [77] The bacterial morphology is characteristic: organisms measure 5 to 9 µm in length (twice as long as *H pylori*) and have five to seven spirals clearly visible with a silver stain. Gastritis caused by *H heilmanni*i is often milder and more patchily distributed than *H pylori* gastritis. The inflammation tends to be more circumscribed and to affect mostly the antrum, although cases with severe corpus active inflammation are seen. Concurrent erosions and ulcers have been reported to be less common than in *H pylori* gastritis. The diagnosis rests on the recognition of the bacterial morphology, although the distinction between *H heilmanni*i and *H felis* is not possible by light microscopy (see Fig. 68-10B).

Treatment of *Helicobacter pylori* Infection

At present, the only universally agreed on indications for treatment are *H pylori*–related duodenal and gastric ulcers and low-grade, primary B-cell MALT lymphoma. *H pylor*i should be eradicated in patients with documented ulcer disease, whether or not the ulcers are currently active, to reduce the likelihood of relapse. Most clinical trials do not provide convincing data in support of the benefits of eradication of infection in patients with nonulcer dyspepsia, and there are no controlled studies showing that eradicating *H pylor*i from a population will reduce the incidence of gastric cancer. For various logistical and ethical reasons, it is unlikely that such trials will be ever carried out to the satisfaction of those who demand unequivocal evidence. [78] The most pressing question then is whether we should hold back and wait for more data or act now based on current information. Today, there is ample epidemiologic and biologic evidence that whereas *H pylori* gastritis may not be the only cause of the development of atrophy and intestinal metaplasia, it almost always provides the necessary background on which these lesions arise. [79] By treating *H pylori* gastritis, we can prevent the development of atrophy and metaplasia, and most likely we would also arrest the progress of these lesions in infected persons who have already developed them. As a result, we should be able to prevent millions of gastric cancers. The incidence of non–NSAID-induced peptic ulcers would also be greatly reduced, and primary gastric lymphomas would all but disappear. Thus, we ought to put aside the teleological questions on the ultimate significance of our immemorial amphibiotic relationship with *H pylori* and its intriguing evolutionary and metaphysical implications [80] and proceed to cure infected patients.

In vitro, *H pylori* is susceptible to a wide range of antibiotics, but monotherapy has been disappointing in vivo, probably because of inadequate antibiotic delivery to the sites of colonization. Thus, several multidrug regimens have been developed, the most successful of which are triple and quadruple combinations that achieve *H pylori* eradication rates of more than 90% in many trials and more than 75% in clinical practice. The most commonly used 7- and 14-day drug regimens consisting of a proton pump inhibitor and two or three antimicrobial agents are listed in Table 68-2. The major determinants of therapeutic failures are inadequate patient compliance and drug resistance, particularly to metronidazole and clarithromycin. [81]

TABLE 68-2 Three Recommended Multidrug Regimens for the Eradication of *Helicobacter pylori* *

There are no established guidelines for posttreatment testing. When eradication therapy is given for gastric ulceration or MALT lymphoma, there is an opportunity to retest for *H pylori* at repeat endoscopy, which is performed to evaluate healing or regression. For duodenal ulceration, a urea breath test, a stool antigen test, or an endoscopy with gastric biopsy should be performed 4 to 6 weeks after treatment. When therapy is administered to treat asymptomatic infections, posttreatment testing is generally not deemed necessary.

Evolution and Associations of *Helicobacter pylori* Gastritis

H pylori gastritis is a life-long infection that can be viewed as a spectral disease. At the one end of the spectrum, inflammation remains mostly confined to the antrum and the cardia, the oxyntic mucosa is mildly affected, and atrophy is absent or minimal. At the other end, severe inflammatory changes involve the entire gastric mucosa and inflict progressive damage that results in loss of the normal gastric glands and their replacement by fibrous tissue and metaplastic epithelia. Although these are aspects of the same disease that can be placed on a continuous scale, the epidemiologic distribution and the associations of the two extremes are profoundly different. [82] Gastritis confined to the antrum and without significant atrophy does not impair acid secretion, is commonly present in patients with duodenal ulcer, and has not been linked to increased cancer risk. Conversely, generalized gastritis with atrophy reduces acid secretion and is strongly associated with gastric adenocarcinoma. [83] Thus, for the practical purposes of classification and prognostic evaluation, it has been expedient to divide gastritis into two phenotypes: nonatrophic antrum-predominant gastritis and multifocal atrophic gastritis.

Antrum-Predominant Gastritis This is the most common form of gastritis in the Western world. Its characteristics are as follows: a moderately to severely inflamed antrum; a mildly inflamed or normal corpus; minimal or absent atrophy or intestinal metaplasia, limited to the antrum; and normal or increased acid secretion. Most patients with this type of gastritis have neither symptoms nor complications. However, they have a risk of duodenal ulcer, estimated at 20% over their lifetime. [84], [85]
Atrophic Gastritis Also called *multifocal atrophic gastritis, metaplastic atrophic gastritis,* and *atrophic pangastritis,* this disorder is characterized by marked diffuse mucosal inflammation, often more severe in the oxyntic mucosa, by patches of atrophy and intestinal metaplasia in both antrum and corpus, and by variously reduced acid secretion. Atrophic gastritis is most prevalent in populations that are—or were, until a few decades ago—living in suboptimal sanitary conditions, including much of South and East Asia, Latin America, and parts of Central, Eastern, and Southern Europe. [86] Socioeconomic factors may be a surrogate for other unknown agents that modulate the evolution of gastritis, because there are notable epidemiologic exceptions to this association. Japan, a country with high levels of sanitation and personal hygiene, has one of the world's highest prevalences of atrophic gastritis and a high incidence of gastric adenocarcinoma. In contrast, Equatorial Africa, in spite of its precarious socioeconomic texture, inadequate sanitary standards, and a prevalence of *H pylori* close to 90%, appears to have a low prevalence of atrophic gastritis and a low incidence of gastric adenocarcinoma. [87] Several explanations have been proposed for this 'African enigma," ranging from diet, human and bacterial genetics, to unreliable statistics. [88] Atrophic gastritis is a risk factor for gastric epithelial dysplasia, a precursor of the intestinal-type adenocarcinoma of the stomach. [79] It also predisposes patients to gastric ulcer.
Peptic Ulcers, Carcinoma, and Lymphoma In addition to peptic ulcer disease (see Chapter 66) and gastric carcinoma (see Chapter 69), *H pylori* infection is also epidemiologically related to primary gastric MALT-lymphomas, which are also discussed in Chapter 69.
Extragastrointestinal Manifestations of *Helicobacter pylori* infection *H pylori* infection has been proposed to be associated with an ever-growing number of extragastric manifestations of *H pylori* infection, even if their causal relationship with *H pylori* is far from conclusively demonstrated. Most of these associations are founded on epidemiologic data; however, both *H pylori* infection and of some of the conditions allegedly associated with it (e.g., atherosclerosis) have a very high prevalence in many populations. Thus, biologic rather than epidemiologic data will be needed to prove causation. For one of these conditions, rosacea, there are several randomized trials that essentially disprove the association with *H pylori.* [89], [90] Conversely, several clinical studies based on treatment results lend some support to the possibility of a pathogenetic involvement of *H pylori* in iron deficiency anemia and autoimmune thrombocytopenic purpura. [91], [92] and [93] For most other conditions, data are insufficient to reach informed conclusions; however, the biologic plausibility in some of the proposed associations (e.g., with migraine) is so low that one must wonder whether attempts to prove causality are worth the effort.

INFECTIOUS GASTRITIS (EXCLUDING *HELICOBACTER* GASTRITIS)

Because of the high acid content of the normal stomach, the gastric environment is inhospitable to most infectious agents. However, in patients with atrophic gastritis and decreased acid secretion, in patients with impaired immune responses, or as part of systemic infections, numerous viruses, bacteria, and parasites can infect the stomach. Although rare, some of these infectious gastritides have characteristic clinical and pathological features.

Viruses

Enteric rotaviruses and *caliciviruses* probably infect the stomach during the course of gastroenteritis, but no pathological changes in the gastric mucosa have been documented in volunteer studies with these agents. Only *cytomegalovirus* (CMV) infection is known to have a distinct pathological appearance in the stomach. CMV gastritis is seen almost exclusively in young children and immunocompromised patients, and it is usually associated with concurrent CMV infection of other sites of the digestive tract. Endoscopically, the gastric mucosa may appear completely normal or may show erosions, shallow ulcers, [94] or hemorrhagic gastritis. [95] Rarely, the condition may present as grossly nodular mucosa that has been referred to as a pseudotumor. [96] CMV inclusions may be abundant and thus easily detected using the routine hematoxylin and eosin stain, or they may be rare and impossible to demonstrate without using immunohistochemistry or in situ hybridization techniques. A characteristic manifestation of CMV infection in the stomach of young children is massive foveolar hyperplasia accompanied by edema and mild inflammation of the lamina propria. The resulting endoscopic appearance is that of a giant-fold hypertrophic gastropathy indistinguishable from Ménétrier disease. [97]

The diagnosis of gastric CMV infection is made by demonstrating the characteristic nuclear or cytoplasmic viral inclusions (Fig. 68-11A). The only effective therapeutic agent is ganciclovir, a guanosine derivative that selectively inhibits CMV DNA polymerase. In patients with acquired immunodeficiency syndrome (AIDS) and CMV colitis, ganciclovir has a response rate of 70% to 90%. [98], [99]

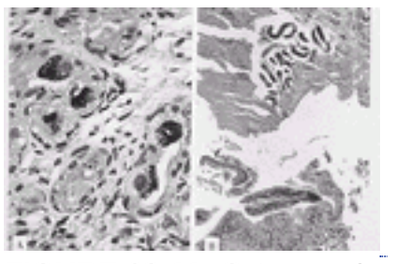

FIGURE 68-11. Cytomegalovirus cytoplasmic and nuclear inclusions (**A**) and *Strongyloides stercoralis* larvae (**B**) in gastric biopsy specimens from immunocompromised patients.

Bacteria

Bacterial overgrowth may occur in stomachs that have become achlorhydric as a result of atrophy, complete antrectomy, or vagotomy or as a result of long-term use of histamine H_2-receptor antagonists or proton pump inhibitors. [100] Patients with scleroderma and other severe motility impairments are also prone to bacterial overgrowth. [101] In contrast to *H pylori,* however, these bacteria colonize rather than infect the gastric mucosa, and they neither elicit inflammatory responses nor cause symptoms.

An extremely rare condition is *acute suppurative gastritis,* also known as *phlegmonous gastritis.* This life-threatening condition is caused by pyogenic bacteria (streptococci, staphylococci, *Escherichia coli, Proteus,* and *Haemophilus* spp.) and is characterized by large areas of purulent necrosis involving the full thickness of the gastric wall. When it is caused by gas-forming organisms, the term *emphysematous gastritis* has been used. Few cases have been reported, mostly in very young children, elderly persons, patients with alcoholism, and immunocompromised patients. Potential iatrogenic causes include polypectomy [102] and mucosal injection with India ink. [103] The diagnosis is made endoscopically or at surgery. Antibiotic treatment may have to be accompanied by surgical intervention. [104]

Primary gastric tuberculosis is rare, particularly in industrialized countries. [105], [106] However, in patients with *disseminated tuberculosis, necrotizing granulomata* may be found in the gastric mucosa. Another *Mycobacterium* that has gained prominence with the spread of AIDS is *Mycobacterium avium-intracellulare* complex, but the stomach is rarely involved; when it is, typical lesions consist of accumulations of foamy histiocytes in the lamina propria, sometimes with formation of ill-defined granulomata without necrosis.

In the 1980s and early 1990s, increasing numbers of cases of *gastric syphilis* were reported in patients infected with human immunodeficiency virus. [107] When associated with secondary syphilis, syphilitic gastritis is characterized by a prominent mixed inflammatory infiltrate consisting predominantly of plasma cells and with mucosal ulcerations. The infiltrate may be dense enough to cause the swelling of gastric folds, which may also undergo erosion and ulceration, sometimes mimicking the endoscopic appearance of lymphoma or infiltrating carcinoma. [108] Symptoms include severe dyspepsia, nausea, vomiting, and anorexia, with rapid weight loss. The diagnosis is often delayed by a low index of suspicion. Although spirochetes may be seen in sections stained with appropriate silver stains (Dieterle, Steiner, or Warthin-Starry), the search may be painstaking and is usually beyond the reach of the nonspecialist pathologist. Standard treatment for secondary syphilis is rapidly effective.

Fungi

Candida species, *Histoplasma capsulatum,* and Mucoraceae have been found in the stomach of immunocompromised patients, particularly those with AIDS, with disseminated infections, but none of these fungi have been reported as a primary cause of gastritis.

Parasites

The stomach is not a preferred site for human parasitic infections, but *Cryptosporidium* spp. [109] and *Giardia intestinalis* [110] have been identified in the gastric mucosa (see Fig. 68-11B). *Strongyloides stercoralis* has been found in the stomach of a few patients with widespread infections. [111]

The only nematodes that invade the human gastric wall are those of the family collectively known as Anisakidae, or “sushi worms.” *Anisakiasis* is an important cause of morbidity in countries such as Japan, where large quantities of raw fish are consumed. [9], [112] The muscle of many species of edible fishes contain larvae of Anisakidae. In a small proportion of persons who eat infected fish, larvae penetrate the gastric wall and cause a sudden onset of epigastric pain. Because the worms can be easily removed endoscopically by an experienced operator and the disease is self-limited in any case, patients presenting with epigastric pain in high-prevalence countries should be asked routinely about ingestion of raw or undercooked fish within 12 hours before the onset of symptoms. This practice would help to avoid unnecessary surgery.

AUTOIMMUNE GASTRITIS

Autoimmune gastritis is a corpus-restricted chronic atrophic gastritis associated with circulating serum anti–parietal cell and anti–intrinsic factor antibodies and intrinsic factor deficiency, with or without pernicious anemia. [12]

Clinical Manifestations

Most clinical manifestations of autoimmune gastritis become apparent only many years after the onset of the disease, when the parietal cell mass decreases beyond a critical point and the stomach becomes unable to produce sufficient amounts of acid, pepsinogens, pepsin, and intrinsic factor. *Achlorhydria,* the most direct result of the destruction of acid-producing oxyntic cells, typically occurs in the most advanced stages of the disease. *Hypochlorhydria,* however, may also occur in patients with moderate to large numbers of surviving parietal cells, suggesting that anti–proton pump antibodies or inhibitory lymphokines released by subsets of inflammatory cells may participate in the inhibition of acid secretion. Patients with corpus atrophy and achlorhydria have hypergastrinemia, which tends to correlate with the severity of the mucosal damage. [113] Injury to chief cells leads to a reduction of pepsin activity in gastric juice and of pepsinogens in blood. A low serum pepsinogen I level (<20

ng/mL) is a sensitive and specific indication of corpus atrophy. [113], [114]

Many patients with autoimmune gastritis develop either iron deficiency or pernicious anemia. Hypochromic anemia is associated with corpus-restricted chronic atrophic gastritis in approximately 15% of patients. [12] Achlorhydria seems to be the major contributor to the pathogenesis of iron deficiency anemia: gastric acid is important in the absorption of nonheme iron, which in Western diets supplies at least two thirds of nutritional iron needs. [115] Pernicious anemia is usually preceded by corpus-restricted chronic atrophic gastritis and reduced acid secretion by approximately a decade, and it is generally associated with a histological pattern of end-stage atrophic gastritis. [116] Pernicious anemia is a rarely diagnosed condition, with a reported prevalence of less than 1% even in elderly persons in high-incidence countries. [117], [118] Its true prevalence could be higher, but most patients are successfully treated by hematologists or general practitioners for their anemia and cobalamin (vitamin B_{12}) deficiency, and they are never referred to a gastroenterologist for the evaluation of atrophic gastritis, pepsinogens levels, or anti–parietal cell antibodies. Cobalamin deficiency affects the rapidly proliferating gastrointestinal epithelium, and patients with severe deficiency may complain of a sore tongue, which may be smooth and beefy red. Anorexia with moderate weight loss may also be evident, possibly accompanied by diarrhea and other gastrointestinal symptoms. Neurological manifestations include numbness and paresthesia in the extremities, weakness, and ataxia. There may be sphincter disturbances.

Autoimmune gastritis is a risk factor for hyperplastic and adenomatous polyps, carcinomas, and endocrine tumors. Polyps are found in 20% to 40% of patients with pernicious anemia, and they are mostly sessile, smaller than 2 cm in diameter, and often multiple. Most polyps are hyperplastic, but up to 10% contain dysplastic foci. [119] Gastric cancers associated with pernicious anemia are of the intestinal type and arise from intestinal metaplasia, a finding suggesting that the link between autoimmune gastritis and carcinoma may be intestinal metaplasia and its dysplastic transformation. [120]

Pathogenesis

Autoimmune gastritis is substantially more common in patients with other diseases thought to be of immunologic origin (Graves disease, myxedema, thyroiditis, idiopathic adrenocortical insufficiency, vitiligo, and hypoparathyroidism) than in the healthy population. The high prevalence of specific familial histocompatibility haplotypes such as human leukocyte antigen (HLA)-B8 and HLA-DR3 in patients with corpus-restricted atrophic gastritis is another strong indicator of its autoimmune origin. The precipitating factors, however, remain unknown. The hypothesis that autoimmune gastritis could be initiated by *H pylori* infection has received considerable attention. A high prevalence of antibodies with high specificity for gastric mucosa antigens has been reported in patients with *H pylori*–associated gastritis; preabsorption of the serum from these patients with *H pylori* removed most of these autoantibodies. [121] Furthermore, 20% of these patients had autoantibodies that reacted with the secretory canalicular structures of parietal cells, which are among the major targets in autoimmune gastritis. In other studies, *H pylori*–positive patients with and without previously demonstrated anticanalicular antibodies had a 30% to 50% prevalence of anti–H^+,K^+-ATPase antibodies, in contrast to a less than 3% prevalence in noninfected persons. [122] It has also been demonstrated that *H pylori* lipopolysaccharides express Lewis x and y blood group antigens, which are also expressed by either H^+,K^+-ATPase or gastric epithelial cells. [123], [124] Collectively, this information lends support to the concept that a cross-mimicking mechanism between *H pylori* and gastric mucosa antigens participates in the pathogenesis of autoimmune gastritis. This correlation, however, remains unproven, and much stronger biologic, clinical, and epidemiologic evidence is needed before *H pylori* can be viewed as the cause of autoimmune gastritis. [125]

Endoscopic Appearance

Atrophy causes a progressive thinning of the mucosa of the gastric corpus; this explains why few folds are left and why fine submucosal vessels are easily recognized on endoscopic examination, especially in advanced disease. The antral mucosa is endoscopically normal in the majority of cases. Polyps become common in the advanced stages of the disease; therefore, atrophic gastritis must be ruled out in patients in whom multiple hyperplastic gastric polyps are detected at endoscopy.

Histopathology

The main histopathological features of autoimmune gastritis are diffuse corpus-restricted chronic atrophic gastritis with mild to moderate intestinal metaplasia and, in the absence of concurrent *H pylori* infection, a normal gastric antrum. This pattern is characteristic of the advanced stage of the disease and is found in patients with pernicious anemia. Persons with parietal cell antibodies and no pernicious anemia show a broad spectrum of atrophic changes, from minimal oxyntic gland loss to severe and diffuse atrophy of the oxyntic mucosa. [12] In the early phases, one sees diffuse or multifocal, dense mononuclear cell infiltration of the lamina propria and lymphocytic infiltration of individual oxyntic glands. Later, marked atrophy of the oxyntic glands with diffuse mononuclear cell infiltration of the lamina propria develops. Pyloric metaplasia is extensive, whereas intestinal metaplasia tends to be still limited to few foci. The end stage is characterized by a great reduction in corpus mucosal thickness, foveolar hyperplasia, and replacement of oxyntic glands by pyloric, pseudopyloric, or intestinal metaplasia. The inflammatory infiltrate is minimal, although scattered lymphoid aggregates and follicles may be found.

In the majority of patients, the antral mucosa is either normal or shows only focal areas of mild chronic inflammation with intestinal metaplasia, similar in degree and extension to what is observed in the general asymptomatic population. Hyperplasia of gastrin cells secondary to achlorhydria is often seen. Enterochromaffin-like cell carcinoids may arise during the florid phase, but they are found more commonly in association with an end-stage histopathological pattern. [120]

Diagnosis

Autoimmune gastritis should be suspected in patients with megaloblastic anemia, with evidence of clinically significant cobalamin deficiency with values lower than 150 pg/mL, or with multiple gastric polyps. The diagnosis must be confirmed by the characteristic histopathological findings of corpus-restricted atrophic gastritis and by the presence of serum anti–intrinsic factor or anti–parietal cell antibodies.

Management

The management of patients with autoimmune gastritis should address two aspects of the condition: the gastric lesions and the manifestations related to the cobalamin deficiency. Gastric mucosal atrophy is irreversible. Patients with extensive intestinal metaplasia and those with multiple polyps may be at increased risk of gastric cancer. Although there are no accepted guidelines, a surveillance gastroscopy every 1 or 2 years may represent a sensible empiric approach.

With cobalamin replacement, most abnormalities resulting from cobalamin deficiency undergo complete and lifelong correction, except for the neurological manifestations. Their improvement depends on the extent that irreversible changes in the nervous system may have occurred before treatment.

LYMPHOCYTIC GASTRITIS

Lymphocytic gastritis is characterized by the presence of large numbers of mature lymphocytes infiltrating the surface and foveolar epithelium. [11]

Clinical Manifestations

In his original report of this condition, Haot suggested that lymphocytic gastritis corresponded to the endoscopic entity previously known as *varioliform gastritis.* The histological features of lymphocytic gastritis may also be found in endoscopically normal stomachs and in patients with celiac disease, and the varioliform aspect (numerous thickened folds capped by small nodules that contain a central erosion or ulceration) can be found in *H pylori*–infected stomachs. [126], [127]

Lymphocytic gastritis is rare, found in 1% to 3% of persons who undergo endoscopy with biopsy sampling. [128], [129] It is most commonly diagnosed in the sixth decade and appears to affect men and women equally. [130]

In contrast to patients with chronic active gastritis, patients with the varioliform type of lymphocytic gastritis are often symptomatic; rapid weight loss and anorexia are reported in about half of affected patients, whereas epigastric pain is less common. Hypoproteinemia, hypoalbuminemia, and peripheral edema suggesting protein-losing gastroenteropathy have been documented in approximately 20% of patients. [11] Lymphocytic gastritis is a chronic disease, but there have been few case reports of spontaneous resolution. When it is associated with gluten enteropathy, the signs, symptoms, and clinical course are those of celiac disease (see Chapter

76).

Pathogenesis

Both the etiology and the pathogenesis of most lymphocytic gastritides are unknown. Because virtually all intraepithelial lymphocytes are CD8 $^{+}$ suppressor T cells, the same cells that form the intraepithelial infiltrate in celiac disease, an allergic pathogenesis has been proposed. This hypothesis is supported by the increasingly apparent association between a subtype of lymphocytic gastritis and celiac disease. [129], [131], [132] The relationship with *H pylori,* initially enthusiastically embraced, then vigorously rejected, is now viewed with an agnostic attitude by most investigators.

Macroscopic and Endoscopic Appearance

Approximately 80% of patients in whom a histopathological diagnosis of lymphocytic gastritis is made have endoscopic lesions described as varioliform, aphthous, verrucous, or chronic erosive gastritis. [11], [133] The appearance is that of a complex pattern of enlarged folds, predominantly in the corpus, which are covered by thick mucus, are crossed by large erosions, and may be crested with clusters of elevated aphthoid nodules. Flat erosions may be found in the antrum. The remaining 20% of patients (including those with celiac disease and collagenous gastritis) have less dramatic lesions, with only scattered superficial erosions in the corpus or antrum. Some patients have an endoscopically normal stomach. This last group of patients with a normal-appearing stomach may have a pathogenetically distinct condition, even though the histopathological features are indistinguishable. Some authors have suspected a relationship between lymphocytic gastritis and Ménétrier disease. [134]

Histopathology and Diagnosis

Because the endoscopic appearance of varioliform gastritis may result from either *H pylori* infection or lymphocytic gastritis, the diagnosis can be suspected clinically, but it can be confirmed only by histopathologists. In biopsy specimens from these patients, a substantial increase in intraepithelial lymphocytes, particularly in the corpus, is associated with a histopathological spectrum ranging from marked chronic inflammatory cell infiltration of the lamina propria, activity, and focal erosions to a minor increase in chronic inflammatory cells with no activity (Fig. 68-12A). In most cases, the histological picture can be readily distinguished from that of chronic *H pylori* gastritis, in which few intraepithelial lymphocytes are present (rarely more that 5 or 6 per 100 epithelial cells). The diagnostic threshold for lymphocytic gastritis is generally accepted as more than 25 intraepithelial lymphocytes per 100 epithelial cells, but in most cases the counts are much greater, between 25 and 50 lymphocytes. [135] If *H pylori* infection is present, immunohistochemistry to detect CD8 $^{+}$ T cells may be helpful: in pure lymphocytic gastritis, most intraepithelial lymphocytes are CD8 $^{+}$, whereas a heterogeneous infiltrate characterizes *H pylori* gastritis.

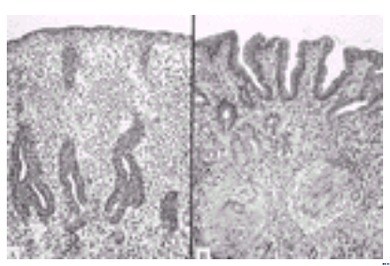

FIGURE 68-12. (**A**) Lymphocytic gastritis: a dense, mostly mononuclear infiltrate obliterates the lamina propria, and large numbers of CD8 $^{+}$ suppressor T cells infiltrate both the surface and the foveolar epithelium. (**B**) Two large, nonnecrotizing granulomata in the antral mucosa of a patient with no known infection or systemic granulomatous condition. In such a case, the provisional label of “idiopathic granulomatous gastritis” may be used.

Therapy

When concurrent *H pylori* infection is present, eradication of the infection may resolve the inflammation and is therefore recommended. [136], [137] Patients with gluten enteropathy will benefit from the standard dietary limitations recommended to restore the small intestinal integrity. For patients with “pure” lymphocytic gastritis and severe gastric mucosal lesions, there are no consistently effective therapies. The use of proton pump inhibitors has resulted in healing of the ulcers and erosions in some patients. Therapy with glucocorticosteroids or sodium cromoglycate, often successfully used for the treatment of eosinophilic gastroenteritis, [138], [139] has obtained unclear results.

GRANULOMATOUS GASTRITIS

Rather than a clinical entity, *granulomatous gastritis* can be viewed as a histopathological category to which stomachs bearing granulomata are temporarily assigned while the condition responsible for their development is identified. In most cases the morphologic appearance of granulomata does not provide useful clues as to their cause, except when foreign materials, acid-fast bacilli, or fungal forms are found. Thus, a specific diagnosis can be made only by integrating histopathological data with clinical and laboratory information.

Clinical Manifestations and Pathogenesis

Because granulomata can be found in the gastric mucosa of patients with infectious, inflammatory, and neoplastic diseases, as well as in otherwise healthy persons, neither clinical manifestations nor endoscopic appearances are useful to predict the presence of gastric granulomata. Thus, the stomach may be completely normal or may exhibit characteristics of the associated conditions.

Mycobacterium tuberculosis **and** ***Histoplasma capsulatum*** **Infection** *Tuberculosis* is the most common cause of granulomatous disease of the gastrointestinal tract, but the stomach is rarely affected, even in the presence of severe ileocecal involvement. Primary gastric tuberculosis has been reported mostly from developing countries with a high prevalence of *Mycobacterium tuberculosis* infection. [106], [140] In almost all such cases, gastric tuberculosis was diagnosed because of the presence of a large, nonhealing gastric ulcer. A few cases of primary infection of the stomach by the dimorphic fungus *Histoplasma capsulatum* have been reported. As in patients with gastric tuberculosis, these patients presented with signs and symptoms that led to the discovery of a large gastric ulcer initially interpreted clinically as malignant. [141], [142]

Helicobacter pylori **Infection** Unexplained granulomata have been found in patients with *H pylori* gastritis, but this finding is extremely rare, on the order of less than 1 in 1000 infected patients. Although a role for *H pylori* in the causation of granulomata has been postulated, there is no evidence to support this hypothesis. [143], [144]

Anisakiasis Early lesions of *anisakiasis* range from interstitial edema with a loose, eosinophilic inflammatory infiltrate to eosinophilic abscesses, in which well-preserved larvae are often detected. In later lesions, the most common finding is the presence of foreign body granulomata, sometimes associated with fragments of helminthic cuticles. [112], [145]

Foreign Bodies A common cause of gastric *foreign body granulomata* is suture material in patients who have undergone a partial gastrectomy. In patients with gastric ulcer, food particles may become engulfed in the ulcer crater and may cause a foreign body reaction. When such granulomata are found in biopsy specimens obtained from active ulcers, their origin is readily apparent; diagnostic difficulties may arise when granulomata are found in specimens from healed ulcers and the pathologist is unaware of the relevant clinical information.

Tumors Rarely, *adenocarcinomas* (particularly mucin-secreting tumors) may induce the formation of foreign body granulomata in the gastric mucosa or perigastric lymph nodes. Granulomata have also been noted in the gastric mucosa of few patients with gastric *non-MALT lymphoma.*

Other Unusual Causes In rare instances, granulomatous gastritis may be part of an immune-mediated vasculitis syndrome or Wegener granulomatosis. Sometimes, it may assume a form akin to xanthogranulomatous cholecystitis. [146]

Granulomatous Gastritis in Sarcoidosis and Crohn’s Disease

Granulomata detected in the gastric mucosa of a patient with established *sarcoidosis* or *Crohn's disease* can be assumed to be part of the systemic process, and no further investigation is required. Because the finding of gastric mucosal granulomata may precede the discovery of the disease in other organs, the careful interpretation of gastric biopsy findings together with appropriate suggestions for further tests may lead to the prompt diagnosis of a condition that could otherwise remain obscure for a long time. [143]

In sarcoidosis, involvement of the gastrointestinal tract is found occasionally at autopsy, but only rarely has it clinical importance. However, severe gastric disease with outlet obstruction or bleeding has been reported. Endoscopic findings may include nodularity, polypoid changes, erosions, ulcers, and segmental, usually distal, rigidity resembling linitis plastica. [147], [148] These gross changes reflect the presence of numerous mucosal granulomata and severe fibrosis.

Studies have challenged the perception that gastric involvement is rare in Crohn's disease, and they found a prevalence of gastric granulomata of approximately 10% to 15% and a prevalence of "focally enhanced" *H pylori*–negative active gastritis of between 30% and 70%. [6], [149], [150] In these patients, focal gastritis was almost twice as frequent in the corpus as in the antrum, and epithelioid granulomata were twice as prevalent in the antrum.

Isolated Granulomatous Gastritis

Isolated granulomatous gastritis is a "holding category," applied as a temporary diagnostic label to cases of granulomatous gastric inflammation for which no cause has yet been determined (see Fig. 68-12B). Support for this approach derives from studies showing that most gastric granulomata are an expression of either concurrent or incipient Crohn's disease or systemic sarcoidosis. [143], [151], [152] Even after careful evaluation, some gastric granulomata will remain unexplained. These lesions are usually asymptomatic, there is no information on their natural history or evolution, and, therefore, no treatment can be recommended.

CHEMICAL (REACTIVE) GASTROPATHY

An association between the presence of bile in the stomach and gastric mucosal damage (*duodenogastric reflux*) was first postulated by William Beaumont in 1859, and several subsequent clinical observations led to the development of surgical techniques to prevent or minimize the regurgitation of duodenal contents into the stomach. In 1983, Dewar, Dixon, and Johnston [24] systematically described the histopathological changes associated with bile reflux in the stomachs of patients who had undergone gastrectomy as well as patients with duodenal or gastric ulcer. The original term *bile reflux* [4], [24], [153] was later replaced by *chemical gastritis,* to include the recently discovered NSAID-induced changes in the gastric mucosa. The terms *reactive gastritis, type C gastritis,* and *chemical gastropathy* have also been used. Chemical gastropathy is now defined as the constellation of endoscopic and histological changes caused by chemical injury to the gastric mucosa. This is an implicit admission that this diagnosis can be made only when converging clinical and histopathological evidence is present. *Radiation gastritis*, which results from a physical agent rather than a chemical one, is described in Chapter 132.

Clinical Manifestations

Three categories of patients may exhibit the endoscopic and histological changes of chemical gastropathy: patients with alkaline reflux after partial gastrectomy, patients with duodenogastric bile reflux as part of a poorly understood dysmotility syndrome, and patients who take NSAIDs.

Postgastrectomy alkaline reflux may present with a syndrome characterized by burning midepigastric pain unresponsive to antacids and aggravated by eating and recumbency. [154], [155] Bilious vomiting, anemia, and weight loss may occur. Endoscopic confirmation of bile reflux and documentation of the characteristic histopathological findings support the diagnosis, and corrective surgery (e.g., creation of a 40- to 50-cm Roux-en-Y gastrojejunostomy) is successful in about half of all cases. [156]

Duodenogastric bile reflux secondary to gastroduodenal dysmotility or to cholecystectomy is a controversial condition, rarely considered in the differential diagnosis of dyspepsia in patients with an intact stomach. [157] Thus, the frequency of endoscopic or histological changes of chemical gastropathy in these patients is unknown.

Millions of persons take daily doses of *NSAIDs* for indefinite periods, in many cases for life, to control pain caused by osteoarthritis, rheumatoid arthritis, or other chronic conditions. Unknown numbers of these NSAID users experience epigastric pain; approximately 10% per year develop erosions or ulcers, and 1% to 2% per year have a major gastric bleeding episode. [158], [159] Reactive gastropathy has been documented histopathologically in 10% to 45% of long-term users of NSAIDs, but no relationship could be established between the appearance of the mucosa and dyspeptic symptoms.

Pathogenesis

Duodenogastric reflux (with alkaline pancreaticoduodenal secretions as well as acids, bile salts, and lysolecithin) disrupts the mucous barrier and directly damages the gastric surface epithelium. [160] This combined injury leads to accelerated exfoliation of surface epithelial cells and a histamine-mediated vascular response that manifests as edema and hyperemia. Persistent epithelial damage may lead to the release of other proinflammatory agents, such as platelet-derived growth factor, which among its many actions stimulates smooth muscle and, later on, fibroblastic proliferation. [161] Epithelial injury after exposure to NSAIDs appears to be mediated by reduced prostaglandin synthesis. Prostaglandins are important cytoprotective agents in the gastric mucosa and exert their effects by maintaining mucosal blood flow, by increasing secretion of mucus and bicarbonate ions, and by augmenting epithelial defense against cytotoxic injury. Thus, NSAID-inflicted injury can be partially prevented by simultaneous administration of prostaglandin analogs such as misoprostol [162] and by suppression of gastric acid production with proton pump inhibitors. [163] Newer selective cyclooxygenase 2 inhibitors (inhibitors, second-generation NSAIDs, or selective NSAIDs) are reportedly better tolerated by the gastric mucosa. [164] Whether the initial encouraging results will hold true when these drugs become widely used, remains to be evaluated.

Endoscopic Appearance

In patients who have undergone a Billroth II gastrectomy, the gastric mucosa at the anastomotic site may have a polypoid appearance with congestion, edema, and friability. [165] Superficial erosions may be present in more proximal areas of the gastric stump, but they are not specific, because they can be caused by a variety of injuries. In patients with nonoperated stomachs and possible duodenogastric bile reflux, the mucosa may exhibit congestion, edema, and erosions. In long-term NSAID users, the mucosa may be normal or may show congestion, erosions, or ulcers.

Histopathology

Although some histological features are more frequently found in regular NSAID users, the histopathological diagnosis of chemical gastropathy remains a challenging problem. The histopathological changes that have been associated with reactive gastropathy (see Fig. 68-4A) include evidence of epithelial regeneration, foveolar hyperplasia, edema of the lamina propria, and expansion of the smooth muscle fibers into the upper third of the mucosa, an area in which they are not normally found. Both the specificity and the predictive value of these features are low because of several potential confounding factors. Surreptitious use of NSAIDs, other substances in the diet (e.g., alcohol, spices, salt) that may cause similar mucosal changes, and clinically silent bile reflux [153], [157] can rarely be excluded; furthermore, the difficulty of obtaining a perfect control population cannot be overemphasized. *H pylori* infection induces some of the features traditionally considered characteristic of chemical gastropathy: mucosal hyperemia and edema, superficial erosions, foveolar hyperplasia, and regenerative changes. Therefore, the pathologist can suspect chemical gastropathy and communicate this suspicion to the clinician, but a firm histopathological diagnosis can be made only when supportive clinical data are available and *H pylori* infection is absent. [5]

Partial Gastrectomy and Carcinoma

The polypoid appearance of the distal portions of the gastric stump in patients who have undergone gastrectomy has been referred to as *gastritis cystica polyposa.* [166] Several studies, mostly conducted in Europe and Asia, have reported a high prevalence of low-grade dysplasia in these polypoid areas, as well as an increased incidence of gastric adenocarcinoma 2 to 3 decades after gastrectomy. [167], [168] The implications of these findings, potentially important because of the suggestion that patients who undergo partial gastrectomy may need endoscopic surveillance, seem less urgent in the present era, when partial gastrectomy for peptic ulcer disease

has become an exceedingly rare operation.

HEMORRHAGIC GASTROPATHY

Hemorrhagic gastropathy (hemorrhagic gastritis) refers to a group of conditions characterized by subepithelial hemorrhages and erosions. [169] These mucosal lesions do not cause major bleeding unless ulcers develop. Three major factors are involved in the pathogenesis of hemorrhagic gastropathy: use of NSAIDs, ingestion of large quantities of alcohol, and severe physical stress.

Aspirin and other NSAIDs may induce mucosal edema, hyperemia, and multiple erosions and ulcerations. Such lesions may occur suddenly, without warning symptoms such as pain or discomfort, in first-time NSAID users and in patients who have taken NSAIDs regularly for years. Except for generic risk factors such as older age, female sex, and previous episodes, there is no known trait to identify NSAID users prospectively who may be susceptible to severe gastric injury.

Similar mucosal lesions, although usually less severe and only rarely evolving to ulcerations, can be caused by ingestion of large quantities of alcohol. [169, 170] Because alcohol and aspirin may act synergistically to break down mucosal defenses, one wonders how many hemorrhagic gastropathies have been caused by attempts to prevent hangovers by taking aspirin after an alcoholic binge. [171]

The most severe degrees of hemorrhagic gastropathy are those induced by stress. Originally described in 1842 by Thomas Curling, [172] stress-induced gastroduodenal mucosal breakdowns (known as Curling ulcers) can be found in most patients admitted to an intensive care unit; approximately 20% are a source of overt bleeding, and 2% to 5% of these ulcers cause life-threatening hemorrhage. [173]

Pathogenesis

The pathogenesis of stress-induced hemorrhagic gastritis is not known, but lumenal acid seems to be essential. Acid exerts its deleterious effects when the mucosal defense mechanisms (e.g., the mucous-bicarbonate barrier and the epithelial layer) lose their integrity. [173] Vascular disturbances—in association with stasis, vasoconstriction, and increased vascular permeability—may further contribute to mucosal vulnerability. Aspirin and NSAIDs act by interfering with prostaglandin synthesis, as noted earlier. Alcohol causes direct damage to the gastric mucosa; at a concentration of 12.5% (that of table wine), it induces hyperemia and petechiae, and concentrations greater than 40% (“hard liquors”) cause necrosis of the surface epithelium and capillaries and subsequent interstitial hemorrhage. [169, 174]

Clinical Manifestations

Acute hemorrhagic gastritis is characterized by a hyperemic edematous mucosa with erosions and various degrees of active bleeding. The clinical history (e.g., shock, burns, recent alcohol binge, ingestion of aspirin), rather than the widely overlapping nature of the lesions, will help the endoscopist to determine the precipitating factors. Because the diagnosis is often clear from the clinical context, gastric biopsies are rarely obtained from critically ill patients who undergo endoscopy because of upper gastrointestinal hemorrhage.

Histopathology

Acute hemorrhagic gastritis, irrespective of its cause, is characterized by dilation and congestion of the capillaries, edema, and various degrees of interstitial hemorrhage in the lamina propria. Epithelial erosions are generally small; aggregates of fibrin and polymorphonuclear cells replace the eroded epithelium and may project above the surface to form small, elevated clumps of necrotic debris. In the absence of concurrent *H pylori* infection, there is no significant inflammation in the unaffected areas of the stomach. [169] Therefore, a diagnosis of erosive hemorrhagic gastritis can usually be made, and possible etiologic agents may be listed (e.g., alcohol or NSAID ingestion). If *H pylori* gastritis is present, widespread active inflammation often obscures or worsens the changes caused by other agents, and a separate diagnosis of the diverse causes of the changes is usually impossible.

Management

The suppression of acid with H_2-receptor antagonists or proton pump inhibitors helps to reduce the severity of the mucosal damage and facilitates healing. Sucralfate, although less commonly used, is also effective. [159, 169, 170]

VASCULAR GASTROPATHIES

Gastric vascular gastropathies [175] comprise a heterogeneous group of conditions characterized by alterations in the gastric circulation and their effects on the gastric mucosa. The best-defined conditions, from morphologic and pathogenetic viewpoints, are the *watermelon stomach,* which is described in Chapter 130, and *portal hypertensive gastropathy.*

Portal Hypertensive Gastropathy

Clinical Manifestations and Pathogenesis *Portal hypertensive gastropathy* is a dilation of the mucosal vessels, more prominent in the proximal stomach, that occurs in a proportion of patients with cirrhosis of the liver [176]; its prevalence parallels the severity of portal hypertension. Bleeding from this lesion is relatively uncommon and rarely severe; in general, patients with the most severe portal hypertension have diffuse lesions and higher rates of gastric bleeding. [177]
Endoscopic Appearance The endoscopic appearance of portal hypertensive gastropathy is nonspecific and does not correlate well with the degree of portal hypertension. The endoscopic patterns have been variously described as snake skin, scarlatina rash, cherry-red spots, and mosaic. [178] The mosaic pattern was found by a consensus conference [179] to be the most reliable indicator of mild portal hypertensive gastropathy with a low risk of hemorrhage. Red marks suggest a more severe degree of hypertension and a greater risk of hemorrhage.
Histopathology Dilation and tortuosity of small arteries and veins, with occasional thickening of the walls, are among the pathological changes of portal hypertensive gastropathy. The changes are more prominent in the corpus and are more apparent in submucosal vessels than in mucosal capillaries. Because of the location of these changes and the understandable reluctance of most gastroenterologists to obtain large and deep biopsy samples from patients who may have an increased risk of bleeding, the diagnosis of portal hypertensive gastropathy is not commonly reached by evaluating mucosal biopsies. In patients with concurrent *H pylori* gastritis, it is difficult, if not impossible, to separate the respective contribution of infection and congestion to the resulting complex of changes observed in the mucosa. [180, 181]
Management Because bleeding is relatively uncommon, most patients do no require specific therapy. Sclerotherapy of esophageal varices does not seem to influence the natural history of this condition. [177] In severe cases, portal decompression surgery, but not transjugular intrahepatic portosystemic shunting, is effective in reducing the risk of hemorrhage. [182]

HYPERTROPHIC GASTROPATHIES

In numerous inflammatory and noninflammatory conditions, the mucosal folds (*rugae*) that confer a rugged appearance to the normal gastric corpus may become extremely enlarged and may give the mucosa an appearance that has been compared to that of the cerebral cortex (cerebriform). Based on this macroscopic morphologic characteristic, shared in various degrees by all of them, certain etiologically heterogeneous conditions have been categorized as *hypertrophic gastritis, hypertrophic gastropathy,* or, more recently, *giant-fold gastropathies.* To complicate our understanding of these diverse conditions further, many authors have used indiscriminately the term *Ménétrier disease,* after the condition described in 1888 by the French gastroenterologist who initially called it *polyadenomes en nappe* (polyps in layers). [183]

In 1973, Ming [184] introduced the term *hyperplastic gastropathies* and proposed a classification that recognizes three main histological types:

1. Foveolar hyperplasia, with normal or atrophic oxyntic glands and corresponding to Ménétrier’s description
2. Hyperplasia of oxyntic glands, with a largely unaffected mucous component and corresponding to Zollinger-Ellison syndrome
3. A mixed type, in which both mucous and oxyntic glands show variable degrees of hyperplasia; it incorporates various conditions that may cause mixed glandular hyperplasia, including infections (*H pylori* infection, CMV infection in children, syphilis, and histoplasmosis) and other diseases of uncertain origin (lymphocytic

gastritis, eosinophilic gastroenteritis, sarcoidosis, and Cronkhite-Canada syndrome).

Zollinger-Ellison syndrome is covered in Chapter 67. Cronkhite-Canada syndrome is discussed in Chapter 90.

Ménétrier Disease

Ménétrier, in his original description, included patients with multiple hyperplastic polyps and patients with giant folds and focused his observations on the increased gastric cancer risk of these patients. Today, the condition associated with his eponym is defined as an idiopathic diffuse enlargement of the gastric folds in the antrum. Histologically, glands show massive foveolar cell hyperplasia with normal or slightly reduced numbers of parietal and chief cells. Neither significant inflammatory infiltrates in the lamina propria nor epithelial lesions (erosions, intestinal metaplasia, or cellular atypia) are present. If chronic active inflammation or lymphocytic infiltration of the epithelium is seen, the large-fold type of *H pylori* gastritis or lymphocytic gastritis should be considered. In children, giant folds are almost always associated with CMV infection.[185] This association has rarely been reported in adults. The hyperplastic foveolar cells secrete large amounts of mucus and fluid resulting in protein-losing enteropathy (found in almost all patients) and hypoacidity (in part from dilution of the acid produced by oxyntic cells).

Pure Ménétrier disease is a rare condition, with an estimated prevalence of no more than 300 or 400 persons worldwide. Patients are more often men in their fifth or sixth decade who present with dramatic weight loss, epigastric and abdominal pain, nausea, and vomiting. Later in the course of the disease, usually protracted for several years and even decades, virtually all patients develop hypoalbuminemia as a consequence of the protein-losing enteropathy. The pathogenesis is unknown, but an interesting hypothesis has been put forward. Transforming growth factor-a (TGF-a), a critical mediator of gastric mucosal homeostasis normally produced by the gastric mucosa, inhibits acid secretion, stimulates mucosal repair, cell migration, and proliferation, and augments gastric mucin levels. Overproduction of TGF-a could explain several of the disturbances occurring in Ménétrier disease.[186] Support for this hypothesis is further lent by the successful treatment of some patients by a monoclonal antibody against the TGF-a receptor (the epidermal growth factor receptor).[187] Other forms of treatment, including antacids, anticholinergic drugs, corticosteroids, H_2-receptor antagonists, and proton pump inhibitors, have been proven consistently ineffective. Eradication of *H pylori* has been reported to have successfully cured patients with Ménétrier disease.[188], [189] One of the possible pathological aspects of *H pylori* gastritis is the development of large, edematous folds,[190] and this variant may have been interpreted as a type of *H pylori*–induced Ménétrier disease. Not surprisingly, it regresses after the eradication of *H pylori* infection.

GASTRIC CARDIA

Since the 1970s, a rise in the incidence of *adenocarcinoma of the cardia* has occurred in the very populations in which the incidence of gastric cancer has been decreasing.[191], [192] Thus, there has been an emerging interest in exploring the pathology of this relatively ill-defined area of the stomach. Virtually all patients who have *H pylori* gastritis in other regions of the stomach also have bacteria and inflammation in the region immediately distal to the gastroesophageal junction.[193], [194] and [195] Some patients, including those without *H pylori* infection and patients with and without gastroesophageal reflux disease, have a localized inflammation of the cardia, commonly referred to as *carditis* (Fig. 68-13).[196] Intestinal metaplasia is found in the cardia of approximately 20% of patients with a variety of gastric disorders, even in the absence of *H pylori* infection, and apparently also in healthy persons. The relationship between intestinal metaplasia in this location and adenocarcinoma of the junction remains unclear,[197], [198] but it is important to differentiate the intestinal metaplasia of the cardia from Barrett specialized epithelium. Cytokeratin 7 and 20 immunoreactive patterns may help to distinguish between intestinal metaplasia in long-segment Barrett esophagus and junctional metaplasia[199]; conversely, the epithelium of short-segment Barrett esophagus may be impossible to separate from metaplasia originating in the cardia.[200] Until the implications of such findings are clarified, it is advisable to collect as much specific information as possible carefully from each patient with changes at the gastroesophageal junction. Lesions of uncertain prognostic value today could acquire clinical significance when new knowledge is acquired.

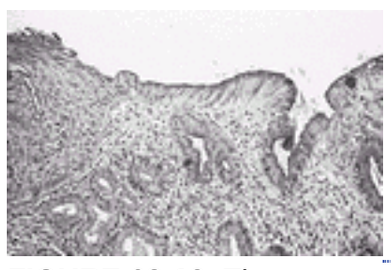

FIGURE 68-13. The squamocolumnar junction in a patient with gastroesophageal reflux and no *Helicobacter pylori* infection. The marked inflammation in the cardia contrasts with the lack of infiltrate in the squamous epithelium. The term “non- *H pylori* carditis” has been used for this entity of uncertain origin and significance.

CHAPTER 69

Wai K. Leung, Enders K. W. Ng, and Joseph J. Y. Sung

TUMORS OF THE STOMACH

Gastric cancer is the second most common cause of cancer mortality, after lung cancer, worldwide. Although relatively uncommon in the United States, gastric cancer is the most common cancer in many Asian countries. With the changing global socioeconomic environments, and also possibly with the improvements in sanitary conditions, the incidence of gastric cancer is on a declining trend in many developed countries, a finding suggesting that this disease is preventable.

Because most gastric tumors are adenocarcinomas, that is the focus of this chapter. Other less common gastric malignant diseases such as lymphoma, stromal tumor, and gastric polyps are discussed briefly.

EPIDEMIOLOGY

Gastric cancer is the most common gastrointestinal malignant disease and is only second to lung cancer in global cancer mortality (Fig. 69-1). It is estimated that gastric cancer causes more than 620,000 deaths per year worldwide. [1] In the United States, approximately 21,500 new cases of gastric cancer were diagnosed in 2000, and 13,000 patients died of this disease the same year. [2]

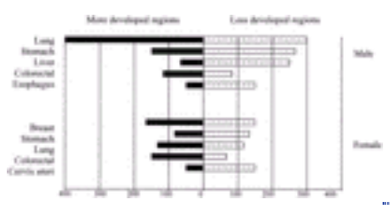

FIGURE 69-1. Estimated number of deaths (in thousands) from five leading cancers in men and women of more developed and less developed regions of the world.

In many developed countries, the incidence of gastric cancer is slowly declining. As shown in the time-trend analysis of the United States (Fig. 69-2), the incidence of gastric cancer decreases with time in both sexes. A similar pattern is observed in other parts of the world, including Japan, but the exact reason remains unknown. Nonetheless, because of the rapidly growing populations in developing countries with a high incidence of gastric cancer, the total number of gastric cancer cases in the world has actually remained the same as in the 1990s. [1] Murray and Lopez [3] projected that the annual number of new cases will continue to increase in the developing world over the next few decades as a result of population growth. Notably, the reduction in gastric cancer incidence largely reflects a decline in cancers in the distal stomach and mostly of the intestinal type. Conversely, there has been a steady rise in the incidence of adenocarcinoma of the proximal stomach and the gastroesophageal junction since the 1970s. [4], [5] From 1970 to 1995, hospitalization and death rates for gastric cancer in the United States Department of Veterans Affairs database fell, whereas the hospitalization rates for gastroesophageal reflux disease rose significantly. [6] According to the United States National Cancer Institute Surveillance, Epidemiology, and End Results database, an annual increase in proximal gastric lesions was estimated to be 3.6% to 5.6%. [4] This increase of gastric cancer in the proximal stomach is alarming because the increase on percentage basis is even greater than that of lung cancer or melanoma, and this disease is associated with poorer prognosis.

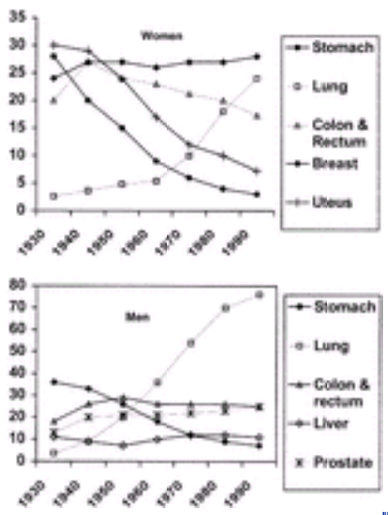

FIGURE 69-2. Time trend of the age-adjusted cancer death rates (per 100,000 population) for women and men in the United States from 1930 to 1996.

In all ethnic groups and countries, gastric cancer has a predilection for elderly patients, with incidence peaks at the seventh decade. Men are more commonly affected than women. Incidence rates in men are double those in women. Besides gender differences, the incidence of gastric cancer also appears to be inversely related to social class. Rates are higher in unskilled laborers (class V) and lower in professional groups (class I). [7] Conversely, there are considerable geographic variations in the incidence of gastric cancer (Table 69-1). The highest rates are observed in East Asia (the age-adjusted standardized rate of male patients is 44 years), where gastric cancer is still the most frequent cancer in men. The age-adjusted standardized rate of gastric cancer is 35 per 100,000 in Japan and China, [1] whereas the corresponding figure in the United States is less than 5 per 100,000. Even within the same country, variations in cancer incidence and mortality are also observed among different ethnic groups. In the United States, African Americans, Hispanic Americans, and Native Americans are 1.5 to 2.5 times more likely to have gastric carcinoma than are whites. [8] Similarly, in Singapore, the incidence of gastric cancer in Chinese persons is about twice that of Indians and is five times greater than that of Malays. [9] The reason of this discrepancy is unclear. It has been attributed to differences in socioeconomic factors and dietary and environmental conditions. In Japan and China, there appears to be a dichotomized distribution in which mortality and incidence of gastric cancer are higher in the northern parts than in the southern parts of those countries. [10], [11]

Adapted from ref. 2.

TABLE 69-1 Age-Adjusted Gastric Cancer Death Rates per 100,000 Population from Different Countries, 1994–1997

ETIOLOGY

With the contrasting global epidemiology of gastric cancer, tremendous effort has been made to look into the causation of this malignant disease. It is now generally believed that gastric cancer has multiple etiologic factors including diet, exogenous chemicals, intragastric synthesis of carcinogens, genetic factors, and infectious agents (Table 69-2). Of these, the most extensive studied factors are dietary habits and *Helicobacter pylori* infection.

FACTOR	SOURCE
Diet	Consumption of salted, smoked, and poorly preserved foods
	Low consumption of fruits and vegetables
Infection	*Helicobacter pylori*
	Epstein-Barr virus
Genetic	Hereditary nonpolyposis colon cancer syndrome
Previous gastric resection	

TABLE 69-2 Possible Etiologic Factors in Gastric Cancer

Dietary Factors

Although dietary habits may influence the development of gastric cancer, it is extremely difficult to measure food consumption accurately. Most of these studies were based on retrospective data collection, which could be subject to recall bias. In spite of these caveats, many epidemiologic studies from regions with a high incidence of gastric cancer have identified several dietary factors to be related to the high cancer incidence and mortality. Apart from case control studies on dietary contents, migrant studies also provide invaluable information relating to the role of diet in gastric carcinogenesis. Migration is accompanied by changes in lifestyle, especially diet. The risk of developing gastric cancer changes slowly in populations moving from a high-risk community to a low-risk community. Japanese persons who migrated to the United States had a significant reduction in mortality from stomach cancer when compared with the native Japanese population. [12] These observations implicate the role of environmental factors in the pathogenesis of gastric cancer, with diet the most likely cause.

Most of the case control studies have shown a rather consistent inverse relationship between the consumption of fresh fruits and vegetables and the risk of gastric cancer. [13], [14], [15], [16] and [17] This observation may be partly related to the presence of vitamins present in fruit and vegetables, such as vitamins C and E, carotenoids and flavonoids. These vitamins may act through various mechanisms, such as antioxidant effects, the ability to inhibit nitrosamine formation, [18] and dilution or binding of carcinogens, thereby reducing the risk of cancer development. An epidemiologic study from China demonstrated that the risk of progression to gastric dysplasia and carcinoma was reduced by 80% (95% confidence interval, 30% to 90%) in study subjects with baseline ascorbic acid levels in the highest tertile when compared with those in the lowest tertile. [19]

Conversely, food substances rich in nitrates, nitrites, and secondary amines, which combine to form *N*-nitroso compounds, are known mutagens or carcinogens. Nitrates and nitrites were previously used in food preservation before the era of refrigeration. Consumption of preserved meat and vegetables has been consistently linked to an increased risk of developing gastric cancer. [14], [20] Humans are exposed not only to preformed *N*-nitroso compounds, but also to a wide range of precursors and nitrosating agents that can react in vivo to form potentially carcinogenic *N*-nitroso compounds. This process is facilitated in the presence of nitrate-reducing bacteria of the digestive tract. With the advent of refrigerators and the growth of the frozen food industry, consumption of preserved meat and vegetables declined in most developed countries. This has been postulated to be a crucial factor in the reduction of gastric cancer incidence in North America and Western Europe. [21]

High intake of carbohydrates and salt has also been suggested to increase the risk of stomach cancer. A high-salt diet in humans and experimental animals is associated with a higher risk of atrophic gastritis, a preneoplastic lesion. [22], [23] Salt also enhances the colonization of *H pylori* in mice and may therefore perpetuate the development of gastritis and glandular atrophy. [24] In Japan, a significant correlation was found between the amount of salt excreted in urine and stomach cancer mortality rates. [25] A study from 65 Chinese counties also recognized a significant positive association between stomach cancer mortality and consumption of salted vegetables. [26] Conversely, consumption of a carbohydrate-rich diet was also found to have a positive association with gastric cancer. A study from Shanghai showed a 1.5- to 1.9-fold increase in risk of gastric cancer for the highest quartile of carbohydrate intake. [17] Nonetheless, this association was not confirmed in other studies, [27] and the mechanisms of carbohydrate and gastric carcinogenesis remain poorly defined. Notably, the estimation of carbohydrate consumption is usually confounded by the amount of salt intake.

The polyphenols in green tea have been postulated to have an anticarcinogenic effect, including gastric cancer, through an antioxidant effect. This hypothesis is particularly attractive to Asian investigators. Several case control studies suggested the inverse association between consumption of green tea and risk of gastric

cancer. [28] However, the anticarcinogenic effect of green tea was refuted by a large-scale, population-based, prospective cohort study in Japan that involved more than 26,000 residents. [29] The role of green tea in the prevention of gastric cancer needs further evaluation.

Infectious Agents

Helicobacter pylori *H pylori* is a gram-negative, spiral-shaped organism found in the mucus layer of the human stomach. It was first successfully cultured by Marshall and Warren in 1984. [30] Since the discovery of this pathogen, numerous reports had been published to link this bacterium with various gastroduodenal diseases and even extraintestinal conditions. Based on several large-scale epidemiologic cohort studies published in the early 1990s, [31], [32], [33] and [34] the International Agency for Research on Cancer classified *H pylori* as a group 1 carcinogen in 1994. [35] Data from case control studies were summarized by a metaanalysis of 19 studies that included 2500 cases and 4000 controls. [36] The pooled data showed that the combined odds ratio for gastric cancer in *H pylori*–infected subjects is 1.92 (95% confidence interval, 1.32 to 2.78). Nonetheless, the attributable risk of *H pylori* infection to gastric cancer is still believed to be an underestimate. Because elderly patients with severe atrophic gastritis may have spontaneous remission of infection, the association of *H pylori* with gastric cancer is particularly strong in young persons with *H pylori* infection. In this regard, the odds ratio increased from 1.05 at age 70 years or older to 9.29 at age 29 years or younger (Fig. 69-3).

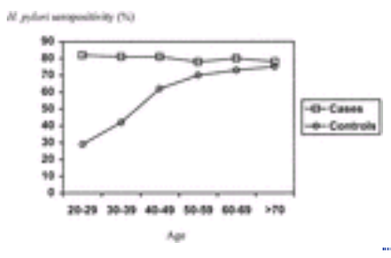

FIGURE 69-3. Age distribution of *Helicobacter pylori* seropositivity in gastric cancer cases and controls. (Modified from ref. [36].)

It is well known that *H pylori* infection is associated not only with gastric cancer but also with gastric and duodenal ulcers. Factors determining individual susceptibility to diverse disease outcomes remain poorly understood. In a large Swedish cohort study, the standardized incidence ratio for gastric cancer among patients with gastric ulcers was 1.8 (95% confidence interval, 1.6 to 2.0), whereas in patients with duodenal ulcer it was only 0.6 (95% confidence interval, 0.4 to 0.7). [37] This paradoxical relationship between duodenal ulcer and gastric cancer may be at least partially related to the distribution of gastritis. [38], [39] In some patients, chronic *H pylori* infection results in a corpus-predominant type of gastritis. The profound acid suppression predisposes them to the development of gastric ulcer and gastric carcinoma. Conversely, chronic *H pylori* can lead to antral-predominant gastritis in other patients that favors the development of duodenal ulcer (Fig. 69-4).

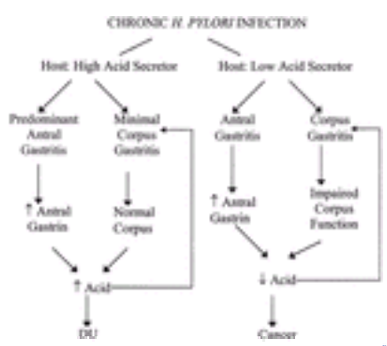

FIGURE 69-4. Divergent host response to *Helicobacter pylori* infection. (Modified from McColl KE, et al. *Helicobacter pylori* gastritis and gastric acid secretory function: an integrated approach. In: Hunt RH, Tytgat GN, ed. Basic mechanisms to clinical cure. Boston: Kluwer Academic Publishers, 1996.)

H pylori infection is linked to both intestinal and diffuse-type cancers. However, only noncardiac or distal gastric tumors are associated with this bacterium. Data from the National Cancer Institute even suggest an inverse relationship between *H pylori* infection and proximal gastric carcinoma [40]; that is, *H pylori*–infected persons had a reduced risk of gastroesophageal and cardia cancers. The logic of this observation may be related to the suppressed acid output in persons with *H pylori* infection. [41], [42] The presence of corpus gastritis protects them against gastroesophageal reflux and hence Barrett esophagus, the precursor of adenocarcinoma of distal esophagus and proximal stomach. Despite the availability of a wealth of epidemiologic data, some investigators are still skeptical about the causal relationship between *H pylori* infection and gastric cancer. In particular, gastric cancers still occur in persons without evidence of *H pylori* infection, and not all infected persons will develop cancer during their lifetime. An animal study from Japan may clear this skepticism. In the absence of exogenous mutagens, Japanese investigators demonstrated that Mongolian gerbils infected with *H pylori* developed severe active chronic gastritis, ulcers, and intestinal metaplasia within 6 months of infection. [43] After 1 year, adenocarcinoma of stomach was detected in one third of the infected gerbils. Although these data support a direct gastric carcinogenic effect of *H pylori,* most workers believe that gastric cancer is a multifactorial disease involving genetic and dietary factors. With the large number of *H pylori*–infected persons globally, it is difficult to explain why so few of them develop gastric cancer. In particular, the unexpectedly low incidence of gastric cancer in African countries with high prevalence of *H pylori* infection remains elusive. [44] It was found that concurrent helminth and *H pylori* infection modulates the type 1 T helper cell (Th1) responses, which normally promote cell-mediated immune responses and tissue injury, to a less damaging Th2 response. [45] Thus, the progression of *Helicobacter*-associated gastric atrophy, a premalignant lesion, is attenuated. This finding illustrates the potential interaction between *H pylori* infection and environmental factors that may partly explain the “African enigma.”

Epstein-Barr Virus The virus most extensively studied as an etiologic factor in gastric cancer is Epstein-Barr virus (EBV). EBV, an icosahedral herpevirus containing linear double-stranded DNA, is ubiquitous in all human populations. It was estimated that about 10% of gastric carcinomas throughout the world show monoclonal proliferation of EBV-infected cancer cells. [46] In contrast to Burkitt lymphoma and nasopharyngeal carcinoma, which are endemic in Africa and Southeast Asia, EBV-positive gastric carcinoma is a nonendemic disease distributed throughout the world. The highest rates are reported in the United States and Germany (16% to 18%), and the lowest rates are observed in China (3.1%). [46] Although EBV has been detected in all types of gastric cancer, it is closely linked to a form of undifferentiated gastric carcinoma called *lymphoepithelioma-like carcinoma.* Histologically, these tumors resemble nasopharyngeal carcinomas. They tend to be located proximally, they are of diffuse histological types, and they have a lower frequency of lymph node metastasis. [47] The prevalence of *H pylori* infection in this tumor is also found to be lower than those with cancer that is not lymphoepithelioma-like carcinoma. In EBV-associated gastric cancer, the EBV genome was detected in the adjacent preneoplastic lesions. [48]

Tobacco and Alcohol Although several studies have shown a 1.5- to 3.0-fold increase in the risk of gastric cancer among smokers, a clear dose-response relationship cannot be demonstrated. [49] Moreover, smoking may be related more to cancer in the cardia than to cancer in the distal stomach. Given the rapid rise in lung cancer incidences and the progressive fall in stomach cancer incidences worldwide (see Fig. 69-2), tobacco use is unlikely to be an important etiologic factor in gastric cancer. Reports of a positive association between smoking and stomach cancer may be confounded by other factors, such as lower socioeconomic class and dietary habits. Conversely, epidemiologic studies failed to show any significant correlation between alcohol use and stomach cancer. [15], [16]

Previous Gastric Resection

Many studies have suggested an increased incidence of gastric cancer in the remaining stump of the stomach after gastrectomy. An incidence of 3% was reported in a previous study. [50] Rates of gastric cancer appear to remain low for 15 to 20 years after resection of the distal stomach and increase substantially thereafter. [51], [52] Notably, Billroth II gastrectomy was associated with higher risk than Billroth I gastrectomy. This may be explained by the changes in gastric environment after acid-reducing surgery. As gastric surgery reduces acid production in the stomach and causes neutralization of the gastric milieu, the lumenal bacterial contents will increase. Of particular interest is the presence of anaerobic bacteria in the gastric remnant that could convert nitrates from the diet into nitrites, a potential gastric carcinogen. In addition, bile reflux after gastric surgery promotes gastric epithelial proliferation in the stomach remnant and possibly favors cancer development. [53]

Genetic Factors

Considerable evidence suggests the role of genetic factors in gastric carcinogenesis. Familial clustering of gastric cancer has been reported in the literature. The best-known example comes from the famous Bonaparte family of France. [54] Napoleon’s father and grandfather died of the disease, and so did several of his siblings.

Case control studies showed that first-degree relatives of patients with gastric cancer have a two- to threefold increase in the risk of gastric cancer. [55] Yet, a single gene defect to account for this disease clustering has not been found, except in family kindreds of hereditary nonpolyposis colorectal cancer syndrome. Conversely, the familial clustering of gastric cancer can be potentially explained by the socioeconomic status and the common exposure to various environmental factors, such as *H pylori* infection [56] and diet. It was shown that relatives of patients with gastric cancer had an increased prevalence of hypochlorhydria and gastric atrophy, [57] which were linked to the polymorphisms of the interleukin-1ß gene. [58] Interleukin-1ß is a proinflammatory cytokine as well as a potent inhibitor of gastric acid secretion. This finding may provide the missing link between genetic factors in the host and bacterial factors. However, further testing in different ethnic groups is still needed to confirm this observation.

In contrast to colorectal cancer, which has well-defined mechanistic pathways of carcinogenesis, the picture is far from clear for gastric cancer. Since the early 1980s, numerous genetic alterations have been implicated in the carcinogenesis of gastric cancer. To a certain extent, many of these alterations are akin to those found in colorectal cancer and were initially described as inactivation of tumor suppressor genes or activation of oncogenes. However, as our understanding of carcinogenesis broadens, other alterations, such as genes involved in apoptosis and proliferation control, cell cycle regulations, overexpression of growth factors, and genomic instability, have also been found to play a role. Mutations of tumor suppressor genes such as *p53* and *APC* have been reported in gastric cancer. *p53* is involved in the induction of apoptosis after DNA damage. Loss of heterozygosity in chromosome 17 or mutations of *p53* were observed in more than 60% of gastric cancer. [59], [60], [61], [62] and [63] Similarly, *APC* mutations were detected in more than 50% of well-differentiated, but not in any poorly differentiated, gastric cancers. [64] However, activation of protooncogenes, such as the *ras* oncogenes and c- *myc,* was infrequently detected in gastric cancer. [65] In addition, a broad spectrum of regulatory peptides is also incriminated in the gastric carcinogenesis pathways. This includes epidermal growth factor, transforming growth factor, platelet-derived growth factor, insulin-like growth factor II, and basic fibroblast growth factor.

Microsatellite instability (MSI), a form of genomic instability and a manifestation of cell defective in DNA mismatch repair, is present in 17% to 48% of gastric cancers. [66], [67], [68], [69], [70], [71] and [72] Gastric cancers with MSI phenotypes tend to have specific clinicopathological characteristics such as intestinal type, prominent lymphocyte infiltration, and location in the antrum, and they are associated with better prognosis. [67], [68], [69], [70] and [71] Interestingly, MSI can also be detected in gastric intestinal metaplasia, a preneoplastic lesion, in patients without gastric cancer. [72], [73] In contrast to hereditary forms of colorectal cancers with MSI phenotypes, germline mutations of DNA mismatch repair genes are infrequent in MSI-positive gastric cancer. It was found that hypermethylation of the promoter region of *hMLH1,* a DNA mismatch repair gene, that results in transcriptional silencing of the gene is the major mechanism underlying MSI in sporadic gastric cancers. [74], [75]

Cyclooxygenase-2 (COX-2) has also been implicated in the development of gastric cancer. COX-2 is an inducible form of prostaglandin synthase responsible for the conversion of arachidonic acid into prostanoids. Up-regulation of the *COX-2* gene and overexpression of COX-2 enzyme are frequently detected in cancer. In colorectal cancer, overexpression of COX-2 confers resistance to apoptosis, higher metastatic potential, and angiogenesis. [76], [77] and [78] Previous studies showed that approximately 70% of gastric cancers demonstrated COX-2 expression. [63], [79], [80], [81] and [82] Gastric carcinomas with COX-2 overexpression tend to have a higher frequency of lymphatic invasion, [80] and they are associated with a worse prognosis. [81], [82] Interestingly, COX-2 expression was also detected in *H pylori*–associated gastritis [83], [84] and [85] and intestinal metaplasia. [86] It thus appears that the persistence of COX-2 in *H pylori*–associated chronic gastritis may contribute to the pathogenesis of gastric cancer.

PATHOLOGICAL FEATURES

Adenocarcinoma accounts for 95% of the stomach cancers, whereas squamous cell carcinoma, carcinoid tumors, leiomyosarcoma, and lymphoma constitute the rest of the gastric tumors. Macroscopically, gastric cancers can be broadly categorized by their location and appearances. Categorization of tumors into proximal (cardia) versus distal (including body and antrum) cancers bears major etiologic significance. Distal cancers are more common in areas with a high gastric cancer incidence, whereas cardia cancers are more prevalent in whites from populations with a low background incidence of gastric cancer. The former may be closely related to chronic *H pylori* infection, whereas the latter is often the consequence of chronic gastroesophageal reflux disease and Barrett esophagus. Of interest, the fall in incidence of gastric cancer is more of the result of the decline in distal gastric cancer. By contrast, the incidence of gastroesophageal junction carcinomas is actually increasing in the United States [4] and in many other developed countries.

Gastric tumors can also be classified by their gross appearances. The macroscopic appearance has been classified by Borrmann into four types (Fig. 69-5). Type I represents polypoid lesions without necrosis or ulceration, type II encompasses fungating cancers that may contain superficial ulceration, type III represents ulcerated lesions infiltrating the gastric wall, and type IV tumors are diffusely infiltrating tumors or linitis plastica lesions. There is considerable overlap among the different subtypes, and this typing system does not appear to correlate with histological typing. Approximately 40% to 50% of tumors are fungating or polypoid in appearance, and similar numbers of tumors are ulcerative. *Linitis plastica* is an aggressive infiltrating tumor consisting of high-grade tumor cells accompanied by a marked desmoplastic reaction that results in a rigid stomach resembling a leather bottle. This form of tumor spreads through the submucosa and is associated with worse prognosis.

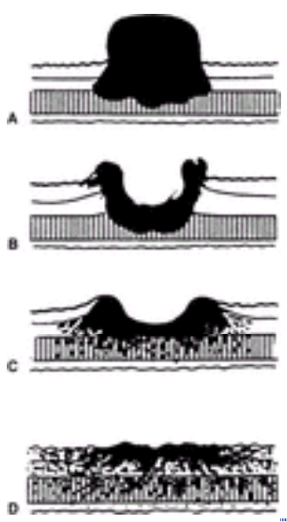

FIGURE 69-5. Macroscopic appearance of tumor as classified by Borrmann. (**A**) Polypoid. (**B**) Fungating with surface ulceration and hemorrhage. (**C**) Ulcerated without major lumen component. (**D**) Infiltrative. (From Borrmann R. Geshwulste des Magen und Duodenums. In: Henke F, Lunbarsch O, eds. Handbuch der speziellen pathologischen Anatomie und Histologie, vol 4. Berlin: Julius Springer, 1926:812.)

Microscopically, several histological classifications of gastric cancer are used. The most widely used classification, proposed by Lauren, [87] broadly divides gastric cancer into diffuse and intestinal types (Fig. 69-6; see also Color Fig. 69-6). Despite its simplicity, this classification categorizes tumors into two distinct types with contrasting epidemiology, etiology, and prognosis. The intestinal type is named by its histological morphology, and the diffuse type is characterized by its biologic behavior. Intestinal-type cancer is characterized by cohesive neoplastic cells forming glandular tubular structures, whereas diffuse-type cancer shows sheets of epithelial cells or cells scattered in a stromal matrix without evidence of gland formation. Diffuse cancers may contain signet-ring cells. Intestinal-type cancer is more common in the distal stomach and is often preceded by preneoplastic stages such as intestinal metaplasia. It is more prevalent in regions with a high background incidence of gastric cancer and is generally associated with a better surgical outcome than the diffuse type. Nonetheless, approximately 5% to 10% of tumors remain unclassified, and they are called mixed-type tumors. These unclassified tumors are usually regarded as diffuse-type tumors during clinicopathological evaluations.

(**B**) Diffuse-type cancer with infiltrative and discohesive tumor cells. (Courtesy of Dr. K. F. To, Chinese University of Hong Kong, Prince of Wales Hospital, Hong Kong.)

Another classification system that is proposed by the World Health Organization [88] divided gastric tumors into ten types (Table 69-3). This classification is highly reproducible and is useful for routine pathological diagnosis of gastric cancer. Based on the degree of differentiation in architectural and cellular levels, gastric tumors can be divided into well-differentiated, moderately differentiated, or poorly differentiated types. Tubular adenocarcinoma, in which the glands form branching tubules, is the most common type of gastric adenocarcinoma. In papillary tumor, there are prominent intraglandular folding and projections with cuboidal to high columnar carcinoma cells lining the narrow bands of interstitial tissue in an arborizing pattern. Both types contain cells with absorptive type and tend to form a polypoid or fungating mass macroscopically. Signet-ring cell carcinomas are named because of the shape of the tumor cells that contain abundant intracytoplasmic mucus. There is minimal gland formation, and this type of tumor tends to infiltrate. Mucinous adenocarcinoma, also called mucoid or colloid carcinoma, is diagnosed when mucus occupies more than 50% of the tumor mass. [89]

Cascade of Gastric Carcinogenesis

Based on extensive observational studies in populations with high gastric cancer incidences, gastric cancer is generally believed to be a multistep progression from chronic gastritis, atrophy, and intestinal metaplasia ultimately to dysplasia and cancer. [90] This paradigm of gastric carcinogenesis has been coined the *Correa cascade* (Fig. 69-7), which was subsequently modified to incorporate *H pylori* in the initial stage of the sequence. [91] In this context, gastric atrophy and intestinal metaplasia are regarded as preneoplastic gastric lesions, particularly for intestinal-type cancer. These lesions are more prevalent in area with high gastric cancer incidences and are frequently linked to chronic *H pylori* infection. Both conditions are multifocal and are more prevalent in the antrum.

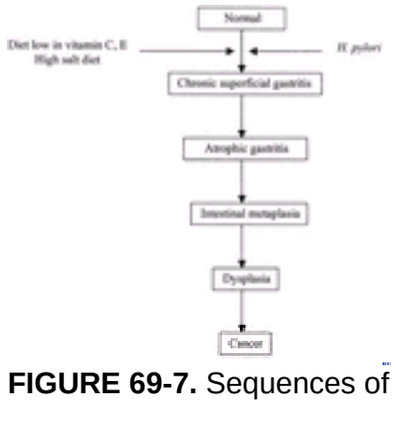

FIGURE 69-7. Sequences of gastric carcinogenesis.

Gastric atrophy usually predates the development of intestinal metaplasia and can be detected in 80% to 90% of patients with gastric cancer. It has been estimated that 10% of patients with chronic atrophic gastritis will develop gastric carcinoma in a 15-year follow-up period. [92] Because of the focal nature of gastric atrophy, the definitive diagnosis of gastric atrophy may be sometimes difficult, particularly with the sampling error of endoscopic biopsy. To evaluate the topographic distribution and extent of atrophy correctly, multiple representative samples are necessary. [93] By contrast, type A or autoimmune atrophic gastritis typically affects the corpus only, as compared with *H pylori*–associated multifocal atrophic gastritis, which involves both the antrum and the corpus. Patients with pernicious anemia are estimated to have a two- to threefold excess risk of stomach cancer. [94] However, the diagnostic yield from screening of these patients is generally considered to be low, and thus, the current recommendation by the American Society for Gastrointestinal Endoscopy involves only a single endoscopic study to identify the prevalent lesions such as carcinoid tumors or gastric cancer. [95] Currently, there are insufficient data to support the use of surveillance endoscopy in this group of patients.

The detection of small intestinal mucosa in the stomach can be dated back to the 19th century. [96] Intestinal metaplasia is recognized by the presence of goblet cells, absorptive cells, and cells resembling colonocytes or by its mucin content. It can be further divided into small intestinal and colonic types, or complete and incomplete types, on the basis of morphology and enzyme histochemistry. This classification of intestinal metaplasia into different subtypes is of clinical importance. By using mucin histochemistry, intestinal metaplasia can be divided into three types according to morphology and glycoprotein content. Type I (complete) refers to the presence of goblet cells containing sialomucins interspersed between nonsecretory absorptive cells with well-delineated brush borders. Type II (incomplete) indicates the presence of sialomucin-containing goblet cells scattered among gastric-type cells containing either neutral mucin or sialomucins. Type III (incomplete or colonic type) is diagnosed when there are tortuous and branched crypts lined by tall columnar cells containing abundant sulfomucins. Sulfomucins can be differentiated from sialomucins by using high iron diamine/Alcian blue staining (Fig. 69-8; see also Color Fig. 69-8). Complete or type I is generally believed to carry the lowest risk of gastric cancer, whereas type III (colonic) has the strongest association. In a large cohort study from Slovenia with 10 years of follow-up, patients with all types of intestinal metaplasia had at least a tenfold increased risk of cancer compared with those without intestinal metaplasia. [97] Furthermore, patients with type III intestinal metaplasia had a fourfold risk of cancer development compared with those with type I. In a cohort study from Shandong Province, China that involved more than 3000 subjects with a follow-up of 4 to 5 years, the odds ratio of progression from intestinal metaplasia to gastric cancer varied from 17 to 29. The risk was particularly high for those with more advanced baseline histological lesions such as the presence of dysplasia. [98] In spite of this finding, there are currently no data to support the use of screening endoscopy in these patients.

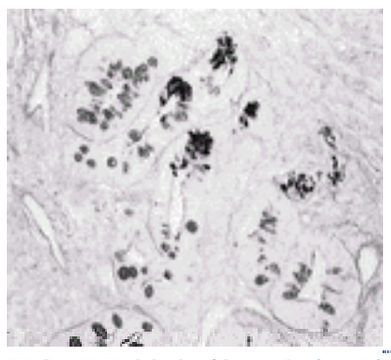

FIGURE 69-8. (See Color Fig. 69-8.) Type III intestinal metaplasia of stomach. The presence of sulfomucin in type III intestinal metaplasia is illustrated by the high iron diamine (*HID*)/Alcian blue staining.

Although it is universally accepted that dysplasia is a precursor of gastric neoplasia, the definition of dysplasia is controversial. The Japanese Research Society for Gastric Cancer (JRSGC) proposed a five-tiered group classification for interpretation of gastric biopsies, but this was not widely adopted by Western pathologists. Additionally, Japanese pathologists diagnose gastric carcinoma on nuclear and structural criteria, even in the absence of tumor invasion from a Western viewpoint. Thus, dysplasia according to Western pathologists is frequently interpreted as early carcinoma in Japan. [99], [100] Several consensus meetings have been held to arrive at a globally accepted histological classification of gastric dysplasia. [101], [102] However, the validity of these proposed classification systems is yet to be tested.

The question whether treatment of *H pylori* infection can actually prevent gastric cancer development remains unanswered. These studies are extremely difficult to perform because of the long cancer development process, which may take several decades. To look into the potential benefits of *H pylori* eradication, studies have been designed to intervene in the intermediate stages (i.e., intestinal metaplasia or atrophy) and to examine the regression of these changes as the surrogate end point of treatment success. An uncontrolled study from Japan demonstrated the regression of intestinal metaplasia at 12 months after *H pylori* eradication. [103] Gastric atrophy improved in 89% of patients, whereas intestinal metaplasia in the antrum improved in 61% of patients. Additionally, two large-scale, randomized, controlled studies confirmed that eradication of *H pylori* resulted in significant improvement of gastric histology, particularly intestinal metaplasia and gastric atrophy, when compared with patients with persistent infection. [104], [105] The study by Correa and colleagues [105] with a 6-year follow-up showed a significant regression of intestinal metaplasia and gastric atrophy. Interestingly, the supplementation of ß-carotene or ascorbic acid alone results in a similar degree of improvement in gastric histology. Whether it can translate into absolute reduction in cancer incidence awaits study with long-term follow-up.

Early Gastric Cancer

Early gastric cancer refers to tumor confined to the mucosa or submucosa, regardless of the presence or absence of metastasis. This disease entity carries an extremely good prognosis and is particularly prevalent in Japan, where mass screening of gastric cancer is performed. This entity is estimated to represent up to 65% of gastric cancers diagnosed in Japan. A 5-year survival rate of more than 90% was reported in Japan after gastrectomy and removal of primary and secondary lymph nodes. [106]

The JRSGC classified early gastric cancer into three types based on macroscopic appearances [107] (Fig. 69-9). JRSGC type I is an exophytic lesion, type II is flat (or superficial), and type III is an ulcerated or depressed lesion. Type II is further divided into three subtypes, depending on whether it is elevated (IIa), flat (IIb), or depressed (IIc). In addition, combined types have been defined to include complex configurations. The protruded-type (type I and type IIa), with a diameter of less than 25 mm, and the excavated type (type IIc), with a diameter of less than 20 mm, seldom produce lymph node metastasis. Moreover, the depth of tumor invasion also bears important prognostic significance. The incidence of nodal metastasis of intramucosal and submucosal cancer is reported to be 3% and 20%, respectively. [108] Other parameters that may determine the rate of lymph node metastases are the size of the tumors and the presence of ulcerations. Distant metastasis is uncommon in early gastric cancer.

FIGURE 69-9. Classification of early gastric cancer by the Japanese Gastroenterological Endoscopy Society. (From Japanese Research Society for Gastric Cancer. The general rules for the gastric cancer study in surgery. Jpn J Surg 1973;3:61.)

Symptoms and abnormal physical findings are unusual in early gastric cancer. Staging of early gastric cancer resembles that of non-early gastric cancer. Early gastric cancer is T1 carcinoma according to the TNM system. Treatment of early gastric cancer is dependent on the size, location, endoscopic appearance, and histological subtypes of the tumors, as discussed in the next section.

Many argue that early gastric cancer is not a genuine malignant condition, because of the diagnostic criteria for cancer adopted by Japanese pathologists. [109] Some are skeptical whether these so-called “early” cancers would eventually develop into advanced cancers. Tsukuma and colleagues reported their long-term follow-up of 56 patients with early gastric cancer diagnosed by endoscopy and confirmed by histology and in whom surgical resection was delayed or was not performed. [110] Over a period of 6 to 137 months, 36 (64%) patients progressed to the advanced stage. The cumulative risk of progressing to advanced cancer over 5 years was 63% in this series. Because of the inconsistency in the histological diagnosis of early gastric cancer, this result should be interpreted with caution. However, it appears that early gastric cancer progresses at a relatively slow pace.

CLINICAL FEATURES

Early gastric cancer typically produces no symptoms. Only patients with advanced disease will notice any discomfort. The most frequent symptoms and signs patients experience are weight loss and abdominal pain. [111] Persistent vomiting can occur in antral tumors obstructing the gastric outlet. Dysphagia may be present when tumors obstruct the gastroesophageal junction. Early satiety, although not a common presentation of gastric cancer, may suggest a diffusely infiltrative tumor resulting in loss of distensibility of the stomach. Gastrointestinal bleeding has been reported in about 10% to 15% of patients, but frank bleeding is rare. Overt massive upper gastrointestinal bleeding may be more common in gastric stromal tumors.

Physical signs are usually absent in patients with gastric carcinomas, except in metastatic disease. A palpable abdominal mass is rare before regional extension of the tumor. Gastric carcinomas spread by local extension to adjacent structures or metastasize by lymphatic, peritoneal, and distant routes. Tumor may penetrate through the gastric wall and may directly invade the omentum, pancreas, kidney, colon, spleen, and liver. Gastrocolic fistula is uncommon, but it may result in vomiting of fecolith material or passage of recently ingested food into stool. Lymphatic metastasis occurs early, and local lymph nodes are usually the first to be involved. Metastasis to the left supraclavicular lymph node produces the so-called *Virchow node.* Tumor spreading along the peritoneal surfaces may result in a periumbilical nodule (*Sister Mary Joseph node*), ovarian mass (*Krukenberg tumor*), or tumor mass in the cul-de-sac (*Blumer shelf*). Peritoneal seeding of tumor may produce malignant ascites. Hematogenous spread usually involves the liver and occasionally the lung, bone, or brain. Patients with gastric cancer occasionally present with paraneoplastic syndromes, such as acanthosis nigricans, membranous glomerulonephritis, microangiographic hemolytic anemia, arterial and venous thrombi (*Trousseau syndrome*), seborrheic dermatitis (*Leser-Trélat sign*), and dermatomyositis.

DIAGNOSIS

Because of the silent nature of the disease, timely diagnosis of gastric cancer is difficult. Conventionally, radiologic imaging played a major role in the initial diagnosis of gastric cancer. A barium meal was once the investigation of choice for all upper gastrointestinal symptoms. With the use of double-contrast techniques, better

visualization of mucosal detail can be obtained. However, false-negative rates of up to 25% have been reported in lesions between 5 and 10 mm in diameter. [112] Furthermore, it may not be possible to differentiate a benign from a malignant ulcer by barium studies. A malignant ulcer typically has an asymmetric ulcer crater eccentrically located in an irregular mass with distortion or obliteration of the normal mucosal fold surrounding the ulcer. Other features such as nodularity, clubbing, fusion, or amputation of radiating folds also suggested malignancy. The use of radiologic imaging has gradually been replaced by endoscopy.

Since its introduction in the 1960s, upper gastrointestinal endoscopy and biopsy have been the standards for the diagnosis of gastric cancer. However, the endoscopic appearance alone is insufficient for the diagnosis of stomach cancer (Fig. 69-10; see also Color Fig. 69-10). Diagnostic accuracy of 95% was reported, [112], [113] and [114] and this can be further improved by increasing the number of biopsies. [115] Biopsy should be taken from the edge and the base of a malignant ulcer. [116] The additional use of brush cytology may further increase the sensitivity of endoscopic diagnosis. The identification of two of the following cytologic features makes the diagnosis of gastric cancer more likely: single atypical cells with intact cytoplasm and with eccentric and atypical naked nuclei. [117] The diagnosis of early gastric cancer can be difficult because lesions may not be conspicuous. Endeavors to improve the diagnostic accuracy of endoscopy and to locate the proper site for the biopsy sample have led to the development of new technologies. Light-induced fluorescence endoscopy is a technique that detects the autofluorescence from tissues after irradiation with blue or violet light. Characteristically, gastric tumors emit a different fluorescence from that of normal tissues, and this can be used as an adjunctive technique for the evaluation of presumptive neoplastic tissue. [118], [119]

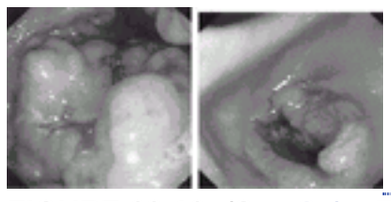

FIGURE 69-10. (See Color Fig. 69-10.) Endoscopic appearance of gastric cancer.

Screening of Gastric Cancer

Screening of gastric cancer in asymptomatic persons may increase the chance of detecting early cancer and hence may improve overall survival. In Japan, a screening program of gastric cancer used double-contrast radiology since the 1960s. [120] Seven-film photofluorography is the standard, which is then followed by endoscopic biopsies in suspicious cases. It was estimated that 40% to 60% of cancers diagnosed by the screening program were early cancer, with no lymphatic metastasis. [121] This program has been attributed as one of the reasons for the decline in stomach cancer mortality in Japan. However, a formal randomized study to evaluate the effectiveness of this screening strategy is lacking. Given the low incidence of gastric carcinoma in many developed countries, it is unlikely that a similar population-based screening program can be adopted. In areas with a low incidence of gastric cancer, screening may have to be targeted to high-risk persons only, such as those with family history of gastric cancer, chronic atrophic gastritis, previous gastric surgery, or pernicious anemia.

Apart from contrast study and endoscopy, other biochemical markers have been developed to identify those at risk of developing gastric carcinoma. Low serum pepsinogen I, which correlates with corpus atrophy, has been found to be significantly associated with gastric cancer. [122] In an evaluation, Kitahara and colleagues [123] showed that a pepsinogen I concentration of less than 70 ng/mL and a ratio of pepsinogen I to pepsinogen II of less than 3 are useful indicators, with a sensitivity of 84.6% and a specificity of 73.5% for detecting gastric cancer. In this context, an elevated serum gastrin level has also been used in the screening of severe atrophic gastritis. [124] Although an elevated gastrin level higher than 200 ng/L appears to be specific, the sensitivity is low (30%), thus precluding its use as a screening tool. The other potential serologic marker that may be used in screening of gastric cancer is *H pylori* antibody testing. However, because of the high prevalence of *H pylori* infection in most countries, a more discriminatory serologic test is necessary to identify which infected subgroups are at risk of developing gastric cancer. Antibody against CagA is the most extensively studied marker of *H pylori* infection for the diagnosis of gastric cancer. CagA is an immunodominant protein of *H pylori,* which is associated with the *cag* A gene or the cag pathogenicity island. Initial studies in countries with low *H pylori* prevalence suggested the link between gastric cancer and CagA antibody response. [125], [126] However, a similar association cannot be demonstrated in high-risk regions such as Japan and Colombia, probably because most *H pylori* strains circulating in these countries are CagA $^{+}$. [127] One study showed that no screening test (including *H pylori* and CagA serology, pepsinogen, and gastrin) was sensitive and specific enough to be used for the screening of chronic atrophic gastritis in populations with a high gastric cancer incidence. [128]

STAGING

The clinical and pathological staging of gastric carcinoma is of paramount importance in the management of the patient. The depth of the tumor invasion (T) (Fig. 69-11), the involvement of lymph nodes (N), and the presence of metastasis to other organs (M) are the major considerations. This TNM staging system has been extensively used in the evaluation of gastric cancer. However, there is considerable disparity between the Western and Japanese systems in the staging of gastric cancer.

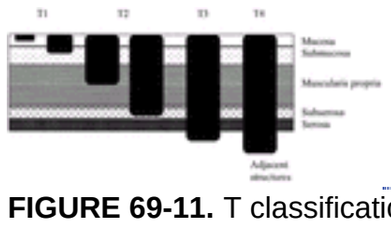

FIGURE 69-11. T classification of gastric carcinoma (TNM staging system).

In 1997, the TNM staging by the International Union against Cancer (UICC) and the American Joint Committee on Cancer (AJCC) underwent a substantial revision of the lymph node staging of gastric cancer. [129] The previous version of TNM staging had been based on the anatomic site or the distance of metastatic lymph nodes from the primary tumor, as in the Japanese classification system. [130] In the fifth edition of the TNM staging system, lymph node staging is determined by the number of regional lymph nodes involved (Table 69-4), which will ordinarily include sampling of 15 or more lymph nodes, instead of the sites of metastatic lymph nodes. If fewer than 15 lymph nodes are sampled, the N staging is defined as Nx. Regional lymph nodes are the perigastric nodes along the lesser and greater curvatures, the nodes located along the left gastric, common hepatic, splenic, and celiac arteries, and the hepatoduodenal nodes. Involvement of other intra-abdominal lymph nodes such as retropancreatic, mesenteric, and paraaortic are now classified as distant metastasis (M1). This change is supported by the observation that the absolute number of positive lymph nodes is of equal or even greater importance than the location of the lymph node. [131], [132] and [133] This new classification is easier to follow than the sophisticated localization of lymph nodes around the stomach and reduces the problems involved in the lymph node retrieval process. In this context, better reproducibility and standardization of histopathological examination can be achieved. Reports from various groups favor the use of this lymph node staging method over the previous version in determining the prognosis of patients. [134], [135], [136], [137] and [138] However, the possibility of unclassified cases (Nx) will increase by using this new system because of the inadequate number of lymph nodes sampled. In a Japanese study, 13% of patients were unclassified because fewer than 15 lymph nodes were examined. [137] This may be an even more serious problem in Western countries, where surgeons do not routinely perform extended dissection. If inadequate nodal dissection is performed, comparison of treatment results among different institutions will be difficult.

T: Primary Tumor	
Tis	Carcinoma in situ; intraepithelial tumor without invasion of lamina propria
T1	Tumor invades lamina propria or submucosa
T2	Tumor invades muscularis propria or subserosa
T3	Tumor penetrates serosa (visceral peritoneum) without invasion of adjacent structures
T4	Tumor invades adjacent structures
N: Regional Lymph Node	
N0	No regional lymph node metastasis
N1	Metastasis in 1 to 6 regional lymph nodes
N2	Metastasis in 7 to 15 lymph nodes
N3	Metastasis in more than 15 regional lymph nodes
M: Distant Metastasis	
M0	No distant metastasis
M1	Distant metastasis

TABLE 69-4 Fifth Edition of the International Union Against Cancer (UICC) and American Joint Committee on Cancer (AJCC) TNM Classification of Gastric Cancer

Conversely, the JRSGC uses a TNM classification that is based on meticulous surgical and pathological findings. [107] Whereas the tumor staging resembles that of the UICC TNM system, lymph node metastases are divided into stations that fall into four N categories (Fig. 69-12). Additionally, the Japanese system has a P staging, which represents the presence of peritoneal metastases. Grouping of tumors into different stage also varies from the UICC system.

FIGURE 69-12. Regional lymph node stations as proposed by the Japanese Research Society for Gastric Cancer. (From Hermanek P, Huttter RVP, Sobin LH, et al, eds. TNM atlas, 4th ed. Berlin: Springer, 1997:82.)

Preoperative Staging

Traditionally, staging of gastric cancer is performed at the time of surgery. However, this approach includes many patients with unresectable tumors who may not benefit from surgery. In general, no single imaging technique is reliable as a sole diagnostic tool in the preoperative staging of gastric cancer. Multiple test modalities are required for accurate preoperative staging.

Endoscopy is widely used in the initial diagnosis of gastric cancer and has generally replaced contrast radiologic studies in many centers. However, its role in the staging of disease is not widely recognized, except in Japan, where emphasis has been put on macroscopic appearance of cancers. This approach may be more useful in the selection of early gastric cancer that is suitable for endoscopic resection.

Despite the widespread use of computed tomography (CT) scanning in the preoperative staging, its value remains disputable. Early studies in the 1980s reported encouraging results of CT imaging, [139] but these findings were not substantiated subsequently. [140] One of the limitations of CT is the inability to differentiate between different layers of the gastric wall and hence the inability to define the T stage. The role of CT is confined to its ability to demonstrate invasion outside the stomach wall and the presence of distant metastasis. However, the sensitivity of CT is generally considered to be low. Even with the use of spiral CT, the sensitivity of detecting tumor invasion into colon or mesocolon and pancreas was 76% and 50%, respectively. [141] Pancreatic invasion is extremely difficult to detect on CT because inflammation and neoplastic infiltration is difficult to differentiate. Moreover, although the presence of a clear fat plane between the stomach and the pancreas indicates noninvasion, the absence of such a tissue plane does not necessarily imply tumor invasion. For lymphatic metastasis, the sensitivity of CT varies widely, from 48% to 91%. [142], [143], [144], [145], [146] and [147] Nonetheless, CT appears to be quite specific (>90%) for the detection of lymph node metastasis. This in part may be related to the conventional cutoff size (10 mm) of the malignant lymph node used by most studies. By reducing the cutoff size to less than 10 mm, sensitivity will increase, but there is a compromise in specificity. Furthermore, the presence of a conglomeration of enlarged lymph nodes is more likely to be malignant than is a solitary enlarged lymph node. Although the two most common sites of metastasis of gastric cancer are the liver and the peritoneum, most liver metastases are small and peripheral and hence have a low rate of detection by CT. Sensitivity in detection of distant metastasis was reported as 57%, [141] but false-positive results were not uncommon. Finally, it is generally recognized that CT is poor in visualization of small peritoneal nodules, except in the presence of ascites. [148] Overall, CT tends to understage gastric cancer. It is more useful in identifying advanced-stage disease that may not be suitable for primary curative resection.

The role of magnetic resonance imaging (MRI) in the preoperative staging of gastric cancer is yet to be defined. MRI requires a longer scan time than CT and thus is easily subjected to artifact from respiration and bowel movement. The other limitation of MRI is the lack of a widely accepted oral contrast medium to distend the stomach. Nevertheless, MRI is superior to CT in delineating the layered structure of the stomach wall, and it may be used in predicting the depth of tumor invasion (T staging). In a small study involving 30 patients with gastric cancer, MRI was marginally superior to helical CT (73% versus 67%). [149] For N staging, the accuracy of MRI and helical CT is comparable. Little information is provided regarding the role of MRI in evaluating distant metastasis.

Whole-body [^{18}F]fluorodeoxyglucose (FDG) positron emission tomography (PET) is being increasingly used in the evaluation of gastrointestinal malignant disease. The preferential accumulation of positron-emitting FDG by tumor cells has been used in the detection of human cancers. Data on staging of gastric carcinoma are limited. Preliminary study showed that although PET appears to be sensitive in the detection of gastric tumors, it is of limited value in locoregional staging because of poor differentiation of primary tumor from metastatic lymph nodes. [150] Conversely, it may be more useful in the follow-up of treatment response. Changes in tumor FDG uptake were seen in gastric carcinomas after chemotherapy. [151]

Another imaging modality that has been gaining popularity in the preoperative staging is endoscopic ultrasonography (EUS). With the use of medium- to high-frequency ultrasound probes (7.5 to 30 MHz), the gastrointestinal tract is clearly delineated as a five-layered structure by EUS corresponding to the mucosa, submucosa, muscularis propria, and serosa of the gastric wall. EUS provides an accurate assessment of T staging and is superior to other imaging modalities for the local staging of gastric cancer (Fig. 69-13). The overall accuracy of EUS in T staging was estimated to be 78%. [152] The accuracy tends to be lower for T2 tumors because of the tendency to overstage these tumors as a result of poor differentiation between inflammation and infiltration. The overall accuracy of N staging was estimated to be 70%, [152] which is also superior to CT. It is more accurate for N0 status (85%) but least for N2 status (65%). EUS is generally unsuitable for the assessment of distant metastases because of the low penetration of high-frequency ultrasound. There are several caveats relating to the use of EUS in gastric cancer staging. The accuracy of EUS is highly operator dependent. Differentiation between malignant infiltration and fibrosis at the base of peptic ulcer can be difficult. Obstructing tumors, usually at the cardia, that prevent passage of echoendoscope into the stomach may limit its use. Moreover, the presence of metastases within a normal-size lymph node may be missed.

(**A**) Intramucosal early gastric cancer (T1is) with focal mucosal thickening (*short arrow*); the lamina propria (*long arrow*) is intact. (**B**) T2 gastric cancer (*short arrow*) invades into the muscularis layer, and the serosa (*long arrow*) is intact. (**C**) Small gastric cancer (*short arrow*) invades through the serosa (T3). (**D**) Large T4 gastric cancer (*short arrow*) invades into the neck of pancreas (*long arrow*). (Courtesy of Dr. Y.T. Lee, Prince of Wales Hospital, Hong Kong.)

Preoperative laparoscopy often detects unexpected peritoneal or liver metastasis that may not be identified by other imaging techniques (Fig. 69-14; see also Color Fig. 69-14). The role of laparoscopy in preoperative staging is difficult to evaluate because most published series involved heterogeneous patient populations and gave inconsistent results. The overall rate of detecting peritoneal and liver metastases by laparoscopy ranged from 3% to 37% and 2% to 25%, respectively. [153] Based on these findings, a corresponding treatment plan was altered in 6% to 42% of patients. The use of laparoscopic ultrasound has been advocated to enhance the ability to detect liver metastases. The use of laparoscopy may be particularly useful in a subgroup of patients with T4 disease who may benefit from multimodality treatment. [154]

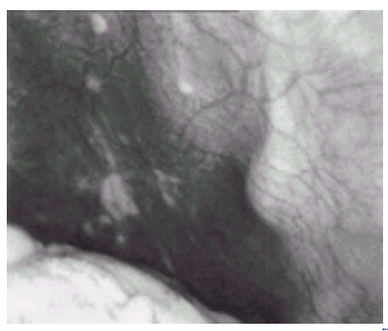

FIGURE 69-14. (See Color Fig. 69-14.) Laparoscopic view of a patient with gastric carcinoma with peritoneal metastasis (whitish nodule).

TREATMENT

To date, surgery remains the mainstay of treatment for gastric cancer. Unfortunately, two thirds of patients present with advanced disease and are thus incurable by surgical excision only. Even with the use of aforementioned advance staging techniques, 10% to 20% of patients who undergo surgical exploration for potentially curative resection are found to have peritoneal seeding at the time of laparotomy.

Surgery

Certain definitions need to be clarified before discussion of treatment options. Curative resection is defined according to the UICC/AJCC combined rules. [129] R0 resection indicates potentially curative removal of the tumor with no residual disease. R1 refers to resection that leaves behind microscopic tumors, whereas R2 resection indicates that gross residual tumors remain (i.e., palliative resection). Conversely, surgical resection is classified by the extent of lymph node dissection, as designated by D. D0 denotes no or incomplete dissection of the N1 nodes. D1 refers to dissection of tumor and adjacent nodes (N1) only, whereas D2 indicates dissection of nodes along the major celiac vessels (N1 and N2 nodes). D3 dissection removes the entire tumor mass together with N1, N2, and N3 lymph nodes.

Although few argue that surgery is the best treatment option, the extent of resection, particularly the extent of lymph node dissection, remains highly controversial. In practice, the extent of dissection is determined primarily by tumor location and staging and the premorbid conditions of the patient. Extensive resection has the benefit of removing the major tumor bulk, at the cost of higher risks of operation and postoperative complications. Even though total gastrectomy offers a larger surgical resection margin, studies failed to demonstrate any advantage of total gastrectomy over subtotal gastrectomy. [155], [156] The French multicenter study showed similar postoperative morbidity and mortality rates and 5-year survival rates for total and subtotal gastrectomy. The Hong Kong study, which compared subtotal D1 gastrectomy with total D3 gastrectomy, also showed a significant increase in morbidity from splenectomy and distal pancreatectomy in the latter group. The survival rate was actually better in the group with limited resection only. Conversely, total gastrectomy may be indicated for tumors involving the proximal stomach, particularly carcinoma of the gastric cardia, [157] because of the functional defect of proximal gastrectomy leading to reflux esophagitis. Yet, data suggested that total gastrectomy may not have any influence on the morbidity and survival of patients with proximal gastric carcinoma. [158]

There is considerable difference between Western and Japanese surgeons in the extent of lymphadenectomy for gastric cancer. Japanese surgeons systematically perform a more extended lymph node dissection (D2) than Western surgeons, based on the belief that the primary tumor will disseminate through lymphatic channels in an orderly manner from the nearest to the farthest lymph nodes. This practice is considered to be the major reason for the contrasting outcomes between Western and Japanese patients with gastric cancer. However, prospective randomized controlled trials from Western countries comparing D1 with D2 lymphadenectomy failed to demonstrate any survival benefit of the more aggressive approach with D2 dissection. [159], [160] and [161] Notably, both the British Medical Research Council trial and the Dutch Gastric Cancer Group trial showed a significantly higher short-term morbidity and hospital mortality among patients undergoing D2 dissection without improving the 5-year survival (Table 69-5). The high initial complication rate of D2 gastrectomy has been attributed to pancreaticosplenectomy and the unfamiliarly of the surgeons with this kind of operation. Conversely, the perioperative mortality of D2 resection, particularly with the spleen and pancreas preserved, by surgeons experienced with this procedure, is reported to be about 1% to 3%. [162], [163] and [164] Another controversial issue relating to these two trials is the high rates of noncompliance with either D1 or D2 gastrectomy, which may interfere with the final outcome. Patients randomized to D1 dissection may receive a more aggressive dissection, and patients randomized to D2 dissection may receive inadequate lymph node dissection. Thus, the extent of lymphadenectomy remains controversial despite the publications of these randomized controlled trials, and further studies are needed. [165]

TABLE 69-5 Short-Term and Long-Term Results of Major Randomized Trials Comparing D1 and D2 Lymph Node Dissection in Gastric Carcinoma

Patients with locally advanced disease may benefit from a more aggressive resection, such as splenic resection with left-sided pancreatectomy in cases with splenic hilar lymph node involvement. This en bloc procedure can remove all metastatic lymph nodes along the splenic artery. As shown by the British Medical Research Council and Dutch trials, [159], [160] and [161] the removal of extragastric organs, whether directly involved or not, was associated with higher morbidity and hospital stay. Both splenectomy and distal pancreatectomy are therefore not routinely recommended in D2 resection except in the presence of direct tumor invasion. Conversely, Japanese surgeons may favor a more aggressive approach in patients with T4 tumors in the absence of distant metastasis, to reduce the chance of subsequent tumor bed recurrence.

Because most cases of gastric cancer are diagnosed at an advanced stage, fewer than 50% of patients with gastric cancer can undergo potentially curative gastric resections. Nonetheless, palliative surgery may still be considered in certain circumstances such as tumor obstruction, perforation, and bleeding. There is also a reduction in the incidence of debilitating ascites after palliative gastrectomy. [166] If gastrectomy is performed, gross disease immediately adjacent to the stomach should be removed. Leaving behind a primary tumor mass in the stomach not only invites bleeding and perforation but also diminishes the likelihood of response to subsequent palliative chemotherapy. Alternatively, a bypass procedure or gastrojejunostomy can be performed, but it has been found to be associated with significantly shorter palliation period when compared with gastric resection. [167] There is also no significant difference in terms of operation-related morbidity and mortality. However, gastric resection may not be indicated in patients with a poor chance of survival, and the final decision is usually dictated by the overall clinical condition of the patient.

Endoscopic Therapy

In addition to its role in diagnosis, endoscopy has been developed as a curative as well as palliative treatment for gastric cancer. *Endoscopic mucosal resection* (EMR) or strip biopsy was first described by Tada and colleagues. [168] It is widely practiced in Japan as the treatment of choice for early gastric cancer after EUS confirmation of disease confined to the mucosa. Because of the low incidence of lymph node and distant metastasis, surgical resection of the stomach for early gastric cancer is considered unnecessary, and a limited resection is therefore more appealing. Various techniques of EMR have been described. [169] and [170] The procedure involves injection of saline into the submucosa under the lesion to lift the mucosal and submucosal layer from the muscle, to avoid perforation. Methylene blue may be added to the saline to demarcate the plane of separation. The endoscope is fitted with suction cap at its tip. The lesion is sucked into the chamber and is resected by an EMR snare. Resection of the mucosa may then be achieved by using a cap-fit device at the tip of the endoscope and a mucosectomy snare. The malignant tissue can be removed en bloc or by piecemeal resection. Muscle fibers can be seen at the base of the resected area. Re-epithelialization usually occurs within weeks. In contrast to ablation by laser or argon plasma, EMR can provide the original resected specimens for histological evaluation. The major complications of EMR are bleeding and perforation, which were estimated to be about 5%. [171] The indications for EMR as suggested by the Japanese Gastroenterological Endoscopy Society are as follows: elevated-type intramucosal cancer less than 20 mm in size; depressed-type mucosal cancer without ulceration, less than 10 mm in size; and intestinal-type adenocarcinoma. In a review of the 11-year results of EMR for early gastric cancer at the National Cancer Center Hospital of Japan, in which 479 cancer patients were treated by EMR, 69% of tumors were resected with clear margin, and 17 local recurrences were detected during subsequent follow-up. [171] There were no gastric cancer–related deaths during the follow-up period (3 to 120 months). In cases with residual tumor after EMR, patients can be offered surgery or local therapy such as laser ablation. However, to date, there is no randomized controlled trial comparing the efficacy of EMR with conventional modalities of treatment. [172] An alternative method in EMR is to employ an insulated-tip needle-knife, as described by Ohkuwa. [173] Although this technique allows resection of a much larger piece of mucosa, it is associated with significantly higher risks of the complications of bleeding and perforation. [173] Further refinement of this technique is necessary.

For advanced inoperable gastric cancer with obstruction, laser or argon plasma coagulation therapy and endoscopic stenting procedures can be considered. Laser ablation of tumors requires expensive equipment, and thus argon plasma coagulation is preferred by most gastroenterologists. The advent of self-expanding metallic stents made possible the palliation of malignant stricture with minimal complications. It is particularly useful in the palliation of proximal gastric cancer as well as gastric outlet obstruction. In addition, fistulae and perforations can be sealed by the covered stent. Endoscopic stenting can also be used to relieve obstruction at anastomosis after partial or total gastrectomy as a result of tumor recurrence (Fig. 69-15; see also Color Fig. 96-15). Tumor ingrowth, stent migration, and gastroesophageal reflux are complications of endoscopic stenting. Various newer covered stents are available to overcome the problem of tumor ingrowth, and antireflux mechanisms have been devised to avoid gastroesophageal reflux.

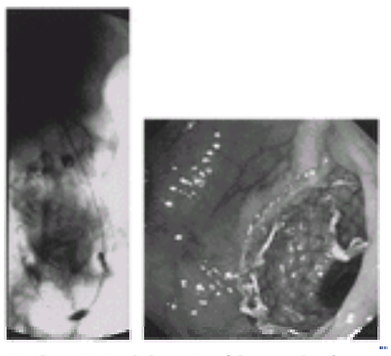

FIGURE 69-15. (See Color Fig. 69-15.) Self-expandable metal stent in patient with recurrent gastric carcinoma causing gastric outlet obstruction after subtotal gastrectomy.

Chemotherapy

Chemotherapy can be given preoperatively (neoadjuvant), intraoperatively, or postoperatively to reduce the chance of local or systemic tumor recurrence. Numerous chemotherapeutic agents, either given alone or in combination, have been used with variable success. The *response rate* refers to a 50% reduction of tumor mass. The activity of a single agent ranges from 5% to 31%. [174] 5-Fluorouracil (5FU) is the most frequently used agent, with a response ranging from 20% to 30%, depending on the route of administration. Mitomycin C, commonly used in Japan, has an overall objective response rate of 30%. Other agents with reported response rates of 19% to 26% include epirubicin, doxorubicin, cisplatin, and hydroxyurea.

Adjuvant therapy is generally considered as additional treatment for patients who have already undergone potentially curative surgical procedures (i.e., R0 resection). In patients who had gross residual disease remaining after surgery, treatment should be considered palliative therapy instead of adjuvant therapy. Numerous trials have been performed. Unfortunately, most of these have major methodological flaws or merely represent anecdotal reports. Two early studies conducted by the Veterans Administration Study Group with single-agent chemotherapy, using thiotepa or 5FU, after surgical resection failed to demonstrate any improvement in long-term survival. [175], [176] As a result of the poor response rate from single-drug chemotherapy, various combination therapies were devised. As yet, no consensus combinations are available for the treatment of gastric adenocarcinoma. Various combinations such as FAM (5FU, doxorubicin [Adriamycin], mitomycin C), FAMTX (5FU, doxorubicin [Adriamycin], methotrexate), FEP (5FU, etoposide, cisplatin), FAP (5FU, doxorubicin [Adriamycin], cisplatin), and ECF (epirubicin, cisplatin, infusional form of 5FU) have been used in various studies. [177] The median survival associated with multidrug chemotherapy ranges from 6 to 10 months, and the real survival benefit is debatable. Most of the published trials focused on response rate to chemotherapy without a formal evaluation of the patients' quality of life.

Overall, results from early trials were disappointing. In a review of adjuvant therapy for gastric cancer since the mid-1980s, investigators concluded that adjuvant therapy does not confer any survival benefits and thus cannot be recommended. [178] Nonetheless, the timing and mode of postoperative chemotherapy given in Western countries may undermine the effect of adjuvant chemotherapy. Whereas chemotherapy is usually given at 4 to 6 weeks after surgery, Japanese oncologists favor early institution of treatment during or immediately after the operation. Conversely, a multicenter study from Japan using adjuvant mitomycin and 5FU followed by oral uracil plus tegafur for 18 months in serosa-negative gastric cancer (T1 and T2) after curative gastrectomy failed to show any difference in survival between treatment and control groups. [179] The 5-year survival was 82.9% in the control group and 85.8% in the treatment group. Thus, it appears that, even in Japan, this group of patients with early-stage disease may not benefit from adjuvant treatment.

The rationale for neoadjuvant (preoperative) chemotherapy is to reduce tumor burdens before surgery with the hope of achieving a higher rate of R0 resection and better patient survival. Furthermore, treatment is targeted to minimize distant micrometastasis before operation and to limit potential cancer cell dissemination during the surgical procedure. Numerous trials have been conducted, but the only conclusion that can be drawn is that neoadjuvant chemotherapy does not increase postoperative morbidity and mortality. [180] In one small series, response to neoadjuvant chemotherapy was found to be the single most important predictor of overall survival. [181]

In addition to the administration of chemotherapeutic agents by the systemic route, antitumor drugs can be delivered intraperitoneally. The potential benefit of intraperitoneal chemotherapy is based on the ability to control locoregional tumor recurrence after curative resection. Hagiwara and colleagues [182] evaluated the use

of intraperitoneal mitomycin C adsorbed to activated charcoal in high-risk patients after curative resection. There was a highly significant difference in 2-year survival (68.6% versus 26.9%) favoring the use of this regimen. A prospective randomized trial of early postoperative intraperitoneal chemotherapy as adjuvant therapy in resectable gastric cancer also showed significant improvement in 5-year survival rate in a subset of patients with stage III disease. [183] The effects of intraperitoneal chemotherapy remain to be substantiated by further studies.

Radiotherapy

Gastric carcinoma is relatively resistant to radiotherapy. Radiotherapy includes both external beam and intraoperative radiotherapy. The British Stomach Cancer Group [184] found that postoperative radiotherapy in addition to surgery did not confer any benefit in survival. The 5-year survival in patients receiving surgery plus radiotherapy and surgery alone was 12% and 20%, respectively. Conversely, intraoperative radiotherapy is frequently given in Japan. [185] Although it appeared to prolong survival for patients with stage II and III disease, this therapy needs further evaluation.

PROGNOSIS

The mortality of gastric cancer in many parts of the world, with the exception of Japan, has not been changed over the past few decades. A review from the National Cancer Data Base revealed that the overall 5-year and 10-year survival rates of patients diagnosed with gastric cancer between 1985 and 1996 were 28% and 20%, respectively [186] (Fig. 69-16). The stage-stratified survival analysis reviews that men had a poorer prognosis than women, and proximal cancer was associated with worse prognosis than distal cancer. Difficulty in attaining an adequate proximal resection margin and the close proximity to paraaortic lymph nodes around the hiatus may be the reasons contributing to the worse outcome in proximal gastric tumors.

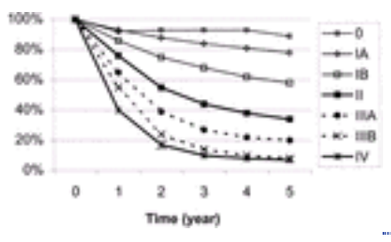

FIGURE 69-16. Five-year survival rates of gastric cancer patients treated by gastrectomy in the United States. (Modified from ref. [186].)

In contrast to the grave prognosis of gastric cancer in many developed countries, 50% of patients with gastric cancer can be cured of the disease in Japan. Several explanations have been put forward to account for this discrepancy. First, the adoption of screening policy for gastric cancer in Japan may lead to detection of early cancer and hence a higher resectability rate. Second, when compared with Western populations where proximal gastric cancers are prevalent, the Japanese population has predominantly distal gastric cancer. [186] Other factors that may contribute to this difference in prognosis include the more precise staging of the disease, the more aggressive surgical approach, and perhaps the use of adjuvant therapy by Japanese clinicians. [164]

GASTRIC TUMORS OTHER THAN ADENOCARCINOMAS

Gastric Lymphoma

Although *primary gastric lymphoma* is a rare malignant disease that accounts for less than 5% of all gastric malignancies, it is the most common form of gastrointestinal lymphoma. It is estimated that approximately 70% of primary extranodal lymphomas of the gastrointestinal tract arise from the stomach. [187] However, the diagnosis of primary gastrointestinal lymphoma is controversial. The definition proposed by Dawson and colleagues [188] requires that primary gastrointestinal lymphoma be limited to the stomach or intestine and its contiguous lymph nodes. This criterion has been criticized as being too restrictive. A more practical definition has been adopted that states that a tumor presenting with the bulk of disease in the gastrointestinal tract can be considered “primary” gastrointestinal lymphoma.

Most (80%) of gastric lymphomas are B cell in origin. The classification of gastric lymphoma, like that of many extranodal lymphomas, is confusing. Several systems have been proposed by various groups, which include the Rappaport classification, the Lukes-Collins classification, the Kiel classification, and the Working formulation (Table 69-6). Direct comparisons of past studies are difficult. Data suggest that the true incidence of primary gastric lymphoma is rising, particularly among elderly persons. [189], [190] This may in part be explained by improved diagnosis and by the increasing incidence of lymphoma in immunosuppressed patients such as in patients with acquired immune deficiency syndrome or those taking immunosuppressive agents. The origin of this disease remains elusive, but many of these tumors, particularly mucosa-associated lymphoid tissue (MALT) lymphoma, are related to chronic inflammation attributed to *H pylori* infection. [191] *H heilmannii* has also been linked to MALT lymphoma. [192]

B-cell	MALT-type
	Low-grade
	High-grade with or without low-grade component
	Mantle cell
	Burkitt
	Immunodeficiency-related
	Posttransplant
	Acquired immunodeficiency syndrome
	Congenital
	Others
T-cell	Enteropathy-associated
	Others

MALT, mucosa-associated lymphoid tissue.

TABLE 69-6 Primary Gastrointestinal Non-Hodgkin Lymphoma

Macroscopically, it may not be possible to differentiate gastric lymphoma from carcinoma. Gastric lymphoma can be polypoid, fungating, infiltrating, or even ulcerative in appearance. Most lymphoma spreads by submucosal infiltration, and the muscular layer is usually spared until a very late stage of the disease. Further spread to local and regional lymph nodes then follows. Microscopically, there is considerable heterogeneity among different classification systems.

Symptoms of gastric lymphoma are nonspecific; the most frequent symptoms are abdominal pain, weight loss, nausea, vomiting, and anorexia. Bleeding occurs in about 20% of cases. [193] Although upper gastrointestinal contrast studies are not the investigations of choice, certain radiologic features may suggest the presence of gastric lymphoma. These include diffuse mucosal hypertrophy with irregular thickening of folds, single or multiple ulcers associated with diffuse mucosal thickening, [194] and lesions larger than 15 cm. [190] Upper gastrointestinal endoscopy is widely used in the diagnosis of gastric lymphoma that can provide histological proof. However, multiple and deep gastric biopsies are usually required for histological diagnosis because tumors may develop in the submucosal lymphoid tissue covered by normal gastric mucosa.

The Musshoff-modified Ann Arbor staging system is widely used for staging of gastric lymphoma (Table 69-7). [195] This staging system was subsequently refined, with an emphasis on separate description of local penetration into neighboring structures. Stage IE was divided into IE_1 (infiltration of the mucosa and submucosa) and IE_2 (infiltration of the muscularis or (sub)serosa). Staging of disease can be done by CT scan and EUS. EUS is reliable in delineating the depth of tumor involvement and is superior to CT in distinguishing stage IE from stage IIE_1 disease. [196] The availability of these imaging techniques has reduced the prior reliance on surgery for staging of gastric lymphoma. To differentiate primary gastric lymphoma from systemic lymphoma with gastric involvement, other investigations such as peripheral

blood smear, bone marrow biopsy, and radiologic imaging are required.

STAGE	DESCRIPTION
IE	Localized involvement of one or more gastrointestinal sites on the same side of the diaphragm without lymph node involvement
IE_1	Confined to the mucosa and submucosa
IE_2	Extending beyond submucosa
IIE	Stage IE with lymph node involvement; penetration of lymphoma through the gut wall
IIE_1	Regional lymph node involvement
IIE_2	Lymph node infiltration beyond the regional wall
IIIE	Involvement of the gastrointestinal tract and/or lymph nodes on both sides of the diaphram
IVE	Diffuse or disseminated involvement of nongastrointestinal organs or tissues

Adapted from ref. 195.

TABLE 69-7 Musshoff's Modification of the Ann Arbor Staging System for Gastric Lymphoma

P>Until recently, gastrectomy was the only treatment available for gastric lymphoma. However, there is a current tendency toward stomach-conserving therapy, and the best treatment for primary gastric lymphoma has yet to be defined. Many of these controversies originate from the differences in classification systems, the small numbers of patients treated with a variety of protocols, and the lack of randomized controlled trials. Surgery is favored by some clinicians because it is potentially curative and can remove all tumor tissues for accurate typing and staging. Moreover, resection can prevent complications such as hemorrhage and perforation during radiotherapy and chemotherapy. It is particularly useful for localized diseases, such as stages IE and IIE, giving a favorable 5-year survival rate of 85% to 100%. [197], [198] and [199] However, the operative mortality rate ranges from 0% to 30%, and there is no consensus on the extent of surgical dissection. Chemotherapy or combination treatment may be more appropriate for patients with advanced-stage (stage IIIE and IVE) diseases. Traditionally, the combination of cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) is the standard regimen used in the treatment of gastric lymphoma. Radiotherapy, either used as primary treatment or as adjuvant therapy, has also been reported. For stage IE and IIE disease, comparable 5-year survival rates have been reported in studies comparing primary radiotherapy with surgery. [200] Although lymphoma is usually sensitive to radiation, there is always the concern of complications related to this treatment option, such as renal toxicity, perforation, and hemorrhage, although studies have shown that these complications are uncommon. [201] Based on experience in the treatment of nodal lymphoma, many investigators favor the use of stomach-conserving treatment, that is, primary systemic chemotherapy or radiotherapy. In the interim analysis of the prospective German multicenter study, the operative approach does not appear to be superior to the conservative management of primary gastric lymphoma. [202]

The grading and staging of gastric lymphoma are the two decisive prognostic factors. In a review by the German-Austrian Gastrointestinal Lymphoma Study Group, [199] the overall 2-year survival rates for low-grade lymphoma ranged from 89% to 96%. Conversely, patients with high-grade lymphoma fare much worse. When surgery was performed, patients with complete resection had significantly better survival than those with incomplete resection (2-year survival of 83% to 88% versus 53%).

Mucosa-Associated Lymphoid Tissue Lymphoma *MALT lymphoma* was first described in 1983 by Issacson and Wright [203] as a distinct pathological entity. They described that certain low-grade B-cell gastrointestinal lymphomas recapitulated the features of Peyer patches or MALT. MALT lymphoma is characterized by the presence of plasma cells, reactive follicles, and centrocyte-like cells that tend to invade mucosal epithelium and form characteristic lymphoepithelial lesions. Most are of B-cell origin, and the most frequent site of involvement is the stomach. These tumors tend to arise as polyclonal proliferation in chronic inflammatory tissues, either autoimmune or infectious. MALT lymphoma was the most common type of the marginal zone lymphomas according to the Revised European-American lymphoma (REAL) classification. [204] In the scheme proposed by Issacson and Wright, [205], [206] B-cell gastric lymphoma, which accounts for most of the gastric lymphoma, can be subdivided into low-grade and high grade MALT lymphomas. Low-grade MALT lymphoma is represented by small lymphocytic cells disrupting the gastric glands and forming characteristic lymphoepithelial lesions (Fig. 69-17; see also Color Fig. 69-17). Tumor cells infiltrate around and between reactive lymphoid follicles. In high-grade lymphoma, one sees confluent clusters or sheets of larger and transformed blastic cells that are usually thought to be centroblasts outside the colonized follicles. Notably, foci of high-grade components may be present in low-grade MALT lymphoma. [207]

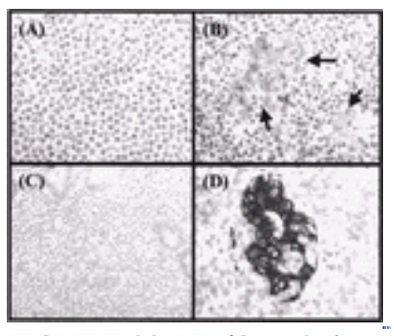

FIGURE 69-17. (See Color Fig. 69-17.) Gastric mucosa-associated lymphoid tissue (MALT) lymphoma: characteristics features of low-grade MALT lymphoma. (**A**) Centrocyte-like cells (hematoxylin and eosin, ×200). (**B**) Lymphoepithelial lesions (marked by *arrows*) (hematoxylin and eosin, ×200). Chan, Chinese University of Hong Kong, Prince of Wales Hospital, Hong Kong.)

The endoscopic appearance of MALT lymphomas ranges from normal mucosa to erosions, ulcers, or protruding masses. These histological diagnoses of MALT lymphoma may sometimes be difficult because of the existence of a wide range of variations in the assessment of intermediate categories. The diagnostic yield for this tumor can be improved by the use of other techniques, such as polymerase chain reaction and immunohistochemistry. The detection of monoclonal rearrangements of the immunoglobulin heavy chain gene by polymerase chain reaction or Southern blotting suggests the presence of lymphoma. The immunophenotypes of low-grade MALT lymphoma overlap those of marginal B cells. Both demonstrate the presence of pan B-cell antigens (CD19, CD20, and CD79a) and the lack of CD5, CD10, CD23, and cyclin D_1 expression. [208] Conversely, the use of immunostaining for cytokeratin enhances the visibility of lymphoepithelial lesions, an important diagnostic criterion of gastric MALT lymphomas. Compelling epidemiologic and pathological evidence suggests the link between chronic *H pylori* infection and gastric MALT lymphoma. [191], [209] This disease is more prevalent in regions with a high prevalence of *H pylori* infection, particularly in northeastern Italy. [210] More than 90% of low-grade gastric MALT lymphomas showed evidence of *H pylori* infection. [209] In addition, clinical studies strongly support the potential for curing MALT lymphoma by eradicating *H pylori* infection. [211], [212], [213], [214] and [215] Cure of the infection results in apparent disappearance of the tumor and eventual decrease or disappearance of the monoclonal B-cell populations from the gastric mucosa. However, the time to complete tumor remission varies considerably and may not be apparent until several months after clearance of the organism. [215] Monoclonal B cells, as detected by polymerase chain reaction, may persist up to several years after cure of *H pylori* infection and complete histological and endoscopic remission. [216] The overall success of antibiotics in achieving complete remission ranges from 50% to 89%. [199], [215], [217] Staging by EUS may be able to predict the response of gastric MALT lymphoma to anti- *Helicobacter* treatment. Patients with stage IE_1 disease (confined to mucosa and submucosa) are more likely to have complete regression of MALT lymphoma after anti- *Helicobacter* therapy. [217], [218] Other factors that may identify nonresponders to antibacterial therapy include *H pylori*–negative status and the presence of high-grade features. Results from cytogenetic studies show that the presence of translocation of (11;18, q21;q21), which results in a chimeric transcript between the *API2* and *MLT* genes, may predict lymphoma resistance to antibiotic treatment. [219] When antibiotic treatment fails or in the presence of high-grade features or the absence of *H pylori* infection, other treatment modalities such as surgery, chemotherapy, and radiotherapy should be considered.

Gastrointestinal Stromal Cell Tumors

Gastrointestinal stromal tumors (GISTs) encompass a heterogenous group of mesenchymal tumors. There has been considerable controversy regarding the nomenclature, origin, cellular differentiation, and prognosis of this disease. Based on light microscopic appearance of primarily spindle-shaped cells, most gastrointestinal mesenchymal tumors were initially thought to be of smooth muscle origin. However, with the advent of immunohistochemistry and electron microscopy, it became apparent that there is considerable variability within these tumors, and further categorization is possible. GISTs can have predominantly myogenic, neural, or mixed features. The understanding of GISTs has evolved to account for most mesenchymal tumors arising within the gastrointestinal tract with an incomplete myogenic and neural or "uncommitted" phenotype. By contrast, gastric stromal tumors with predominant smooth muscle differentiation are termed *gastric smooth muscle tumors.* They were conventionally called leiomyomas and leiomyosarcomas. Gastric mesenchymal tumors of neural origin can be divided into four

main groups depending on the origin: peripheral nerve (schwannoma, neurofibroma, and neuroma); sympathetic or chromaffin system (neuroblastoma, ganglioneuroma, and paraganglioma); gastrointestinal plexus (gastrointestinal autonomic nerve tumor); and undetermined.

The precise cellular origin of GISTs has been proposed to be the interstitial cell of Cajal, an intestinal pacemaker cell. [220], [221] This is supported by the sharing of morphologic, immunohistochemical, and ultrastructural features between GISTs and the interstitial cell of Cajal. The interstitial cell of Cajal demonstrates an incomplete myogenic and neural differentiation on ultrastructural examination and exhibits features that can be identified in GISTs. In particular, immunoreactivity against CD34 and CD117, although not specific, are frequently detected in GISTs and interstitial cells of Cajal. CD34, a transmembrane glycoprotein, is expressed in 50% to 80% of GISTs. [222] However, it is also expressed in true smooth muscle cells. Conversely, CD117/c- *kit* is expressed in 80% to 100% of GISTs and may be more sensitive and specific than CD34. [223] The c- *kit* protooncogene encodes a type III tyrosine kinase growth factor receptor, which can be detected by immunohistochemistry for CD117. Mutations of c- *kit* that cause constitutive activation of the tyrosine kinase function of c- *kit* are detectable in most GISTs and appear to play a pivotal role in the pathogenesis of these tumors. [224] For smooth muscle tumor, immunoreactivity against desmin is frequently (50% to 70%) positive, and CD117 is usually negative.

GIST is an uncommon disease. The Finnish Cancer Registry [222] estimated an annual incidence of 4 cases per million, which may be an underestimation. In a review performed by the Memorial Sloan-Kettering Cancer Center, [225] there were only 200 patients with GIST treated during the previous 16 years. The most frequent site affected is the stomach, which accounts for about 70% of the cases. About 20% to 30% of GISTs are found in the small intestine, and fewer than 10% are found elsewhere in the gastrointestinal tract. [226] The peak incidence is in adults during the fifth and sixth decades, and the disease is uncommon in patients less than 40 years old. Both genders are affected. Etiologic agents have not been identified.

Histologically, the distinction between benign and malignant tumors is difficult, and there is no unequivocal criterion to differentiate the two. Conventionally, various parameters have been used to predict the biologic behavior including mitotic activity (>10/high-power filed), tumor size (>5cm), tumor necrosis, histological type or pattern, immunohistochemical profile, staining for proliferation antigens, and ploidy status. [222] Among these, mitotic activity and tumor size appear to be more reliable in categorizing tumors as benign, borderline, and malignant, but there is no agreed cutoff point for these values. The use of EUS may also help in differentiating benign from malignant tumors. Tumors less than 30 mm in diameter with regular margins and with a homogenous echo pattern are usually benign. [227]

Many of these tumors are asymptomatic and are discovered incidentally, but the clinical courses are highly variable. Patients can present with nausea, vomiting, abdominal pain, gastrointestinal bleeding, and even metastatic diseases. Bleeding is considered the most common presentation. Malignant tumors can metastasize to the liver and peritoneum and, rarely, to lymph nodes, bone, and lung. [225] Accurate preoperative diagnosis can be difficult, and percutaneous biopsy carries a theoretical risk of peritoneal seeding and tumor rupture.

Surgical resection of the tumor remains the only treatment option. Complete tumor resection can be accomplished in about 50% to 80% of cases. [225] For gastric tumors, limited dissection is known to achieve results comparable to those of extended resection. [228] Lymphadenectomy is not routinely practiced because of the low incidence of lymph node metastasis. In general, vital structures should be preserved if gross tumor clearance can be attained. The use of adjuvant therapy remains experimental, and there is no effective therapy for advanced metastatic disease. Promising results were achieved by the use of tyrosine kinase inhibitor in a single patient with metastatic GIST that expressed CD117. [229] This may be a new direction for treatment development, but results need to be confirmed in larger series.

Because of the low incidence of this disease, many of the previous studies were limited to small numbers of patients. The overall 5-year survival of these patients ranges from 28% to 65%. [225] Several features may predict higher chances of survival. These include female gender, tumor size less than 5 cm, and complete tumor resection. However, recurrence of disease is common and can occur years after surgery. A previous report estimated that only about 10% of patients were free of disease after long-term follow-up, [230] and long-term surveillance is necessary to detect tumor recurrence.

Gastric Carcinoid Tumors

Carcinoid tumors are traditionally divided into foregut, midgut, and hindgut in origin. Foregut carcinoids comprise bronchial, gastric, and duodenal carcinoids. By far, the most frequent sites of gastrointestinal carcinoids are the small bowel, appendix, and rectum. Gastric carcinoid tumors are rare, accounting for only about 3% of all carcinoids. [231]

Three distinct types of gastric carcinoid tumors have been proposed, with characteristic biologic behavior and prognosis. Enterochromaffin-like cells are the main endocrine cell types in type 1 and type 2 disease. Type 1 is the most frequent form (about 65%) of gastric neuroendocrine tumor and is localized in the oxyntic mucosa at the fundus and body. Patients usually have chronic atrophic gastritis, achlorhydria, and pernicious anemia. They often have elevated basal gastric levels and are highly sensitive to trophic stimulus of gastrin. Type 1 tumors tend to be small (<100 mm) and multiple. They are considered the most benign of the three forms of carcinoid tumors and have a relatively low frequency of metastasis, between 9% and 23%. [232], [233], [234] and [235] Type 2 tumor is associated with the gastrin-producing neoplasms in Zollinger-Ellison syndrome as part of the multiple endocrine neoplasia syndrome type I. This type of carcinoid has intermediate metastatic potential. By contrast, type 3 or sporadic carcinoid lesions are encountered less frequently. They are not associated with hypergastrinemia and are frequently solitary large lesions in nonatrophic mucosa. This type of tumor behaves more aggressively, with a high tendency of advanced local invasion and metastasis. [232]

The clinical presentations of gastric carcinoids are usually nonspecific and variable including pain, vomiting, anemia, and bleeding, or they can be discovered incidentally during endoscopy for other reasons. Presentation with the typical carcinoid syndrome of flushing, diarrhea, cutaneous edema, and bronchoconstriction is uncommon. [232], [234] This is more closely related to the secretion of histamine than to that of substance P, serotonin, or 5-hydroxyindoleacetic acid. In a review of the cases identified by the Surveillance, Epidemiology, and End Results program of the National Cancer Institute from 1973 to 1991, 52.9% of gastric carcinoids were localized, 10.3% were regionalized, and 20.6% with associated with distant metastasis. [231]

Upper gastrointestinal endoscopy is the most useful diagnostic tool, and typical lesions are small, rounded, submucosal masses that may often be yellow. [236] There is no definite histological criterion for establishing the degree of malignant potential, and the best indicator available is still the evidence of invasive growth and the presence of regional or distant metastases. [231] Because of the rarity of this disease, the best treatment remains controversial. For small type 1 gastric carcinoids, local removal such as by endoscopic polypectomy may be adequate. Surveillance endoscopy is recommend at 6-month intervals after initial removal. Antrectomy can be considered in patients with lesions larger than 1.0 cm, more than five lesions, and lesion recurrence after initial removal. [234] This operation can reduce serum gastrin levels and can thus result in regression of enterochromaffin-like cell carcinoids. [237] For type 3 gastric carcinoids, a more radical approach is necessary because of the high malignant potential and high risk of metastasis. Complete or partial gastrectomy with regional lymph node dissection is recommended. [238] Treatment with interferon-a or octreotide may be used to control symptoms associated with carcinoid syndrome, although the use of these agents may be more appropriate in patients with midgut carcinoid and pancreatic endocrine tumors. [233]

The overall 5-year survival in patients with all types is 49%. However, patients with type 3 gastric carcinoids have a significantly worse prognosis than do those with type 1 and 2 lesions. Five-year survival of patients with localized gastric carcinoid is 64.3%, whereas survival in patients with distant metastases drops to 10%. [231]

GASTRIC POLYPS

Gastric polyps are uncommon. The estimated incidence is less than 1% in autopsy or radiologic surveys. [239] However, up to 50% of gastric polyps are discovered incidentally during endoscopy for unrelated symptoms. [240] They may be solitary or multiple, and occasionally they are associated with other polyposis syndromes such as familial adenomatous polyposis, Peutz-Jeghers syndrome, Cowden syndrome, and Cronkhite-Canada syndrome. Different classification systems for gastric polyps have been proposed in the past, resulting in confusion. In essence, gastric polyps can be divided into neoplastic and nonneoplastic lesions. Neoplastic polyps are composed of adenomas similar to those present in the colon, whereas nonneoplastic polyps comprise hyperplastic, hamartomatous, inflammatory, and heterotopic types. One of the most important characteristics of gastric polyps is the potential for malignant transformation, particularly in adenomatous polyps. It is believed that the histological composition and size of the polyps may determine their malignant potential. The frequency of malignant transformation varies from 6% to 75% in the literature. [241]

In most reports that do not include fundic gland polyps, hyperplastic polyps are the most common (70% to 90%) gastric epithelial polyps. [239] Hyperplastic or

regenerative polyp frequently occurs in association with gastritis, particularly *H pylori*–associated gastritis. In general, the malignant potential of the hyperplastic polyp is minimal and has been reported to be between 1.5% and 3%. [242], [243]

Adenomatous polyps account for about 10% of gastric polyps, [244] and they are more prevalent in areas with a high incidence of gastric cancer. This type of polyp is associated with a higher risk of malignant transformation, and the risk is size dependent. [245] Coexistence of adenoma with carcinoma is not uncommon.

Fundic gland polyps are also known as fundic gland hyperplasia or glandular cysts. They are recognized as the most frequent type of gastric polyp, accounting for nearly half of all gastric polyps. [244] These lesions are composed of fundic glands lined with increasing numbers of normal-appearing parietal and chief cells. They are located exclusively in the acid-producing mucosa and thus are not found in the antrum. Notably, the polyp may regress and may have no malignant potential. Gastric polyps occurring as part of the familial adenomatous polyposis syndrome are usually fundic gland polyps.

Occasionally, misplaced gastric glands can present as a polypoid mass in the stomach. These heterotopic polyps are composed of tissue from the neighboring pancreas or duodenum. Heterotopic pancreas is frequently found in the prepyloric region and presents as a submucosal, nipplelike lesion, composed of mainly exocrine glands and ducts.

In a review by the American Society for Gastrointestinal Endoscopy, [95] all polyps causing symptoms, such as bleeding and obstruction, and those larger than 2 cm should be removed. Polyps smaller than 2 cm can be initially examined by biopsy and excised. If biopsies reveal adenomatous change, endoscopic excision should be considered. Most gastric polyps can be safely removed by snare polypectomy. Complications such as bleeding, perforation, and abdominal pain are rare. Surveillance endoscopy is recommended only in adenomatous gastric polyps 1 year after removal, to assess for any recurrence or the development of new polyps.

CHAPTER 70

Neal E. Seymour and Dana K. Andersen

SURGERY FOR PEPTIC ULCER DISEASE AND POSTGASTRECTOMY SYNDROMES

The surgical treatment of peptic ulcer is most frequently required when complications of previously unappreciated ulcers occur. The elucidation of peptic ulcer pathogenesis and development of therapies that directly address the underlying causes of gastroduodenal mucosal injury have defined the management of uncomplicated ulcers. Eradication of *Helicobacter pylori,* withdrawal of nonsteroidal antiinflammatory drugs, and the use of potent antisecretory medications have essentially removed the surgeon from what can now be viewed as a historically important role in the elective management of peptic ulcer. However, old surgical therapies for peptic ulcer may continue to pose problems in clinical management, and it remains important to understand the impact of vagotomy and other surgical alterations of the foregut. It is also vitally important to understand when surgical care can contribute to the management of patients with complicated peptic ulcers.

ELECTIVE SURGERY FOR PEPTIC ULCER DISEASE

Duodenal Ulcers

Elective operation for peptic ulcer disease is now rarely offered in developed nations. Elective surgical treatment of duodenal ulcer implies that medical treatment has been ineffective or unfeasible. True failure of appropriate medical therapy is exceedingly rare, and it should prompt investigation for other disease such as gastrinoma. Antisecretory medications (generally proton pump inhibitors) given in the event of anti- *Helicobacter* treatment failure can represent a considerable expense, depending on duration of treatment. Cost analyses of elective surgical treatment versus maintenance antisecretory therapy, taking into account the impact of eventual treatment failures (ulcer recurrence) or of long-term morbidity, are not likely to be performed, and it is difficult to make rational arguments for one versus another treatment based on these factors. Patients who are noncompliant with reasonable medical regimens or who do not have reliable access to medication may be offered surgical treatment in the hope of definitively eradicating the disease.

Gastric Ulcers

The indications cited for elective operation for duodenal ulcer apply for gastric ulcer as well. However, it falls to the clinician caring for a given patient to decide when multiple cycles of evaluation and nonsurgical treatment may be excessively difficult, expensive, and burdensome to the patient. Nonhealing of any gastric ulcer raises the possibility of gastric carcinoma and warrants consideration of surgical treatment. Multiple endoscopic biopsies of the ulcer, if results are negative, reduce but do not eliminate the possibility of gastric carcinoma. [1] The clinical behavior of the ulcer as well as the results of endoscopic biopsy should influence the timing of operation, to avoid delaying treatment of a potentially early gastric cancer.

"Giant" Ulcers

The question whether ulcer size should influence the decision to offer early operative treatment has long been a source of controversy. Data suggesting that gastric and duodenal ulcers larger than 3 cm are more likely to bleed, perforate, or prove intractable were acquired before the availability of proton pump inhibitor and anti-*Helicobacter* therapy. [2], [3] Of 62 cases of giant gastric ulcers treated in Singapore between 1984 and 1989, 31% demonstrated penetration into adjacent structures (pancreas, liver, colon). [3] Malignant disease was found after histological examination in 13% of resected specimens, although it was not clear to what extent efforts were made preoperatively to obtain this information. Unexpected malignancy has not been a problem noted in more recent reports on the outcomes of medical therapy for large ulcers. These reports indicate that ulcer size has little bearing on response to appropriately aggressive treatment, [4], [5] and [6] although surgery may be necessary for ulcer complications in as many as 16%. [6]

SURGERY FOR DUODENAL ULCER

Vagotomy in the Treatment of Duodenal Ulcer

The reduction of acid secretion by gastric denervation serves as the physiological basis of all modern surgical treatments for duodenal ulcer. Truncal vagotomy reduces basal and maximal acid output by 85% and 50%, respectively. [7] This reduction in acid secretion results from the removal of the direct acetylcholine influences on the parietal cell, as well as reduction in sensitivity of the parietal cell to gastrin and histamine. [8], [9] Although pepsin may play a role in mucosal injury in patients with duodenal ulcer, the clinical benefit of vagotomy in reducing pepsinogen secretion and gastric proteolytic activity is less clear. [10] Gastric motor function is dramatically altered by truncal vagotomy. Receptive relaxation, or decrease in muscular tone of the proximal stomach with ingestion of food, and antral peristaltic and proximal gastric nonphasic motor activity are abolished by vagotomy. [11], [12] Loss of vagus-dependent gastric motor function and regulation of pyloric resistance require that truncal vagotomy be performed in conjunction with a procedure to facilitate gastric emptying. The combined effect of vagotomy and bypass or destruction of the pylorus appears to be differential emptying of solids and liquids. Emptying of liquids is accelerated, probably secondary to increased intragastric pressure with loss of receptive relaxation, [13], [14] whereas emptying of solids is more variable. [15], [16] Vagotomy-induced acceleration of emptying of liquids may contribute to dumping syndrome after gastric drainage or resection procedures.

Gastric denervation procedures have been devised that preserve a more normal neural relationship with the remainder of the gastrointestinal tract than is possible after truncal vagotomy (Fig. 70-1). Selective vagotomy preserves the celiac and hepatic branches of the vagus but still results in gastric atony and requires a concomitant drainage procedure to facilitate gastric emptying. The advantage of this procedure over truncal vagotomy in preventing postvagotomy diarrhea is not clear. [17] Highly selective vagotomy preserves the anterior and posterior nerves of Latarjet as well as their terminal branches to the pyloroantral region, while selectively denervating the acid-producing parietal cell mass. The previously described accelerated emptying of liquids from the stomach after vagotomy is least after

highly selective vagotomy. [14] Highly selective vagotomy has become the most widely accepted antiulcer procedure in the elective setting because it avoids the morbidity associated with loss of pyloroantral function.

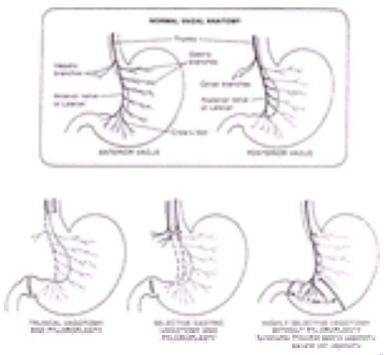

FIGURE 70-1. Normal vagal anatomy and types of vagotomy. Truncal and selective vagotomies are shown with a gastric drainage procedure (pyloroplasty). During truncal vagotomy, nerve trunks are divided above the celiac and hepatic branches. During selective vagotomy, the anterior and posterior nerves are divided *distal* to the celiac and hepatic branches, thus preserving extragastric innervation of the gastrointestinal tract and theoretically reducing the risk of gallstone formation and diarrhea. During highly selective vagotomy, individual branches of the anterior and posterior nerves of Latarjet to the body of the stomach are divided, sparing the terminal branches to the pylorus and antrum ("crow's foot"). Pyloroantral motor function is thus preserved, and gastric drainage is unnecessary. (From Debas HT, Orloff SL. Surgery for peptic ulcer disease and postgastrectomy syndromes. In: Yamada T, ed. Textbook of gastroenterology, 2nd ed. Philadelphia: JB Lippincott, 1995.)

Specific Operations

Vagotomy and Drainage If truncal or selective vagotomy is performed, the clinical effects of resulting gastric atony can be minimized by pyloroplasty, gastroduodenostomy, or gastrojejunostomy (Fig. 70-2). The Heineke-Mikulicz pyloroplasty has historically been the most widely used method of drainage. Vagotomy and drainage offer no real advantage over highly selective vagotomy in terms of recurrent ulcer risk, and they add the potential complications of diarrhea and dumping syndrome. The most common use of this procedure has been in the setting of bleeding duodenal ulcer in which a gastroduodenotomy is required to gain access to the bleeding site, and closure as a pyloroplasty is very convenient.

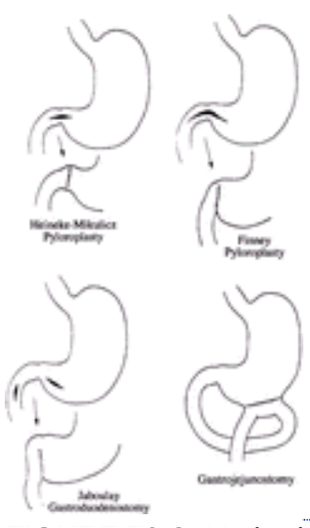

FIGURE 70-2. Methods of gastric drainage: The Heineke-Mikulicz pyloroplasty is most frequently used in cases of duodenal ulcer bleeding, because the transpyloric incision required to expose the bleeding ulcer can easily be closed in a transverse orientation. The Finney pyloroplasty and Jaboulay gastroduodenostomy were historically performed when the duodenal bulb was badly deformed by chronic ulcer scar. A gastrojejunostomy may be performed if access to the pyloroduodenal area is limited.

Highly Selective Vagotomy The ideal operation for peptic ulcer disease is one that is associated with a minimal risk of ulcer recurrence and is tolerated extremely well by patients to whom it is offered. In practice, although highly selective vagotomy is associated with better patient tolerance than other antiulcer procedures, there is considerable variability in reports pertaining to how well it achieves the goal of minimizing risk of ulcer recurrence. Parietal cell vagotomy, superselective vagotomy, and proximal gastric vagotomy are synonymous terms used to describe the procedure. Highly selective vagotomy is accomplished by dividing the terminal branches of the nerves of Latarjet to the lesser curvature of the stomach, from a point approximately 6 cm proximal to the pylorus to a point at least 5 to 6 cm proximal to the esophagogastric junction on the esophagus (Fig. 70-3). These nerves are found in the anterior and posterior peritoneal leaves of the lesser omentum (gastrohepatic ligament). The two to three terminal branches of the nerves of Latarjet ("crow's foot") to the antrum and pylorus are preserved. Great care must be taken to ensure sufficient periesophageal dissection, because high vagal branches can easily be missed.

FIGURE 70-3. Highly selective vagotomy. Selective denervation of the parietal cell mass is achieved by careful division of all proximal anterior and posterior vagal branches, distally to a point approximately 6 cm from the pylorus. All surrounding tissues are dissected from a 5- to 6-cm segment of esophagus proximally. Antropyloric innervation must be carefully preserved to prevent postoperative gastric stasis. The bare area on the lesser curvature can be closed with seromuscular sutures, but it is more typically left undisturbed.

Ulcer recurrence rates after highly selective vagotomy are variable and are thought to depend on operator skill as well as duration of follow-up. Ulcer recurrence rates between 9% and 17% have been reported at centers where the procedure has been done frequently. [18], [19], [20], [21], [22], [23], [24], [25], [26], [27], [28], [29], [30], [31], [32], [33], [34], [35], [36], [37], [38] and [39] A consistently described, time-dependent rise in the incidence of recurrent ulcer suggests that long periods of follow-up (>10 years) are required to examine the results of highly selective vagotomy reliably. [23], [25] Based on patterns of Congo red staining (a surface pH lower than 3.0 will stain black) during standard highly selective vagotomy, an "extended" highly selective vagotomy has been proposed that adds division of the right and left gastroepiploic pedicles to the other cardinal features of the operation. [26] Reports describing the use of extended highly selective vagotomy with intraoperative assessment of completeness of gastric

denervation suggest that very low rates of recurrent ulceration can be achieved by the skilled application of these procedures. [26], [27], [28] and [29] Highly selective vagotomy has been shown to result in an immediate decrease in both basal and maximal acid outputs. [20], [30] Afterward, there is a time-dependent recovery of basal and maximal acid outputs to approximately 30% and 50% of preoperative levels, respectively. [20] Patterns of acid secretion that have been associated with increased risk of ulcer recurrence after highly selective vagotomy include high preoperative or persistently elevated postoperative basal acid outputs. [31], [32] High postoperative maximal acid output has also been reported to correspond to an increase in the risk of ulcer recurrence. [33], [34] These patterns of postoperative acid secretion in patients evaluated on a long-term basis after highly selective vagotomy were correlated with untreated *H pylori* infection. [35] In addition to selected patterns of gastric acid hypersecretion, there are data indicating that the ulcer recurrence rate is higher in patients with prepyloric ulcer treated by highly selective vagotomy than in patients with ulcers of the first portion of the duodenum (Fig. 70-4). [36], [37] and [38] The role of *Helicobacter,* if any, and the potential impact of "extended" procedures in this pattern of disease are uncertain.

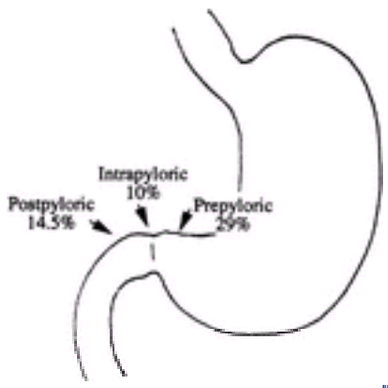

FIGURE 70-4. Ulcer recurrence rate after highly selective vagotomy according to preoperative site of ulcer. The data reported by Schafmayer and colleagues reflect 5-year follow-up of 392 patients. Prepyloric ulcer location appears to be associated with a higher risk of ulcer recurrence than duodenal or intrapyloric location. (Adapted from Schafmayer A, Börger WH, Köhler H, et al. Recurrent ulcers after proximal gastric vagotomy: special aspects of the prepyloric ulcer. Dig Surg 1989;6:4).

Even in the current era of peptic ulcer treatment, highly selective vagotomy will probably continue to play a role, albeit minor, in the management of duodenal ulcers that are *Helicobacter* negative or unresponsive to repeated cycles of antibiotic therapy. Because highly selective vagotomy is now performed so infrequently, referral of patients to tertiary care centers for this highly technical procedure is advisable. [39]

Vagotomy and Antrectomy Of the procedures historically performed for duodenal ulcer, antral resection coupled with truncal or selective vagotomy is associated with the lowest risk of ulcer recurrence (0% to 2%). [40], [41] However, the risk of postgastrectomy and postvagotomy problems associated with this procedure rendered it a less-favored option as compared with highly selective vagotomy even before the advent of anti- *Helicobacter* therapy. Removal of the gastrin-secreting tissues of the distal stomach retains a large gastric reservoir, which must be anastomosed to either the duodenum (Billroth I) or the proximal jejunum (Billroth II) (Fig. 70-5). After antrectomy for benign disease, gastroduodenostomy (Billroth I) is preferred to gastrojejunostomy, to avoid the problems associated with an afferent anastomotic jejunal limb and duodenal stump. To avoid retained antrum syndrome, it is advisable histologically to verify the presence of duodenal Brunner glands at the distal margin of resection by frozen section after antrectomy, particularly if scarring or active inflammation makes clear identification of the pylorus difficult.

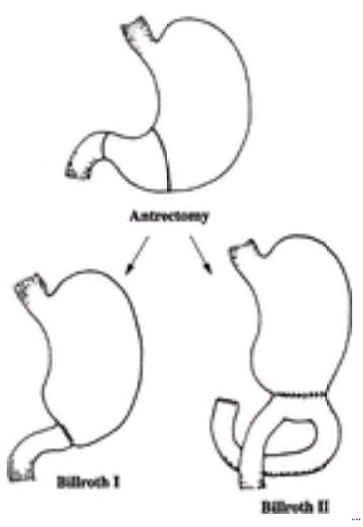

FIGURE 70-5. Reconstruction after gastrectomy: Billroth I (gastroduodenostomy) and Billroth II (loop gastrojejunostomy). Billroth I is the preferred reconstruction after gastrectomy for benign disease.

The decision to perform vagotomy and antrectomy for benign duodenal ulcer disease is an infrequent and difficult one. In the elective setting, highly selective vagotomy offers the advantage of greater patient tolerance, albeit with a higher risk of ulcer recurrence. In complex situations when *Helicobacter*-negative ulcers have failed to respond to antisecretory therapy and ulcer recurrence may be more likely after highly selective vagotomy (prepyloric ulcer or ulcers that are highly resistant to treatment with antisecretory agents), vagotomy and antrectomy may be more satisfactory operations despite their higher associated long-term morbidity.

Laparoscopic Procedures for Peptic Ulcer Disease Posterior truncal vagotomy and anterior seromyotomy, described by Taylor and colleagues, [42], [43] have been performed laparoscopically without substantially modifying the procedures [44], [45] and [46] (Fig. 70-6). Gastroparesis, dumping syndrome, and postvagotomy diarrhea are encountered no more frequently than after highly selective vagotomy, despite division of the posterior vagal trunk. The major concerns surrounding these operations relate to their unproven efficacy. No data examining extent of residual acid-secreting tissue either intraoperatively or postoperatively are available, nor has eventual gastric reinnervation after anterior seromyotomy been excluded. One report, which examined a modified stapled technique of anterior seromyotomy, described effectively reduced acid secretion and the absence of recurrent ulcer at a mean of 5 years after surgery in a small group of patients. [47] Similar results have been achieved with laparoscopic posterior truncal anterior highly selective vagotomy (Hill-Barker procedure). [48] The technical feasibility of laparoscopic highly selective vagotomy, [49], [50] and [51] as well as laparoscopic bilateral truncal vagotomy with pyloromyotomy for drainage, [52] has been reported, although the long-term results of these operations are unavailable.

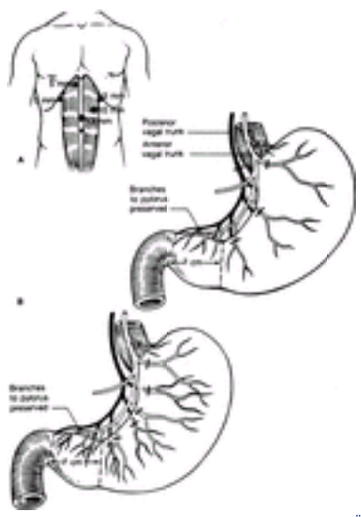

FIGURE 70-6. Laparoscopic operations for peptic ulcer. Procedures typically require five upper abdominal operative ports. Parietal cell denervation is accomplished by (**A**) anterior seromyotomy and posterior truncal vagotomy (Taylor procedure), interrupting the branches of the anterior nerve of Latarjet within the wall of the stomach, or (**B**) a more formal highly selective vagotomy, interrupting the branches of the posterior nerve of Latarjet as well. (From Debas HT, Orloff SL. Surgery for

peptic ulcer disease and postgastrectomy syndromes. In: Yamada T, ed. Textbook of gastroenterology, 2nd ed. Philadelphia: JB Lippincott, 1995.)

Laparoscopic truncal vagotomy and antrectomy have been performed at several centers worldwide, albeit in limited numbers. [53], [54], [55] and [56] These procedures are impressive technical accomplishments, and they offer the advantages conferred by laparoscopic access (decreased postoperative pain and early return to normal function). However, the long-term morbidity of such foregut alterations remains an active concern, irrespective of the method used for access to the abdomen.

SURGERY FOR GASTRIC ULCER

Like duodenal ulcers, benign gastric ulcers rarely require elective surgical management. However, the pathogenesis of gastric ulcers may be multifactorial, and nonhealing or recurrent ulceration is more frequent than after medical treatment of duodenal ulcers. Classification of gastric ulcer by location (Fig. 70-7) serves to define specific operations that could be applicable to management. [57], [58] Various surgical procedures may be used to treat benign ulcers at specific gastric sites (Fig. 70-8). Antrectomy inclusive of the ulcer is the standard operative approach for more distal (type I and II) ulcers. For more proximally situated ulcers on the lesser curvature, a narrow extension of the resection can be made to remove the ulcer en bloc with the antral specimen (Pauchet procedure). Reconstruction by Billroth I method is preferred to avoid a duodenal stump and afferent jejunal limb. Vagotomy provides no additional benefit over resection alone and is not routinely performed, except when a *Helicobacter*-negative patient has duodenal ulcers as well (type III). Local excision alone is technically feasible for small lesser curvature or gastric body ulcers, although it is associated with a high ulcer recurrence rate and has traditionally been reserved for situations in which more extensive procedures are contraindicated.

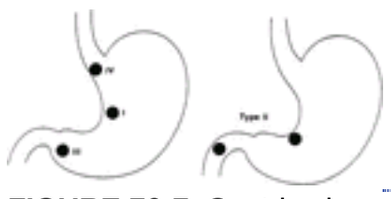

FIGURE 70-7. Gastric ulcer classification according to location. Type I describes an ulcer at the incisura angularis on the lesser curvature. A type II gastric ulcer is associated with a simultaneous duodenal ulcer. Type III describes a prepyloric ulcer, and type IV is a gastric cardia ulcer. (From Debas HT, Orloff SL. Surgery for peptic ulcer disease and postgastrectomy syndromes. In: Yamada T, ed. Textbook of gastroenterology, 2nd ed. Philadelphia: JB Lippincott, 1995.)

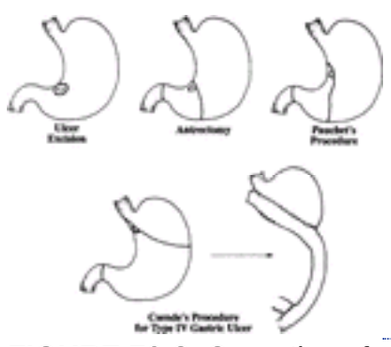

FIGURE 70-8. Operations for benign gastric ulcer.

Ulcers near the esophagogastric junction are more formidable technical challenges than distally situated ulcers. Csendes and colleagues [59] described resection of cardia ulcers (type IV) by subtotal gastrectomy that extends to the esophagogastric junction and is reconstructed with a large Roux-en-Y esophagogastrojejunostomy. These high gastric ulcers, although rare in the United States and Europe, accounted for 27% of the gastric ulcers reported by Csendes and associates in Chile.

SURGICAL TREATMENT OF PEPTIC ULCER COMPLICATIONS

Despite the availability of increasingly effective medical therapies, it has not been possible to demonstrate a clear reduction in the overall incidence of ulcer complications since the early 1980s. In contrast to the decrease in incidence of uncomplicated ulcers that preceded the availability of H_2-receptor antagonists, population-based studies suggest that the incidence of complicated ulcers did not diminish at all before 1990. [60], [61] and [62] Other data suggest that effective medication has been associated with a dramatic decrease in the incidence of such complications in children. [63] Mortality from complicated duodenal ulcers that require surgical treatment is high, particularly in elderly patients. [64] Expedient diagnosis and treatment offer the best chance of a favorable outcome, particularly in cases of massive hemorrhage or perforation. The immediate goals of surgical treatment are to control damage (e.g., suture of bleeding site, closure of perforation). Based on available data, which show a high incidence of *H pylori* infection in complicated ulcers, the role of definitive antiulcer procedures in the emergency setting has become questionable.

Hemorrhage

Life-threatening bleeding from duodenal and gastric ulcers requires prompt but carefully planned treatment, of which surgery can be an important component. Comprehensive management of upper gastrointestinal hemorrhage is beyond the scope of this chapter (see Chapter 33), but aggressive resuscitation and early identification of the bleeding source by endoscopy are the most important initial steps before direct treatment of the bleeding. Endoscopic bipolar cautery, heater probe, and chemical injection treatments have been established as expedient means of arresting hemorrhage. Avoiding operation in these often direly ill patients is thought ultimately to lessen mortality, although this benefit has been difficult to demonstrate clearly. A metaanalysis compiling data from 30 randomized trials of endoscopic therapy for nonvariceal bleeding showed a clear reduction in the need for surgery with all hemostatic methods employed. [65] However, a significant decrease in mortality was observed only for laser therapy and not for the more frequently used thermal contact methods. Despite the availability of advanced endoscopic methods, persistent or recurrent hemorrhage may occur in 20% to 33% of patients. [66] Mortality in the presence of this event may exceed 30%. [67]

Approximately 5% of patients with transfusion-requiring hemorrhage from peptic ulcers will require surgical treatment to control bleeding. [68] These patients can be separated from those not requiring surgery at decision points in a definable management algorithm (Fig. 70-9). Ongoing nonvariceal hemorrhage not amenable to endoscopic treatment requires immediate operation. The inability to control hemorrhage endoscopically may result from difficult ulcer location, high rate of bleeding, or insufficiently localizable bleeding point within the ulcer. Gastric ulcers are three times as likely to rebleed as duodenal ulcers. [69] Prompt surgical treatment after one or two unsuccessful endoscopic attempts to control bleeding is a highly definitive management strategy. High transfusion requirements have historically been associated with poor outcomes, and ongoing need for banked blood should be a general indicator of the need for surgical intervention. [68], [70] Several factors, in addition to rebleeding, have been associated with risk of mortality (Table 70-1). Immediate recognition of ongoing or recurrent hemorrhage, aggressive resuscitation, and prompt surgical management after failed endoscopic intervention are the best means of minimizing death rates from peptic ulcer bleeding.

TABLE 70-1 Factors Predicting Mortality in Bleeding Duodenal Ulcer

FIGURE 70-9. Algorithm for management of bleeding peptic ulcer. (Adapted from Seymour NE. Surgery of the stomach and duodenum. In: Feldman M, ed. Gastroenterology and hepatology: the comprehensive visual reference. Philadelphia: Current Medicine, 1996.)

When operative management is undertaken, the most urgent goals are exposure and local control of the bleeding site. For bleeding ulcers of the first portion of the duodenum, this is achieved by a longitudinal incision across the pylorus and proximal duodenum. This permits exposure of the point of erosion into the gastroduodenal artery or branch vessel in the posterior wall of the duodenal bulb. Exposure through a duodenotomy alone with preservation of the pylorus has also been described. [71] Hemorrhage is controlled by direct suture, undersewing the vessel on either side of the bleeding (Fig. 70-10). The gastroduodenotomy can be closed as a pyloroplasty, and a truncal vagotomy can be performed. Alternatively, highly selective vagotomy with longitudinal closure of the gastroduodenotomy and precise reconstruction of the pylorus have been described. [72], [73] However, it is now unclear that the addition of vagotomy confers additional benefit once local control of bleeding is obtained. Reports of higher early ulcer rebleeding rates and associated mortality rates [74], [75] without vagotomy are subject to bias and are poorly controlled for perioperative medical therapy. Eradication of *H pylori* infection has been shown to prevent ulcer rebleeding in nonsurgical situations, [76] and it has become standard postsurgical treatment in conjunction with antisecretory therapy. The role of vagotomy for ulcer bleeding in the era of anti- *Helicobacter* therapy is very much in doubt, because the likelihood of ulcer recurrence after definitive postoperative medical therapy is probably less than the likelihood of significant postvagotomy symptoms.

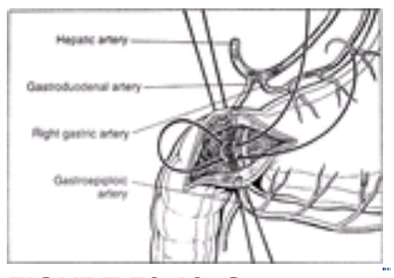

FIGURE 70-10. Suture control of bleeding posterior duodenal ulcer. Exposure is by longitudinal gastroduodenotomy. The bleeding point in the gastroduodenal artery is undersewn with nonabsorbable monofilament suture. Additional transfixing sutures along the course of the vessel above and below this point provide more secure hemostasis. (From Seymour NE. Surgery of the stomach and duodenum. In: Feldman M, ed. Gastroenterology and hepatology: the comprehensive visual reference. Philadelphia: Current Medicine, 1996.)

A bleeding gastric ulcer may be exposed by appropriate placement of a longitudinal gastrotomy, based on preoperative endoscopic data. If the gastric bleeding site was not visualized at endoscopy, both a pyloroduodenal incision and a longitudinal gastrotomy may be necessary to identify the lesion. Bleeding may be managed by antrectomy inclusive of the ulcer, ulcer excision alone, or simple oversewing of the bleeding site if the patient's condition is unstable.

Perforation

Perforation of a peptic ulcer occurs only after deep penetration of the ulcer through the full thickness of the stomach or duodenal wall to a free peritoneal surface. Perforation is generally followed by chemical peritonitis that, if untreated, can progress to bacterial peritonitis, sepsis, and death. Some perforations spontaneously seal, usually as the result of omental adhesion to the site.

Clinical suspicion of perforated duodenal ulcer may be prompted by abdominal pain, which is often very acute in onset. The differential diagnosis includes biliary tract disease and pancreatitis, although many other catastrophic abdominal problems can mimic a perforated ulcer, including acute appendicitis. The diagnosis of perforated gastric or duodenal ulcer must be considered in any patient with peritonitis of uncertain origin. Pneumoperitoneum may be observed on upright chest or left lateral decubitus radiographs in up to one half of patients.

Immediate abdominal exploration and repair of the perforation comprise the standard management, although this approach is probably not mandatory in all patients (Fig. 70-11). Factors predictive of mortality after ulcer perforation include major medical illness, preoperative shock, and duration of perforation for longer than 24 hours. [77] In a prospective evaluation of these risk factors in 259 patients with perforated ulcers, Boey and colleagues [77] reported a mortality rate of 100% in patients with all three risk factors. Other identified risk factors for mortality include advanced age, pulmonary disease, a perforation of more than 24 hours' duration, and glucocorticoid use. [78] An evaluation of patients treated by laparoscopic methods defined the APACHE II score as an important predictor of morbidity and mortality in perforated ulcer. [79]

FIGURE 70-11. Algorithm for management of perforated peptic ulcer. (Adapted from Seymour NE. Surgery of the stomach and duodenum. In: Feldman M, ed. Gastroenterology and hepatology: the comprehensive visual reference. Philadelphia: Current Medicine, 1996.)

Nonoperative management of perforated ulcer may be attempted in selected patients who present without diffuse peritonitis or sepsis. This requires demonstration of a contained perforation by water-soluble contrast study and should be attempted only in conjunction with nasogastric drainage and antibiotics. [80], [81] Reports advocating this approach indicate that abdominal exploration can be avoided in up to 70% of these highly selected patients. Increased mortality when necessary operative treatment is delayed by unsuccessful nonoperative management in patients who are more than 70 years old suggests that even careful observation may not be safe in this group. [82]

A perforated duodenal ulcer is repaired by applying a pedicle of greater omentum directly to the site of perforation and securing it there with absorbable sutures (Fig. 70-12). Direct suture closure of the inflamed edges of the perforation is at high risk of failure and is unnecessary if the omental patch is applied correctly. Although gastric ulcer perforations may also be repaired by omental patch, gastric resection inclusive of the ulcer is preferred, to lessen the risk of recurrent ulcer, provided the patient's clinical condition permits the more extensive procedure. Although highly selective vagotomy has been recommended in the setting of perforated duodenal ulcer, [83], [84] the addition of any antiulcer procedure to local closure is of questionable value. Current data indicate that more than 80% of duodenal ulcer perforations occur in the setting of *H pylori* infection, and postoperative treatment results in an expected low ulcer recurrence rate. [85]

FIGURE 70-12. Omental patch of perforated duodenal ulcer. If no omentum is available, falciform ligament may be similarly used to patch the perforation.

Numerous reports indicate that peritoneal toilet and omental patch closure of peptic ulcer perforation can be effectively performed by laparoscopic method. [86], [87] and [88] The essential features of this procedure are the same as would be accomplished by open technique. Reported results of uncontrolled trials are excellent, [86], [87] with rapid recovery times and extremely low mortality rates. In a randomized, prospective evaluation of open versus laparoscopic management, although analgesic use in the laparoscopic group was less, there were no significant differences noted in duration of hospital stay, time to resume diet, and duration of nasogastric decompression. [89]

Obstruction

Gastric outlet obstruction is the peptic ulcer complication encountered least frequently by the surgeon. Obstruction generally results from a combination of chronic scarring, acute edema, and spasm in the pyloroduodenal area. Patients may present with significant weight loss and complaints of early satiety, bloating, nausea, and vomiting. If vomiting is significant, hypovolemia, alkalosis, and hypokalemia may be present. Early upper endoscopy is mandatory to rule out carcinoma and is generally reliable. After a 1-week course of total parenteral nutrition, nasogastric decompression, and antisecretory therapy, in the absence of improvement, surgical treatment should be undertaken. If Heineke-Mikulicz pyloroplasty is unfeasible because of pyloroduodenal deformation, then Finney pyloroplasty, Jaboulay gastroduodenostomy, or simple gastrojejunostomy may be performed. There are few data defining the role of *H pylori* in gastric outlet obstruction, and truncal vagotomy has typically be performed in conjunction with these decompressive procedure. Because of concerns regarding denervation of an enlarged, paretic stomach, highly selective vagotomy has been used in the management of pyloroduodenal obstruction, in combination with pyloric dilation, [90], [91] and [92] or with surgical decompression. [93], [94] and [95] Although the necessary bypass or destruction of the pyloric mechanism in this setting may seem to negate the advantages of highly selective vagotomy, dumping syndrome appears to occur less frequently than after similar drainage procedures performed in conjunction with truncal vagotomy. [95] A prospective comparison of procedures performed for gastric outlet obstruction suggested that highly selective vagotomy with gastrojejunostomy yields nutritional results superior to those with selective vagotomy with either antrectomy or pyloroplasty. [96]

COMPLICATIONS OF SURGERY FOR PEPTIC ULCER

Early Complications

The potential complications after gastric surgery are numerous (Fig. 70-13.). Bleeding, infection, and thromboembolism are potential complications after any abdominal procedure. Acute afferent limb obstruction with potential duodenal stump leak after Billroth II reconstructions remains a feared complication. A retrospective analysis of Billroth II resections for duodenal ulcer in 545 patients revealed a 7% incidence of major complications and a 1.5% mortality rate. [97] Multivariate analysis identified cirrhosis, leukocytosis greater than 10,000 white blood cells/mm [3], previous abdominal surgery, and ulcer involvement of contiguous structures as significant risk factors for complications and death.

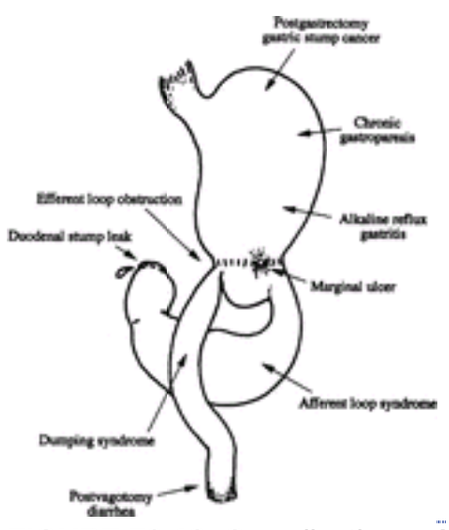

FIGURE 70-13. Complications of operations for peptic ulcer.

Recurrent Ulcer

Ulcer recurrence rates after operations for chronic peptic ulcer vary according to the nature of the procedure performed (Table 70-2). Although in the past, recurrent ulcer was attributed to a variety of factors, it now appears that *H pylori* infection accounts for most postoperative recurrent ulcers. [98], [99], [100] and [101] However, other specific issues associated with recurrent ulcer must be considered when examining specific cases. For example, Billroth II gastrojejunostomy (but not Billroth I or pyloroplasty) may result in retained antral mucosa in the closed duodenal stump that can be a source of hypergastrinemia. Recurrent ulcer after previous truncal vagotomy raises the possibility that the vagotomy may have been incomplete. Completeness of previous vagotomy can be determined by quantification of gastric acid with sham feeding. [102] Unsuspected gastrinoma must be considered in any patient with recurrent ulcer after what is believed to be an "adequate" operation, although

this situation is exceedingly rare.

OPERATION	RECURRENCE RATE (%)	REMARKS
Gastric resection	2–5	Varies according to amount resected; 75% optimal
Vagotomy and drainage	10–15	Pyloroplasty most frequent drainage procedure
Vagotomy and antrectomy	0–2	Lowest recurrence rates
Parietal cell vagotomy	10–17	Operator-dependent results

Adapted from ref. 103.

TABLE 70-2 Ulcer Recurrence Rates After Surgical Procedures

It is now standard therapy to treat *H pylori* infection in any patient with recurrent ulcer. In patients found on study to be infected in the absence of ulcer recurrence, specific treatment guidelines are more difficult to define. In *H pylori*–negative patients, effective antisecretory therapy is generally used on a maintenance basis to treat recurrent ulcers, to avoid further surgical treatment. Surgery for postoperative recurrent ulcers is a significant challenge not only because of the technical difficulties associated with reoperative upper abdominal surgery but also because a procedure more radical than the first is usually required to address the patient's disease. [103] For example, in a patient is known to have had an incomplete truncal vagotomy, repeat vagotomy is an appropriate option, as is antrectomy in a patient with recurrent ulcer after pyloroplasty.

Long-Term Complications of Surgery for Peptic Ulcer

Surgical alterations of gastric innervation, pyloric architecture, and gastric capacity may have profound effects on nutrition and quality of life. Even though elective operations for peptic ulcer are performed far less frequently than in the past, patients with chronic postoperative problems may continue to be encountered in clinical practice. Nutritional disturbances were well described and commonly encountered after extensive gastrectomy, but they occur rarely now that this procedure has been abandoned in the treatment of benign ulcer disease. Patients who continue to be seen after having had subtotal (three fourths) gastrectomy in the remote past may have disorders of calcium homeostasis or significant anemia secondary to iron and, less frequently, vitamin B_{12} deficiency, and they require appropriate nutritional supplementation. Extensive gastrectomy can also be associated with symptoms of a small gastric reservoir. Patients typically complain of early satiety and a sensation of epigastric postprandial discomfort that can be prevented by eating small, frequent meals. Although quality-of-life alterations may be significant, partial gastrectomy for benign ulcer disease does not appear to impart an increased risk of mortality beyond 1 year after the surgical procedure. [104]

Dumping Syndrome

Early dumping syndrome is thought to result from unregulated egress of gastric contents into the small intestine after gastroenteric anastomosis or pyloroplasty. It consists of vasomotor and gastrointestinal symptoms such as dizziness, flushing, and nausea, which typically occur 15 to 30 minutes after eating (Table 70-3). The precise pathophysiology of dumping is unclear, but current data suggest that rapid fluid shifts from the intravascular space to the gut lumen, [105] and [106] and release of vasoactive substances such as vasoactive intestinal polypeptide, neurotensin, and possibly motilin [107], [108] and [109] may be underlying causes. Symptoms are most marked after ingestion of high-carbohydrate, high-osmolarity substances and may be worsened if large volumes of liquids are also consumed. Up to 50% of patients will experience some degree of dumping symptoms after vagotomy and drainage. These symptoms are mostly mild and respond to minor dietary alterations such as avoidance of high-sugar foods and excessive fluid intake with meals. Most dumping symptoms improve with time, but severe dumping for extended periods can occur in 1% of cases. Octreotide acetate is generally effective in treating severe dumping symptoms that have not responded to appropriate dietary alterations. [110], [111]

VASOMOTOR	GASTROINTESTINAL
Tachycardia	Nausea
Palpitations	Vomiting
Sweating	Crampy abdominal pain
Flushing	Diarrhea
Dizziness	Belching
Syncope	

TABLE 70-3 Clinical Features of Early Dumping Syndrome

"Late" dumping syndrome consists of symptoms similar to those already described, but they occur 2 to 4 hours after eating. These are probably related to rapid delivery of sugars to the small intestine and an excessive serum insulin response to the resulting rapid rise in blood sugar. As in early dumping, dietary modification is generally effective in preventing late dumping symptoms. The addition of pectin and acarbose to the diet to delay carbohydrate absorption in the small bowel has been advocated for patients with continued symptoms after appropriate dietary changes. [112] Octreotide acetate is recommended in cases that are otherwise refractory to treatment.

Patients who which fail to respond significantly to the medical treatments described are extremely rare. Reversed jejunal segment Roux-en-Y gastrojejunostomy has been reported to achieve relief of dumping symptoms in 65% of the most severe cases. [113] However, most results of remedial operations for dumping predate the use of octreotide, and the role of these procedures is uncertain, given the demonstrated effectiveness of this agent.

Postvagotomy Diarrhea

Chronic diarrhea is a potential complication of truncal vagotomy and, to a far lesser extent, of selective and highly selective vagotomy. Although this clinical problem has been attributed to changes in intestinal motility after division of the posterior trunk proximal to the celiac branch, its actual pathogenesis is uncertain. Among the possible factors that may influence bowel habit changes after vagotomy are diminished intestinal transit time, decreased absorption, increased excretion of bile acids, and release of humoral factors that may stimulate episodic secretory diarrhea. Although clinically severe diarrhea is held to be a rare occurrence, the actual incidence of significant change in bowel habit after vagotomy is unclear, and reported rates range between 5% and 40%. [114], [115] Patients usually describe waxing and waning symptoms, although less frequently unrelenting diarrhea may occur. Kaolin-pectin may be helpful for very mild cases, but more typically loperamide or diphenoxylate/atropine are required for adequate relief.

Alkaline Reflux Gastritis

Excessive jejunogastric or duodenogastric reflux after gastric resection or drainage procedure for peptic ulcer has been associated with a syndrome of chronic abdominal pain and, less frequently, bilious vomiting. Although it is uncertain which components of the refluxate mediate gastric injury, bile acids were previously held to be likely candidates. An infrequently performed alkaline Bernstein test [116] has been described to assist in the diagnosis. Work characterizing histological change in the stomach after gastrectomy produced an association between *H pylori* and some of the changes that have generally been attributed to alkaline reflux. [117] However, at present it is uncertain whether *H pylori* plays a causative role in this clinical problem. The treatment of alkaline reflux symptoms can be quite difficult. Bile acid binding resins and sucralfate are not generally successful, [118], [119] and the most severe cases may require operative treatment to separate the gastric mucosa from pancreatobiliary secretions. This is accomplished by constructing a Roux-en-Y gastrojejunostomy with the Roux limb at least 45 to 60 cm in length to minimize the chances of ongoing reflux of alkaline small bowel contents into the stomach. [120] Although this approach is highly effective in controlling reflux, long-term follow-up suggests that alkaline reflux-like symptoms may continue to be reported by up to one half of patients. [121], [122] These clinical problems are seen less frequently as the number of operations for peptic ulcer has waned and the population of patients with prior surgical procedures for peptic ulcer grows older.

Delayed Gastric Emptying

Although symptoms of early satiety, nausea, and bloating are frequently reported in the early postoperative period after gastric surgery, chronic gastroparesis is an unusual occurrence. It most frequently observed after truncal vagotomy, but it may complicate any operation for peptic ulcer. Its incidence is smallest after highly selective vagotomy, which preserves antral motility. Risk factors for postoperative gastroparesis symptoms include diabetes mellitus and gastric outlet obstruction. [123] Treatment with metoclopramide or erythromycin can alleviate the symptoms of chronic postoperative gastroparesis. On the rare occasion when gastroparesis follows highly selective vagotomy, a drainage procedure may be necessary to facilitate gastric emptying. Although an extremely rare circumstance, some patients may require total gastrectomy to relieve unremitting symptoms. [124]

Gastric Cancer

Gastric adenocarcinoma in the proximal gastric stump after distal gastrectomy is a long-delayed event of uncertain pathogenesis. Hypochlorhydria, alkaline reflux, diminished gastrin production, uneradicated *H pylori* infection, and nitrosation have been suggested as possible causative factors. [125], [126] and [127] Gastric cancers diagnosed within 5 years of an initial gastrectomy are not generally regarded as true gastric remnant cancers, [128] although this is a somewhat arbitrary determination. Risk appears to be time dependent, reaching a four- to fivefold increase over the age- and gender-matched general population at 20 to 25 years after gastrectomy. [125] The precise incidence of gastric stump cancer is uncertain, and rates of 1% to 4% have been reported. [129], [130], [131] and [132] In a group of 285 patients operated on for benign ulcer disease in Finland between 1948 and 1954 and followed over 30 years, 2.1% developed cancer in the gastric remnant. [129], [130] Given this significant cancer risk, aggressive endoscopic screening has been recommended as a means of early detection. In 153 patients in the United States examined, including by biopsy, at least yearly over a 14-year period of surveillance, 8.4% developed severe dysplasia, and 54% of these were eventually proven to have adenocarcinoma. [132] All patients with cancer underwent total gastrectomy and were found to have limited disease. All had survived until the time of the report. Although it is a commonly held belief that gastric remnant cancers present at a more advanced stage and have a worse prognosis than gastric cancers as a whole, a comparison of stage of disease and survival for gastric remnant cancers and for proximal cancers of the previously unoperated stomach failed to show such a difference. [131] Surgical treatment for gastric remnant cancer usually requires completion of the gastrectomy or an esophagogastrectomy.

CHAPTER 71

John C. Rabine and Timothy T. Nostrant

MISCELLANEOUS DISEASES OF THE STOMACH*

HIATAL HERNIAS

Under normal circumstances, the stomach is held in position by the gastrophrenic, gastrohepatic, gastroduodenal, and gastrosplenic ligaments. Furthermore, the phrenoesophageal membrane helps to prevent herniation through the diaphragmatic hiatus. This membrane attaches near the squamocolumnar junction and extends approximately 1 cm above this structure. During swallowing and longitudinal esophageal muscle contraction, there is “physiological” herniation of the gastric cardia through the diaphragmatic hiatus. The phrenoesophageal membrane has a recoil action to pull the squamocolumnar junction back into its normal anatomic position. When these mechanisms are defective, true herniation can develop.

Type I Hernias

The most common type of *hernia* is the *sliding, or type I, hernia,* with a prevalence of 10% to 80% depending on age (see Chapter 60). Predisposing factors include a widened hiatal tunnel and laxity of the phrenoesophageal membrane, resulting in passage of the gastric cardia into the posterior mediastinum. This herniation is often transient and asymptomatic, but larger hernias (typically defined as greater than 3 cm in length) are often nonreducing and predispose to gastroesophageal reflux.

The sliding hernia is an acquired condition, with a peak prevalence in the fifth decade of life. [1] Factors such as pregnancy, obesity, deep inspiration, vomiting, coughing, and the Valsalva maneuver that cause a positive peritoneopleural pressure gradient predispose to this type of hernia. Long-standing gastroesophageal reflux may also result in a hiatal hernia because of esophageal shortening from acid-induced tonic longitudinal muscle contraction. Age-related degeneration of the phrenoesophageal membrane likely increases vulnerability toward herniation as well. Endoscopically, a sliding hiatal hernia results in cephalad displacement of the squamocolumnar junction above the diaphragm and widening of the angle of His. [2] The cardia, identified by gastric folds, is seen extending above the diaphragmatic impression. In gastric retroflexion, one can see this herniation through the diaphragmatic hiatus because the lower esophageal sphincter has been displaced (Fig. 71-1; see Color Fig. 71-1A). As a result of disruption of the antireflux barrier (which is composed of the diaphragmatic crura, the phrenoesophageal membrane, and the lower esophageal sphincter in anatomic unity), the distal esophagus can also be clearly visualized while in gastric retroflexion.

FIGURE 71-1. (See Color Fig. 71-1.) (**A**) Endoscopic view of a type I hiatal hernia while in gastric retroflexion. (**B**) Appearance of a large hiatal hernia on a barium examination. (From Eisenberg RL. Diaphragmatic hernias. In: Gastrointestinal radiology: a pattern approach, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2003.)

Normally, the squamocolumnar junction is located 0.5 cm below the diaphragmatic hiatus, and the gastroesophageal junction high-pressure zone extends about 1 cm distal to this. [3] With a hiatal hernia, two high-pressure zones can be found manometrically as a result of disruption of the antireflux barrier, one corresponding to the lower esophageal sphincter and one corresponding to the diaphragmatic hiatus. The distal high-pressure zone (at the level of the diaphragm) is augmented by inspiration and abdominal compression. With regard to gastroesophageal reflux, patients with large hernias that are longer than 3 cm have weaker and shorter lower esophageal sphincters than do patients with smaller or no hernias; distal esophageal peristalsis and acid clearance are less effective as well. [4] Although esophagitis is more common in patients with a hiatal hernia of any size, it is often more severe in patients with large hernias. Not surprisingly, given the correlation between gastroesophageal reflux disease and Barrett esophagus, hiatal hernias are also associated with Barrett esophagus. [5] Gastroesophageal reflux disease and Barrett esophagus and their association with hiatal or gastric herniation are discussed in greater detail in Chapter 50 and Chapter 60.

Type II to IV Hernias

Approximately 5% of hiatal hernias are *types II to IV, the paraesophageal hernias.* [6] Unlike type I hernias, these hernias are associated with fundic herniation into the thoracic cavity (i.e., alongside the gastroesophageal junction), whereas the gastroesophageal junction may or may not be displaced as well. Although relatively uncommon, these hernias are associated with severe complications such as gastric volvulus and strangulation. These hernias frequently develop after surgical procedures in the region of the hiatus, such as fundoplication and splenectomy. In an era when laparoscopic Nissen fundoplications are becoming more prevalent, it is important to realize that postoperative paraesophageal hernias develop in 1% to 6% of cases. [7], [8], [9] and [10]

In type II hernias, there is a localized phrenoesophageal membrane defect allowing the gastric fundus to become the lead point of a herniation. The gastroesophageal junction is still in proper anatomic attachment to preaortic fascia and the phrenoesophageal membrane (Fig. 71-2 and Fig. 71-3; see also Color Fig. 71-2). As more fundus herniates into the thoracic cavity, in part because of gastrocolic and gastrosplenic ligament laxity, gastric rotation can develop along the longitudinal axis of the stomach. This organoaxial volvulus (see section “ Gastric Volvulus”) results in the greater curve lying anterior to the lesser curve. Type II hernias can also result in a mesenteroaxial volvulus in which rotation is along the transverse axis, but this is much less common. Type III hernias are a combination of types I and II; the fundus herniates through the hiatus, but stretching of the phrenoesophageal membrane results in displacement of the gastroesophageal junction above the diaphragm as well (Fig. 71-4). Type IV hernias are rare and require a massive hiatal defect that results in herniation of abdominal organs (colon, small bowel, spleen, and pancreas) into the thoracic cavity.

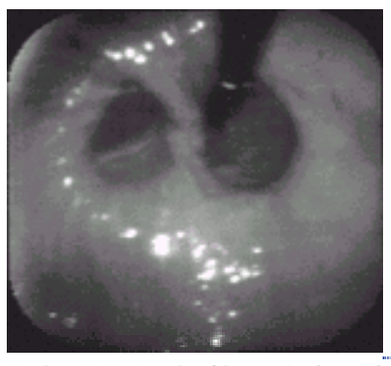

FIGURE 71-2. (See Color Fig. 71-2.) Endoscopic view of a paraesophageal hernia while in gastric retroflexion. The fundus is herniating into the thoracic cavity alongside a concomitant type I hernia.

FIGURE 71-3. Radiographic view of a type II paraesophageal hernia. The *arrow* denotes the gastroesophageal junction, which remains below the diaphragm. There is an associated gastric volvulus with a portion of the stomach within the hernia sac. (From Eisenberg RL. Diaphragmatic hernias. In: Gastrointestinal radiology: a pattern approach, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2003.)

FIGURE 71-4. A type III, or mixed, paraesophageal hernia in which the gastroesophageal junction is markedly elevated because of gastric herniation. The leading gastric edge has also herniated through the phrenoesophageal membrane and hence is the paraesophageal component of the hernia. (From ref. [11].)

Common symptoms of the paraesophageal hernias include epigastric and substernal pain, postprandial fullness, nausea, pyrosis, dysphagia, and nonproductive retching. [11] Acute bleeding from gastritis or ulceration is rare, but up to one third of these patients may have iron deficiency anemia resulting from erosions (Cameron ulcers) or venous dilation and engorgement from hiatal constriction and ischemia. [12], [13] Similar to type I hernias, these hernias are also associated with a hypotensive lower esophageal sphincter, shortened intra-abdominal lower esophageal sphincter length, distal esophageal dysmotility, and impaired acid clearance. [14], [15] Because of the vague nature of many complaints, the true prevalence of paraesophageal hernias is unclear. Nonetheless, up to 20% of such patients may present with acute gastric strangulation or perforation, with associated mortality rates of 50%. [16], [17]

As a general rule, surgical repair of paraesophageal hernias is indicated only in patients with symptoms. [14], [18] Perhaps one exception to this rule is the immediate repair of paraesophageal hernias that develop after routine fundoplication. Many authors recommend obtaining routine barium esophagrams in the first week after fundoplication to rule out the development of a hernia that is more easily repaired in the immediate postoperative period, even in asymptomatic patients. [8], [10] This approach is not unreasonable because these patients are considered to have a failed surgical procedure with persistent gastroesophageal junction derangements and a high likelihood of recurrent reflux symptoms at some point. The risks associated with paraesophageal hernia repair include bleeding, pneumothorax, vagal injury, early satiety and bloating, diarrhea, and nausea. Up to 20% of patients will have dysphagia initially, and 6% will have chronic dysphagia. [14], [19] In addition to hernia reduction and repair of the diaphragmatic defect, fundoplication is routinely performed, given the gastroesophageal junction abnormalities associated with paraesophageal hernias. Swanstrom and colleagues [19] followed-up 52 patients after surgery for paraesophageal hernias, most of whom had Nissen fundoplications rather than Toupet or Collis-Nissen procedures. Preoperatively, 59% of these patients had pyrosis, 50% had dysphagia, and 26% had esophageal body dysmotility. Postoperatively, pyrosis was reduced to 10%, dysphagia to 6%, and esophageal dysmotility to 13% after a mean follow-up of 18 months. In addition, more than 60% of patients had improved lower esophageal sphincter pressure after surgery, but 8% developed recurrent herniation. Laparoscopic surgery is feasible in most patients; conversion to an open procedure is necessary about 5% of the time. [20] Although there are no prospective trials with long-term efficacy data that compare open with laparoscopic repair of paraesophageal hernias, one study showed that the laparoscopic approach is associated with decreased operative blood loss, decreased rates of ileus, and decreased intensive care and total hospital stays. [21]

GASTRIC VOLVULUS

A *volvulus of the stomach* occurs when one portion of the stomach twists around another. If the twist occurs around an imaginary line between the pylorus and the gastroesophageal junction, it is an *organoaxial volvulus* (Fig. 71-5). Typically, the greater curve spins upward such that the stomach appears “upside-down,” with the true posterior wall lying anteriorly. The antrum rotates anteriorly and superiorly, whereas the fundus is displaced posteriorly and inferiorly. Alternatively, a *mesenteroaxial volvulus* develops when the distal stomach twists around an imaginary line between the center of the greater curve and the porta hepatis (Fig. 71-6). The antrum and the distal body twist to the right (anteriorly and superiorly) such that the posterior wall again becomes anterior in placement; occasionally, the antrum

rotates posteriorly in a mesenteroaxial volvulus, though this is rare. Approximately 60% of cases are organoaxial, 30% are mesenteroaxial, and the remainder are either mixed or unclassified. [22] There is no clear prognostic value in defining the type of volvulus, although defining the degree of the volvulus is important. [23] A volvulus may be partial, with no symptoms and spontaneous resolution, but a complete volvulus can result in vascular compromise, ischemia, and gastric infarction.

FIGURE 71-5. (**A**) Schematic representation of an organoaxial volvulus. (**B**) Large organoaxial volvulus with much of the stomach trapped within a hiatal hernia. (*A,* From Sandler RS, Todisco A. Miscellaneous diseases of the stomach. In: Yamada T, ed. Textbook of gastroenterology, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 1999; *B,* from Eisenberg RL. Diaphragmatic hernias. In: Gastrointestinal radiology: a pattern approach, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2003.)

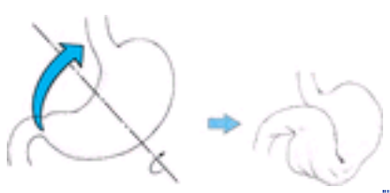

FIGURE 71-6. Schematic representation of a mesenteroaxial volvulus. (From Sandler RS, Todisco A. Miscellaneous diseases of the stomach. In: Yamada T, ed. Textbook of gastroenterology, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 1999.)

The peak incidence of gastric volvulus is in the fifth decade, with no clear gender predomination, but 20% of cases may occur in children, usually in the first year of life. [22], [24] Predisposing factors include paraesophageal hernias, abnormal ligament fixation (of the gastrophrenic, gastrohepatic, gastrosplenic, gastroduodenal, and gastrocolic ligaments), prior trauma, and phrenic nerve injury. [23], [25], [26] Abdominal surgery is another risk factor, in large part because of adhesions, but specific procedures such as Nissen fundoplications and gastrostomies are also frequently associated with gastric volvulus. [27], [28] and [29] In children, ligamentous laxity, splenic mobility, congenital diaphragmatic defects, and hiatal hernias are predisposing factors. [24]

Acute Gastric Volvulus

The acute presentation of gastric volvulus includes substernal or epigastric pain that frequently radiates to the neck and arms and may be confused with a myocardial infarction. Patients may have minimally productive emesis or dry heaves. Hematemesis is rare but suggests mucosal ischemia or tears. The upper abdomen may become tense and distended, whereas the lower abdomen is soft. Tympany is not uncommon, and abdominal tenderness may not be very impressive. Organoaxial rotations are much more likely than mesenteroaxial rotations to cause an acute volvulus. If the volvulus is complete, it may not be possible to place a nasogastric tube. An acute and complete volvulus may be accompanied by the Borchardt triad: abdominal pain, violent retching, and the inability to place a nasogastric tube. [30] In organoaxial volvulus, vascular compromise and gastric infarction occurs in 5% to 25% of cases, and there is a 15% to 20% overall mortality rate with acute volvulus. [27] In cases of intrathoracic volvulus resulting from a hiatal hernia, mortality rates from emergency surgery are 40% but approach 60% if there is gastric strangulation. [25], [31]

The diagnosis is suggested by the presence of a large, gas-filled viscus in the chest or upper abdomen on routine radiography with the appropriate clinical symptoms. Plain films, however, may be difficult to interpret in a patient with an organoaxial volvulus because the stomach still lies in a horizontal position with a single air-fluid level. A nasogastric tube should be placed if possible, although this is unlikely to untwist the volvulus. Although surgery is still considered standard therapy, some have proposed endoscopic reduction as a temporary maneuver in patients in whom vascular compromise is not suspected. There are case reports of volvulus reduction in which the endoscope tip is placed just beyond the torsion, the dials are locked, and the scope is rotated 180° to untwist the volvulus. [32], [33] and [34] Eventually, if not on an emergency basis, surgery should be pursued to untwist and repair the volvulus with either anterior gastropexy (in which the greater curve is fixed to the anterior abdominal wall) or tube gastrostomy. A subtotal or even complete gastrectomy may be necessary in cases of necrosis. Anatomic defects that may have predisposed to the volvulus may be repaired at the same time. Laparoscopic surgery may be a viable option in many patients, although this approach may be a better option in patients with chronic volvulus. [35], [36] Given the risk of ischemic strangulation, perforation, and death with acute volvulus, immediate surgical intervention should probably remain the initial treatment of choice, especially because endoscopic reduction does not prevent volvulus recurrence. [22]

Chronic Gastric Volvulus

Unlike acute volvulus, chronic volvulus is far more likely to involve a mesenteroaxial rotation. Because this volvulus is usually incomplete and intermittent, patients are more likely to present with chronic and vague symptoms. Abdominal discomfort, dysphagia, pyrosis, fullness, bloating, and postprandial borborygmi are the primary symptoms of chronic volvulus. Such symptoms are usually worsened after a large meal, and patients may report that changes in body position or self-induced vomiting help to alleviate the symptoms. [23] The diagnosis is often made incidentally on a chest radiograph or barium study. In a mesenteroaxial volvulus, plain films demonstrate a spherical stomach with two air-fluid levels in the upright position; the upper level reflects the antrum, whereas the lower level reflects the fundus. The mortality associated with chronic gastric volvulus is only 0% to 13%. [23], [37] Although surgery is again considered the mainstay of treatment for chronic and relapsing volvulus, the endoscopic reduction of chronic gastric volvulus and the placement of percutaneous gastrostomy tubes (in the body and antrum) have been reported in patients who are poor surgical candidates. [32], [33] and [34], [38], [39] The need to pursue surgical or endoscopic procedures is unclear in patients with an asymptomatic volvulus or in those with only mild symptoms attributable to the volvulus. In such cases, the risks of surgery or endoscopy must be weighed against the risk of an untreated volvulus.

GASTRIC RUPTURE

Nontraumatic tears of the gastric wall are relatively rare, but the true incidence is not well defined. In one autopsy study, 0.12% of more than 5100 patients were found to have a spontaneous *gastric rupture.* [40] The age group is generally the fourth decade of life, and women are more commonly affected. [41] Gastric ruptures may be as large as 15 cm, and the affected muscle may demonstrate edema and hemorrhage without an inflammatory infiltrate. [42] Initially, there is a mucosal tear, followed by dissection of the deeper muscle layers and serosa.

Numerous conditions may result in gastric rupture. Intragastric pressure and overdistention may play a role in many ruptures, especially if there are pyloric or

gastroesophageal junction obstructions to prevent gastric decompression. Normally, the gastric musculature will relax in response to distention, and it has been suggested that rupture does not occur from distention until the intragastric volume is about 4 L. [42], [43] Mechanical outlet obstruction, preventing decompression at either the gastroesophageal junction or the pylorus, may develop from tumors of the esophagus, pancreas, distal stomach, or duodenum, from complicated peptic ulcer disease, from congenital duodenal obstruction, or from fundoplication. [44], [45] and [46] There can also be functional obstruction at either gastric orifice. For example, increased intragastric pressure will normally result in a tightened lower esophageal sphincter, as well as an accentuated angulation of the esophagus against the right diaphragmatic crus, both helping to prevent gastroesophageal reflux and gastric decompression. [41], [45], [47] Similarly, a distended stomach may cause angulation and obstruction at the pylorus. [48] Other causes of gastric distention and rupture include gastric lavage in the setting of balloon tamponade for bleeding varices, mouth-to-mouth resuscitation with external cardiac compressions, aerophagia, oxygen administration from nasal cannulation, gastric insufflation during general anesthesia, and fermentation of retained gastric food with associated gas production. [45], [49], [50], [51], [52] and [53] Rapid decompression in diving accidents has also resulted in profound gastric distention and rupture. [54], [55] and [56] Finally, excessive use of sodium bicarbonate for indigestion in the setting of existing overdistention has been reported to cause rupture, although large volumes of sodium bicarbonate would be necessary to cause significant carbon dioxide gas production. [43], [57], [58]

Trauma and vomiting can also result in gastric rupture. Surprisingly, gastric rupture from blunt abdominal trauma occurs in fewer than 2% of trauma cases, in part because the stomach is somewhat protected by the ribs and liver. [59] Examples of trauma-induced ruptures include coughing, grand mal seizures, exertion during heavy lifting, the Heimlich maneuver, and motor vehicle accidents with seat-belt compression of the stomach on the vertebrae. [50], [60], [61], [62], [63], [64], [65] and [66] Endoscopic procedures, especially those involving cautery or laser therapies, can result in traumatic rupture. Violent vomiting that results in a gastric tear may be seen in peripartum and postpartum emesis, in retching from pyloric stenosis, and in vomiting induced by ipecac. [67], [68] and [69]

In cases of gastric distention, 60% of ruptures occur along the lesser curve near the cardia or at the fundus. [42] It is much less common for such ruptures to occur along the greater curve, on the anterior or posterior walls, or near the pylorus. Conversely, ruptures induced by vomiting typically occur on the greater curve and fundus because violent emesis results in herniation of the stomach into the chest. [70] Symptom onset is immediate, and patients frequently report a history of recent overeating and emesis. [42] Severe pain, abdominal distention, and dyspnea are typical. Shock may develop from peritonitis, blood loss, and tension pneumoperitoneum (causing inferior vena cava compression with reduced blood return to the heart and hypotension). [48] Subcutaneous emphysema, in which abdominal free air traverses the retroperitoneum and mediastinum to the neck, has also been reported. [47] These symptoms and findings can mimic other intra-abdominal catastrophes such as ulcer perforation, pancreatitis, appendicitis, neoplastic perforation, and splenic rupture. Plain radiographs typically demonstrate the pneumoperitoneum. Other imaging modalities are of questionable benefit because the clinical situation typically necessitates immediate surgical attention.

Gastric rupture carries a 100% mortality rate without intervention. [41] Death is caused by sepsis, bleeding, respiratory failure, and air embolism. [48] Mediastinitis may also develop with similar end results. [60] With surgical intervention, mortality rates still exceed 60%. Larger tears, reflective of increased peritoneal contamination, contribute to the high mortality. Perforated ulcers typically have a small tear of less than 2 cm and a better outcome, whereas gastric ruptures usually measure 5 cm or greater and have a poorer outcome. [57] If abdominal pressure is excessive and compromises the patient's cardiorespiratory status, a decompressive paracentesis may be necessary before surgical correction. [49] Surgery consists of resection of necrotic gastric tissue, correction of any predisposing obstructive lesions, and peritoneal lavage. Broad-spectrum antibiotics against aerobic and anaerobic organisms are warranted perioperatively.

FOREIGN BODIES

Foreign objects are frequently swallowed, either intentionally or accidentally, and approximately 1500 persons die within the United States each year from either swallowing or aspirating foreign bodies [71] (see Chapter 63). In children, small toys are common, but coins clearly account for most accidental ingestions. [72] In adults, items may be accidentally swallowed as a result carelessness, poor vision, or alcohol intoxication. [73], [74] Such items may be articles that are frequently placed in the mouth, such as toothbrushes, dental prostheses, or nails. Patients with dementia or psychological disease are most likely to ingest a foreign body intentionally, but patients with bulimia may inadvertently swallow objects while trying to induce emesis. [75], [76] and [77] Incarcerated criminals may swallow objects for secondary gain (hospitalization), whereas drug traffickers may be "body-packers" who intentionally ingest small packets of illicit drugs. [73], [78]

Most foreign bodies traverse the stomach without causing gastric symptoms; symptoms induced by a gastric foreign body suggest mucosal penetration or perforation, peritonitis, or obstruction. [73], [75] Mucosal tears, ulceration, perforation, abscess formation, hemorrhage, and fistula formation may all develop as a result of a retained foreign object. [73], [74] Sharp objects such as splinters or animal bones are more likely to induce a perforation. When to remove foreign bodies from the stomach is a clinical uncertainty. Objects more than 2 cm in diameter or 5 cm in length should strongly be considered for removal because such items may lead to duodenal obstruction. [79] Owing to the risk of perforation, sharp objects should also be removed promptly. If a sharp object is too large reasonably to retrieve endoscopically, a laparoscopic gastrostomy or other surgical method may be necessary. [80] Blunt objects that are less than 2 cm in diameter or 5 cm in length may be followed with serial radiographs. If the object remains in the stomach for 3 weeks or if the patient develops symptoms of mucosal irritation, endoscopic retrieval of the foreign body should be pursued.

If endoscopic removal is attempted, the patient should be placed in the left lateral decubitus position, and glucagon may be administered to limit motility (although this is more likely to be beneficial for objects in the duodenum rather than in the stomach). Although there is some risk of perforation, a protective overtube may be placed in the esophagus for sharp or difficult-to-grab objects, to prevent the possibility of aspiration or esophagopharyngeal trauma. [81], [82] Standard biopsy forceps or snares may be used, but larger forceps are available specifically for foreign body removal. Oval or round objects may be trapped within a basket or net. Surgery should be considered before endoscopy for large, jagged objects and for "body-packers," who have a significant risk of death from the endoscopic rupture of a packet containing illicit drugs.

The accidental ingestion of button batteries deserves special mention. Such batteries contain alkaline compounds such as sodium or potassium hydroxide. Damage to the stomach may occur as a result of low-voltage burns, pressure necrosis, or direct corrosion. [72] Batteries lodged within the esophagus should be removed immediately by endoscopy. If the plain radiograph demonstrates the battery within the stomach and the patient is asymptomatic, the patient can be followed with serial radiographs. Endoscopic removal is warranted if the battery remains in the stomach at 48 hours, if it is greater than 15 mm in diameter, if it is a mercury-based battery, or if the patient is symptomatic with localized abdominal pain, hematemesis, or melena. [83] Ipecac syrup should never be administered in cases of battery ingestion because it has not been shown to be effective and may result in esophageal impaction of the battery. [83] If there is battery disruption, heavy metal levels (depending on the type of battery) in the blood and urine should be measured.

CAUSTIC INGESTION INJURY

Often more dangerous and damaging than foreign bodies is the ingestion of *caustic materials* (see Chapter 63). Common household cleansers and chemicals may contain compounds such as sodium or potassium hydroxide, sodium carbonate, aluminum hydroxide, and bleaches such as hydrogen peroxide. Acids tend to cause immediate pain and are quickly expelled by the patient, even in the setting of an intentional ingestion. Alkali agents are often odorless and tasteless, leading to more significant ingestions and more damage from their solvent action on lipoproteins. [84] Acute manifestations of a caustic ingestion include persistent salivation, odynophagia or even a complete inability to swallow, and the development of palatal or pharyngeal ulcers and white plaques. [85], [86] Hoarseness, stridor, and hematemesis may also develop. The presence of peritonitis or mediastinitis suggests a perforation. Acute and chronic manifestations of caustic ingestion are more commonly seen in the oropharynx and esophagus, but gastric damage may result in late manifestations such as early satiety, weight loss, and vomiting (symptoms of a possible outlet obstruction). A reasonable approach to the patient with caustic ingestion should begin with abdominal and chest radiographs.

These radiographs are most useful to exclude the presence of free air or esophageal and gastric distention, which are commonly seen after caustic ingestions. If there is no free air but perforation is still suspected, barium studies or a computed tomography scan can be pursued. The patient may be sent home if there is no free air on plain films, if there are no symptoms, and if the ingestion was accidental. Obviously, admission and surgical consultation are warranted if there is evidence of perforation. If the patient has respiratory or gastrointestinal symptoms or if the ingestion was intentional, hospital admission is necessary. The patient should ingest nothing by mouth initially, and psychiatric consultation should be considered. If the patient has significant respiratory complaints, laryngoscopy may be justified to determine the need for intubation or tracheostomy. Endoscopy is warranted in all cases, but the timing of an endoscopic examination is unclear. Although some authors recommend immediate endoscopy, most recommend an examination at 24 to 72 hours to define the extent of injury better. [85], [86] An endoscopic grading system has been proposed: grade I, erythema and edema; grade II, hemorrhage, erosions, blisters, and superficial ulcers (A, linear, B, circumferential); grade III, multiple deep brown or black or gray ulcers; and grade IV, full perforation. For grade IA damage, liquids can be started with diet advancement as tolerated. Patients

with grade IIB or III damage should have a nasogastric tube placed for gastric decompression, and acid suppression should be employed. Oral liquids may be started approximately 48 hours after endoscopy if the patient is swallowing well. Immediate surgery is warranted in patients with grade IV damage.

Acid neutralizers have been used to limit caustic damage in the past, but these are no longer recommended because heat production from the neutralization process has been shown to worsen tissue injury. [87] Owing to the risk of esophageal strictures and antral stenosis, some investigators have proposed oral corticosteroids, based on animal or anecdotal data only. The only randomized controlled trial performed suggested that steroids did little to prevent or limit esophageal strictures, and routine steroid use is not recommended by all clinicians [88] (see Chapter 63).

In the long-term, caustic gastric injury may lead to antral stenosis within 3 to 6 weeks of the ingestion, or it may be delayed for many years. It is not unreasonable to perform an upper gastrointestinal series at 3 to 6 weeks to look for this complication. Some cases of antral or pyloric stenosis may respond well to endoscopic balloon dilation, but most patients will eventually require a surgical pyloroplasty or distal gastrectomy. In patients with prior caustic injury who are undergoing endoscopy for other reasons, antral hyalinization has been reported and may mimic gastric Crohn's disease or malignant disease. [89] Corrosive damage may increase the risk of subsequent gastric cancer, but such reports are isolated. Endoscopic surveillance is not warranted, based on the available literature. [90]

GASTRIC BEZOARS

Bezoars are concretions of foreign material that are retained most frequently within the stomach but have also been found in the esophagus and rectum. [86] Such matter may include plant and vegetable debris (*phytobezoar*), hair (t *richobezoar*), medications (*pharmacobezoar*), and persimmons (*disopyrobezoar*). The true prevalence of bezoars is uncertain because many patients are asymptomatic, but bezoars are uncommon in the intact stomach; that is, they have a prevalence at endoscopy of 0.4%. However, 10% to 25% of patients with prior antrectomies have been found to have symptomatic bezoars. [91], [92]

The formation of bezoars is likely multifactorial. Altered gastric motility and emptying are the primary causes, but size and digestibility of swallowed material are factors as well. Inadequate mastication, missing teeth, and poorly-fitting dentures may also contribute to bezoar formation. [93], [94] Prior gastric surgery, whether it be a pyloroplasty, antrectomy, or partial gastrectomy, clearly places patients at risk for phytobezoar or fungus ball formation. [95] Surgery can induce gastric atony and dysmotility, but outlet obstruction from stenosis and decreased secretion of acid and pepsin may also play a role in bezoar formation. Furthermore, many postsurgical patients develop chronic gastropathy that leads to increased mucus production, and this mucus may act like cement for developing concretions. [96] In addition to surgery, gastric stasis and bezoars have been linked to diabetic gastroparesis, mixed connective tissue disease, hypothyroidism, and myotonic dystrophy. [97], [98], [99] and [100]

Phytobezoars are commonly composed of apples, grapes, oranges, cherries, raisins, bran, oats, cabbage, potato peels, peanuts, and celery. [93], [101] Bezoars may also be composed of nonfood items such as plastic, paper, string, or Styrofoam. Disopyrobezoars develop when unripe persimmon material comes into contact with gastric acid; a tannin in the fruit forms a coagulum that acts as a base for bezoar formation. Trichobezoars may be quite large, depending on the amount of hair consumed. Medications have reportedly been trapped within hair fibers, and drug toxicity has been attributed to altered drug metabolism. [102] Trichobezoars may contain food material and fat as well. *Fungus balls,* also termed yeast bezoars, are associated with prior gastric surgery and frequently resolve without therapy. For symptomatic fungus balls, gastric lavage, antimycotics, and gastric outlet reconstruction have all been used. [103], [104]

Concretions are a type of bezoar that are typically very hard. Shellac, furniture polish, and concrete are classic components of such a bezoar, and surgery may be necessary to remove concretions because other therapies are generally ineffective. Pharmacobezoars may develop in patients with normal or abnormal gastric physiology. Aluminum hydroxide antacids have caused bezoars in patients with renal failure, and the cellulose-based coating of enteric-coated aspirin has been problematic in other patients. [105], [106] In patients with achlorhydria, calcium and magnesium carbonate preparations may not dissolve normally. Sucralfate will occasionally form concretions at normal doses and in patients with gastric outlet obstruction, so this agent should be avoided in patients with outlet obstruction or significant dysmotility. [107] Other drugs with capsules that do not digest (such as certain nifedipine or mesalamine preparations) should be avoided in patients with gastric outlet narrowing as well. [108]

Many patients with bezoars are asymptomatic, but epigastric pain, early satiety, nausea, and vomiting are very common manifestations of a bezoar. [86], [93] Bloating, malaise, and weight loss may also be reported. In some patients, these symptoms may persist despite bezoar resolution; in such cases, the nonspecific symptoms may be more reflective of the gastric dysmotility than of the actual presence of a bezoar. In patients at risk of bezoar formation, symptoms of small bowel obstruction may reflect the passage of a bezoar into the small bowel, although this is rare. [109] Gastric outlet obstruction and gastric bleeding (hematemesis or melena) can also be complications of bezoars. Given the nonspecific nature of the symptoms, the patient's history may suggest other causes such as peptic ulcer disease, gastric cancer, or many other intra-abdominal processes. On physical examination, potential findings include abdominal tenderness, a palpable mass, and a succussion splash. [86] Plain radiographs may demonstrate an air shadow or a mottled-appearing mass in the stomach. Barium studies are much more likely to demonstrate a bezoar; trichobezoars "absorb" barium and have a mottled appearance, whereas phytobezoars and concretions are typically impermeable to barium (Fig. 71-7). Radiographic studies may miss a bezoar, and endoscopy remains the test of choice. Although other studies such as ultrasound scanning or computed tomography may demonstrate a bezoar, endoscopy is the best for determining the type of bezoar, for excluding cancer, and for evaluating the mucosa for associated ulceration or outlet obstruction.

FIGURE 71-7. (**A**) Gastric phytobezoar on barium examination. (**B**) Glue concretion in a model airplane builder. (From Eisenberg RL. Filling defects in the gastric remnant. In: Gastrointestinal radiology: a pattern approach, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2003.)

Enzyme Therapy

Because many bezoars contain cellulose, protein, and mucus, enzymatic degradation of phytobezoars may be possible. For bezoars containing fibrous material, papain may be a useful proteolytic enzyme. Although this enzyme can be individually purchased, papain can be obtained more cheaply by using Adolph's Meat Tenderizer (1 teaspoon in 4 ounces of water before each meal). [86], [101] Some caution should be used with the latter salt-containing preparation because hypernatremia is a potential problem (1800 mg per tablespoon). Cellulase may be used for phytobezoars as well. The tablets are frequently crushed and given after each meal, or 2 L of cellulase solution may be consumed over the course of 2 days (20 g in 2 L of water). [101], [110] Biochemical supply companies can provide papain and cellulase preparations. Because many phytobezoars contain mucus as well, the mucolytic agent acetylcysteine may also be used. This agent has been reported to be effective at a dose of 15 mL in 50 mL of saline administered through a nasogastric tube two times per day for 2 days; although not specifically stated in this case report, it is presumed that a commercially available, 20% acetylcysteine preparation was used and diluted to a 5% solution as recommended by the manufacturer for other indications. [111] If there is ulceration associated with the bezoar, some investigators have suggested that mucolytic and cellulolytic agents may be safer than the proteolytic regimens provided.

Mechanical Therapy

Many bezoars contain insoluble agents that are also not amenable to enzyme therapy, and some patients are so symptomatic that more urgent therapy is warranted. Very small bezoars may be retrieved like other foreign bodies with endoscopic baskets, snares, or forceps. An esophageal overtube is frequently used to prevent inadvertent aspiration of the bezoar. [112] Similarly, many bezoars can be mechanically disrupted into small pieces with forceps such that the pieces are retrieved by suction or are allowed to pass through the pylorus. For soft and permeable bezoars, a large-bore orogastric lavage tube can be placed for aggressive water lavage

with subsequent aspiration of the fragmented bezoar. Frequently, a combination of endoscopic fragmentation and subsequent orogastric lavage is used, with immediate benefits to the patient.

Other modes of mechanical disruption have been proposed. Plastic tubing has been placed through an endoscope channel and attached externally to a Teledyne Water Pik system. Water or an enzymatic solution can be pulsated against the bezoar to allow fragmentation and subsequent gastric lavage. [101], [113] Neodymium:yttrium-aluminum-garnet laser may be useful for refractory bezoars, although multiple sessions may be necessary. [114] Extracorporeal shock wave lithotripsy and mechanical lithotripsy (with a lithotriptor for hard bezoars) have also been successful. [115], [116] In patients who have undergone gastroplasty and in whom the surgical stoma may be too small (predisposing to bezoar formation and not allowing passage of bezoar fragments), the stoma may require balloon dilation or even an endoscopic incision with a papillotome. [117], [118]

Endoscopic management is warranted only for symptomatic patients. If a bezoar is incidentally found or if symptoms are minimal, enzymatic and prokinetic therapies are likely adequate. Endoscopy is clearly indicated for more symptomatic bezoars, especially if complications such as obstruction develop.

Medical Therapy

Prokinetic agents such as metoclopramide may be used on a long-term basis to aid in the prevention and recurrence of bezoars. Metoclopramide has been used alone and with concomitant endoscopic therapy in the acute setting (40 mg intravenously over 24 hours) with some success, but patients should also be placed on a clear liquid diet under such circumstances. [119] Although liquid diets may have some benefit in bezoar dissolution, this is a slow process that is not practical as sole therapy. The prokinetic benefit of long-term metoclopramide use must be weighed against the severity of the patient's symptoms and the significant side effect profile. Domperidone, not available within the United States, may be another option, with fewer side effects. Although cisapride is currently available only on a restricted protocol basis for the treatment of diabetic gastroparesis, this agent may be an option for patients who qualify for study participation. A similar prokinetic, norcisapride, is currently under investigation and may be available in the near future without the cardiac risk and drug interactions that plague cisapride.

For patients with or at risk of the development of bezoars, prokinetic agents should be considered, based on the patient's symptom severity. Conversely, all such patients should follow basic dietary guidelines to limit bezoar formation. Specifically, smaller but more frequent meals are advisable to promote gastric emptying. Patients should chew their food adequately into small pieces. Foods that easily coalesce into a bezoar, such as persimmons, raw fruits, and stringy vegetables, should be avoided. [93]

Surgical Therapy

Surgery is rarely required for bezoars but may be necessary for complications such as perforation, gastric or small bowel obstruction, and uncontrollable hemorrhage. Symptomatic trichobezoars often require surgery more often than other bezoar types because they are very resistant to standard management techniques. Of course, other bezoars may also require surgery if they cannot be treated by the methods outlined earlier. Because surgery is unlikely to correct the underlying cause of bezoar formation and may worsen gastric motility and emptying, such a decision should not be made lightly.

HETEROTOPIC PANCREAS

Heterotopic pancreatic tissue, also termed a *pancreatic rest,* has been identified in 0.5% to 14% of persons at autopsy. [120] These rests are found in the stomach, duodenum, or jejunum in 75% of cases but may also be seen in the lung, gallbladder, common bile duct, ileum, Meckel diverticula, and numerous other locations. Typically, these rests are asymptomatic, but abdominal pain, nausea, vomiting, and rarely bleeding have been attributed to rests located in the stomach. In one series of 17 patients, pancreatic rests were the presumed cause of pain in 77% of patients, of abdominal fullness in 30%, and of melena in 24%. [121] After surgical resection of the rests, significant symptom improvement was reported, but whether rests truly do cause symptoms sufficient to warrant surgical excision is still somewhat controversial. These lesions typically appear as 2- to 4-cm submucosal masses in the prepyloric region, and central umbilication is not unusual (Fig. 71-8; see Color Fig. 71-8A). The nodules are firm and may be yellow. Because this typical appearance is not always appreciated, rests have been mistaken for malignant tumors in 67% of upper endoscopies and in 71% of barium studies. [121] If the endoscopic appearance is not diagnostic, endoscopic ultrasound may be helpful in evaluation. Surgery is indicated only in cases of symptomatic pancreatic rests.

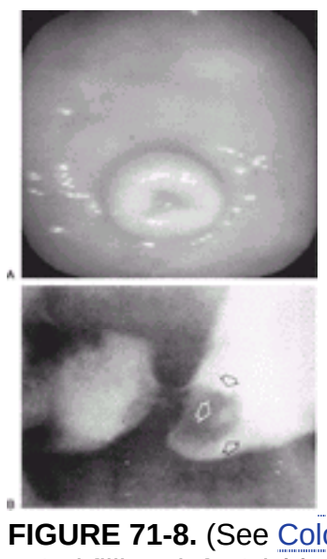

FIGURE 71-8. (See Color Fig. 71-8A.) (**A**) Pancreatic rest identified in the antrum during upper endoscopy. (**B**) Radiographic appearance of a pancreatic rest with an antral filling defect (*black arrows*); the *white arrow* denotes central filling with barium. (From Eisenberg RL. Filling defects in the stomach. In: Gastrointestinal radiology: a pattern approach, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2003.)

SQUAMOUS CARDIAC EPITHELIUM

Squamous epithelial extension into the proximal stomach has been reported in 16 patients. [122] All were male, and nearly all were white. Most patients had pyrosis (75%) and hiatal hernias (100%), and many had Barrett esophagus (38%). No patient had a history of caustic ingestion or prior gastric surgery. Most had solitary tongues of this squamous epithelium, but multiple tongues and islands were also identified. The true incidence and clinical significance of this finding are not known, but prior proximal gastric injury has been proposed as an explanation.

CHAPTER 72

Deborah C. Rubin

SMALL INTESTINE: ANATOMY AND STRUCTURAL ANOMALIES

GROSS ANATOMY

The small intestine begins at the pyloric sphincter of the stomach and extends to the cecum. Approximately 600 cm long, the small bowel is composed of three major segments: the duodenum, the jejunum, and the ileum. The junction between the duodenum and the jejunum is anatomically demarcated by the ligament of Treitz. No similar landmark distinguishes the jejunum from the ileum, but the jejunum is usually defined as the proximal two fifths of the small bowel, and the ileum as the distal three fifths.

After the appropriate rotation of the gut and its return to the abdominal cavity in fetal life, the normal position of the small bowel loops is attained. The jejunum is generally located in the mid upper and left upper quadrants, the proximal ileum in the middle abdominal region, and the distal ileum in the right lower quadrant. [1]

The first part of the duodenum, the bulb, is invested with mesentery. The descending, transverse, and ascending parts of the duodenum are retroperitoneal and partially encircle the pancreatic head (Fig. 72-1). The jejunum begins at the ligament of Treitz as the small intestine reenters the peritoneal cavity. The jejunum and the ileum are invested with mesentery. The very distal ileum may occasionally be retroperitoneally located. [2]

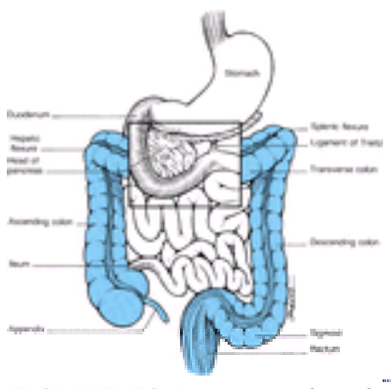

FIGURE 72-1. Anatomic relations of the stomach, small intestine, and large intestine. The duodenum encircles the head of the pancreas and is retroperitoneal. As the intestine reenters the peritoneal cavity at the ligament of Treitz, it becomes the jejunum. Generally, the jejunal bowel loops are located in the left and middle upper abdomen, the proximal ileum in the middle abdominal region, and the distal ileal loops in the right lower quadrant. **Inset:** Retroperitoneal duodenal loop and the ligament of Treitz, located behind the transverse colon.

The gross appearance of the small intestine changes from the jejunum to the ileum. The wall of the jejunum generally is thicker than that of the ileum. Also, the plicae circulares, or circular folds of mucosa and submucosa that invaginate the lumen and increase the gut surface area, are prominent in the duodenum and jejunum and disappear in the middle ileum. [1] Peyer patches usually are found on the antimesenteric border of the small intestine. They are particularly prominent in childhood and atrophy with aging. [1]

Extrinsic Arterial, Venous, and Lymphatic Supply

The arteries, veins, and lymphatics that supply the small bowel travel through the mesentery (see Chapter 131). The hepatic artery gives rise to the gastroduodenal artery, which branches into the anterior and posterior superior pancreaticoduodenal arteries. These anastomose around the duodenum and communicate with the inferior pancreaticoduodenal artery, which arises from the superior mesenteric artery. The superior mesenteric artery also supplies the jejunum and the ileum through a series of branches that form numerous arcades in the mesentery and then penetrate the intestine.

The superior mesenteric vein serves as the major venous conduit and joins the splenic vein to empty into the portal vein. Small lymph channels or villus lacteals drain into mesenteric lymph nodes located near the intestine and along the superior mesenteric and celiac arteries. These drain into the cisterna chyli and the thoracic duct.

Neural Supply

The intestine contains an abundant, complex intrinsic neural supply that coordinates motor activities and consists of myenteric (Auerbach) and submucosal (Meissner) plexuses (see Chapter 2). The extrinsic autonomic innervation of the small intestine consists of components from the parasympathetic and sympathetic systems. [3] Postganglionic fibers arising from the superior mesenteric ganglion supply sympathetic motor innervation. These synapse with preganglionic fibers from the spinal cord in the region of the tenth and eleventh thoracic roots and travel in the lesser splanchnic nerve. Adrenergic neurons innervate both the Auerbach and the Meissner plexuses. Sensory nerves arise from the dorsal root ganglia. The parasympathetic motor innervation consists of preganglionic nerve fibers that arise from the vagus nerve. Vagal fibers originate from the dorsal motor nucleus and then divide into esophageal, anterior, and posterior vagal trunks. Both the anterior and posterior trunks give rise to celiac branches that directly innervate the small bowel by communicating with the intrinsic nervous system.

The axons of a small number of intrinsic nerves project from the intestine to travel with extrinsic nerves and synapse with sympathetic postganglionic neurons at the sympathetic prevertebral ganglia.

Enhancement of Small Intestinal Surface Area: Gross and Microscopic Features

The surface area of the small intestine is enhanced by three features that are peculiar to the gut: the plicae circulares, the villi, and the microvilli (Fig. 72-2). [2] The plicae circulares, or circular folds, consist of visible mucosal/submucosal invaginations that are predominantly located in the duodenum and jejunum. The villi, fingerlike projections that protrude into the intestinal lumen, are approximately 0.5 to 1.5 mm long and cover the mucosal surface. They can be viewed by close inspection of the mucosa under low-power microscopy or as tiny mucosal protrusions at endoscopy. They consist of a layer of epithelial cells overlying the lamina propria. Their microscopic appearance varies; duodenal villi are characteristically broad and leaf-shaped, jejunal villi are tall and thin, and ileal villi are short and broad. The length and shape of the villi also vary with the geographic region; in some underdeveloped regions of the world, villi tend to be shorter than in the United States. [4], [5] At the base of the villi, the epithelium enters the lamina propria and forms the crypts of Lieberkühn (Fig. 72-3 and Fig. 72-4), which extend almost to the muscularis mucosae. The microvilli are sub–light microscopic tubular projections that are extensions of the apical cell membrane and compose the brush border. This complex membranous network contains the enzymes, receptors, and carriers required for terminal digestion and absorption.

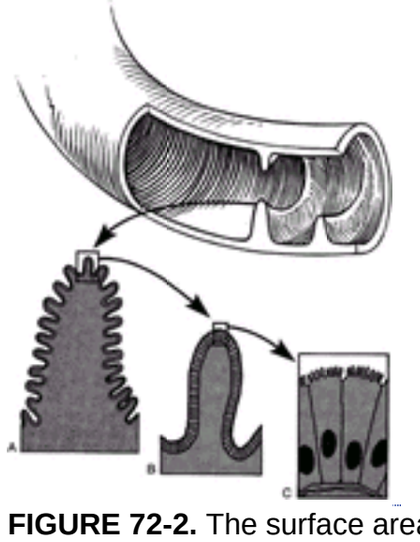

FIGURE 72-2. The surface area of the small intestine is enhanced by three mechanisms: the valvulae conniventes (**A**), the villi (**B**), and the microvilli (**C**). (Adapted from Weaver LT. Anatomy and embryology. In: Walker WA, ed. Pediatric gastrointestinal disease: pathophysiology, diagnosis and management. Philadelphia: BC Decker, 1991:195.)

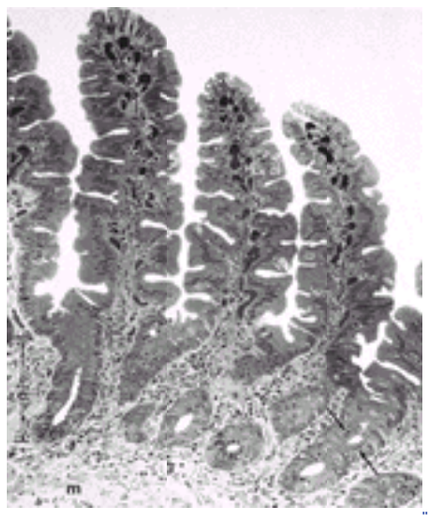

FIGURE 72-3. This semi-thin 1-µm epon section of human jejunum, stained with toluidine blue and viewed by light microscopy, depicts the mucosa. The villi are formed by a continuous sheet of columnar epithelial cells and underlying connective tissue, the lamina propria. The epithelial sheets are composed primarily of enterocytes; mucus-secreting goblet cells are also present but are much less abundant, as are rare enteroendocrine cells. At the base of the villi, the epithelial cells descend into the lamina propria to form the crypts, one of which is denoted at the left (*c*). The crypts are lined mainly by undifferentiated crypt cells, which can be observed in mitosis (*arrows*). Differentiation proceeds as these cells migrate up the villus. Paneth cells at the bases of the crypts are recognized by their dark granules. The muscularis mucosae (*m*), a thin layer of smooth muscle, separates the mucosa from the submucosa below. Original magnification ×150. (From Rubin W. The epithelial “membrane” of the small intestine. Am J Clin Nutr 1971;24:45.)

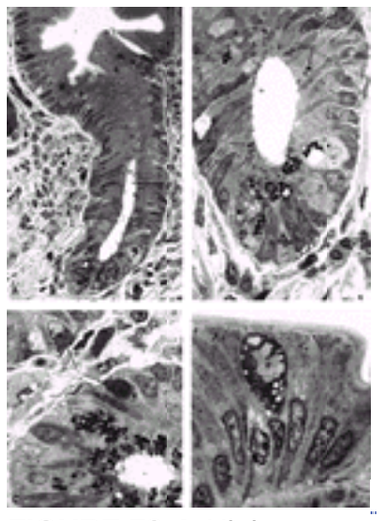

FIGURE 72-4. High-power views of the crypt. **A:** A crypt is observed extending to the base of a villus. Note the prominent brush border on the differentiated cells above the villus base and the inapparent brush border on the crypt cells below. The *arrow* shows a short and irregular brush border on an upper crypt cell. Large, dense Paneth cell granules are evident at the crypt base; the smaller apical granules higher in the crypt are in undifferentiated crypt cells. Original magnification ×300. **B:** The large granules in Paneth cells at the base of another crypt are located mainly in the apical cytoplasm. The scantier, lighter apical granules in cells above (*arrows*) are in undifferentiated crypt cells. Original magnification ×700. **C:** The large, dense apical granules in Paneth cells at another crypt base should be contrasted with the smaller, barely resolved basal infranuclear granules observed in two endocrine cells (*arrows*). Original magnification ×700. **D:** Differentiated villus epithelial cells and a goblet cell. Note the tall, prominent brush border. The narrow, light zone below the brush border represents the terminal web. The numerous light structures within the cells are mitochondria. The occasional dense apical structures are lysosome derivatives (*arrowheads*). The apical densities between adjoining cells at the level of the terminal web (*arrows*) are the terminal bars. They represent the junctional complexes of electron microscopy—the tight junctions, intermediate

junctions, and desmosomes; these are specialized structures that serve to bind adjoining epithelial cells at their apices. The accumulation of mucus granules within the apical cytoplasm of the goblet cell distends it into the shape of a brandy goblet. Original magnification ×1500. (From Rubin W. The epithelial “membrane” of the small intestine. Am J Clin Nutr 1971;24:45.)

MICROSCOPIC ANATOMY

The small intestine is composed of four concentric layers: the serosa, muscularis propria, submucosa, and mucosa.

Serosa and Muscularis Propria

The thin serosal lining of the small bowel consists of mesothelial cells overlying loose connective tissue. This outer layer becomes continuous with the mesentery as it joins the small bowel; many large blood vessels course through it. Those portions of the gut that are invested with mesentery are completely covered by serosa, whereas the retroperitoneal segments are invested only on the anterior surface. The muscularis propria consists of two muscle layers: an outer, longitudinally oriented layer and an inner, circumferential layer. Between the two layers lies the myenteric or Auerbach nerve plexus, composed of intrinsic ganglion cells and nerve fibers. The muscular layers of the gut are responsible for generating coordinated peristaltic movements.

Submucosa

The submucosa is a dense connective tissue layer containing numerous arteries as well as venous and lymphatic plexuses. Typical connective tissue cells are also present, but vascular structures predominate, consistent with the role of this portion of the gut as a conduit for absorptive and digestive products. In the duodenal bulb and descending duodenum are specialized Brunner glands that secrete mucus and bicarbonate. These are branched epithelial glandular structures that fill the submucosa and are thought to be important in neutralizing stomach acid. The submucosa also contains ganglion cells and nerve fibers, termed the Meissner plexus, a collection of autonomic nerves that communicate with the Auerbach plexus. A variety of neuroendocrine substances are produced in the Meissner plexus (see Chapter 2). These plexuses interact to produce regulated, coordinated gut peristalsis.

Mucosa

The mucosal layer of the gut consists of epithelial cells overlying the lamina propria or connective tissue core and resting on a narrow layer of smooth muscle, the muscularis mucosae (see Figure 72-3).

Lamina Propria The connective tissue core of the villus (lamina propria) contains a variety of cells and vascular structures (Fig. 72-5). The immune cellular component includes lymphocytes, macrophages, granulocytes, plasma cells, and mast cells (see Chapter 7). The majority of lamina propria T lymphocytes are T-helper/inducer cells that are surface antigen $CD4^+$, although smaller numbers of T-cytotoxic/suppressor cells ($CD8^+$) are also present. [6] The intraepithelial lymphocytes that reside between villus epithelial cells are primarily $CD8^+$ and, in mice, are ?/d T-cell receptor–positive. [7] The lamina propria plasma cells produce immunoglobulin, especially dimeric immunoglobulin A (IgA), which is taken up into the intestinal epithelium and secreted intralumenally after joining with secretory component. [8] A much smaller number of plasma cells produce IgM or IgG. The maturation of the B cell to an IgA-secreting plasma cell occurs during the course of a migratory journey throughout the body’s vascular system. Cells exit the Peyer patches through lymph vessels, enter the mesenteric lymph nodes, thoracic duct, and peripheral blood, and then finally “home” to the lamina propria of the gut (as well as to other organs, such as the lung, genitourinary tract, and breast). T lymphocytes similarly migrate from one lymphoid organ to another and eventually home to mucosal sites, which are determined by their interactions with specific proteins expressed on lymphoid cells as well as the high endothelial venules, specialized vessels of the lymph nodes, Peyer patches, and appendix. [9] These vascular structures can also proliferate in organs affected by chronic inflammation. Macrophages and eosinophils are present in the normal human intestinal lamina propria. However, neutrophils are primarily found in inflamed rather than normal gut.

FIGURE 72-5. Upper villus region, with lamina propria, goblet cells, enterocytes, and intraepithelial lymphocytes (*arrow*). Hematoxylin and eosin stain; original magnification ×495. (From Phillips AD. The small intestinal mucosa. In: Whitehead R, ed. Gastrointestinal and oesophageal pathology. New York: Churchill Livingstone, 1989:29.)

Lymph follicles are small collections of lymphocytes in the mucosa and submucosa, scattered throughout the gastrointestinal tract. Peyer patches, found in the mucosa and submucosa, are localized collections of lymphoid follicles, may be as large as 30 cm in diameter, [10] and are most prominent in the ileum. The number of Peyer patches in the gut increases after birth. [10] The Peyer patch contains specialized epithelial cells, known as *M cells,* that overlie the lymphoid cells and allow lumenal antigens to enter the mucosa. [11] The dome area of the Peyer patch lies above the lymph follicles and just below the M cells and contains lymphocytes and macrophages. The follicular or central region contains large numbers of precursor B cells that undergo active cell division. The interfollicular zone is populated predominantly by T cells. Other cellular components of the lamina propria include fibroblasts and smooth muscle cells. Arterioles, venules, and a central lacteal function to deliver nutrients into the vascular system (see Figure 72-5).

Epithelium The villi and crypts contain a complex, rapidly proliferating, and perpetually differentiating epithelium, a continuous sheet of simple columnar cells that rests on a filamentous basal lamina or basement membrane (see Fig. 72-3 and Fig. 72-4). It constitutes the major barrier between the intestinal lumen and the lamina propria and regulates flux between these two compartments. The epithelial cells on the villi vectorially transport the products of digestion into the lamina propria, where they enter the venous capillaries or lymphatic system and are transported to other areas of the body. Tight junctions (zonula occludens) bind adjacent epithelial cells tightly together near their apices to restrict flux between adjoining cells (the paracellular route) to small ions, small molecules, and water. [12] The crypt and villus form the basic structural and functional unit of the small bowel (see Fig. 72-3 and Fig. 72-4; Fig. 72-6). Anchored stem cells located in the crypts of Lieberkühn are the source of the four major terminally differentiated cell types: absorptive enterocyte, mucus-secreting goblet cell, enteroendocrine cell, and Paneth cell. Other epithelial cell types include the tuft or caveolated cell, a rare constituent of the villus, and the M cell, a specialized epithelial cell that overlies the Peyer patch. Cellular differentiation proceeds during a complex, bidirectional migration process (see Fig. 72-6). [13] The slowly cycling gut epithelial stem cells are believed to reside in the lower crypt region, approximately four to five cell positions above the crypt base. [14], [15] They give rise to proliferating progenitor cells, which differentiate as they migrate up the crypt onto the villus to become enterocytes, goblet cells, and enteroendocrine cells. In contrast, the Paneth cells arise as their progenitors journey to the crypt base. [16] Several crypts contribute cells to a single villus. The number of crypts supplying each villus varies from the duodenum to the ileum. Epithelial cell migration and differentiation occur continuously, and the process of cellular renewal and migration to the villus tip takes approximately 5 days in humans. Apoptotic cell death occurs spontaneously near the stem cell region in the crypts, presumably to regulate stem cell numbers. Effete cells are removed from the villus tip by a process known as *anoikis,* in which altered cellular adhesion results in apoptosis. [16]

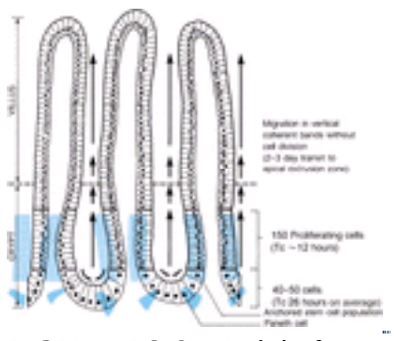

FIGURE 72-6. Model of organization of the crypt-villus axis in the adult mouse small intestine. The small intestinal crypt contains approximately 250 cells. The lower five cell positions contain 40 to 50 cells, which have an average cycle time (*Tc*) of 26 hours. This region includes Paneth cells and is postulated to include undifferentiated, anchored stem cells at the fifth cell position above the base. The undifferentiated cells divide asymmetrically to give rise to proliferating daughter cells (Tc of approximately 12 hours) that migrate up toward the villus and differentiate into enterocytes, goblet cells, and enteroendocrine cells. Paneth cells also arise from this stem cell during downward translocation to the crypt base. Senescent cells are extruded near the villus tips. (Adapted from Gordon JI. Intestinal epithelial differentiation: new insights from chimeric and transgenic mice. J Cell Biol 1989;108:1187.)

Cellular and topographic organization of the crypt. The present model of the organization of the crypt and its cellular kinetics is derived primarily from studies in the mouse. It is postulated that between 4 and 16 stem cells are present per crypt. [14], [15], [17] The number of active stem cells in any one particular crypt is unknown. [13] In the adult gut, these cells are monoclonal. [18], [19] The small intestinal epithelial stem cell presumably undergoes a process of asymmetric division to give rise to actively proliferating progenitor cells while the stem cell is maintained. [15] Proliferating progenitor cells or transit cells are located in the mid crypt region, above the presumptive stem cell region. In mouse gut, these cells enter the cell cycle every 12 hours. [20] The progenitor cells subsequently differentiate into the four major cell types.

Undifferentiated crypt cells. Undifferentiated crypt cells have many ribosomes and polysomes but scant endoplasmic reticulum, mitochondria, and microvilli and undeveloped terminal webs. They are basophilic because they contain large amounts of cytoplasmic RNA. Secretory granules are found near the apical surface (see Fig. 72-4B); their nature is unknown, but they stain with the periodic acid-Schiff (PAS) reaction and are not lysosomes. Undifferentiated crypt cells also synthesize secretory component (the receptor for IgA [21]), contain chloride channels, and are capable of secreting chloride in response to cholera toxin or other enterotoxins. [22], [23]

Absorptive enterocytes. Cellular differentiation commences during migration to the upper crypt and villus base. The cells that are fated to become the absorptive enterocytes begin to express a variety of specific gene products that enable the cells to digest and absorb many different nutrients. These include brush border enzymes (disaccharidases, peptidases, and alkaline phosphatase); proteins involved in lipid absorption (apolipoproteins and fatty acid–binding proteins); and many receptors, carriers, and transporters. [24], [25] Immunohistochemical and in situ hybridization analyses indicate that most major enterocyte genes, such as those encoding disaccharidases, apolipoproteins, fatty acid–binding proteins, and the sodium-dependent glucose transporter, are expressed as cells emerge above the crypt-villus junction, [26], [27], [28] and [29] but are not found in the crypts. This precise vertical differentiation continues as cells migrate up the villus. Microvilli become more prominent, and the capacity of the cell to absorb lipids, sugars, and amino acids increases. [30] Despite rapid cellular renewal, complex spatial differentiation in the gut is maintained from duodenum to colon. Many enterocyte genes are abundantly expressed in the proximal small bowel, but their messenger RNA (mRNA) levels decrease markedly in the distal gut, [27], [31], [32], [33] and [34] /SUP>whereas other genes are specifically expressed in the ileum. [35], [36] Cloning, sequencing, and promotor analysis of these genes have provided some insight into the molecular mechanisms underlying the regulation of regional differentiation in the gut. Transgenic mouse and cell culture transfection techniques have been used to map out regulatory promoter elements. [17], [28], [37], [38], [39] and [40] In addition, transgenic mice and mice in which embryonic stem cell mutations have been created to delete specific gene products (“knock-out” or null mice) have been used to determine the function of these novel regulatory genes, including the homeobox-containing Cdx family. [41], [42]

Ultrastructural features. As undifferentiated crypt cells travel up the villus, they acquire longer, more numerous microvilli, measuring 0.1 µm in width and about 1 µm in height, which produce a prominent striated (brush) border by light microscopy. The development of these long microvilli, fingerlike extensions of the apical cell membrane, markedly increases the absorbing surface of the small intestine (Fig. 72-7). The basolateral membrane is relatively smooth in comparison and contains the Na^{+}/K^{+} exchanger Na^{+},K^{+}-ATPase, which pumps sodium from the cell. These cells also develop a terminal web, an apical zone below the microvilli that contains many filaments and some vesicles. As cells migrate up the villus, they acquire more mitochondria and rough endoplasmic reticulum, lose their secretory granules, and acquire large apical dense bodies, which represent lysosomal derivatives (see Fig. 72-4D and Fig. 72-7). [43], [44] The functional polarity of the enterocyte, with its specific apical and basolateral membrane domains, is strictly maintained, thereby ensuring the vectorial transport of a variety of nutrients and ions from the apical to the basolateral surfaces of these cells.

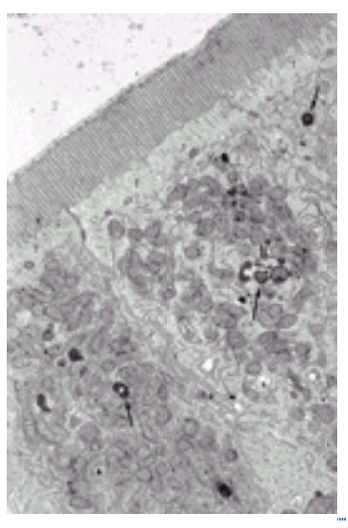

FIGURE 72-7. An electron microscopic picture of the apical halves of differentiated villus epithelial cells. Note the numerous tall microvilli covered with “fuzz” or glycocalyx and an organelle-free apical zone, the terminal web (*T*), just below the microvilli. There are abundant mitochondria and profiles of rough endoplasmic reticulum. The irregularly shaped dense bodies (*arrows*) are lysosome derivatives. Supranuclear Golgi profiles are denoted by *G*. The intercellular space is obliterated between the apices of adjoining cells just below the level of the microvilli by the tight junction (zonula occludens), an apparent fusion of adjoining cell membranes (best seen between the two cells on the left). Transport of substances from the lumen between cells (paracellular route) is restricted to water and small molecules and ions. Most products of digestion enter the cell by crossing the microvillar membrane. Original magnification ×15,000. (From Rubin W. The epithelial “membrane” of the small intestine. Am J Clin Nutr 1971;24:45.)

Filaments composed of actin extend from a dense plaque just beneath the cell membrane at the tip of the microvillus down the core of the microvillus into the terminal web. [43], [45], [46] The terminal web is a dense meshwork of filaments that contain actin, myosin, and other cytoskeletal proteins. The meshwork is oriented parallel to the surface and perpendicular to the microvillus filaments, and it is attached to the lateral cell membrane at the intermediate junction (zonula adherens). [45], [46] The numerous filaments in the microvilli and terminal web, known as the *cytoskeleton of the brush border,* probably confer a structural rigidity to the apices of the differentiated villus cells and may provide for the movement of the microvilli. [45], [47] This cytoskeleton probably also affects the uptake of certain nutrients and paracellular permeability. [45], [48] Short, thin, filamentous material extends from the outer leaflet of the cell membrane covering the microvilli into the intestinal lumen, producing a surface coat, the glycocalyx (or “fuzz”). The glycocalyx represents external extensions of proteins and glycoproteins in the microvillus membrane. [45], [49] The microvillus membrane of the differentiated villus cells contains many of the enzymes, receptors, and carriers necessary for terminal digestion and absorption, such as the disaccharidases, alkaline phosphatase, peptidases, the ileal cobalamin–intrinsic factor receptor, the bile acid receptor, and the Na^{+}-dependent glucose and amino acid transporters. [36], [45], [49], [50] and [51] The active portions of many of these are associated with the glycocalyx. The components of the microvillus membrane and glycocalyx turn over and are replenished by continuous synthesis and are transported from the rough endoplasmic reticulum via the Golgi apparatus to the microvillus membrane. [45], [49], [52], [53], [54], [55] and [56] The selective vesicular transport of microvillus constituents from the Golgi apparatus to the cell apex is dependent on microtubules. Disruption of microtubules with colchicine or vinblastine results in more random routing of these components, with the incorporation of microvillus enzymes into the basolateral surface and even the formation of basolateral microvilli. [52], [55] Some of the microvillus enzymes are finally processed in the glycocalyx by the proteolytic activity of pancreatic enzymes, especially elastase, that are adherent to the glycocalyx. [45], [49], [53]

Paneth cells. Paneth cells are pyramid-shaped cells in the crypt base that contain large apical eosinophilic secretory granules. They are much longer-lived than enterocytes, with a half-life of

approximately 20 days in the mouse. [14] A role in host defense and mucosal barrier function is suggested by their abundant expression of lysozyme, [57] cryptdins, [58] and other antibiotic proteins, and their ability to degranulate in response to live and heat-killed bacteria. [59] Several of the defensins, a family of small peptides that are abundant in human neutrophils, are highly expressed in Paneth cells. [60], [61] and [62] These 3- to 4-kd peptides are also known as *cryptdins,* for *crypt defensins,* [58] and exhibit microbicidal activity toward many different bacterial microorganisms in vitro. [58] mRNAs encoding tumor necrosis factor [63] and a $_1$-antitrypsin [64], [65] have been located in human Paneth cells. Studies in which these cells were specifically ablated in mice, with use of the cryptdin promoter to selectively express an attenuated diphtheria toxin A fragment, revealed no alteration in the differentiation of enterocytes or goblet or enteroendocrine cells and no obvious alteration in host-microbial interactions. [66] Paneth cells release defensins in response to bacteria, but not to fungi or protozoa, and the defensins have potent microbicidal activity. [67]

Enteroendocrine cells. The intestine contains a complex enteroendocrine cell population composed of a variety of paracrine-endocrine cell types. These cells were first characterized as argentaffin or argyrophil cells, depending on their reaction to silver staining in the presence or absence of a reducing agent. Electron microscopy has led to their classification by the appearance of granules. Immunohistochemistry has identified these cells based on their primary neuroendocrine product. The D cell produces somatostatin, the L cell produces glucagon-like immunoreactivity, and the enterochromaffin cell makes serotonin. This cellular population exhibits a very specific spatial distribution along the crypt-to-villus and duodenal-to-colonic axes of the gut. For example, serotonin cells are abundant throughout the gastrointestinal tract, whereas secretin and cholecystokinin cells are much more localized to the duodenum and proximal jejunum. [68], [69] and [70] In the mouse, secretin cells are predominantly located on the villi, whereas substance P–containing cells are found primarily in the crypts. Enteroendocrine cells may also simultaneously express more than one neuroendocrine product [68], [69], [70] and [71]; this coexpression is developmentally regulated in the rodent. [72] Although early data suggested that enteroendocrine cells were derived from the neural crest, later studies have indicated they arise from the undifferentiated crypt stem cell. [14], [15], [17], [73], [74] This differentiation seems to be hard-wired in the absence of lumenal contents, including pancreaticobiliary secretions and dietary factors. [71], [75] The patterns of coexpression of substance P, serotonin, and secretin along the crypt-to-villus axis of the small bowel suggests that these cells are representative of a specific differentiation pathway that arises independently of the other endocrine cell types. [69] Thus, there may be a branch point at which proliferating progenitor cells differentiate into the various endocrine cell lineages. [76] Targeted ablation of secretin cells in transgenic mice markedly decreased the numbers of L and secretin cells, also suggesting a common developmental relationship. [77] The secretions of these cells act in a paracrine manner and function locally, whereas others are true endocrine products. The peptides and amines may affect bowel motility, intestinal cellular secretion (see Chapter 4), and epithelial cell proliferation (e.g., glucagon-like peptide 2, a product of the intestinal L cell). [78], [79] In contrast to exocrine cells, which secrete apically into the lumen of an organ or the duct of a gland, endocrine cells are morphologically oriented toward the basement membrane. They exhibit an appreciable basal surface, and they narrow superiorly so that only narrow bands of apical cytoplasm reach the lumen. Their secretory granules are located predominantly in the basal cytoplasm below the nucleus, ready to be secreted by exocytosis through the basal membrane into the lamina propria (see Fig. 72-4C).

Goblet cells. The mucus-secreting goblet cells are present throughout the entire gastrointestinal tract but are more numerous in the ileum than the jejunum. These cells have the shape of a brandy goblet and apically located granules filled with mucin. Mucin is their primary secretory product and presumably serves a cytoprotective and lubricant function in the gastrointestinal tract. [80], [81] Biochemical differences among mucins are expressed in the stomach, small intestine, and colon, suggesting heterogeneity among goblet cell populations. [21], [82] The expression of specific mucins is also developmentally regulated Intestinal trefoil factor, one of a family of small peptides that includes pS2 and human spasmolysin, is abundantly expressed in goblet cells of the small intestine and colon. [83] Intestinal trefoil factor mRNA is expressed in the crypt and may therefore be a marker of early goblet cell differentiation. Embryonic stem cell gene ablation experiments demonstrate a cytoprotective role in the gut. [84] Goblet cells arise from the same committed stem cell as do the other principal cell types. [74] However, actively proliferating goblet cells have been noted in the crypt; these cells may also contribute to the villus-associated goblet cell population.

M cells. The specialized epithelial membranous, or M, cells are confined to the epithelium overlying the Peyer patch, known as the *follicle-associated epithelium*. Unlike other absorptive cells, they lack a typical brush border, demonstrating fewer, shorter microvilli and numerous apical endocytic vesicles. They serve as antigen-sampling cells and endocytose a variety of macromolecules, viruses, and bacteria from the lumen. These molecules are then rapidly transported across the epithelium and come into contact with immune cells, thereby initiating protective mucosal immune responses. [11], [85], [86] The invaginated basolateral membrane of the M cell forms an intraepithelial pocket and allows lymphocytes and macrophages to come into rapid contact with antigen. [85] Precise mechanisms involved in transepithelial transport of antigen across the M cell are still largely unknown. [86] The presumptive origin of this cell type is also the multipotent crypt stem cell. [85] M cells can be formed by culturing Peyer patch lymphocytes together with the intestinal Caco-2 cell line, or with native enterocytes. [87], [88] These and other data suggest that M cell differentiation may be immunoregulated and that lymphoepithelial cross talk may induce M-cell formation from follicle-associated epithelial cells. [89]

EMBRYOLOGY

In this section, a brief synopsis of the major events in midgut morphogenesis is presented as a basis for understanding the congenital anomalies discussed in subsequent sections (see also Chapter 23).

The primitive human gut forms when the dorsal part of the yolk sac is incorporated into the embryo at the fourth week of development, giving rise to the foregut, midgut, and hindgut. [90] The foregut is the progenitor of the esophagus, stomach, duodenum up to the biliary duct ampulla, pharynx, respiratory tract, liver, pancreas, and biliary tract. The midgut gives rise to the duodenum distal to the common bile duct, jejunum, ileum, cecum, appendix, ascending colon, and half to two thirds of the transverse colon. The rest of the colon and the superior anal canal are derived from hindgut.

The gut endoderm is the precursor of the gastrointestinal tract epithelium. Its endothelium arises from the ectoderm of the stomodeum and proctodeum as well as the endoderm. The splanchnic mesenchyme supplies the muscular and connective tissue components of the gastrointestinal tract. The midgut first freely communicates with the yolk sac and then narrows to be connected by the omphalomesenteric or vitelline duct. The primitive gut forms a U-shaped loop; this grows so rapidly in comparison with the embryo that it herniates into the umbilical cord at the sixth week of gestation. The proximal limb of the loop elongates into multiple intestinal loops, whereas the distal limb simply develops into the cecal diverticulum. The first stage of rotation is 90° counterclockwise around the superior mesenteric artery axis. At 10 weeks, the intestines return into the abdominal cavity and rotate a further 180° counterclockwise in the second stage. Finally, the cecum and appendix descend from the right upper quadrant to the right lower quadrant, and the proximal part of the colon elongates to form the hepatic flexure and ascending colon (third stage of rotation). Fixation occurs as the ascending colonic mesentery fuses with the parietal peritoneum and becomes fixed retroperitoneally. The small bowel mesentery attains a broad-based attachment to the posterior abdominal wall, extending from the duodenal-jejunal junction to the ileocecal region. The end result of this process is a normal location of the small and large intestine, diagrammed in Figure 72-1.

CONGENITAL ANOMALIES

Meckel Diverticulum

Description and Pathophysiology During early gestation, the omphalomesenteric or vitelline duct connects the fetal yolk sac to the primitive gut. By 7 to 8 weeks of gestation, this duct is normally completely obliterated. A Meckel diverticulum, the most common congenital anomaly of the gastrointestinal tract, results when this structure fails to resorb completely. The duct remnant most commonly persists as a diverticular sac; alternatively, the diverticulum may be connected to the mesentery or umbilicus by a fibrous band (Fig. 72-8). Occasionally, only a thick connective tissue band remains, attaching the gut to the umbilicus. These bands may lead to volvulus or the strangulation of bowel loops. Rarely, a fistula remains patent from the ileum to the umbilicus, leading to persistent external drainage of ileal contents. Other, more unusual duct remnants include umbilical polyps and vitelline cysts.

FIGURE 72-8. A Meckel diverticulum is attached to the umbilicus by the obliterated omphalomesenteric duct. A Meckel diverticulum may be unattached to the umbilicus or abdominal wall; alternatively, the vitelline duct may remain attached and patent, creating a fistula. Fibrous bands may predispose to volvulus and strangulation. (From Johns TNP, Wheeler JR, Johns FS. Meckel's diverticulum and Meckel's diverticular disease: a study of 154 cases. Ann Surg 1959;150:241.)

Large autopsy series indicate a 2% to 3% prevalence of Meckel diverticulum in the general population. [91] This anomaly is two to three times more common in males. [92] Meckel diverticula are true diverticula, containing all layers of the bowel from serosa to mucosa. Located on the antimesenteric border of the gut, they are most commonly found within 100 cm of the ileocecal valve but may also be in other regions of the small bowel. Most diverticula are between 1 and 10 cm in size; giant lesions may be as large as 100 cm in diameter. The two types of giant diverticula are the type I lesions, which are long but of the same caliber as the ileum, and the less common type II, or ovoid, lesions. [93] Heterotopic tissue is present in approximately 50% of all diverticula. [94] Most commonly found is gastric mucosa, pancreatic tissue, or a combination of the two. Diverticula containing colonic mucosa, Brunner glands, or jejunal or hepatobiliary tissue have also been described. The presence of heterotopic mucosa correlates with an increased risk for symptomatic, complicated Meckel diverticulum. Heterotopic gastric mucosa may lead to diverticular gastrointestinal bleeding in adults and children when ileal ulceration results from acid secretion [95], [96]; almost all bleeding diverticula contain gastric mucosa. [97], [98] Although the data are conflicting, some studies have indicated that *Helicobacter pylori* may rarely colonize the diverticular gastric mucosa and is associated with gastritis in this site. [99], [100] Heterotopic tissue is also associated with a modestly increased risk for other complications, including small bowel obstruction and diverticular inflammation. [95], [101] The risk for complications dramatically decreases with age, and most adults with a Meckel diverticulum remain asymptomatic. [102] Complications develop in approximately 2% of all adults with a Meckel diverticulum. [95], [96], [102] The complications of Meckel diverticulum include bleeding, intestinal obstruction, diverticulitis, perforation, and carcinoma. Obstruction is caused by intussusception of the diverticulum into adjacent bowel; volvulus around or herniation into a fibrous band; entrapment in inguinal, femoral, or umbilical hernia sacs (Littré hernia); or inflammation and scarring leading to blockage around the diverticular neck and adjacent ileum. The frequency of specific complications varies in adult and pediatric patients. The most common complications in children are gastrointestinal bleeding, most often occurring in infancy and early childhood (before 5 years of age), [97], [103] and intestinal obstruction. In adults, intestinal obstruction is by far the most frequent complication, and gastrointestinal bleeding is relatively uncommon. [95], [96] Whereas adults most often describe melena, children usually present with painless, multiple and rapid, bright or dark red bowel movements. More unusual complications in adults include the development of carcinomas such as carcinoids, sarcomas, and rarely adenocarcinomas. [104] Carcinoid tumors are typically small, with biologic characteristics resembling those of jejunoileal rather than appendiceal carcinoids (e.g., immunohistochemical staining and metastatic potential). [105] Patients with carcinoid of a Meckel diverticulum are generally older (in their sixth decade) and frequently asymptomatic. Tumors larger than 5 mm in diameter have considerable metastatic potential. [105] Other complications include enteroliths, which may become lodged in the diverticulum and cause abdominal pain, vomiting, bleeding, and obstruction.

Diagnosis The diagnosis of Meckel diverticulum remains a challenge. [106], [107] and [108] Sodium pertechnetate Tc 99m radionuclide scanning is particularly useful in children. The ^{99m}Tc isotope is taken up by normal stomach tissue and by ectopic gastric mucosa in the Meckel diverticulum. Surface mucus cells from the intestine as well as the stomach accumulate and secrete this anion. [109] To enhance the sensitivity of this test, cimetidine may be administered to decrease anion secretion from the gastric mucosa. [110] Pentagastrin may also be useful, enhancing anion uptake by a poorly understood mechanism. [111] The major drawback of this detection method is that heterotopic gastric mucosa must be present in the diverticulum if a true-positive result is to be obtained. In children with lower gastrointestinal bleeding from a Meckel diverticulum, this test is sensitive and specific because almost all bleeding diverticula contain gastric mucosa, but in adults, the false-positive and false-negative rates of the method are high, even in patients with bleeding. [106], [112] Crohn's disease and other inflammatory disorders lead to false-positive scans. In children, a scan for Meckel diverticulum is often followed by a technetium or stannous pyrophosphate red blood cell scan to localize the site of bleeding definitively. Small bowel follow-through is usually not useful because the diverticulum may not fill with barium and is also rapidly emptied. Enteroclysis examinations improve the sensitivity of barium studies because the contrast material under increased pressure better fills the diverticulum. Angiography can localize the source of hemorrhage and may also demonstrate the vitelline artery and its embryonic branches. This vessel arises from a distal branch of the superior mesenteric artery and ends in a characteristic blush of tortuous small vessels. Frequently, the vitelline artery involutes, and the diverticulum is directly supplied by branches from the superior mesenteric artery.

Management The treatment of Meckel diverticulum complicated by bleeding, obstruction, or perforation is surgical. Diverticulectomy is performed, possibly with concurrent ileal resection if the adjacent small bowel is ulcerated, inflamed, or obstructed. These operations can be complicated, and postoperative morbidity occurs in up to 6% of all cases. [95], [113], [114] Laparoscopic removal has been reported. [115], [116] and [117] The management of asymptomatic diverticula is controversial. [108] Because of the low risk for complications of Meckel diverticulum in adults, some have not recommended prophylactic removal. [95], [102], [118] However, others prefer to resect asymptomatic diverticula that are highly likely to cause complications, such as large (>2 cm) diverticula; lesions associated with an omphalomesenteric band, which are at risk for volvulus and obstruction; and lesions containing a palpable mass, which may represent tumor or ectopic mucosa. [98] Incidental diverticulectomy is safe and has been suggested for all patients. [113], [114], [119]

Duplications

Duplications of the gastrointestinal tract are rare, congenital cystic anomalies attached to the intestinal mesenteric border (Fig. 72-9). They may be spherical or tubular in shape. They are usually lined by gut mucosa, but like Meckel diverticula, they may contain heterotopic gastric mucosa or less commonly pancreatic, squamous, thyroid, or bronchial epithelium as well as lymphoid aggregates. [120] They share a blood supply with the associated native intestine and may also communicate lumen to lumen. Duplications may occur anywhere along the gastrointestinal tract from mouth to anus. Those of small bowel origin are most commonly found in the ileum. [120] The embryonic origin of gut duplications is unknown. Postulated mechanisms include aberrant recanalization of the gut lumen during morphogenesis, creating two attached yet distinct gut structures; abnormal notochord-midgut interactions; intrauterine ischemic events; and aborted (partial) twinning. [121], [122] Intestinal atresia may be associated with duplications, supporting a possible vascular etiology.

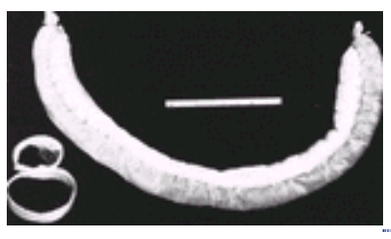

FIGURE 72-9. Tubular duplication of the terminal ileum in a 7-month-old boy. The duplication, lying on the mesenteric border of the bowel, was 29 cm long and communicated with the adjoining bowel near its distal end. The duplication, which is the smaller of the two cross sections, was lined largely by gastric mucosa, and an ulcer was within it, near its point of communication with the bowel. An island of aberrant pancreas was also in its wall. (From Arey JB, Valdes-Dapena M. Embryology and developmental disorders. In: Ming S, Goldman H, eds. Pathology of the gastrointestinal tract. Philadelphia: WB Saunders, 1992:113.)

Signs, Symptoms, and Complications In most patients, duplications are diagnosed in infancy or early childhood, but duplications are occasionally newly discovered in an adult. The frequency of symptoms varies inversely with age. Pediatric patients most commonly present with abdominal pain, obstructive symptoms (e.g., nausea, vomiting, pain), and hemorrhage. [121], [123] Obstruction may result from a mass effect, from volvulus produced by a large lesion, or more rarely from inflammation of the duplication. Much less frequently, these lesions are asymptomatic and are discovered

incidentally. In adults, the evaluation of relatively mild abdominal complaints by computed tomography (CT) or ultrasonography may lead to detection, [124] and ultrasonography has been used for prenatal detection. [125] Intussusception may be precipitated if a duplicated gut acts as a lead point and invaginates into normal intestine. Gastrointestinal hemorrhage may result from ulceration of the duplicated or surrounding mucosa; very frequently, these lesions contain ectopic gastric mucosa that secretes acid and causes ulceration. A rare complication in adults is the development of carcinoma in the duplication. [126] Carcinoid tumors, adenocarcinoma arising in ectopic gastric mucosa, and squamous cell carcinoma have been reported.

Diagnosis Small bowel duplications can be difficult to detect. Plain films may show a partially calcified wall of the duplication. Small bowel follow-through or enteroclysis barium examinations may reveal the duplication if it communicates with the gut lumen. Cysts that contain gastric mucosa may be detected by ^{99m}Tc abdominal scintigraphy, [127] which specifically delineates gastric surface mucus cells (see section " Meckel Diverticulum "). Ultrasonography (effective for prenatal diagnosis) or CT can provide clues to the diagnosis by revealing the presence of a cystic mass, and these tests are also valuable for detecting rare carcinomas, which appear as solid tissue within the cyst. [126]

Management Duplications are treated surgically. If small, the lesions are easily resected with the adjacent small bowel. If the duplicated bowel is quite extensive and resection would require the removal of too much normal bowel, the duplication is opened and the mucosa removed, with the serosa and muscular layers left intact. Alternatively, the common wall can be excised. It is important to remove all mucosa because residual ectopic gastric mucosa can lead to recurrent hemorrhage. [122]

Intestinal Atresia and Stenosis

In intestinal atresia, the lumen of a segment of the gut is totally occluded. Stenosis is a narrowing of the gut lumen that leads to partial obstruction. Atresia is one of the most common causes of bowel obstruction in neonates. [128] Duodenal atresia and stenosis are frequently associated with Down syndrome, midgut malrotation, esophageal atresia, annular pancreas, imperforate anus, and intrauterine growth retardation (see Chapter 64). [129] Jejunoileal atresia is much less frequently associated with other congenital anomalies. Atresias are most often single but may be multiple and are found from esophagus to rectum. The reported incidence of small bowel atresias varies but is approximately 1 in 3000 to 1 in 5000 live births. [130] Several types of small intestinal atresias have been described (Fig. 72-10). [131] In type I atresia, a membranous septum or diaphragm of mucosa and submucosa obstructs the lumen, but the bowel wall and mesentery are intact. In type II, two blind bowel ends are connected by a fibrous cord, with intact mesentery in between. In type IIIa lesions, two blind bowel ends are separated by a mesenteric gap, and type IIIb is the "apple peel" atresia, characterized by proximal small bowel atresia and absence of the distal superior mesenteric artery (<5% of all atresias). [132] In this case, the bowel distal to the atresia is foreshortened and coiled and receives a retrograde blood supply from the ileocolic, right colic, or inferior mesenteric artery. Finally, in type IV, multiple atresias are present throughout the small bowel, creating the appearance of a "string of sausages"; they may be of type I, II, or IIIa.

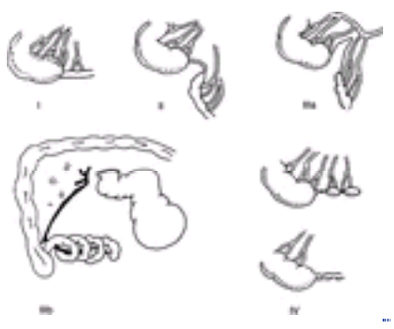

FIGURE 72-10. Classification of intestinal atresias. In *type I,* or membranous atresia, a membranous septum or diaphragm of mucosa and submucosa obstructs the lumen, but the bowel wall and mesentery are intact. In *type II,* two blind bowel ends are connected by a fibrous cord, with intact mesentery between them. In *type IIIa,* bowel lesions are separated by a mesenteric gap. *Type IIIb* is an "apple peel" atresia with features of proximal small bowel atresia, absence of the distal superior mesenteric artery, and coiled and foreshortened bowel. *Type IV* consists of multiple atresias of any type (I–IIIa). (From Smith GH, Glasson M. Intestinal atresia: factors affecting survival. Aust N Z J Surg 1989;59:151.)

Pathophysiology The pathogenesis of atresia and stenosis is unknown. Duodenal atresia is thought to be caused by a failure of recanalization of the intestinal lumen after the solid cord stage, which takes place at 4 to 8 weeks of gestation. [133] Mutations in the α_6- and β_4-integrin genes have been reported in families affected by junctional epidermolysis bullosa and duodenal or pyloric atresia. [134], [135] Ischemic intrauterine events such as midgut volvulus, arterial occlusion, intussusception, and localized volvulus secondary to meconium ileus or duplication have been implicated in the pathogenesis of small intestinal atresia, especially in single atresia and stenosis. [136] Atresia has been associated with intrauterine volvulus, gastroschisis, cardiac and other anomalies, [137] and cystic fibrosis. [137], [138] A retrospective review showed a more than 200-fold increased risk for cystic fibrosis in Caucasian infants with jejunoileal atresia. [139] Meconium ileus is thought to predispose the bowel to ischemia or cause volvulus as a consequence of hyperperistalsis. Pathological examination of atretic segments resected from neonates with multiple intestinal atresias suggests a role for either ischemia or a defect in recanalization of the gut lumen. [140] Rare familial cases of multiple intestinal atresias and apple peel (type IIIb) atresias have been reported. [128], [140], [141] An autosomal recessive inheritance pattern has been suggested, [141] but variability in the types of atresia found within families and discordance in a set of monozygotic twins suggest a more complex genetic transmission. [132] Other factors implicated in the pathogenesis of atresia and stenosis are maternal ergotamine use [142] and fetal exposure to methylene blue, which was formerly used as a marker during amniocentesis of twin pregnancies to ensure that both sacs had been sampled. [143] Multiple intestinal atresias have also been reported to be associated with neonatal immunodeficiency states. [144], [145]

Clinical Presentation Polyhydramnios is frequently detected in proximal gastrointestinal atresia, but the amniotic fluid may be normal in distal atresia. [136] Neonates most commonly present with signs and symptoms of obstruction within hours to 3 days after birth. Bilious vomiting early after birth is a characteristic symptom of proximal atresia, whereas abdominal distention occasionally associated with visible bowel loops, later vomiting, and a failure to pass meconium are frequent presenting complaints of distal lesions. High atresias of the jejunum and duodenum are also associated with jaundice. The course of infants who have intestinal stenosis without atresia may be much more indolent because the obstruction is usually partial. The diagnosis may therefore be delayed.

Diagnosis Polyhydramnios is an indication for ultrasonography, which may identify the obstructing defect. [125] Dilated loops of bowel are frequently detected; the presence of fetal ascites and extralumenal calcifications may indicate aseptic perforation of the bowel, with meconium peritonitis. The intralumenal calcifications found in type IV atresias may also be seen. After birth, routine abdominal radiography may demonstrate multiple air-fluid levels throughout the small bowel or dilated bowel proximal to the obstruction with an absence of gas distally. A double bubble sign on abdominal radiography or ultrasonography is classical for duodenal atresia. Barium enema shows an unused microcolon. The anatomic defect should always be definitively identified by plain films and cautious contrast radiography before surgical intervention is attempted. It is also important to identify all atretic sites, with the risk for multiple atresias kept in mind. Important in the differential diagnosis of neonatal bowel obstruction are Hirschsprung disease, malrotation, meconium ileus associated with cystic fibrosis, duplications, Meckel diverticulum, and mesenteric bands. [146] Barium enema is recommended to rule out Hirschsprung disease and malrotation with volvulus and to identify other atresias in the bowel distal to the primary obstruction.

Treatment and Prognosis Initial therapy consists of intravenous hydration, correction of electrolytes, and nasogastric suction to remove accumulated fluid and decompress the bowel. Surgical resection of atretic small intestine is the primary treatment, which may be challenging because bowel preservation is critical and dilation of the small bowel proximal to the obstruction makes anastomosis difficult. Several different surgical procedures have been developed, including tapering enteroplasty and the creation of an ileostomy. [137], [146] Patients with type IIIb and type IV atresias often require extensive resective surgery, which results in short bowel syndrome and a poor prognosis. All patients after surgery are placed on total parenteral nutrition and monitored for a return of normal bowel function as the diet is slowly advanced. A central venous catheter should be placed early in the course of the disease. Patients with short bowel syndrome frequently require prolonged parenteral nutrition. Isolated case reports of the use of growth hormone in ultrashort bowel syndrome suggest some beneficial effects. [137], [147] The morbidity and mortality rates in infants have dramatically decreased since the 1950s. Postoperative survival is approximately 90% to 95%. [133], [136] Enhanced survival is a result of improved management of the nutritional and pulmonary status. However, overall survival has remained at approximately 84% to 88%. [137] Factors adversely affecting the prognosis include the presence of other congenital anomalies (especially cardiac), chronic pulmonary disease, or pulmonary aspiration. [133], [135]

Malrotation

Description and Pathophysiology Alterations in the normal rotation and fixation of the gut during embryogenesis result in a series of anomalies with various clinical manifestations. Malrotation or incomplete rotation is the most common disorder of rotation and fixation; it occurs when the normal 270° bowel rotation is not completed. As a result, the cecum may lie in the subpyloric region or may be in a subhepatic location. The small bowel is not attached by a broad mesentery but remains suspended from a narrow vascular pedicle. Peritoneal bands (Ladd bands) may pass from the cecum across the duodenum to the right upper quadrant or may attach to the duodenum. The two major complications of malrotation are volvulus, caused by free rotation of the midgut around the vascular pedicle, and duodenal obstruction secondary to the Ladd bands. In nonrotation, the embryonic midgut loop does not rotate and the caudal limb of the loop reenters the abdominal cavity first.

Subsequently, the small intestine (jejunum and ileum) lies on the right side of the abdomen and the colon is entirely on the left. The cecum is usually located in the left iliac fossa. Frequently, the broad attachment of the small bowel mesentery does not develop, and the small bowel remains suspended by a narrow pedicle, at risk for volvulus. [129], [148] In reversed rotation, clockwise instead of counterclockwise rotation of the gut leads to reentry of the colon into the abdomen first. The position of the colon is then posterior to the superior mesenteric artery and the duodenum. The placement of the duodenum is anterior to the superior mesenteric artery. The small bowel mesentery passes in front of the transverse colon, so that a mesenteric tunnel forms that causes colonic compression and obstruction. Finally, failure of the cecum to descend into its normal position in the right lower quadrant may lead to mobile cecum; the cecum remains in the right upper quadrant and is unfixed posteriorly, predisposed to cecal volvulus. The ileum may similarly be unfixed and susceptible to volvulus.

Clinical Manifestations In approximately 50% to 80% of cases of midgut malrotation, symptoms develop in infancy. Related concurrent anomalies are biliary atresia and congenital heart disease. Intestinal atresia and stenosis may result from malrotation, and omphalocele and diaphragmatic hernia may lead to malrotation secondary to abnormal placement of the bowel during rotation. In adults, malrotation is sometimes associated with absence of the superior mesenteric vein and extrahepatic biliary anomalies. [149] The most severe complications of malrotation are small bowel obstruction and volvulus, which cause recurrent bilious vomiting, passage of bloody stools or acute onset of constipation, and bowel loop distention. In patients with Ladd bands, symptoms of duodenal obstruction may develop. Patients from 1 month of age through adolescence may have symptoms that are more varied and indolent, including intermittent vomiting, failure to thrive, and recurrent abdominal pain. [150] Adults may be asymptomatic for many years [151] and then present with midgut volvulus causing abdominal pain, bloody stools, and distention. [152] Alternatively, in adult patients with a long history of recurrent abdominal pain with nausea and vomiting since childhood, the obstruction or volvulus may never have been diagnosed because it was transient and resolved before presentation. [149]

Diagnosis The diagnosis may be challenging in the older child and adult. [153] Plain films may reveal evidence of duodenal or small bowel obstruction. A classic double bubble sign may be seen, indicating duodenal obstruction. However, early in the course of midgut volvulus, plain radiographs may be unrevealing, and children with bilious vomiting should undergo a contrast study to rule out volvulus. [154] Contrast radiographic studies may demonstrate anomalous small bowel, ligament of Treitz, and cecal locations. In adults with midgut volvulus, upper gastrointestinal contrast series may reveal a dilated stomach and duodenum with a typical “corkscrew” appearance of the barium in the twisted duodenum and proximal jejunum. [155] CT may show reversed positions of the superior mesenteric artery and vein. [156]

Treatment The surgical correction of malrotation (incomplete rotation) in symptomatic patients includes relieving the obstruction caused by Ladd peritoneal bands, freeing the duodenum, reducing midgut volvulus, and broadening the mesentery to prevent recurrent rotation of the bowel around a narrow mesentery. In the Ladd procedure, the bowel is placed in the position of nonrotation (small bowel on the right side of the abdomen and colon on the left). Appendectomy is performed because the cecum is incorrectly located. Variations of this operation are used to correct nonrotation and the very rare reversed rotation. In most patients, bowel function returns to normal. However, some children with recurrent and prolonged symptoms of nausea, vomiting, and pain preoperatively do not fare as well postoperatively, possibly because of persistent dysmotility syndromes associated with malrotation or damage to the small bowel resulting from long-standing, indolent obstruction. [157]

Gastroschisis and Omphalocele

Description and Embryonic Origin Although gastroschisis and omphalocele both result from abdominal wall defects, these rare disorders are distinct entities (see Chapter 121). In omphalocele, the abdominal viscera herniate through the umbilical ring and persist outside the body, covered by a membranous sac but not by skin. In gastroschisis, massive evisceration of the intestines occurs through a small defect in the abdominal wall, usually to the right of the closed umbilical ring. The bowel has no membranous covering, has been exposed to amniotic fluid in utero, and is often matted, thickened, foreshortened, and covered with adhesions. It has been hypothesized that omphalocele is caused by a failure of embryonic folding at the level of the lateral folds or persistence of the body stalk. [158], [159] Gastroschisis may be caused by vascular disruption in utero, leading to failure of differentiation of the somatopleural mesenchyme, [160] or later between the time of herniation into the umbilical cord and fixation, or by disruption of the right omphalomesenteric artery. The defect is thought to occur between the fifth and tenth weeks of gestation, but perinatal insults have also been suggested in patients in whom gastroschisis was not detected sonographically. [158], [161], [162] Other congenital anomalies that occur in association with omphalocele are chromosomal; about one third of cases of omphalocele with multiple anomalies have trisomy 13, trisomy 18, or the Beckwith-Wiedemann syndrome, which is characterized by macroglossia, large infant size, and visceromegaly. Gastroschisis is associated with intestinal anomalies, including atresia and malrotation, vascular disruptions, and renal and gall bladder agenesis. [158] Several mouse models of gastroschisis have been described. [163], [164] and [165] In mice that are null for the bone morphogenetic protein 1 (BMP-1) gene, the ALX-4 gene, or the aortic carboxypeptidase-like protein gene, gastroschisis develops with early mortality. Alx-4 is a homeodomain transcription factor. Both BMP-1 and the aortic carboxypeptidase-like protein appear to have important functions in the extracellular matrix. The relevance of these gene defects to human disease is unclear; a mutational analysis of the BMP-1 gene in human patients with gastroschisis was unrevealing. [166]

Prenatal Diagnosis Elevated levels of maternal serum a-fetoprotein are associated with ventral abdominal wall defects. Gastroschisis is detected with greater sensitivity than omphalocele. [159] Improvements in the accuracy of prenatal ultrasonography have led to more frequent detection. [167] One of the major advantages of prenatal diagnosis is that the obstetrician is alerted, so that at the time of delivery, the mother can be taken to a tertiary care center where appropriate surgical and neonatal intensive care support is available. [159] The role of preterm delivery to minimize intestinal damage is still unclear, and the factors that determine the need for this intervention are still being defined. [168] Recommendations for the appropriate mode of delivery (e.g., trial of labor versus elective cesarean section) are presently being debated, [169], [170] and [171] although it is clear that the rate of abdominal delivery is high because of peripartum complications. [172]

Treatment Surgical closure of omphalocele and gastroschisis is attempted shortly after birth. Primary closure may be possible with the use of retention sutures and stretching the abdominal wall. If this cannot be achieved, a silo or Silastic sac can be used with successive compression to reduce the herniation further. The decision to use a silo and a staged procedure may be based on intraoperative bladder or intragastric pressure measurements that reflect the intra-abdominal pressure. [168], [173] Careful regulation of the intra-abdominal pressure is critical for successful repair; high pressures that lead to respiratory distress and intestinal and renal ischemia, the major causes of morbidity and mortality, must be avoided. The material is placed over the herniated bowel or sac and reduced manually and serially sutured to reintroduce the bowel into the abdominal cavity. A comparison of primary emergent closure versus closure following reduction with a spring-loaded silo (for gastroschisis) suggested that silos improve the overall outcome. [174] Because almost all children have bowel hypomotility, total parenteral nutrition is recommended early in the course of the illness. Advances in surgical correction have greatly improved the prognosis of patients with gastroschisis, despite the fact that the bowel is usually damaged and slow to return to normal function. Survival rates now range from 70% to more than 90%. [169], [175], [176] The presence of necrotizing enterocolitis and other anomalies (affecting other organs) or associated intestinal conditions (e.g., atresias, perforations, necrotic segments, volvulus) affects mortality rates. [169], [177] In the absence of severe associated anomalies, the immediate survival and long-term outcome of patients with omphalocele have also improved in the past several years. [178], [179]

STRUCTURAL ANOMALIES

Volvulus

A volvulus is an abnormal twisting of the intestine around the axis of its own mesentery, resulting in obstruction of the more proximal bowel. Twisting of the mesentery may involve the mesenteric vessels and so make the involved loop particularly susceptible to strangulation and gangrene, with resulting perforation, peritonitis, and sepsis. In contrast to colonic volvulus, particularly of the cecum and sigmoid colon, small bowel volvulus is relatively rare in the United States and most of Europe. [180] It occurs more frequently in parts of Africa, the Middle East, and the Indian subcontinent. [180], [181] and [182] Volvulus in these countries occurs in the absence of anatomic abnormalities and is probably related to dietary factors. It has been postulated that ingesting large amounts of bulky foods after fasting may predispose to torsion of the small bowel loops. In the United States, small bowel volvulus is usually caused by a preexisting defect, such as an anomaly of rotation and fixation, postoperative adhesion, or congenital bands. [183]

Clinical Presentation and Diagnosis Patients present with symptoms of small bowel obstruction and an acute abdomen. Abdominal pain, nausea, and vomiting are almost always present [180], [184]; the severity of the pain may be out of proportion to the physical findings. Signs include abdominal distention, rebound, guarding and rigidity, and occasionally a palpable abdominal mass. Plain abdominal radiographs taken in supine and upright positions may demonstrate distended bowel with air-fluid levels, consistent with obstruction. Perforation may be indicated by the presence of free air. Barium studies can be useful. A typical corkscrew-like appearance of the barium in the distorted duodenum and jejunum is diagnostic. Angiography may reveal twisting of the branches of the superior mesenteric artery.

Therapy and Outcome The treatment of small bowel volvulus is surgical. Ischemic or gangrenous loops of bowel should be resected, although derotation of the bowel may be sufficient therapy in itself. Vascular compromise of the small bowel with subsequent gangrene is common and leads to increased morbidity and mortality postoperatively. Rapid recognition of volvulus and prompt surgical intervention are the keys to decreasing the fatality rate associated with this condition.

Intussusception

Description and Pathophysiology Intussusception occurs when a segment of bowel invaginates, or telescopes, into adjacent distal bowel, leading to obstruction and possible ischemic injury. The incidence, causes, clinical presentation, and therapy of intestinal intussusception are different in adult and pediatric patients. Intestinal intussusception is one of the most common causes of small bowel obstruction in children younger than 2 years of age, but it is an unusual cause of bowel obstruction in adults. Most pediatric cases occur in children younger than 5 years of age. [185] Pediatric

intussusception is most often idiopathic but may be associated with a pathological lead point in 8% to 12% of cases, [186], [187] including Meckel diverticulum; a variety of benign and malignant tumors, such as polyps, leiomyomas, and lymphomas; duplications; and Henoch-Schönlein purpura, in which an intramural hematoma acts as a lead point. An association between rotavirus vaccination and intussusception has been described, [188], [189] perhaps secondary to a lead point of vaccine-induced lymphoid hyperplasia. In idiopathic intussusception, an association with prominent Peyer patches and enlarged mesenteric lymph nodes has been observed. In children, ileocolic intussusceptions are most common, followed by ileoileocolic, cecocolic, and, much less frequently, ileoileal involvement. In adults in the Western world, small bowel intussusception occurs rarely, accounting for approximately 5% of all cases of intestinal obstruction. [190] A causative factor can be identified in more than 90% of adult patients, [191] whereas it cannot in children. Small intestinal intussusception may be precipitated by tumors, including leiomyomas, neurofibromas, lipomas, lymphomas, small bowel adenomatous polyps, and metastatic tumors with or without peritoneal carcinomatosis. Other causes include Meckel diverticulum or other diverticular disease and celiac disease with chronically dilated flaccid bowel. Postoperative intussusception may result from adhesions, or intussusception may follow trauma. [192] Jejunogastric intussusception may occur after Billroth II surgery, and bypassed bowel may become intussuscepted after jejunoileal bypass. [191] Patients with acquired immunodeficiency syndrome and Kaposi sarcoma or diffuse enteritis are also at risk. [193] Pregnancy and the use of long intestinal or cantor tubes are other predisposing factors.

Signs and Symptoms The typical pediatric patient is a well-nourished, previously healthy child between the ages of 5 months and 5 years. The peak presenting age is 3 to 11 months. [194] Classical signs and symptoms include the acute onset of intermittent abdominal pain, vomiting, and hematochezia. A palpable abdominal mass, diarrhea, and somnolence are other frequent findings. [186], [187] In older children, these diagnostic signs and symptoms are often not present. [185], [195] In adults, the clinical picture may be confusing. Abdominal pain is almost always present [196] but is often low-grade and chronic; patients may present after several episodes have spontaneously resolved. [190], [197] A partial or complete small bowel obstruction may be present, and an abdominal mass is often palpable. Nausea and vomiting are particularly associated with small bowel compared with large bowel intussusception. Weight loss may also occur in patients with chronic, indolent symptoms.

Diagnosis and Therapy

Pediatric patients. In children, an air or water-soluble contrast barium enema is performed because the ileocecal region is so frequently involved. [187] Contrast enemas demonstrate the location of the intussusception and are often successful in reducing it. Air enemas are also safe and effective in reducing intussusceptions. [154], [198], [199] and [200] The enema is usually administered with a surgeon in attendance in case of perforation or failure to reduce. Sonography may be used to diagnose intussusception and to monitor reduction. [200] In extremely ill patients with peritonitis, perforation, or shock, enema reduction is contraindicated. Radiologic reduction is successful in 50% to 90% of cases. [200] If it is not, the patient is taken to laparotomy for manual reduction. Resection is performed if ischemia or gangrene of the bowel is present. A careful search is made for a possible pathological lead point. Plain films may reveal a crescent of gas capping the intussusceptum, outlining its leading edge, or a target sign, consisting of two concentric radiolucent curvilinear lines outlining the intussusception. [201] A gasless area may also be identified, corresponding with the soft tissue mass of the intussusception. Ultrasonography may show a classical target or doughnut sign, characterized by multiple concentric rings of sonolucency alternating with one or two echogenic foci. The edematous outer and inner walls of the intussusception create two hypoechoic areas ringing the hyperechoic lumenal mucosa. [202] CT may similarly be useful, but it is usually avoided in children. Upper gastrointestinal contrast series may show proximal intestinal dilatation and a “bird’s beak” at the site of obstruction but is contraindicated if perforation or peritonitis is suspected.

Adult patients. Intussusception is diagnosed and treated differently in adult patients because its location and causes are different from those in children. Most intussusceptions in adults are in the small bowel, although they may also occur in the colon. [203] Therefore, a combination of plain film, upper gastrointestinal series, barium enema, and CT or ultrasonography is used in adult patients. Because of the often puzzling presentation of intussusception in this age group, CT is frequently performed. A mass of alternating high and low attenuation may be seen as a target, sausage-shaped, or bilobed lesion. [204] Mesenteric fat appears as areas of low attenuation, whereas the bowel wall itself appears as an area of high attenuation. Thickened bowel loops and an intralumenal soft tissue mass may be seen. However, this technique is not sensitive enough to determine the nature of the pathological lead point. Because a pathological lesion is found so frequently, treatment in adults consists of surgical intervention with bowel resection. Manual reduction alone may be pursued only if it is certain that no other lesions are present. [196] With present diagnostic techniques, however, it is unlikely that a tumor or another anatomic cause can be ruled out preoperatively. Therefore, manual reduction of intussusception in adults is usually not recommended because manipulation can lead to intralumenal or intravenous tumor seeding. [195], [205] Colonic intussusception is never treated with manual reduction because of the extremely high likelihood of malignancy. [197]

Lymphangiectasia

Description and Pathophysiology Intestinal lymphangiectasia is characterized by the obstruction of lymph drainage from the small intestine and the dilation of lacteals and other intestinal lymphatics, such as those in the serosa and mesentery, depending on the level of obstruction. As a result of obstruction and increased pressure in the intestinal lymphatics, the absorption of chylomicrons and fat-soluble vitamins such as vitamin D is impaired, the reentry of intestinal lymphocytes into the peripheral circulation is impeded, and excessive amounts of intestinal lymph “leak” into the intestinal lumen. Lymphenteric fistulae may form, and intestinal lymph containing chylomicrons, protein, and lymphocytes drains directly into the intestinal lumen. Chylomicrons are sequestered in the lamina propria as well as in the distended lymphatics. Blockage of serosal and mesenteric lymphatics may lead to chylous ascites, and blockage of the thoracic duct to chylous pleural effusions. Intestinal lymphangiectasia may occur as a primary congenital disorder or may be secondary to a disease that blocks the intestinal lymph drainage at some level. Causes of secondary lymphangiectasia include extensive abdominal or retroperitoneal carcinoma or lymphoma, retroperitoneal fibrosis, chronic pancreatitis, mesenteric tuberculosis or sarcoidosis, [206] Crohn’s disease, Whipple disease, scleroderma, [207] celiac disease, [208] constrictive pericarditis, [209] systemic lupus erythematosus, [210] and chronic congestive heart failure. Congenital intestinal lymphangiectasia (Milroy disease) results from a malformation of the lymphatics that often affects many areas of the body.

Clinical Presentation Patients present with varying degrees of steatorrhea and malabsorption, lymphocytopenia (especially of T lymphocytes), marked hypogammaglobulinemia with impaired cell-mediated immunity, and prominent manifestations of protein-losing enteropathy. They often have edema and low serum protein levels, the reduction in serum albumin usually being the most pronounced and the only one of clinical significance. Patients with congenital disease present at any time from birth to adulthood, often with asymmetric edema of an extremity caused by peripheral lymphatic obstruction. They may also present, as do the secondary cases, with more diffuse, symmetric edema, usually the result of marked hypoproteinemia. Despite lymphocytopenia and impaired delayed hypersensitivity reactions, opportunistic infections are not common. However, infections with atypical mycobacteria, warts, and cellulitis have been reported. [211] Gastrointestinal symptoms are usually not prominent, but some patients may have diarrhea, abdominal pain, distention, nausea and vomiting, and occasionally gastrointestinal bleeding.

Diagnosis Protein-losing enteropathy should be suspected in any patient with unexplained hypoalbuminemia, and intestinal lymphangiectasia should be considered if lymphocytopenia and steatorrhea are also present. Asymmetric lymphedema, especially dating from infancy or childhood, should suggest congenital (Milroy) disease. A diagnosis of lymphangiectasia rests on peroral jejunal biopsy demonstrating dilated lymphatic lacteals. Several specimens may be required to demonstrate the diagnostic findings because the lesions are often patchy and localized. [212] Endoscopy may reveal dilated lacteals that appear as white opaque spots or white-tipped villi, and nodular lesions and xanthomatous plaques have also been noted. [213], [214] These findings aid the endoscopist in selecting appropriate regions to sample. Other pathological findings include moderate villus blunting and mild to moderate inflammatory infiltration. [212] Other tests demonstrate protein-losing enteropathy by detecting excessive enteric loss of plasma proteins. The use of radiolabeled plasma proteins, such as ^{131}I-albumin, ^{51}Cr-albumin, and ^{51}Cr-chloride, has been generally replaced by the measurement of gastrointestinal clearance of a $_{1}$-antitrypsin. Double-contrast radiographs of the small bowel may reveal folds thickened by intestinal edema, nodular protrusions, and an absence of mucosal ulceration. [215] If secondary lymphangiectasia is suspected, appropriate tests such as CT of the abdomen should be performed to diagnose the underlying disease. The degree of malabsorption and nutritional deficiency may be assessed by quantifying stool fat and by measuring the prothrombin time, which is nonspecific, and the serum levels of calcium and carotene. In congenital cases, if necessary, the malformed, hypoplastic lymphatics can be demonstrated by lymphangiography. Pleural effusions and ascitic fluid may be tapped for conventional diagnostic studies and examined for chylomicrons.

Therapy The therapy for lymphangiectasia should be directed toward treating the pathophysiological consequences, and in the case of secondary lymphangiectasia, the underlying disease (e.g., lymphoma, tuberculosis, sarcoidosis, constrictive pericarditis) should be diagnosed and treated. Substituting medium-chain triglycerides for the usual long-chain triglycerides may reduce enteric protein loss, malabsorption, and diarrhea and may improve serum albumin levels. [216], [217] Medium-chain fatty acids are more water-soluble and may be more readily absorbed through portal venous channels than through the lymphatics. The concomitant reduction in dietary long-chain fat presumably reduces chylomicrons in obstructed lymphatics and thereby decreases the lymphatic pressure and rate of lymph loss. Anecdotal reports have demonstrated the efficacy of octreotide [218], [219] and [220] or antiplasmin therapy in a patient with increased plasma fibrinolytic activity, [221] yet it is probable that most patients do not respond to this treatment. [222] Peripheral edema can be minimized by postural drainage and the use of elastic stockings to reduce the risk for cellulitis and lymphangitis.

Celiac Artery Compression

The topic of celiac artery compression is covered in Chapter 131.

CHAPTER 73

Michael Camilleri

DYSMOTILITY OF THE SMALL INTESTINE AND COLON

The functions of intestinal and colonic smooth muscle are controlled mainly by the intrinsic and extrinsic nerves of the gastrointestinal tract and, to a lesser degree, by gastrointestinal hormones (see Chapter 11). Therefore, any abnormality of smooth muscle, intrinsic or extrinsic nerves, or gastrointestinal hormones can theoretically cause intestinal or colonic dysmotility. Abnormal circulating levels of gastrointestinal hormones have not definitely resulted in dysmotility; however, diarrhea in patients with carcinoid syndrome and irritable bowel syndrome is associated with elevated circulating levels of serotonin, and acceleration of small bowel and proximal colonic transit in these patients may at least partly reflect abnormal motor function.

The human small bowel and colon display widely divergent patterns of absorption, motility, and transit. Propulsive, peristaltic motility can move contents over long distances of the small intestine very rapidly, with efficiency approaching that of the esophagus. The small intestine functions to facilitate emptying from the stomach, the mixing of chyme with digestive enzymes and bile, and ultimately delivery of residue to the colon. The ileum possesses a specialized type of contraction (giant migrating contraction) that sweeps unabsorbed residue to the colon and is analogous to the high-amplitude colonic contractions. Intermittent emptying ensures that enough time is available for salvage of the remaining nutrients in the small intestine. The small intestine and colon also set up feedback inhibitory reflexes (e.g., ileal brake) that retard proximal motor functions such as gastric emptying.

In contrast to the fundamental motor programs of other regions in the gut, those of the colon are under strong inhibitory influences, slowing colonic transit for fecal contents to solidify. The well-developed muscular wall of the colon exhibits basal tone, but at the same time, it has a pronounced propensity to relax. [1] As the organ responsible for the final stages of absorption and elimination, the colon is highly relevant to diarrhea and constipation. Colonic fermentation of dietary residues, mainly the “unavailable carbohydrates,” generates hydrogen, carbon dioxide, short-chain fatty acids, and methane through the anaerobic action of bacterial enzymes; [2] distention of the abdomen and flatulence can follow. Finally, for imagined, cultural, and psychosocial reasons, many populations focus on their habits of elimination. Constipation is thus a major concern of many persons, and disturbances of colonic motility figure prominently in the minds of patients and physicians.

Dysmotility of the small intestine and colon has a wide range of clinical manifestations, regardless of the underlying cause of the disorder. Patients at one end of the spectrum may be asymptomatic, and at the other, they may have chronic intestinal pseudoobstruction, a syndrome characterized by recurrent or chronic symptoms that suggest obstruction in the absence of structural occlusion of the lumen. Between the two extremes, patients may have dyspeptic symptoms, including intermittent postprandial epigastric or periumbilical abdominal pain, bloating, nausea, vomiting, and diarrhea.

In patients with small intestinal dysmotility, motor function in other parts of the gastrointestinal tract also is usually abnormal. In this chapter, we focus our initial discussion on the small intestine; motility disorders of the colon are manifested predominantly as constipation and megacolon. Motility disorders of other parts of the gastrointestinal tract are discussed in other chapters (see Chapter 59, Chapter 65, and Chapter 86).

EPIDEMIOLOGY

The prevalence of small intestinal dysmotility varies according to the underlying disease, and it seems to be less frequent than esophageal, gastric, or colonic dysmotility. The lack of sensitive techniques to evaluate small intestinal motility has made it difficult to estimate its prevalence. Since the early 1970s, several hereditary diseases with small intestinal dysmotility have been reported, including two groups of diseases associated with smooth muscle degeneration, termed *familial visceral myopathies (FVMs)* [3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15 /SUP>, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28 and 29 and *childhood visceral myopathies (CVMs),* [30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55 and 56 and a group of diseases associated with myenteric plexus degeneration, termed *familial visceral neuropathies (FVNs)*. [57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67 and 68 Only a small number of families have been reported, mostly Caucasian and less often African American [9] and Latino. [69] These rare familial disorders are discussed in the first part of this chapter.

Hirschsprung disease, the prototypical congenital colonic dysmotility, affects 1 in 5000 newborns. In contrast, constipation affects about 12% to 15% of the population, with epidemiologic data suggesting an equal split between functional constipation and evacuation disorders. [70, 71] A telephone survey of approximately 10,000 adults assessed the prevalence of constipation (defined as an inability to have spontaneous complete bowel movements). Consistent with the results of prior studies, the overall prevalence was approximately 15%; however, only 2% of the respondents were classified as having constipation-predominant irritable bowel syndrome (IBS). [72] In contrast to the results of prior studies, which suggested that constipation increases with advancing age, these data showed an inverse trend, with a slightly lower prevalence associated with increasing age. [72] Other studies of clinic patients have indicated an overlap in the diagnoses of constipation-predominant IBS and functional constipation despite the use of strict definitions. [73, 74]

NEURAL CONTROL OF SMALL INTESTINAL AND COLONIC MOTILITY

The enteric nervous system (ENS) is a vast network of ganglionated plexuses located in the wall of the gastrointestinal tract. [75, 76] Although several plexuses are identified anatomically, the most important, from a functional perspective, are the myenteric and submucosal plexuses. In association with the muscle layers, the networks of interstitial cells of Cajal are recognized as the likely pacemakers activating neuromuscular function. The ENS consists of approximately 100 million neurons in higher mammals, and this number is roughly equal to the number of neurons in the spinal cord (Fig. 73-1).

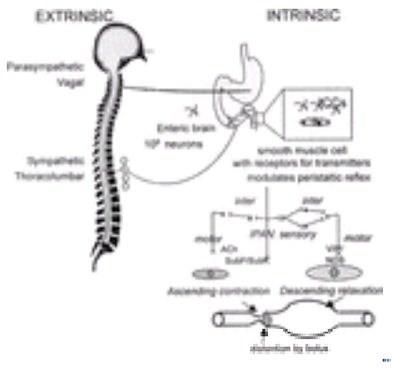

FIGURE 73-1. Extrinsic and enteric control of gut motility. The enteric nervous system controls stereotypical motor functions such as the migrating motor complex and the peristaltic reflex; enteric control is modulated by the extrinsic parasympathetic and sympathetic nerves, which respectively stimulate and inhibit nonsphincteric muscle. *ICC,* interstitial cells of Cajal; *IPAN,* intrinsic primary afferent neuron.

The ENS develops in utero as neural crest cells migrate to the developing alimentary canal. The migration of neural crest cells, and the sequence of innervation of different levels of the gut, are regulated by specific signaling molecules that include transcription factors (e.g., Mash-1), neurotrophic factors (e.g., the glial cell line–derived neurotrophic factor [GDNF] and its receptor subunits), and the neuregulin signaling system. These facilitate the growth, differentiation, and persistence of the migrating nerve cells once they arrive in the gut. Neuregulins are a large group of structurally related signaling proteins that are likely to have important roles in the development, maintenance, and repair of the nervous system and other selected tissues. Their receptors are the Erb-B protein tyrosine kinases, which are important in cell signaling.

Histological and electrophysiological studies [77], [78], [79] and [80] of the intestinal tract have characterized the properties of the neurons and transmitters mediating its functions, including the peristaltic reflex and the interactions between neurons and inflammatory cells. [81]

ONTOGENY OF THE ENTERIC NERVOUS SYSTEM

Migration

The ENS cells are derived from precursor cells from three axial levels of the neural crest. These include the vagal, [82] rostral-truncal, [83] and lumbosacral [82], [84] levels. The enteric neurons mainly arise from the vagal neural crest of the developing hindbrain and colonize the gut by migrating in a rostrocaudal direction. Vagal crest cells are not restricted to a particular intestinal region. Some enteric neurons arrive in the hindgut from the lumbosacral level via a caudorostral wave of colonization. Rarely, the migrating cells do not reach the entire gut; usually, the terminal portion of the bowel is affected, as in classical forms of Hirschsprung disease. Even more rarely, a zonal form of Hirschsprung disease may occur (Fig. 73-2 and Fig. 73-3), which is postulated to result from the incomplete caudorostral migration of neuroblasts during embryonal development. [85] The neural crest cells that migrate and colonize the gut become neuroblasts or neuronal support cells, glioblasts. However, *differentiation* into neurons and glial cells seems not to take place until they reach their final destinations in the gut. Movement through the gut mesenchyme, survival in the gut, and differentiation into mature cells are influenced by contacts of the precursor cells with the *microenvironment*.

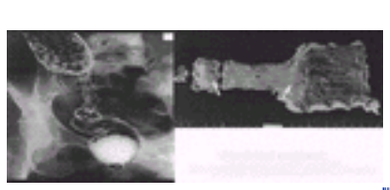

FIGURE 73-2. Zonal Hirschsprung disease in an adult: narrowed segment of the sigmoid colon on barium enema and gross pathological examination. (From ref. [85].)

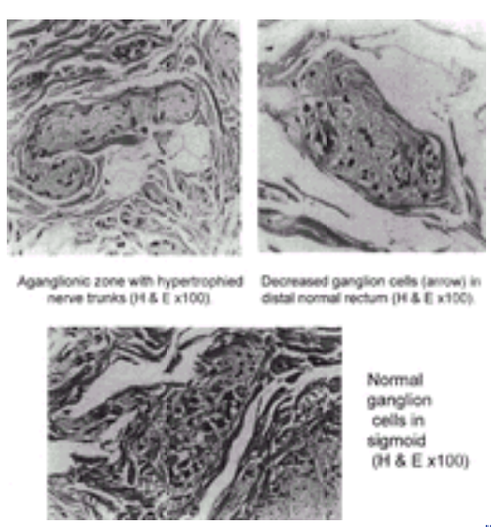

FIGURE 73-3. Zonal Hirschsprung disease in an adult: variation in the number of ganglion cells in different segments of the resected specimen. (From ref. [85].)

The microenvironment consists of other cells in the mesenchyme, neural crest–derived cells, and the extracellular matrix. The extracellular matrix components provide directional signals to migrating neural crest cells and, together with neighboring cells, provide signals for neural crest cell differentiation. For example, the appearance of neural crest cells in the gut is preceded by the expression of extracellular matrix molecules, [86] and other factors, such as GDNF, ensure the survival of committed neuroblasts. [87]

A subpopulation of sacral neural crest cells appears predetermined to function in the hindgut. These cells do not require the presence of vagus-derived enteric precursors to colonize the hindgut, nor are they capable of dramatically altering their proliferation or differentiation. [88] On the other hand, the environment at the sacral level allows neural crest cells from other levels of the axial region of the developing nervous system to enter the mesentery and gut mesenchyme. At least two environmental conditions at the sacral level enhance ventral migration of the sacral neural crest cells. First, sacral neural crest cells take a ventral rather than a medial-to-lateral path through the somites and arrive near the gut mesenchyme many hours *earlier* than their counterparts at the thoracic level. The window of opportunity to invade the mesenchyme of the mesentery and the gut is narrow, so their earlier arrival ensures that the sacral neural crest cells will gain access to the gut. Second, the gut endoderm is more dorsally situated (i.e., closer to the crest with its migrating cells) at the sacral level than at the thoracic level. As a result, sacral neural crest cells preferentially populate the colorectum. Moreover, a *barrier to migration* at the thoracic level prevents neural crest cells at that axial level from migrating to the gut. [89] The barrier also prevents lumbosacral crest neurons and glial cells from migrating to the nearby small intestinal tissue. [90]

Defects of the neural crest cells themselves or alterations of the microenvironment of the pathway through which the neural crest cells migrate may result in maldevelopment of the ENS. In humans, such disordered development results in congenital enteric neuromuscular diseases.

Differentiation of Neurons

Migrating crest cells are multipotent. [91] The gut wall is itself a critical site where *terminal differentiation of the enteric neurons and glia* occurs and determines what kind of nervous system arises within the bowel. [92] Enteric growth factor–receptor combinations influence differentiation. Combinations that enhance differentiation include the following: GDNF–GFR-1–RET, NT-3–Trk-C, and 5-HT–5-HT$_{2B}$. The RET protooncogene encodes a tyrosine kinase receptor necessary for the development of the ENS. A qualitatively different effect on nervous system development is shown by the peptide-receptor combination ET-3–ET-B, which *prevents the premature differentiation* of enteric neurons before colonization of the gastrointestinal tract has been completed.

The first molecule found to affect the development of enteric neurons and glia was neutrotrophin-3 (NT-3). [93] Crest-derived cells in the fetal bowel express tyrosine kinase C (Trk-C), the high-affinity receptor for NT-3. Overexpression of NT-3 in transgenic mice causes an increase in the size of developing ganglia and neurons in the myenteric plexus. [92] The ENS, however, is relatively normal in the bowel of mice following the knock-out of NT-3, [94] suggesting that NT-3 affects the development of only a subset of enteric neurons or glia. [91, 95]

Stimulation by GDNF is *absolutely* necessary for the survival of the vagal and sacral crest–derived cells that colonize the gut. If either GDNF [96, 97] or its signaling receptor RET [98] is knocked out in developing mice, the vagal and sacral domains of the bowel become totally aganglionic, and ganglia persist only in the small region of the gut that is colonized by cells from the truncal crest. GDNF potently promotes neuronal development in vitro [99, 100] and acts as a mitogen in early development, [99] greatly expanding the numbers of enteric crest–derived neural precursors. The initial GDNF-dependent crest-derived precursor that colonizes the bowel gives rise to multiple cell lineages that require particular growth or transcription factors. For example, the truncal crest depends on GDNF, not RET, [83] but it also requires Mash-1. From this GDNF- and Mash-1– *dependent* lineage, all the serotoninergic neurons (which develop early in ontogeny) and many excitatory and inhibitory motor neurons develop. Later, GDNF loses its ability to promote proliferation, and it acts only as a growth-differentiation factor for enteric neurons, not for glia. All enteric neurons that contain calcitonin gene–related peptide are derived from Mash-1– *independent* neurons and differentiate late in ontogeny, after the last serotoninergic neuron has become postmitotic (i.e., terminally differentiated).

Both crest-derived and non–crest-derived cells of the enteric mesenchyme also contain GFR-1, [99] a peripheral glycosylphosphoinositol-anchored molecule that binds GDNF and is necessary for the activation of RET. [101] Neural crest cells anchor GFR-1 to their plasma membranes (perhaps in a complex with RET), where GDNF can bind to it and ensure survival of the crest-derived cells that colonize most of the bowel. [92]

Enteric serotoninergic neurons appear so early that they coexist in primordial enteric ganglia with still-dividing neural precursors. Serotonin (5-HT) may be more than a neurotransmitter; the 5-HT$_{2B}$ receptor in the fetal bowel is regulated and optimal at specific times, so that 5-HT strongly promotes the development of neurons at specific times and affects the development of late-arising enteric neurons. [102]

These growth-differentiation factors affect virtually the entire bowel. The peptide endothelin-3 (ET-3) and its receptor, ET-B, play a critical *localized role* in ENS development. [103, 104] Examples of tyrosine kinase receptor mutations associated with specific genetic disorders, such as the multiple endocrine neoplasia (MEN) syndromes, are shown in Figure 73-4.

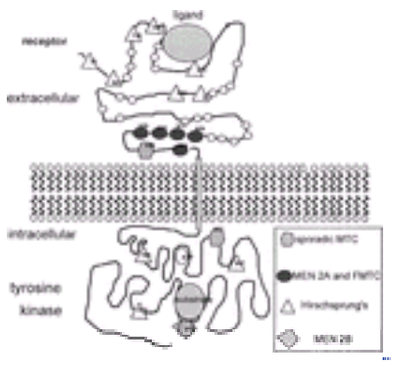

FIGURE 73-4. Tyrosine kinase receptor with examples of mutations associated with specific genetic disorders. *[F]MTC,* [familial] medullary carcinoma of the thyroid; *MEN,* multiple endocrine neoplasia. (Drawn from Edery P, Lyonnet S, Mulligan LM, et al. Mutations of the RET proto-oncogene in Hirschsprung's disease. Nature 1994;367:378.)

CHRONIC SMALL INTESTINAL PSEUDOOBSTRUCTION

For a review, the reader is directed to Di Lorenzo. [105]

Etiology

Table 73-1 lists the causes of small intestinal dysmotility. The mechanisms and manifestations of small intestinal dysmotility are shown in Figure 73-5. In general, small intestinal dysmotility may be secondary to neuropathy or myopathy. This is best distinguished by specialized histological and immunohistochemical study of the full thickness of the gastrointestinal wall, which is available at few centers. Smooth muscle is best studied by sectioning across the muscle fibers and using trichrome stain. [106] The best way to evaluate the myenteric plexus is still evolving. Silver staining of sections of the gastrointestinal wall taken parallel to its long axis, described by Smith [107] and by Schuffler and Jonak, [108] was state of the art but has been superseded by immunohistochemistry and confocal examination of neurons and a search for genetic markers (see below). Thus, a detailed description of phenotypes in familial cases is less pertinent than the more mechanistic or etiologic descriptions that appear below.

Primary Causes
Familial types
Familial visceral myopathies: types I, II (MINGE), III
Familial visceral neuropathies: types I, II
Childhood visceral myopathies: type I, type II (megacystis-microcolon-intestinal hypoperistalsis)
Nonfamilial or sporadic types
Visceral myopathies
Visceral neuropathies
Secondary Causes
Disease involving the intestinal smooth muscle
Collagen diseases (e.g., scleroderma, dermatomyositis, systemic lupus erythematosus, mixed connective tissue disease)
Muscular dystrophies (e.g., myotonic dystrophy, Duchenne muscular dystrophy)
Amyloidosis
Neurological diseases
Chagas disease, ganglioneuromatosis of the intestine, paraneoplastic neuropathy, Parkinson disease, spinal cord injury
Endocrine disorders
Diabetes mellitus, thyroid disease (i.e., hyperthyroidism, hypothyroidism), hypoparathyroidism
Pharmacological agents
Phenothiazines, tricyclic antidepressants, antiparkinsonian medications, ganglionic blockers, clonidine
Narcotics (morphine and meperidine)
Miscellaneous intestinal disorders
Celiac disease
Small intestinal diverticulosis
Radiation enteritis
Diffuse lymphoid infiltration of the small intestine
Jejunoileal bypass
After gastrointestinal viral infection

MNGIE, mitochondrial neurogastrointestinal encephalomyopathy.

TABLE 73-1 Causes of Small Intestinal Dysmotility

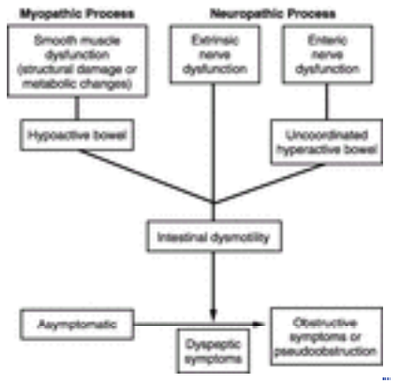

FIGURE 73-5. Mechanisms and manifestations of small intestinal dysmotility.

Primary Causes of Small Intestinal Dysmotility Primary dysmotilities are rare compared with secondary dysmotilities. They may be familial or sporadic.

Familial visceral myopathies. The FVMs are a group of genetic diseases characterized by the degeneration and fibrosis of smooth muscle of the gastrointestinal tract and, in a certain type, the urinary tract. At least three types of FVM have been reported based on gross lesions of the gastrointestinal tract and the pattern of inheritance (Table 73-2), and on documented mitochondrial DNA disorders in type II FVM, also called *oculogastrointestinal neuropathy*. On routine pathology, the histological features of these three types of FVM do not differ. [106] The involved areas show a characteristic change, consisting of degenerating muscle cells and fibrosis that may involve the full thickness of the muscularis propria but often is more prominent or limited to the external layer (Fig. 73-6). Degenerating muscle cells appear pale, poorly defined, and fragmented. As residual threadlike remnants become surrounded by collagen, the longitudinal and circular muscles take on a vacuolated appearance that is easily recognized microscopically (Fig. 73-7). Recognition of this change is greatly facilitated by the use of a trichrome stain. However, special histochemical stains may identify giant mitochondria as ragged red fibers in skeletal muscle or affected bowel; cytochemistry can also identify mitochondrial enzyme deficiencies in mitochondrial neurogastrointestinal encephalomyopathy (MNGIE), or type II FVM. Because several advances in our understanding of this condition have been made, a further detailed discussion of MNGIE is warranted.

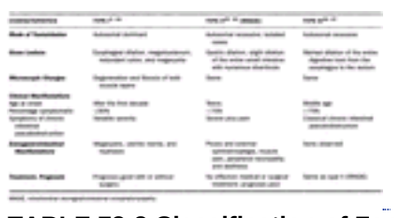

TABLE 73-2 Classification of Familial Visceral Myopathies

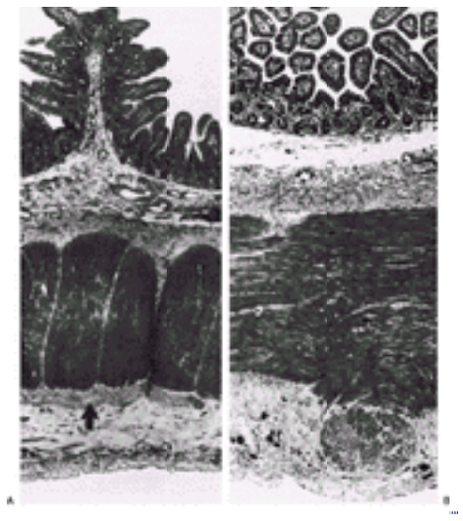

FIGURE 73-6. A: Longitudinal section of jejunum from a patient with familial visceral myopathy shows normal circular muscle layer and a prominent neural bundle (*arrow*). Scattered muscle fibers and collagen are observed in the longitudinal layer. Trichrome stain; original magnification ×40. **B:** Cross section of jejunum from area depicted in **A.** The outer muscle layer contains one large bundle of preserved smooth muscle fibers and scattered individual fibers throughout the collagen elsewhere. Trichrome stain; original magnification ×40. (From ref. [106].)

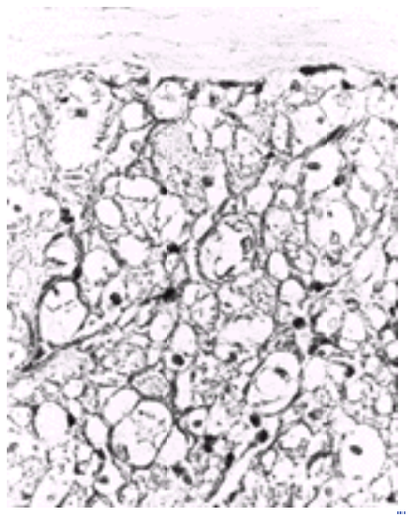

FIGURE 73-7. The characteristic vacuolar change, with collagen fibers encircling spaces filled by fragmented muscle cells, in a patient with familial visceral myopathy. Trichrome stain; original magnification ×470. (From ref. [106].)

Mitochondrial DNA and myopathies. These diverse diseases are characterized by mitochondrial abnormalities in skeletal muscle, which show “ragged red fibers” on a Gomori trichrome stain. The metabolic abnormality involves cells in other tissues: central and peripheral nervous system, gut, heart, kidney, liver, thyroid, pancreas, and bone marrow. The enzymes in the respiratory chain of mitochondria are encoded by nuclear and mitochondrial DNA. The disorders may be sporadic or inherited in an autosomal dominant, autosomal recessive, or X-linked pattern; maternal inheritance is more frequent. Mitochondria are involved in the production of energy (ATP), the generation of reactive oxygen species, and the initiation of apoptosis through activation of the mitochondrial

permeability transition pore. [109] Mitochondrial DNA is made up of two to ten double strands of circular DNA in the mitochondrial matrix. At least 37 genes have been discovered, some of which encode the respiratory chain enzymes. The transcription of mitochondrial DNA is not closely related to the cell cycle, and mitochondrial DNA is more susceptible to mutation than is nuclear DNA. Mitochondrial disorders manifest organ disturbances that reflect the importance of mitochondria to normal function, as in skeletal muscle and the nervous system; similarly, metabolic disorders result from deranged cellular mitochondrial functions. The locations of selected mutations in the mitochondrial 16,569-base pair genome that result in pathological disorders and syndromes have been documented. [109] The mitochondrial disorder affecting the gut is MNGIE, also referred to as *MEPOP, oculogastrointestinal muscular dystrophy,* and *FVM type II*. This is an autosomal recessive condition with gastrointestinal and hepatic manifestations that may present at any age, typically with hepatomegaly or hepatic failure in neonates, seizures or diarrhea in infants, and hepatic failure or chronic intestinal pseudoobstruction in children or adults. MNGIE is characterized clinically by severe gastrointestinal dysmotility, external ophthalmoplegia, ptosis, peripheral neuropathy, and leukoencephalopathy. The small intestine is dilated, or multiple diverticula are present (Fig. 73-8), and the amplitude of contractions is typical of a myopathic disorder. [110] Some patients have a combination of intestinal dysmotility and the Kearns-Sayre syndrome, or transfer dysphagia secondary to abnormal coordination and propagation of the swallow through the pharynx and skeletal muscle portion of the esophagus. Clearly, this becomes even more devastating when the smooth muscle portion of the esophagus is affected by the associated MNGIE.

FIGURE 73-8. Enteroclysis in a patient with type II familial visceral myopathy demonstrates numerous diverticula in the small intestine.

Apart from the obvious external ophthalmoplegia, these patients manifest skeletal muscle pain and cramps, and systemic (lactic) acidosis. Circulating levels of muscle enzymes (creatine phosphokinase [CPK], alanine aminotransferase [ALT], aldolase, others) are elevated, and muscle biopsy shows characteristic ragged red fibers on modified Gomori stain. This appearance results from the hypertrophy of mitochondria in the subsarcolemmal position in a few muscle fibers and the lack of mitochondria in other muscle fibers. Special stains for the respiratory muscle enzymes can identify the precise functional defect. For example, succinate dehydrogenase–positive fibers appear "ragged blue," and staining of the adjacent tissue section with cytochrome *c* oxidase demonstrates a deficiency of the latter enzyme and a gene defect in the control of the complex IV respiratory chain proteins (Fig. 73-9). [110] In the intestine, hypertrophy of the circular muscle layer, atrophy of the longitudinal muscle, and megamitochondria in myenteric neurons and muscle cells are seen (Fig. 73-10). [111]

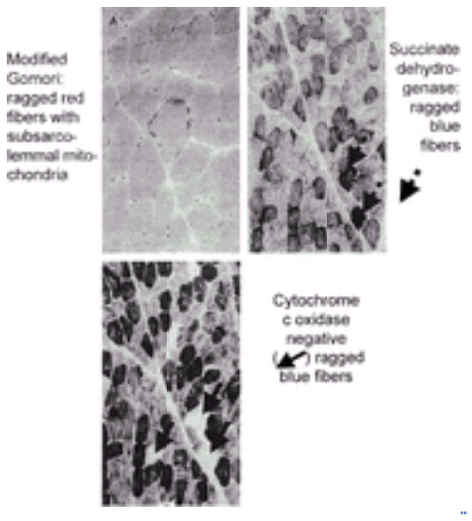

FIGURE 73-9. Histological and histochemical studies of a skeletal muscle biopsy specimen from a patient with mitochondrial myopathy; note the ragged red fibers, characterized by a subsarcolemmal location of giant mitochondria in a few fibers and a paucity of mitochondria in other fibers. On histochemical analysis, a few fibers are positive for succinate dehydrogenase (ragged blue appearance), but the same fibers do not express cytochrome *c* oxidase, suggesting a defect in the respiratory enzyme chain that results in mitochondrial dysfunction and systemic acidosis. (From ref. [110].)

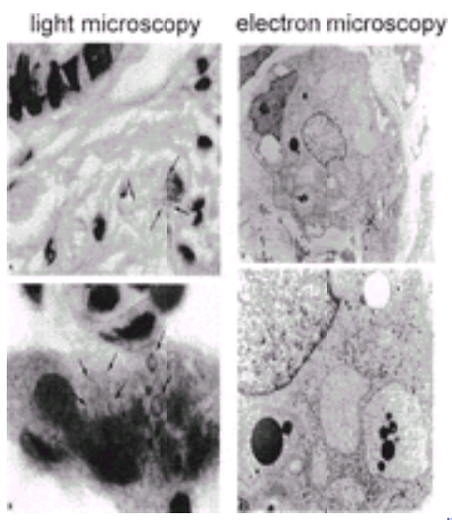

FIGURE 73-10. Submucosal plexus neurons showing megamitochondria in a rectal biopsy specimen from a patient with mitochondrial myopathy. (From ref. [111].)

The screening tests for MNGIE are measurement of serum lactic acid, muscle enzymes, and thymidine phosphorylase in circulating leukocytes. [112] The latter test is based on mutations identified in the gene for thymidine phosphorylase in 21 probands with MNGIE. [112]

Familial visceral neuropathies. The FVNs are a group of genetic diseases characterized by degeneration of the myenteric plexus. At least two distinct phenotypes, I and II, have been identified and are summarized in Table 73-3. A number of syndromic congenital neuropathies are related to disturbances in the ontogeny of the neural crest and the ENS.

TABLE 73-3 Classification of Familial Visceral Neuropathies

Congenital neuropathic motility disorders. These disorders can be broadly classified as follows: [113]

1. *Disorders of colonization* by migrating neural crest derived neurons, as in Hirschsprung disease, related to abnormalities in the RET gene and GDNF, or the disorder of ET-3 and its receptor, ET-B.
2. *Disorders of differentiation* of enteric nerves, as in intestinal ganglioneuromatosis, related to a specific germ-line point mutation in RET at codon 918 of exon 16 (M918T) or at codon 883 (A883F) in MEN type 2B syndrome.
3. *Disorders of survival or maintenance of enteric nerves,* as in hypoganglionosis and possibly congenital achalasia, which can result from one of several mechanistic derangements: GFR $_{a2}$/neurturin, GFR $_{a3}$/artemin, Trk-C/NT-3, and 5-HT $_{2B}$/5-HT.

Hirschsprung disease, a relatively common condition affecting 1 in 5000 live births and causing intestinal obstruction in neonates and megacolon in infants and adults, is often associated with mutations in genes encoding GDNF-RET [114], [115] or ET-3–ET-B. [104], [116] Mutations in RET and ET-B (i.e., the receptors) are much more frequently encountered than mutations in the two ligands. At least two different mechanisms can cause the terminal colon to become aganglionic. In the first, a deficiency of GDNF-RET is not so severe as to cause the entire bowel to become aganglionic. In the second, a deficiency of ET-3–ET-B, crest-derived cells differentiate prematurely and precursors cease dividing and migrating before the gut has been entirely colonized, leaving the last segment uncolonized. The roles of endothelins and of gene mutation M918T in the maldevelopment of the ENS and their role in Hirschsprung disease are discussed later. At least six separate genetic loci are involved in the control of four different intracellular mechanisms that result in models of congenital dysmotility and their phenotypic manifestations in the gut and other tissues (Table 73-4). These include abnormalities of c-RET, the gene that encodes the tyrosine kinase receptor; the ET-B system; the SOX-10 transcription factor; and c-kit, which is a marker for the interstitial cells of Cajal. Disturbances in these mechanisms result in syndromic dysmotilities such as Hirschsprung disease, Waardenburg-Shah syndrome (piebaldism, neural deafness, megacolon), and idiopathic hypertrophic pyloric stenosis. Figure 73-4 shows some of the mutations in the tyrosine kinase receptor that have been reported in dysmotilities associated with familial or sporadic medullary carcinoma of the thyroid, MEN types 2A and 2B, and Hirschsprung disease. Visceral neuropathy may result in bowel dilation (Fig. 73-11), although this is generally less frequent or less severe than in visceral myopathy. MEN type 2B is discussed in greater detail below because it is a prototypical illness that demonstrates the multiple effects of the mutations in the control of neural crest development.

TABLE 73-4 Genetic Models of Hirschsprung Disease

FIGURE 73-11. Small bowel radiograph from a patient with type I familial visceral neuropathy shows a normal stomach, duodenum, and proximal jejunum, but a dilated distal small bowel (*arrow*). (From ref. [58].)

Multiple endocrine neoplasia type 2B syndrome. MEN type 2B is a serious congenital neuropathic condition associated with tumors of the neuroendocrine system. It presents with severe constipation or megacolon (Fig. 73-12), diarrhea (when associated with enterocolitis), or obstruction, often in infancy. [117], [118] Other external stigmata of MEN 2B are a characteristic facies, “blubbery lips” resulting from mucosal neuromas, marfanoid habitus, medullated corneal nerve fibers, and even medullary thyroid carcinoma. [117], [119] The latter develops eventually in almost all patients.

FIGURE 73-12. Megacolon in a patient with multiple endocrine neoplasia type 2B; note the marked distension of the colon with a relatively small rectal diameter (**A**), and the massive dilation of the transverse colon with scoliosis and deviation of the mediastinum (**B**).

In MEN type 2B, a feature of the intestinal pathology is transmural intestinal ganglioneuromatosis, in which massive proliferations of neural tissue (neurons, supporting cells, and nerve fibers) appear as thickened nerve trunks among mature nerve cells (Fig. 73-13).

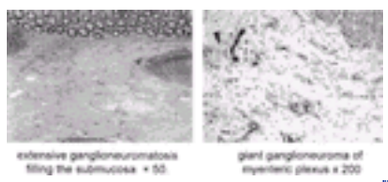

FIGURE 73-13. Histopathological features of ganglioneuromatosis in multiple endocrine neoplasia type 2B; note the extensive ganglioneuromatosis filling the submucosa and the giant ganglioneuroma of the myenteric plexus. (From ref. [125].)

MEN type 2B is a dominantly inherited disorder, but at least half of all patients present with a de novo mutation because only a few survive to reproductive age and are disabled by a variety of neurological symptoms that impair reproduction. The precise molecular abnormality is in the RET protooncogene (see Fig. 73-4), which encodes a tyrosine kinase receptor expressed particularly in neural crest–derived cells, including the enteric ganglia. A specific germ-line point mutation in RET in exon 16 at codon 918 (M918T) occurs in 95% of patients; the remainder have a point mutation at codon 883 (A883F). [120], [121] The M918T mutation alters RET substrate specificity and appears to act in a ligand-independent fashion (a gain-of-function mutation). [122], [123] and [124] Receptor tyrosine kinases with these mutations also bind to and phosphorylate substrates preferred by nonreceptor tyrosine kinases. A883F RET has not been directly tested, but given its location, it is thought that kinase specificity may also be altered in this mutant. [121] The receptor is expressed in the neural crest cell–derived ENS, adrenal medulla, parathyroid, and C cells of the thyroid. The gain-of-function mutations are susceptibility factors for endocrine tumors (medullary carcinoma of the thyroid, pheochromocytoma, and parathyroid tumors). Because surgery is the only curative procedure for medullary carcinoma of the thyroid, Smith and colleagues [125] recommend that patients who present with a clinical phenotype of Hirschsprung disease undergo adequate full-thickness biopsy of the bowel at the time of the pull-through operation, and that those with transmural intestinal ganglioneuromatosis undergo molecular diagnostic testing by RET mutation analysis. If germ-line M918T or A883F mutations are found, a prophylactic thyroidectomy is indicated; furthermore, adrenal gland surveillance with abdominal ultrasonography and urinary fractionated catecholamines and metanephrine or vanillylmandelic acid are indicated because a pheochromocytoma may develop subsequently in about 50%.

Other familial visceral neuropathies. A few reported families do not fit into the two types of FVN discussed previously. [20], [67], [68] Schuffler and colleagues [67] reported two siblings who had generalized neurological disease and intestinal pseudoobstruction. One had ataxic gait; small, irregular, poorly reactive pupils; dysarthria; absent deep tendon reflexes; and impaired vibratory and positional senses. Radiographs revealed hyperactive, nonpropulsive contractions in a dilated esophagus and small intestine, and extensive colonic diverticulosis. The postmortem examination revealed degeneration of the myenteric plexuses of the esophagus, small intestine, and colon with reduced number and round, eosinophilic, intranuclear inclusions. The neurons and glial cells of the brain and spinal cord and the dorsal root and celiac plexus ganglia contained identical intranuclear inclusions. Intestinal smooth muscle was normal histologically. In the family reported by Cockel and colleagues, [68] affected members had megaduodenum, generalized dilation of the small intestine, malabsorption, redundant colon, mental retardation, and calcification of the basal ganglia. Histological studies showed degeneration of the argyrophobe cells, which produce acetylcholine. The patients became symptomatic for intestinal pseudoobstruction during late childhood. Faber and colleagues [20] reported five patients with chronic intestinal pseudoobstruction in two families. Hypertrophy of nerve fibers and an absence of ganglion cells were noted. The disease was transmitted by an autosomal recessive gene. All patients had megaduodenum; one had jejunal diverticulosis, and another dilation of the entire small intestine. Three had gastric dilation. Most patients had external ophthalmoplegia, ptosis, distal weakness of all extremities, gait disturbances, and acroparesthesia. The symptoms developed during the teen years, and the prognosis was poor.

Childhood visceral myopathies. The CVMs have been recognized as distinctive diseases. There are two forms of CVM (Table 73-5), the second of which is identified by the phenotype of megacystis-microcolon-intestinal hypoperistalsis. These two diseases differ from the FVMs in their clinical manifestations and modes of inheritance. Degeneration and fibrosis of gastrointestinal tract and urinary tract smooth muscle can be detected in both types of CVM [28], [34], [45], [126] and result in bowel dilation (Fig. 73-14), ureteropelvic pyelocaliectasis (Fig. 73-15), or megacystis, which results from bladder degeneration (Fig. 73-16).

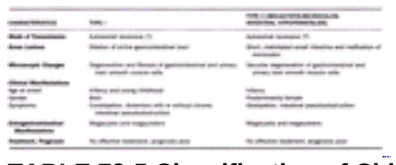

TABLE 73-5 Classification of Childhood Visceral Myopathies

FIGURE 73-14. Upper gastrointestinal radiograph from a patient with type I familial visceral myopathy demonstrates severe megaduodenum.

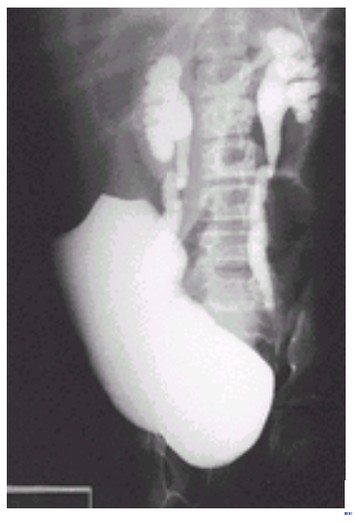

FIGURE 73-15. An intravenous pyelogram of a child with type I childhood visceral myopathy shows megacystis and bilateral ureteral pyelocaliectasis. (From ref. [126].)

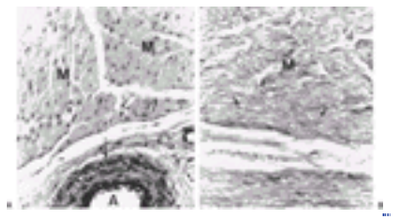

FIGURE 73-16. A: Bladder muscularis from a control specimen demonstrates elastic fibers (*arrow*) in the adventitia of a small artery (*A*). No elastic fibers are present within muscle bundles (*M*). **B:** Bladder muscularis from a patient with type I childhood visceral myopathy demonstrates numerous parallel, coarse, wavy, elastic fibers (*arrows*) within muscle bundles (*M*). Verhoeff-van Gieson stain; original magnification ×325. (From ref. 126.)

Nonfamilial visceral myopathies (sporadic hollow visceral myopathy). Nonfamilial visceral myopathies in adults have been reported a few times. 127, 128, 129, 130, 131, 132 and 133 The disease is heterogeneous, with some similarities to FVM types I and III. 130 Histologically, no difference is seen between the familial and nonfamilial types. Diffuse mixed inflammatory cell infiltration, including eosinophils, was observed in one patient. 127 In one reported case, 133 acetylcholinesterase stain of the small intestine showed a considerably increased number of positive fibers, but no degeneration of neurons in the myenteric plexus. The nonfamilial type of visceral myopathy is uncommon. A careful family history must be obtained in these patients to exclude a diagnosis of FVM.

Idiopathic nonfamilial visceral neuropathies (sporadic hollow visceral neuropathy or chronic idiopathic intestinal pseudoobstruction). Nonfamilial visceral neuropathy or chronic idiopathic intestinal pseudoobstruction typically results from damage to the myenteric plexus by chemicals, drugs, or viral infections. Delayed gastric emptying has been observed in patients after viral gastroenteritis, 134, 135 which may cause permanent damage to the myenteric plexus in some cases. In patients with nonfamilial visceral neuropathies, 136, 137, 138, 139, 140, 141, 142 and 143 the motility of the entire gastrointestinal tract is usually disturbed, but the urinary tract is generally not affected. The intestine is dilated but shows active, nonperistaltic contractions on barium examination. 142 In contrast, patients with familial visceral myopathies have an inactive, dilated intestine. 142 Histological examination of the myenteric plexus with the Smith silver staining technique in sporadic visceral neuropathy reveals a reduction in the number of neurons, and those that remain are markedly abnormal (Fig. 73-17). The neurons are enlarged, with thick, irregular, clubbed processes. The number of Schwann cells in the nerve trunks is increased, and the number of axons is reduced. Some of the remaining axons are beaded and fragmented. Hypertrophy of one or both muscle layers of the muscularis propria may also be observed. All reported cases have chronic intestinal pseudoobstruction. Infants and young children are also affected. 143

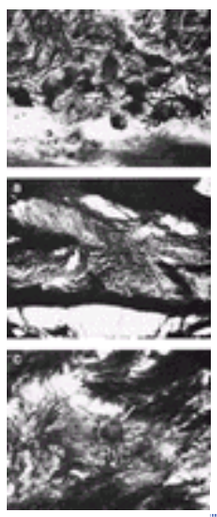

FIGURE 73-17. A: Ganglionic area from normal control ileum demonstrates numerous argyrophilic neurons and nerve fibers. Silver stain; original magnification ×230. **B:** Ganglionic area from a patient with type II familial visceral neuropathy demonstrates absence of argyrophilic neurons and few nerve fibers. There is a faint cluster of small nuclei of unknown cell type. Silver stain; original magnification ×230. **C:** Another ganglionic area from the same patient shows only one poorly staining, argyrophilic neuron (*arrow*). Silver stain; original magnification ×362. (From ref. 58.)

In a study of 40 patients with chronic idiopathic intestinal pseudoobstruction, the results of intestinal phasic pressure studies were abnormal, but the histologic features of the gastrointestinal tract were normal in those whose tissue was available for analysis. 144 Similar findings have been reported in children with chronic idiopathic intestinal pseudoobstruction. 145 In earlier reports, 146, 147 and 148 histological studies of smooth muscle or myenteric plexus were not generally available for evaluation. The precise mechanism and neurotransmitter deficiencies of this disorder are unclear. Differentiation from severe IBS may be difficult if the gut is not dilated. Manometric studies may also show similar features, such as bursts or clusters of phasic pressure activity; 149, 150 and 151 slow transit of chyme through the stomach or small bowel 152 provides an objective, noninvasive means by which dysmotility can be suspected.

Secondary Causes of Small Intestinal Dysmotility The secondary causes of small intestinal dysmotility are summarized in Table 73-6 and discussed in the next sections.

TABLE 73-6 Gastrointestinal Dysmotility Manifestations of Some Systemic Diseases

Scleroderma (progressive systemic sclerosis). The small bowel is the second most frequently involved gastrointestinal organ in scleroderma, after the esophagus. Radiographic evidence of gastric sclerosis, intestinal sclerosis, or both is found in 40% of patients with scleroderma. 153, 154, 155 and 156 Contrast studies reveal dilation of the duodenum and jejunum, delayed barium transit, and narrow valvulae conniventes, which remain tightly packed together despite the bowel dilation, producing an accordion appearance (Fig. 73-18). 10, 156, 157 Wide-necked diverticula may be seen but are more frequent in the colon. 158 An uncommon and potentially serious finding is pneumatosis cystoides intestinalis, which usually signifies a poor prognosis. 159

FIGURE 73-18. Upper gastrointestinal series in a patient with scleroderma shows dilation of the small bowel with normal appearance of the stomach. In some cases, the valvulae conniventes are not thickened, as is usually seen in disorders that produce dilation. In contrast, they remain narrow and crowded, producing the accordion appearance shown here. (From ref. [156].)

Degeneration of the smooth muscle and replacement with collagen is responsible for small bowel dysmotility in scleroderma. The circular muscle layer is involved more often than the longitudinal muscle layer. [10], [160], [161] The submucosal and myenteric plexuses appear normal by conventional staining. Small bowel dysmotility leads to bacterial overgrowth, resulting in steatorrhea, malabsorption, and weight loss. Intestinal pseudoobstruction is a well-described gastrointestinal complication of scleroderma. [10], [162], [163], [164] and [165] In patients with scleroderma and intestinal involvement, disturbances of small bowel motility [166], [167] and [168] and transit [169] have been documented in several studies. Many patients have a complete absence of the interdigestive migrating motor complex (MMC); clusters of propagated and nonpropagated contractions may be the only finding in others. An abnormally prolonged MMC cycle, diminished activity of phase III, and hypomotility of the fed pattern are other abnormal findings. [166], [168], [170] Antral hypomotility, when present, is characterized by low-amplitude contractions, typically below 40 mm Hg; intestinal involvement usually causes the contractile amplitude to fall below 10 mm Hg during fasting and postprandially. [171] In patients who have scleroderma without gastrointestinal involvement, the small bowel manometric pattern [171] and small bowel transit time are normal. [172] Treatment with cisapride, a prokinetic agent, improves gastric emptying and relieves upper abdominal symptoms in patients with scleroderma. [173] Oral erythromycin was effective in short-term studies that evaluated gastric emptying and symptoms in an open-label study. [174] Octreotide, a long-acting somatostatin analog, induces phase III activity in patients with a complete absence of MMCs and may reduce bacterial overgrowth and symptoms (Fig. 73-19). [167] More studies are required to confirm these observations and the long-term benefit of the treatments.

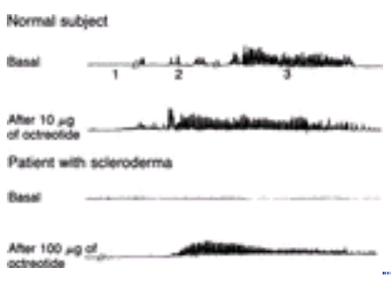

FIGURE 73-19. Effect of octreotide in a healthy person and in a patient with scleroderma. In the normal person, octreotide stimulates phase III activity. In the patient with scleroderma and pseudoobstruction, octreotide induces phase III activity even though no migrating motor complex activity was present in the basal state. (From ref. [167].)

Dermatomyositis and polymyositis. The inflammatory disorders dermatomyositis and polymyositis are characterized by weakness and atrophy of the skeletal muscles; an associated skin rash distinguishes the former from the latter. The gastrointestinal tract is involved in half of cases. Esophageal involvement causes dysphagia, which often is a presenting symptom. Studies of the small bowel in these patients are limited mainly to radiography and histology. Megaduodenum and delayed intestinal transit of barium are prominent features. [175], [176] and [177] Autopsy findings have shown atrophy and fibrosis of intestinal smooth muscle, suggesting a visceral myopathy. [176], [177] Acute colonic pseudoobstruction was reported in one patient with dermatomyositis, but it was limited to the colon. [178]

Systemic lupus erythematosus. Abdominal pain is the most common gastrointestinal symptom in systemic lupus erythematosus, occurring in 10% to 20% of patients. Autopsy studies disclose a 60% to 70% prevalence of previous peritoneal inflammation, but documented cases of serositis as the sole cause of abdominal pain are rare. [179] The term *lupus enteritis* is used to describe the bowel changes resulting from lupus-induced vasculitis of the small blood vessels. Ischemia leads to intestinal mucosal ulceration, edema, and hemorrhage. Smooth muscle dysfunction results in dilation of the small bowel and ileus. In severe cases, necrosis of the bowel wall develops, with perforation or infarction. Lupus enteritis is diagnosed radiographically. Small bowel changes include dilation, coarsened folds, and “thumbprinting” secondary to submucosal edema and hemorrhage. [180], [181] Diarrhea occurs in 5% to 10% of lupus patients. Unusual intestinal manifestations can pose diagnostic difficulties. Small bowel involvement in lupus may simulate Crohn’s ileitis in some cases. [182], [183] A severe protein-losing enteropathy was described in one patient with lupus, who demonstrated vasculitis and basement membrane thickening on full-thickness jejunal biopsy. [184] Transit or manometric studies of the small bowel have not been performed in patients with lupus.

Mixed connective tissue disease. Mixed connective tissue disease is a clinical entity characterized by overlapping features of scleroderma, polymyositis, and rheumatoid arthritis. It has a distinct serologic finding of high titers of antinuclear antibody against ribonucleoprotein. The extent of gastrointestinal involvement is unknown but appears to resemble that of scleroderma, with esophageal involvement being most common. Duodenal and jejunal dilation are seen radiographically, and pneumatosis cystoides intestinalis may complicate severe disease. [185]

Diabetes mellitus. Many diabetic patients have diarrhea, which has a variety of causes (e.g., bacterial overgrowth, pancreatic exocrine insufficiency, bile salt malabsorption, impaired absorption or secretion). Early radiographic studies of the small bowel demonstrated variable findings, including normal, delayed, or rapid transit. Similarly discrepant results are found when the hydrogen breath test is used, and the correlation of rapid transit, based on that test, with diarrhea is poor. [186], [187] and [188] The small bowel may be affected in patients presenting with the gastroparesis syndrome, and this can be detected by manometry [189] or prolonged transit. [169] Pathologically, demyelination of the proximal vagus nerve and sympathetic nerves supplying the bowel develops in diabetes. The intrinsic nervous system of the gut appears to be unaffected because no morphologic abnormalities of the myenteric or submucosal plexuses have been noted. [190], [191] Although thickening of the small bowel muscle layers and eosinophilic hyaline bodies in smooth muscle cells have been observed, [192], [193] and [194] most authorities do not believe that myopathy is a cause of gastrointestinal dysmotility in diabetic patients. The results of motility studies of the small bowel in patients with diabetes have been mixed. The MMCs are normal in many patients with documented gastroparesis. [195] Absence of intestinal phase III has been demonstrated in some patients. [186], [196], [197] Other abnormalities include MMCs originating in the distal duodenum or jejunum and uncoordinated (nonpropagated or abnormally propagated) bursts of powerful contractions lasting up to 2 minutes (Fig. 73-20). [186], [189] The clinical relevance of these abnormal findings is uncertain. In one study, abnormal transit time and manometric abnormalities could not be correlated. [186] Hyperglycemia, which can weakly delay gastric emptying, induces intestinal phase III–like activity and alters orocecal transit time in healthy subjects. [198] However, the relevance of these findings to diabetic bowel dysmotility is unclear. Among community diabetics, constipation and the use of laxatives are significantly more common than in age- and gender-matched controls. [199], [200] Constipation is probably multifactorial in diabetes, as it is in nondiabetic patients [201]; acute hyperglycemia does not significantly affect colonic motor function or tone. [202]

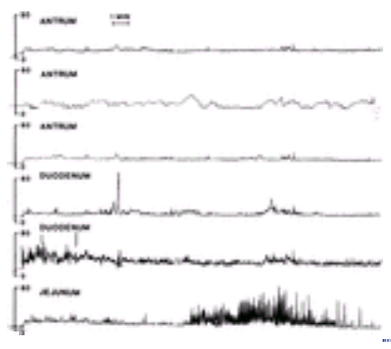

FIGURE 73-20. Small bowel dysmotility in diabetes. In this patient, phase III of the migrating motor complex begins in the jejunum, with no antecedent activity in the antrum or duodenum. Other patients may have a complete absence of phase III activity. (From ref. [186].)

Parkinson disease. Symptoms of gastrointestinal dysmotility are common in patients with Parkinson disease. High dysphagia, nausea, bloating, constipation, and difficulty with evacuation of stool occur frequently. [203] Dilation of the small bowel may be seen radiographically. [204] Small bowel dysmotility does occur; however, its frequency is not known. Manometric studies in patients with Parkinson disease reveal infrequent MMCs (which are even absent in some cases), hypomotility in the fed state, and an increased incidence of retrograde and tonic contractions in comparison with controls. [205] The contribution of these abnormalities to symptoms is not clear. The pathogenesis of small bowel dysmotility is unknown. In patients with dysphagia and megacolon, Lewy bodies, which are neurons containing cytoplasmic hyaline inclusions, have been found in the myenteric plexus of the esophagus and colon. [206], [207] Lewy bodies were originally identified in the brain and are highly characteristic of Parkinson disease. Lewy bodies have not yet been reported in the small bowel. Dopaminergic neurons are reported to be deficient in the colon of patients with parkinsonism and constipation. [208] Therapy for Parkinson disease includes drugs that adversely affect gut motility, such as dopamine agonists and anticholinergics. Symptoms are as common in untreated as in treated patients, however, suggesting that the disease itself is the primary factor producing dysmotility and resultant symptoms. [203]

Spinal cord injury. Extrinsic denervation of the small bowel by spinal cord injury usually produces just mild and probably insignificant dysmotility in the small intestine. The only change revealed in manometric studies performed in a group of patients with spinal cord injury was that a greater number of phase III contractions began in the duodenum rather than the antrum in those with high spinal cord lesions. [209] Patients with injury to the lower spinal cord demonstrated no abnormal findings, consistent with the preservation of innervation to the bowel from the vagus and third thoracic sympathetic levels. In one report, a woman with cervical spinal stenosis and paraplegia displayed normal MMCs but a twofold to threefold prolonged interval between MMCs. [210] Immediately after a spinal cord injury, a state of spinal shock develops. This is characterized by the complete loss of all sensory, motor, and reflex function below the level of injury. Paralytic ileus with abdominal distention follows and usually resolves in a few days. In the long term, postprandial abdominal distention and discomfort occur in more than 40% of patients with spinal cord injury. [211] These symptoms are likely caused by the more significant problem of constipation. In many stable patients with spinal cord injury, the amount of gas in the small and large intestine is increased on routine abdominal x-ray films (Fig. 73-21). [212] Colonic dysmotility is well recognized and is responsible for the common problems of constipation and difficulty of evacuation in these patients. [213]

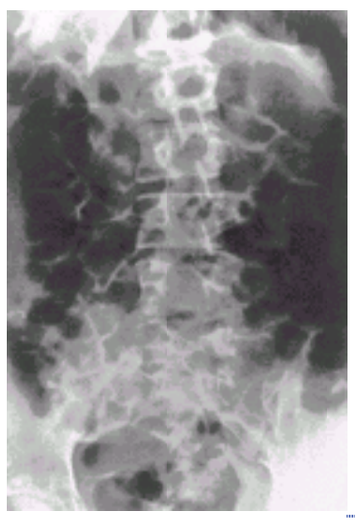

FIGURE 73-21. Abdominal radiograph from a stable, healthy patient with a spinal cord injury. A nonobstructive gassy abdomen is frequently observed, even in the absence of abdominal complaints. (From ref. [212].)

Neurofibromatosis (von Recklinghausen disease). Gastrointestinal neurofibromas are most commonly found in the small intestine. They are reported to occur in up to 10% of patients with neurofibromatosis; the true incidence of neurofibromas is probably underestimated, however, because they are generally asymptomatic. Small bowel neurofibromas may be single or multiple and are most frequently found in the ileum. These tumors are submucosal, and they may become quite large and extend to the serosa. Their presence is usually established by a small bowel series. [214], [215] Ulceration through the mucosa can cause acute or chronic bleeding. Mechanical small bowel obstruction or intussusception requires exploratory surgery. Chronic intestinal pseudoobstruction has been described in one patient with neurofibromatosis. The small bowel manometry findings were abnormal, and small bowel transit was markedly delayed. [152] Pathological studies of the nerves and muscles in the small bowel are lacking in this disease. Neurogenic changes consisting of nerve fiber proliferation in the myenteric and submucosal plexuses were found in the colon of a patient with megacolon. [216]

Paraneoplastic visceral neuropathy (pseudoobstruction). Chronic intestinal pseudoobstruction has been reported in association with small cell carcinoma of the lung [217], [218], [219], [220], [221], [222] and [223] and epidermoid carcinoma of the lip. [224] This phenomenon represents a paraneoplastic syndrome caused by visceral neuropathy. The small bowel, like the colon, shows widespread neuronal and axonal degeneration of the myenteric and submucosal plexuses, in addition to mononuclear cell infiltration and Schwann cell proliferation. [221] There are no metastases to the bowel. Symptoms of pseudoobstruction are the presenting features in patients with visceral neuropathy and small cell carcinoma. The lung cancer is usually occult, missed on chest radiography, and is often found at autopsy or by chest computed tomography (CT) and mediastinoscopy. The small bowel is usually not dilated on x-ray films, but barium passage through the small bowel is somewhat delayed. Small bowel manometry shows features suggestive of neuropathy, such as incoordinated bursts. [220], [221] In older patients with intestinal pseudoobstruction or feeding intolerance of unknown cause and recent onset, a malignancy, especially small cell carcinoma of lung, must be suspected. A screening blood test (antineuronal enteric antibody, or anti-Hu) is highly specific. [221] If the result is positive, CT of the chest and mediastinoscopy may be necessary to confirm the diagnosis.

Myotonic dystrophy. Myotonic muscular dystrophy is a slowly progressive disease characterized by myotonia, or difficulty in muscle relaxation. Besides muscle wasting, the patient often has a nasal voice as a result of pharyngeal and palatal weakness, an early onset of cataracts, and cardiac conduction defects. Dysphagia is the most common gastrointestinal symptom resulting from esophageal involvement. Diarrhea and abdominal cramping occur in up to one third of those affected. Malabsorption and steatorrhea have been reported in a few cases. [225], [226] and [227] Constipation also is frequent and can alternate with diarrhea. Intestinal pseudoobstruction is rare. [228], [229] The small bowel may demonstrate abnormal but nonspecific radiographic changes, including dilation, diminished motility, and delayed transit of barium. [230] Dysmotility of the small intestine may play a significant role in the production of intestinal symptoms. In a group of ten patients with symptoms of intestinal dysmotility but normal findings on small bowel contrast examinations, small bowel motility was abnormal in all. Manometric findings included low-amplitude contractions in the fasting and fed states, retrograde propagation of phase III, interruption of phase III, and an increased incidence of tonic contractions. [231] In one patient with chronic pseudoobstruction and dilated small bowel, manometry revealed low-amplitude duodenal contractions and an increased maximal rate of contractions in the duodenum. [229] Histologically, the small intestinal smooth muscle shows changes similar to those found in dystrophic skeletal muscle; it is swollen, partially destroyed, decreased in size, and replaced by fat. [232], [233] Silver stain revealed degenerative changes in the myenteric plexus of the colon in a patient with megacolon, [234] indicating that intestinal dysmotility may be caused by smooth muscle as well as enteric nerve dysfunction. In most patients, the predominant cause of dysmotility appears to be smooth muscle damage.

Duchenne muscular dystrophy. Duchenne muscular dystrophy is a severe, pseudohypertrophic muscular dystrophy that follows an X-linked recessive pattern, affecting young boys early in childhood. Skeletal and cardiac fibers are infiltrated and eventually replaced by connective and fatty tissue. Similarly, the smooth muscle of the gastrointestinal tract also is involved. Histological changes comprise degeneration and atrophy of smooth muscle fibers and separation of the fibers by connective tissue. [235], [236] and [237] The myenteric plexus is not involved. Despite typical dystrophic changes in the small bowel in most postmortem specimens, gastrointestinal symptoms are usually related to dysmotility of the esophagus and stomach, which are more severely affected than the small bowel. Dysphagia is the predominant symptom (36% in one series), followed less often by vomiting, diarrhea, and constipation. [237] The orocecal transit time is normal in asymptomatic subjects; [238] however, severe bowel dysmotility can occur. Episodes of acute intestinal pseudoobstruction, manifested by abdominal distention, persistent vomiting, and gastric or small bowel dilation, can be life-threatening. [239], [240] and [241] Chronic intestinal pseudoobstruction has also been reported in Duchenne dystrophy. [242]

Amyloidosis. Amyloid protein is deposited in the small bowel in all forms of amyloidosis: primary, secondary, myeloma-associated, and familial or hereditary. The degree of dysmotility is related to the amount and distribution of amyloid deposited. In all forms, the deposition of amyloid in blood vessel walls leads to ischemic ulcers, infarction, and occasionally perforation. In primary and myeloma-associated forms of amyloidosis, the muscle layers of the small bowel are more severely affected than the mucosa, resulting in dysmotility. In the secondary and hereditary forms, the mucosa is predominantly involved, resulting in malabsorption. Amyloid deposits are infrequently found in the myenteric plexus, although in hereditary forms, familial amyloidosis neuropathy may result from deposition in major nerve trunks supplying the bowel. [243], [244] Gastrointestinal symptoms include diarrhea, constipation (which is often present for years and then followed by diarrhea), malabsorption, and pseudoobstruction. Diarrhea can occur without malabsorption and is relieved by antibiotic therapy. [245] Radiographic features include coarsening of the small bowel mucosal pattern, dilation, and diminished motility with prolonged transit of barium. [246] These changes are nonspecific and can be mistaken for those of scleroderma. In a mixed group of patients with amyloidosis, the

orocecal transit time was prolonged to more than twice that of controls. [247] With heavy infiltration of the small bowel muscle layers, acute intestinal pseudoobstruction is a serious and often fatal complication (Fig. 73-22). [248] , [249] and [250]

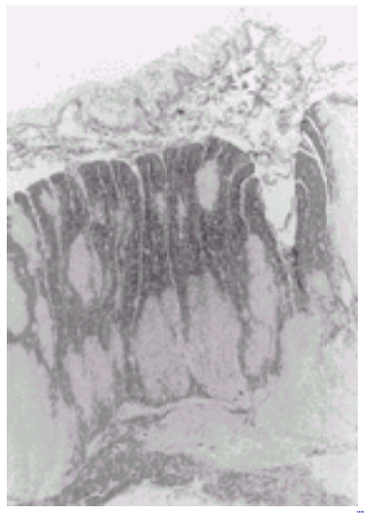

FIGURE 73-22. Small bowel myopathy in a patient with amyloidosis and pseudoobstruction. The large, pale areas in the muscle layer represent heavy amyloid deposition. The myenteric plexus is less frequently involved than the mucosa and muscle layers. (From ref. [250] .)

Chagas disease. Chronic infection with *Trypanosoma cruzi* leads to destruction of the submucosal and myenteric plexuses along the entire length of the gastrointestinal tract. Megacolon and megaesophagus are the most common presentations, although the small bowel may be similarly affected, with the development of megaduodenum and megajejunum. Small intestinal manometric studies in these patients demonstrate normal frequency of the MMCs, but the velocity of propagation of the activity front is significantly slowed to about half the normal value. [251] Patients with small bowel involvement may be entirely asymptomatic despite significant neuronal destruction. [252] Diarrhea, constipation, or intestinal pseudoobstruction can occur.

Thyroid disease. Thyroid dysfunction may present primarily as gastrointestinal disease. Hyperthyroid patients may have diarrhea and mild steatorrhea, whereas hypothyroid patients frequently are constipated. [253] , [254] and [255] Intestinal dysmotility resulting from the altered thyroid state has been historically recognized as the cause of symptoms. This is supported by abnormalities found in the intrinsic electrical control of gut motor activity. In the duodenum, slow wave frequencies are increased in hyperthyroid patients and decreased in hypothyroid patients. [256] , [257] These abnormalities return to normal after correction of the thyroid dysfunction.

Hyperthyroidism. Early radiographic studies, in which the crude barium meal test was used, reported rapid gastric emptying and small bowel transit. [258] , [259] Later studies, in which the hydrogen breath test was used, confirmed a rapid orocecal transit time; this is a consequence of accelerated small bowel transit because the rate of gastric emptying is actually unchanged. [253] , [260] , [261] and [262] Hyperthyroid patients may present with malabsorption; more than 25% of hyperthyroid patients excrete more than 7 g of fat in their stool daily. [263] , [264] This is apparently caused by decreased contact time of the lumenal contents with small bowel mucosa as a result of rapid transit; the abnormality regresses after correction of the hyperthyroid state.

Hypothyroidism. In contrast to small bowel transit in hyperthyroidism, which is accelerated, small bowel transit is significantly slowed in hypothyroidism. [253] With adequate hormone replacement, transit may be normalized. Constipation develops in many hypothyroid patients, probably a result of colonic dysmotility. A manometric study in one patient revealed decreased amplitude of the small bowel contractions and an overall decreased motility index. [265] In severe hypothyroidism (i.e., myxedema), paralytic ileus and intestinal pseudoobstruction can occur. [266] , [267] , [268] , [269] and [270]

Hypoparathyroidism. The mechanism by which parathyroid hormone affects gastrointestinal motility is not known. However, calcium is essential for smooth muscle contraction, and hypocalcemia may impair gut contractile activity. Intestinal pseudoobstruction and malabsorption have been reported in association with small bowel dysmotility in hypoparathyroid subjects. [271] Barium studies reveal dilated loops of small bowel and a prolonged transit time. The symptoms are relieved by calcium administration.

Drug-induced changes in small intestinal motility. Many drugs profoundly affect gastrointestinal motility. Although the colon is usually recognized as the organ most susceptible to drug-induced dysmotility, the small bowel also is frequently affected. Phenothiazines and some antiparkinsonian drugs decrease colonic and small bowel motility and can cause constipation, colonic pseudoobstruction, and adynamic ileus. [272] , [273] , [274] and [275] Tricyclic antidepressants in particular are noted for causing iatrogenic ileus. The anticholinergic agents atropine and scopolamine and related belladonna alkaloids decrease intestinal tone as well as the amplitude and frequency of peristaltic contractions. [276] Opiate analgesics are well known to suppress motility throughout the gastrointestinal tract. Morphine enhances the amplitude of nonpropulsive small bowel contractions and markedly decreases propulsive contractions by its effects on μ-opiate receptors on intestinal muscle cells. [277] , [278] The upper small bowel is more prone to these effects than the ileum. The net effect is delayed small bowel transit. Morphine and nalbuphine significantly delay small bowel transit in comparison with placebo. [279] Loperamide, a synthetic opiate used to treat diarrhea, also reduces small bowel motility and delays transit time. This effect is antagonized by the concomitant administration of naloxone, which by itself has no effect on transit time. [280] , [281] Ketorolac, a nonsteroidal antiinflammatory agent used for postoperative pain, has significantly less effect on small bowel transit than morphine. [282] Whether ketorolac slows motility in comparison with controls is not known. Calcium channel antagonists, especially verapamil, cause constipation in up to 20% of patients. The small bowel transit time in subjects taking verapamil was unchanged from pretreatment values; transit through the colon was slowed, however, and this effect likely accounts for the constipation associated with this drug. [283] Clonidine, an a_2-adrenergic agent used as an antihypertensive agent, prolongs the orocecal transit of liquids; [284] however, a comprehensive dose-response study of the transit of solids did not show any significant effects on gastric small bowel or colonic transit in healthy individuals. [285] Clonidine has been used successfully to treat diabetic diarrhea; however, its therapeutic benefit may also result from its known action of increasing fluid and electrolyte absorption from the gut. [286] Drugs that stimulate small bowel motility include cisapride, octreotide, erythromycin, and cholinergic agonists. Erythromycin binds to motilin receptors on the smooth muscle of the gastric antrum and duodenum. Motilin, in physiological doses, induces interdigestive motor complexes in the upper gut. Erythromycin has been used to treat diabetic gastroparesis; the long-term beneficial effects are not as pronounced as the short-term effects. [287] Cholinergic agonists, such as bethanechol, augment the amplitude of small bowel contractions and overall motility. [288] Octreotide is a long-acting synthetic analog of somatostatin. In normal individuals, it increases the frequency of MMCs by significantly shortening the duration of phase II. [289] , [290] It was shown to be useful in the short term in a small group of patients with scleroderma by inducing phase III contractions and possibly reducing small bowel bacterial overgrowth. [167] When given after a meal, intravenous somatostatin interrupts the fed pattern of motility and induces bursts of propagated activity similar to phase III in health [291] and disease. [292] , [293] Octreotide retards small bowel transit in health when given before meals. [294] Cisapride is a nondopaminergic prokinetic agent that works by stimulating 5-HT_4 receptors to release acetylcholine in the myenteric plexus. It accelerates the transit of both liquids and solids through the small intestine [295] and has been found useful in treating patients with chronic intestinal pseudoobstruction. [152] Cisapride induces phase II–type activity in the fasted state and also augments small bowel motility after a meal. [296] , [297] The latter effect is generated after a small meal but not after a larger meal.

Celiac disease. Intestinal pseudoobstruction occurs in association with nontropical sprue. [298] , [299] and [300] Dilated loops of small bowel in which the passage of barium is delayed are observed radiographically. In one patient who underwent exploratory laparotomy with full-thickness jejunal biopsy, the nerves and muscle coats appeared normal on both light and electron microscopy. [300] Parenteral nutrition may be required during prolonged periods of pseudoobstruction.

Jejunal diverticulosis. Diverticula can occur anywhere in the small intestine, but they are most common in the jejunum. Like their counterparts in the colon, they represent herniations through the mesenteric side of the bowel and are usually acquired. [250] Jejunal diverticulosis is associated with many diseases, including scleroderma, celiac disease, Fabry disease, type II FVM, and Cronkhite-Canada syndrome. [301] Patients present with diarrhea, steatorrhea, weight loss, and megaloblastic anemia. Chronic intestinal pseudoobstruction occurs in jejunal diverticulosis and can mimic mechanical obstruction. [165] , [302] The concept that dysmotility causes diverticula and not vice versa is supported by a case report in which resection of the small bowel segment containing diverticula failed to relieve the patient's symptoms of pseudoobstruction. [10] In one patient, small bowel manometry showed that contractions can be antegrade, retrograde, or both simultaneously. [301] Histology of the bowel reflects the heterogenous causes of dysmotility (e.g., visceral neuropathy, visceral myopathy). [303]

Irradiation. Ionizing radiation damages all structures of the small intestine, including the mucosa, blood vessels, connective tissue, enteric nerves, and smooth muscle. Radiation damage to the bowel can be classified as acute or chronic.

Acute injury. Above a certain threshold dose of radiation to the abdomen, symptoms of nausea, vomiting, abdominal pain, and diarrhea are common. These abate soon after exposure is discontinued. Reversible changes in small bowel absorptive function have been considered the main cause of diarrhea. Small bowel dysmotility may play a significant role in acute radiation enteropathy. In dogs, a single large dose of radiation abolishes the interdigestive MMCs. [304] Smaller, fractionated doses, which are used for radiation treatment in humans, also result in dysmotility in the dog model. In the fasting state, manometric changes during exposure include an increased frequency of giant migrating contractions and retrograde contractions, with only a mild decrease in MMC cycle length. [305] These features revert to a normal pattern within a few days after exposure. Other studies, however, show decreased fasting and fed intestinal motility, particularly in the distal small

bowel, persisting up to 1 month after the last exposure. [306], [307] Motility studies have not been performed in humans in the acute phase of radiation sickness. One study demonstrated accelerated small bowel transit in a group of patients undergoing abdominal and pelvic irradiation in comparison with pretreatment values. [308] More than 75% of the patients had diarrhea during treatment.

Chronic injury. Delayed gastrointestinal complications may occur months, years, or even decades after radiation exposure. Both neuronal and muscular structures of the small bowel are affected. The resulting dysmotility leads to bacterial overgrowth, diarrhea, and malabsorption. Edema, atrophy, and fibrosis of smooth muscle fibers are characteristic histological findings. [309], [310], [311] and [312] The myenteric plexus can appear normal on routine staining; however, proliferation of the submucosal neurons with extension into the circular muscle coat has been observed. [311], [312] Latent gastrointestinal symptoms resulting from previous radiation damage have been attributed to altered gut motility. Recurrent episodes of intestinal pseudoobstruction were described in two patients many years after they received abdominal radiation. [312], [313] Small bowel contrast studies show dilated loops of bowel with air-fluid levels and a thickened bowel wall. Manometric evaluation in one patient revealed normal MMCs in the proximal duodenum, decreased amplitude and frequency of contractions in the distal duodenum, and an absence of peristaltic contractions in the jejunum. Subsequent histological examination of the bowel suggested smooth muscle damage as the cause of dysmotility. [312]

Diffuse lymphoid infiltration. Four cases of chronic intestinal pseudoobstruction in association with diffuse lymphoid infiltration of the small bowel have been described. [314] All four patients were women who presented with diarrhea at an early age. Histology revealed lymphocytic infiltration of the lamina propria, muscularis propria, and myenteric plexus. The infiltrates were shown to be polyclonal by immunochemical stains, reflecting a pseudolymphoma rather than a true neoplasm. The myenteric plexus appeared normal with routine and silver stains. Smooth muscle cells were noted to be absent in the areas of lymphoid infiltration.

Jejunoileal bypass. Recurrent episodes of intestinal pseudoobstruction can occur in patients after jejunoileal bypass for morbid obesity. [165], [315] Symptoms begin as early as 1 week postoperatively and consist of abdominal distention and pain, diarrhea, vomiting, and fever. Radiography reveals massively dilated small bowel loops and occasionally pneumatosis cystoides intestinalis. Bacterial overgrowth of the bypassed small intestine causes this enteropathy; small bowel cultures typically grow fecal flora and anaerobes similar to those described in blind loop syndrome. Over time, either the symptoms disappear or the frequency and severity of pseudoobstruction decrease significantly. Intermittent antibiotic therapy may benefit patients with chronic symptoms. In contrast to intestinal pseudoobstruction, mechanical obstruction secondary to ileal volvulus at the jejunoileal anastomotic site can occur and presents a difficult diagnostic challenge. [316] Contrast radiography may aid in establishing the correct diagnosis. Recurrent acute colonic pseudoobstruction also has been reported after jejunoileal bypass. [317], [318] The effect on intestinal motility of bypassing a long segment of small bowel is unknown. In patients undergoing reoperation for various metabolic or hepatic complications, the bypassed segment appears normal, and normal small bowel function is restored after reversal of the bypass. [319]

Anorexia nervosa and bulimia. Both anorexic and bulimic patients frequently report bloating and constipation. Delayed gastric emptying of solids is a well-established abnormality in these disorders. The orocecal transit is also modestly delayed, [320], [321] as is the whole-gut transit time, measured by radiopaque markers, in comparison with controls. [321] Additional transit and manometric studies are required in patients with these disorders.

Clinical Manifestations

The small intestine is essential for the absorption of nutrients; therefore, individuals cannot survive without parenteral nutrition if a long segment of small intestine functions poorly. Fortunately, the small intestine is usually the last organ in the gastrointestinal tract to be affected by severe dysmotility. Severe dysmotility of the esophagus, colon, and even the stomach occur much more frequently than dysmotility of the small intestine. Isolated severe small intestinal dysmotility is very unusual; small intestinal dysmotility is generally associated with dysmotility in other parts of the digestive tract. In this chapter, the discussion is limited to the small intestine. Dysmotility in other organs of the digestive tract is discussed elsewhere in this book.

With a few exceptions, most patients with small intestinal dysmotility have similar clinical manifestations regardless of the underlying causes. The spectrum of clinical manifestations varies widely (see Fig. 73-5). At one end, the patient may be asymptomatic, and at the other, the patient may have recurrent symptoms and signs of small intestinal obstruction, termed *chronic small intestinal pseudoobstruction*. Between these two ends of the spectrum, the patient may have recurrent symptoms of postprandial cramping, periumbilical, and epigastric abdominal pain, in addition to abdominal bloating, easy satiety, anorexia, weight loss, nausea, and vomiting. The symptoms are usually related to eating. Diarrhea can occur in patients with bacterial overgrowth and malabsorption. In severe cases, the patients have episodes of chronic intestinal pseudoobstruction syndrome. Plain abdominal x-ray films of patients with intestinal pseudoobstruction during exacerbations show multiple air-fluid levels and dilation of the small intestine. The prevalence and severity of recurrent obstructive episodes vary from patient to patient and from episode to episode in the same patient.

The findings on physical examination vary according to the severity of the symptoms. Patients may be cachectic and malnourished because they are unable to take in adequate nutrients, or they may have malabsorption as a consequence of bacterial overgrowth in the small intestine. The abdomen may be distended and mildly tender. The bowel sounds are inactive and infrequent in patients with smooth muscle dysfunction, but they are hyperactive and high-pitched in those with myenteric plexus dysfunction. Borborygmi may be detected in some cases. In less symptomatic patients, the abdominal examination findings may be normal. In those with chronic intestinal pseudoobstruction, during an obstructive episode, the abdominal examination findings may be indistinguishable from those of true mechanical obstruction.

As mentioned previously, patients with small intestinal dysmotility usually also have symptoms of dysmotility in other parts of the gastrointestinal tract. Therefore, patients with chronic intestinal pseudoobstruction may have symptoms and signs of multiple-organ dysmotility.

Extragastrointestinal manifestations may be detected in some patients, depending on the underlying disease. Megacystis and megaureter are common in type I FVM and CVM and may be associated with urinary retention and infection. Mydriasis, ptosis, and external ophthalmoplegia may be seen in certain forms of FVM, and ataxia, dysautonomia, and neurological symptoms in some forms of visceral neuropathy.

In the secondary forms of small intestinal dysmotility, patients may also have systemic manifestations of the underlying disease (e.g., scleroderma, muscular dystrophies, autonomic neuropathy). These are important clinical clues in patients whose underlying disease has not yet been diagnosed.

Complications

Malnutrition Malnutrition develops in patients with severe dysmotility of the small intestine as the result of an inadequate intake of food and of vomiting. Postprandial abdominal pain and bloating limit oral intake. Anemia may develop secondary to iron, folate, and vitamin B_{12} deficiency. Serum cholesterol, calcium, and albumin levels may be low. Supplemental formulas are useful to improve nutrition. In severe cases, long-term parenteral nutrition may be the only method to provide adequate nutrients, particularly to patients with familial or sporadic forms of hollow visceral myopathy.

Bacterial Overgrowth in the Small Intestine Bacterial overgrowth in the small intestine may complicate severe intestinal dysmotility. [30], [129], [147], [322] The small intestine of these patients is usually dilated and atonic, and they have malabsorption and steatorrhea, which causes additional weight loss. The diagnosis can be made by culturing intestinal aspirates for both aerobic and anaerobic bacteria. A number of different species are found, and the total bacterial concentration generally exceeds 10^5 aerobic organisms per milliliter or 10^3 anaerobic organisms per milliliter. Another approach to diagnosing bacterial overgrowth is the timed analysis of breath excretion of volatile metabolites produced by intralumenal bacteria. The measurement of both expired ^{14}C-carbon dioxide after the oral administration of ^{14}C-labeled substrates (e.g., D-xylose) and expired hydrogen after the administration of nonlabeled substrates has been used. This method is less accurate than culture of duodenal aspirates. [323] The patients may have macrocytic anemia secondary to vitamin B_{12} deficiency. Tetracycline, metronidazole, ciprofloxacin, or ampicillin can be used intermittently to treat intestinal bacterial overgrowth for 7 to 10 days, depending on the recurrence of diarrhea. In some cases, an antibiotic may have to be given for 1 week of every 3 to 4 weeks. Abdominal bloating may be relieved by antibiotics in some cases.

Pneumatosis Cystoides Intestinalis Pneumatosis cystoides intestinalis is a rare condition characterized by multiple, gas-filled cysts in the wall of the small and large intestine. Pneumoperitoneum may occur. Pneumatosis cystoides intestinalis can develop in patients with small intestinal dysmotility and dilation. In most cases, the condition is found incidentally on radiographs. The pathogenesis is unknown, and no specific treatment is available. It has been recommended that surgery be avoided except in the cases of a complication such as an abscess or peritonitis because surgery usually causes the patient's condition to deteriorate. [164]

Diagnostic Studies

The diagnostic studies for patients with small intestinal dysmotility are outlined in Table 73-7.

Blood Tests
Complete blood cell count
Blood chemistries, including blood sugar
Antinuclear antibody
Thyroid functions: triiodothyronine, thyroxin, thyroid-stimulating hormone
Serum creatine phosphokinase and isoenzymes
Hemagglutination and complement fixation for Chagas disease
Antineuronal nuclear antibody or antititer for paraneoplastic process
Radiologic Studies
Plain abdominal radiography in patients with abdominal distention
Radiopaque marker transit
Upper gastrointestinal and small bowel radiography
Enteroclysis or small bowel radiography with fluoroscopy
Barium enema
Scintigraphic gastric, small bowel, and colonic transit
Intravenous pyelography
Computed tomography of chest and abdomen
Other Studies
Skeletal muscle biopsy
Cultures of small bowel aspirates
Small intestinal or colonic manometry
Anorectal manometry and balloon expulsion
Histological studies of full-thickness biopsy specimens to examine the smooth muscle and myenteric plexus by special silver stain, immunohistochemistry, confocal microscopy of enteric plexuses

TABLE 73-7 Diagnostic Studies for Patients with Small Intestinal or Colonic Dysmotility

Blood Tests A complete blood cell count may reveal anemia and macrocytosis secondary to malnutrition and bacterial overgrowth. Blood chemistries also reflect malnutrition and malabsorption. Diabetic patients have hyperglycemia, and hypoparathyroid patients may have hypocalcemia. Patients with connective tissue disease are positive for antinuclear antibody or SCL-70. Patients with thyroid disease have altered serum levels of triiodothyronine, thyroxine, and thyroid-stimulating hormone. Patients with muscular dystrophy may have elevated levels of CPK and isoenzymes. The results of hemagglutination testing and complement fixation for Chagas disease may be positive in patients who have lived in Central or South America. Antineuronal nuclear antibody testing is required in patients with a history of smoking to exclude paraneoplastic pseudoobstruction. Determinations of blood lactate, pyruvate (signs of acidosis), CPK, ALT (muscle damage), and leukocyte thymidine phosphorylase are used to screen for mitochondrial cytopathy.

Radiologic Studies

Plain abdominal x-ray films. These are very useful in patients with abdominal distention and bloating because they may show gaseous distention of the gastrointestinal tract. Upper gastrointestinal and small bowel x-ray films may show lesions typical of certain diseases. Areas affected by severe dysmotility usually are dilated.

Enteroclysis. Enteroclysis, or small bowel enema, [324] is very useful to detect lesions in the small intestine and rule out mechanical obstruction. Experienced radiologists can identify structural lesions in the small intestine in up to 98% of patients with mechanical obstruction. Barium enema and intravenous pyelography may be useful in detecting abnormalities of the colon and urinary tract, respectively.

Whole-gut transit with radiopaque markers. Discrete barium-impregnated, polythene markers that move with the colonic contents have become simple but robust measures of transit. Hinton and colleagues [325] measured gastrointestinal transit times using small solids (2- to 5-mm polythene pellets) containing barium sulfate. These inert, radiopaque, nonabsorbable markers, which have a specific gravity similar to that of gut contents, were completely recoverable in the stool. Followed by either abdominal or stool radiography, the movement of such markers was taken to represent the transit of meal residues through the gut (Fig. 73-23). Of 25 normal male subjects, all but one had passed 80% of the markers by the fifth day after ingestion, but none had passed 80% by the end of the first day.

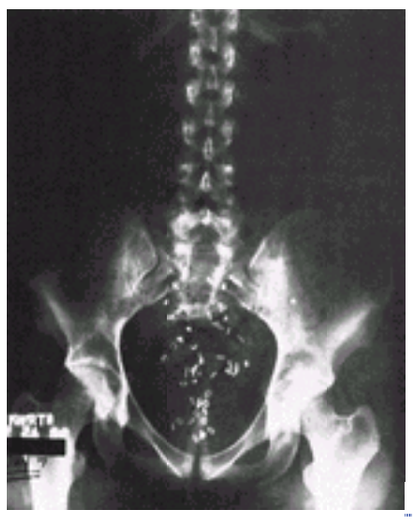

FIGURE 73-23. Radiograph of radiopaque markers as a measure of colon transit. Most of the markers are in the rectosigmoid colon of this patient.

Segmental colonic transit. The rate of disappearance of radiopaque markers from colonic segments was monitored with daily abdominal x-ray films obtained after the administration of a single dose of radiopaque markers. [326], [327] Right and left colonic, sigmoid, and rectal segments were defined simply by drawing lines between bony landmarks of the vertebral column and pelvis. Methods were then developed to calculate actual segmental transit times, rather than the rate of disappearance of markers from colonic segments. [328] Metcalf and colleagues [329] simplified this method so that only one x-ray film, obtained with a fast, high-kilovolt technique, was necessary; radiation exposure was therefore minimal. By this method, a fixed number of radiopaque markers were taken (24 per day) at the same time each day (9:00 AM arbitrarily) for 4 days. On day 5, again at the same time, an x-ray film was obtained. The method works on the assumption that a 24-hour sampling interval approximates continuous observation. In rapid transit, all the markers can be lost in the feces before radiography on day 4; conversely, in slow transit, all 96 markers may be present on the single radiograph. A film obtained on day 7 can then provide more information.

Radioactive isotope transit by scintigraphy. The transit of gamma ray–emitting radioactive isotopes through the colon can be quantified with a gamma camera linked to a computerized recording and processing system. [330] The isotope can be monitored for long periods without increasing radiation exposure; this is not possible with x-ray methods. The transit of solids and liquids can be measured simultaneously [331] if different isotopes are used to label liquid and solid bowel contents, and segmental regions of interest in the colon can be easily defined. A pH-sensitive polymer that dissolves at the pH of the ileum is used to coat capsules containing isotope-labeled beads. [330] With this approach, it has been possible to image the unprepared colon without the use of intubation; it is likely that such methods allow more “physiological” measurements of colonic transit. The net effects of fast or slow colonic transit are most clearly seen in the consistency of the stools. O’Donnell and colleagues [332] developed a 7-point scale for describing stool form and consistency, ranging from liquids to hard solids; they were able to relate stool consistency to the overall mouth-to-anus transit time. Faster transit was associated with looser stools. Stool form was then related specifically to colonic transit [331] after colonic transit times had been altered experimentally by rapid cecal infusions of fluid. When this noninvasive approach was used, [333] a good correlation was found between stool consistency and colonic transit; however, the correlation is clearly influenced by the extremes of transit and form, with little predictive value of stool that is not watery or extremely hard (Fig. 73-24).

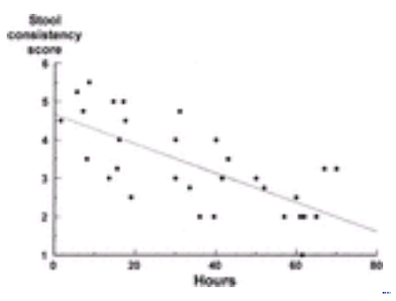

FIGURE 73-24. Correlation between mean colonic transit time (radiopaque markers) and physical appearance of stools (ranges from *1,* small and hard, to *6,* loose and semiliquid). (From ref. [333].)

Other Studies A biopsy of skeletal striated muscle may be required for patients suspected of having muscular dystrophy or mitochondrial cytopathy. Cultures of small bowel aspirates should be

obtained from patients with clinically suspected bacterial overgrowth (e.g., steatorrhea, bloating). Small intestinal manometry is indicated if no known underlying disease is present and the nature of the dysmotility (myopathy versus neuropathy) is unclear. If a full-thickness biopsy specimen of the dysfunctional part of the intestine is available, careful pathological examination for abnormalities in the smooth muscle or myenteric plexus with special trichrome and silver stains must be carried out. The most informative evaluation now includes assessment of the neurotransmitters by immunohistochemistry and morphologic assessment of the interstitial cells of Cajal with confocal microscopy.

Small Intestinal Manometry A low-compliance water infusion technique is the method most often used, but ambulatory studies with miniature transducers and radiotelemetry are also used. Impedance measurements have the potential to provide pressure profiles from very closely spaced sensors, although it is unclear whether these aid in the diagnosis. The small intestine has a unique pattern of motility. During fasting, a cyclic pattern of motility, the MMC, is seen. [334] The MMC is divided into three phases. Phase I is a quiescent period that lasts for about 15 to 30 minutes. Phase II, which lasts for about 60 minutes, is a period of intermittent contractions that increase in frequency with time until phase III is initiated. During phase III, intense contractions propagate aborally from the duodenum to the ileum. Phase III lasts for 4 to 10 minutes. After phase III, the small intestine become quiescent again (i.e., enters phase I) to start a new MMC cycle. This cyclic pattern continues until the subject eats. After eating, the MMC is replaced by frequent, intermittent, irregular contractions—the fed pattern. The fed pattern usually lasts for 2 to 6 hours, depending on the size of the meal; after it is complete, the fasting pattern, or MMC, returns. Small intestinal manometry has been used to study patients with various types of small intestinal dysmotility. [144, 145, 151, 167, 170, 186, 189, 195, 231, 322, 335, 336, 337, 338, 339, 340, 341] and [342] However, motility patterns are not diagnostic for any specific diseases. Many studies have been performed in patients with various clinical syndromes rather than specific diseases, which make the results difficult to interpret. Small intestinal motility studies have been performed in patients with small bowel bacterial overgrowth secondary to scleroderma, [322] chronic neuropathic intestinal pseudoobstruction, [144, 151] autonomic disorders, [343] FVM, [5, 17, 27, 337, 338] and [339] nonfamilial visceral myopathy, [30, 339] FVN, [58, 59] nonfamilial visceral (paraneoplastic) neuropathy, [219, 221] scleroderma, [167, 169] myotonic dystrophy, [231] and diabetes mellitus with gastroparesis. [187, 190, 341, 342] Three important patterns have been recognized from these studies.

Visceral myopathic pattern. In patients with smooth muscle dysfunction or degeneration, manometry demonstrates a decrease in the frequency and amplitude of contractions in the affected segment, generally during both the fast and fed periods. During fasting, the MMC is usually present but is diminished in amplitude. Myoelectric recordings may reveal abnormalities of the slow wave, such as variability in rate or rhythm, and abnormalities of propagation, such as loss of coupling or shortening of the length or even changes in the direction of propagation. These recordings are characteristic of diseases involving the smooth muscle, such as FVM, advanced scleroderma, dermatomyositis, the muscular dystrophies, and amyloidosis. [243, 246, 247, 343] Weston and associates [171] showed that in myopathic disorders, antral amplitudes are usually less than 40 mm Hg and duodenal amplitudes less than 10 mm Hg.

Visceral neuropathic pattern. Neurological disorders tend to produce disorganization and incoordination of motor activity. The MMC is often absent or abnormal. An abnormal rate of migration, as well as retrograde propagation of the activity front (phase III), also may be noted. Activity fronts may appear normal proximally and then become arrested or disappear in the more distal segments of the small intestine. In neurological disorders, the normal fed pattern may not replace the fasted pattern; MMC-like activity persists postprandially, and the frequency of antral contractions in the first hour is typically less than 1/min. [171] These abnormalities occur because the motility patterns are regulated by the ENS. The amplitude and frequency of contractions are usually normal when the inhibiting innervation and the coordinating function of the ENS are perturbed. Many of these abnormalities are seen best during sleep, when motor activity is quite stereotyped and normal phase II activity is suppressed. [344] The neurological disorders that have been described as producing manometric abnormalities include diabetes mellitus, Chagas disease, early scleroderma and amyloidosis, neurofibromatosis, paraneoplastic neuropathy, primary autonomic neuropathy, Parkinson disease, brain tumors, and multiple sclerosis. [58, 186, 189, 205, 251, 345, 346]

Mechanical obstruction pattern. Recurring episodes of intense contractions followed by periods of rest have been observed radiographically in the part of the intestine proximal to an obstruction. This phenomenon can be detected manometrically as clustered runs [151] or simultaneous prolonged contractions in conjunction with periods of intervening quiescence lasting longer than 1 minute (Fig. 73-25). [347, 348] Manometry is not the usual way to establish the diagnosis of mechanical obstruction, but these patterns should alert the physician to the possibility of mechanical obstruction and mandate careful small bowel barium radiography (e.g., enteroclysis).

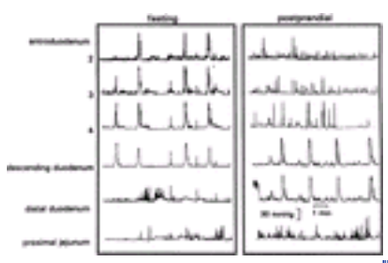

FIGURE 73-25. Gastroduodenal motility tracing demonstrating simultaneous prolonged contractions during fasting (**left**) and postprandial (**right**) phases. Contractions were present in the duodenum but not in the proximal jejunum (*bottom tracing*), a suggestion of mechanical obstruction in the distal duodenum or the proximal jejunum. (From Loftus EV, Farrugia G, Donohue JH, Camilleri M. Duodenal obstruction: diagnosis by gastroduodenal manometry. Mayo Clin Proc 1997;72:130.)

Overall, small intestinal manometry lacks the specificity to diagnose the underlying disease other than suggesting the pathophysiological process. The relative merits of a laboratory-based study [349] and ambulatory manometry [350] have been discussed in the literature. From a diagnostic standpoint, the latter does not significantly enhance the results of the shorter laboratory-based studies, which have the added advantage of examining antral motor function more accurately; however, the ambulatory study is more practical and probably less costly.

Colonic Manometry Pressure waves recorded manometrically are generally equated with contractile forces. Colonic contractions are often irregular, of varying frequency and amplitude, and subject to the emotional state of the subject, the type of meal eaten, and the composition of chyme entering the colon from the ileum. [351, 352, 353, 354] and [355] The colon is often “quiet” or exhibits isolated contractions (perhaps reflecting the dominant inhibitory control). At times, pressure waves are recorded in continuous bursts ranging in duration from 10 to 30 minutes, [353] with a dominant frequency of approximately six contractions per minute in the right side of the colon and approximately three to seven per minute in the distal colon. Phasic colonic contractions are stimulated by meals, beginning 20 to 30 minutes after a meal and lasting for up to 3 hours; sometimes, a second peak of activity occurs at approximately 70 to 90 minutes postprandially. [351, 352, 353, 354] and [355] This response to eating (gastrocolic reflex) remains after gastrectomy and after vagotomy. [356] If the stomach is intact, gastric distention and chemical stimulation by nutrients elicits a comparable response; lipids and a caloric content of more than 500 kcal are the most potent stimuli. [1, 357] Control of the colonic response to eating involves neural and possibly hormonal mechanisms. The part of the response mediated by gastric mechanoreceptors is very sensitive to blockade by atropine, but the part originating in the small intestine is only partially under muscarinic control. Cholecystokinin (CCK), which is normally secreted after meals, has been thought to play a role in the response because high blood concentrations of CCK stimulate contractile activity in both the small and large intestine. However, loxiglumide, a CCK A receptor antagonist, did not block the gastrocolic response to food. [358] Low-amplitude irregular phasic activity does not propagate and probably equates with segmentation; on the other hand, high-pressure, propagating waves are the equivalent of peristalsis. Isolated, high-amplitude (~200 mg Hg) peristaltic contractions (Fig. 73-26), propagating at about 1 cm/s over long distances, are thought to be important for transit or “mass movement” in the colon. These occur infrequently (mean of six per day in healthy humans) and are most frequent after waking and meals. [359] They can be reliably induced by instilling irritants like bisacodyl [360] or fatty acids [361] into the colon.

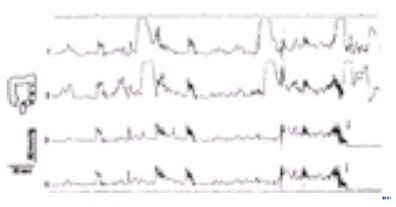

FIGURE 73-26. High-pressure waves recorded sequentially from four sites in the human colon. These contractions (giant migrating contractions) are thought to correspond to mass movements of colonic content. Their frequency is reduced in patients with constipation. (From ref. [359].)

An important variant of manometry uses the electromechanical barostat. [1, 362, 363] and [364] Originally developed to detect volume changes in the gastric fundus, the methodology is well suited for identifying relaxation in any hollow viscus. The 8- to 10-cm-long polyethylene bag used in humans is of large volume and “infinite compliance” until it reaches a volume of 500 to 600 mL. Air is introduced or withdrawn from the bag by a servomechanism to maintain a preset low pressure in the bag. Changes in volume are reflections of changes in wall tone. Basal tone in the proximal and distal colon exhibits rhythmic fluctuations, [1] and food induces an immediate and prolonged increase in tone. The postprandial response is inhibited by 5-HT $_3$ blockers [365] and modified by hyperglycemia. [366] The rectum also shows a tonic response to eating, [367] one that is impaired in patients with chronic slow transit constipation. [368] The rectum also demonstrates prominent relaxation during distention. [369, 370] and [371]

Differential Diagnosis between Chronic Intestinal Pseudoobstruction and Mechanical Obstruction

In patients with severe dysmotility of the small intestine, chronic intestinal pseudoobstruction may develop. Partial small bowel obstruction from adhesions, tumors, intussusception, or stricture can mimic chronic intestinal pseudoobstruction. The features listed in Table 73-8 can be used to differentiate between these two problems. Enteroclysis or careful small bowel radiography with fluoroscopy is probably the most helpful way to differentiate chronic intestinal pseudoobstruction from mechanical obstruction. In our experience, however, enteroclysis may not conclusively differentiate chronic intestinal pseudoobstruction from mechanical obstruction in some patients. Manometry proved useful in one series; [348] however, in most cases, exploratory laparoscopy may be necessary to rule out an obstructing lesion.

TABLE 73-8 Differentiation of Chronic Intestinal Pseudoobstruction from True Mechanical Obstruction

Treatment

Drug Therapy to Improve Small Intestinal Motility Theoretically, it is difficult to envision a drug that can either stimulate damaged muscle to contract effectively or normalize the coordinating functions of a damaged myenteric plexus. Drugs that stimulate intestinal motility in normal subjects (e.g., bethanechol, neostigmine, metoclopramide, erythromycin, tegaserod, prucalopride) have no beneficial effects in patients with small intestinal dysmotility. No information is available on the use of domperidone for small bowel dysmotility. Cisapride decreased the transit time of meal through the small bowel in normal subjects [295] and in patients with neuropathic forms of chronic intestinal dysmotility. [372], [373], [374] and [375] In a small, short-term study, octreotide, a somatostatin analog, stimulated intestinal motility, possibly reduced bacterial overgrowth, and relieved abdominal symptoms in patients with scleroderma. [167] Other open-label studies confirmed the long-term effectiveness of octreotide with erythromycin in the treatment of chronic intestinal pseudoobstruction. [293]

Symptomatic and Supportive Treatments Abdominal pain, bloating, nausea, and vomiting in patients with small intestinal dysmotility are often related to eating. Most of these symptoms can be minimized by manipulating the size, nature, and frequency of meals. The important point to keep in mind is to provide sufficient calories without overloading the inefficient bowel. A rule of thumb is to give approximately 25 cal/kg of the patient's ideal body weight per day. Adult patients should consume 1500 to 1800 cal/d divided into three or four equal feedings. At least half of the calories should come from supplemental formulas such as Ensure because a liquid meal empties faster from the stomach and probably progresses more easily through the small bowel than a solid meal. These formulas are lactose free and contain the daily requirements of vitamins and minerals. When patients still feel full several hours after the first meal, it is important that they not force themselves to eat subsequent meals to avoid aggravating their symptoms, and they that restrict their oral intake to fluids for the rest of the day. Patients with vagal dysfunction appear to respond less than those with myopathic dysfunction or no autonomic dysfunction. [374] In the long term, 60% appear to benefit from cisapride, and this benefit persists for up to 1 year. [375] In patients with chronic intestinal pseudoobstruction, recurrent symptoms and signs of intestinal pseudoobstruction may occur despite implementation of the previously described regimens. In these situations, nasogastric suction and intravenous fluids are needed when obstructive symptoms develop. When obstructive symptoms and pain persist or occur several times a week despite dietary manipulation, long-term parenteral nutrition is the only treatment that will relieve symptoms and improve nutrition. Abdominal pain unrelated to eating is uncommon in patients with small intestinal dysmotility, and if a patient has pain predominantly unrelated to meals, questions should be raised about the diagnosis. During episodes of obstruction, parenteral administration of narcotics such as morphine or meperidine may be required. Long-term narcotic use should be discouraged because addiction is possible, and narcotics can further disturb gastrointestinal motility. Constipation is common in patients who also have colonic involvement. It is important to make certain that the patient has a good bowel movement at least once every few days because constipation tends to increase the symptoms of intestinal dysmotility. We prescribe 30 to 60 mL (or two tablets three times daily) of Milk of Magnesia per day. Enemas may be used if the patient has no bowel movement for 3 days. Those with severe small intestinal dysmotility should avoid bulk-forming laxatives because they increase the load on an inefficient intestine and exacerbate symptoms.

Treatment of Secondary Causes A few types of secondary small intestinal dysmotility, such as those associated with myxedema, celiac sprue, and drug-induced dysmotility, can be treated with thyroid replacement, a gluten-free diet, and discontinuation of the offending drug, respectively. No specific treatments are available for most of the secondary types of small intestinal dysmotility.

Surgical Treatment Patients with dysmotility limited to short segments of the small intestine, such as those with megaduodenum, have a better prognosis than those with dysmotility throughout the length of the bowel because the dysfunctional segment can be resected or bypassed. [376] Megaduodenum, which is commonly seen in FVM type I and scleroderma, has been drained with a side-to-side duodenojejunostomy, which usually relieves symptoms. In some patients with a massively dilated duodenum, a side-to-side duodenojejunostomy may be inadequate to drain the duodenum. In these cases, resecting as much of the duodenum as possible with preservation of the papilla of Vater and anastomosing the opened jejunum to the cut edge of the duodenum to create a small conduit may be required as treatment. [13], [377] For patients with long segments of small intestinal dysmotility (i.e., >1.2 m), no effective surgical treatment is available. Any unnecessary surgery should be avoided in these cases because it can create adhesions and additional difficulties. Venting decompression by percutaneous jejunostomy or minilaparotomy or laparoscopy relieves symptoms and reduces the rate of hospitalization for recurrent exacerbations of pseudoobstruction. [378], [379]

Small bowel transplantation. Small bowel transplantation has become a reality with the introduction of effective immunosuppression (chiefly tacrolimus and mycophenolate); however, prognosis, survival, and complications seem quite different in children, in whom efficacy is greater than in adults. In a review of the world experience for the period from 1985 to 1997, the survival of patients and grafts was about 60%, and about three fourths of the survivors were free of parenteral nutritional support. [380] However, adults seem to fare less well; the actuarial survival rates of patients and grafts were 48% and 36%, respectively, at 3 years. [381] In reaching a decision about transplantation, it is important to recall that the 3-year survival of patients on home total parenteral nutrition (TPN) is 85%. [382] Several factors limit the success of small bowel transplantation and may result in death: infection (including infection with cytomegalovirus and Epstein-Barr virus, which accounts for approximately 50% of deaths); rejection (approximately 8% of deaths); technical problems; and lymphoproliferative disease (20%–40% of deaths in different programs). The latter is particularly linked to Epstein-Barr virus infection, the use of OKT3 immunosuppression, and steroids. [383], [384] In general, small bowel transplantation is restricted to life-saving situations, such as necrotizing enterocolitis, intestinal failure (short bowel syndrome) in patients who cannot be maintained on TPN, and rarely chronic intestinal pseudoobstruction in young patients who have TPN-related or other liver failure and lack intravenous access for TPN. In the future, gastroenterologists may be involved in the management of patients after small bowel transplantation. Recent observations that are likely to affect this practice include the following: (1) Zoom videoendoscopy is capable of showing the enlarged crypt areas and villus blunting or flattening that correlate with histological evidence of rejection. [385] (2) Severe rejection (mucosal necrosis with loss of villi) is of grave prognostic significance (11% graft, 18% patient survival) [386] and, pending newer immunosuppressive regimens, may be an indication for removal of the graft. (3) Living-related small bowel transplantation is technically feasible and has been reported to be followed by complete functional adaptation of the graft. [387] It is clear that survival after this formidable procedure depends on the experience of the entire transplant team and center, aggressive treatment of infection and rejection, and the rate of mortal complications, including lymphoproliferative disease, remains high. [388] The use of tacrolimus in immunosuppression is associated with a fivefold increase in lymphoproliferative disease relative to cyclosporine in children receiving liver transplants. [389] Molecular methods to screen for Epstein-Barr virus infection, improved immunosuppression, and possibly bone marrow transplantation to enhance chimerism may change the biology or prevalence of lymphoproliferative complications in the future.

COLONIC DYSMOTILITY (PSEUDOOBSTRUCTION) AND MEGACOLON

Interstitial Cells of Cajal in Maldevelopment and Acquired Diseases of the Colon

The significance of the interstitial cells of Cajal (ICCs) was established during the last 25 years through the careful histological and electrophysiological observations of Faussone-Pellegrini and colleagues [77], [78] and Thuneberg; [79] the latter established the candidacy of ICCs as the intestinal pacemaker cells. The protooncogene c-kit encodes a tyrosine kinase receptor that facilitates the development of the ICCs. [390] Furthermore, mice with mutations in the dominant white spotting (W) locus, which have cellular defects in hematopoiesis, melanogenesis, and gametogenesis as a result of mutations in the c-kit gene, also lack the network of ICCs and intestinal pacemaker activity. [391] In the last decade, the role of ICCs has become more clearly understood through studies of a mutant strain of mice (*w/w v*) that lack c-kit–positive cells and in which gastrointestinal dilation and failure of peristalsis develop. [392], [393], [394], [395] and [396]

ICCs are typically surrounded by collagen fibers and form close contacts (Fig. 73-27) with smooth muscle cells. [392] These gap junctions with smooth muscle cells allow transmission of the pacemaking activity that reflects the spontaneous oscillation in resting membrane potentials, which is unaffected by 10^{-6}-M verapamil, an L-type calcium channel blocker. [392] When studied in short-term primary culture, the cells assume a triangular shape with three to four branches that are in apposition with co-cultured smooth muscle cells (Fig. 73-28). Huizinga, Ward, Sanders, and their colleagues [393], [394] and [395] have characterized the expression profiles of pacemaker ICCs isolated from the murine small intestine and ICCs and smooth muscle cells involved in neurotransmission from the gastric fundus. All cell types express muscarinic receptor types M_2 and M_3, neurokinin receptors NK_1 and NK_3, and the inhibitor receptor vasoactive intestinal peptide 1 (VIP_1). [395]

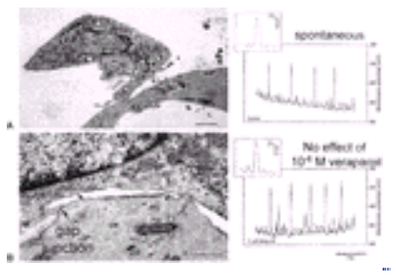

FIGURE 73-27. Gap junctions between interstitial cells of Cajal and smooth muscle cells; note the spontaneous electrical oscillations of the resting membrane potential of the interstitial cells of Cajal and the lack of inhibition by the L-type calcium channel blocker verapamil. (From ref. [392].)

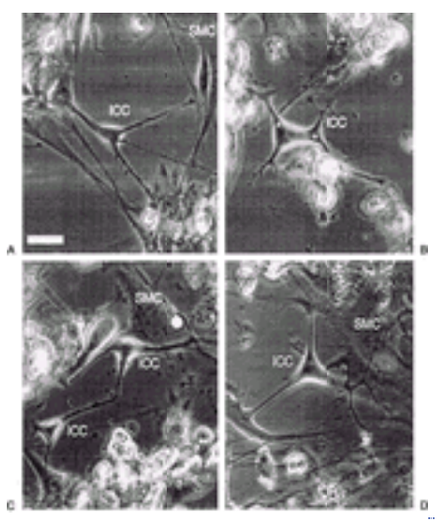

FIGURE 73-28. In short-term culture, interstitial cells of Cajal assume a triangular shape and have three to four branches that establish contact with cultured smooth muscle cells. (From ref. [392].)

In clinical studies, a relative deficiency of c-kit–positive cells has been reported in Hirschsprung disease, chronic intestinal pseudoobstruction, [396], [397] gastrointestinal stromal tumors, and multiple gastrointestinal autonomic tumors. [398], [399]

Delayed maturation or maldevelopment of ICCs is well documented (Fig. 73-29). [400] At 1 month of age, a child with chronic colonic pseudoobstruction underwent biopsy of the affected colon, which showed no peristaltic activity and no c-kit immunoreactivity within the circular muscle layer or the submuscular layer (see Fig. 73-29) but a normal ICC population in the myenteric plexus. At 6 months of age, the peristaltic activity was normal, and the ICCs were fully developed in all layers of a full-thickness biopsy specimen of the colon. This careful case study illustrates several points: (1) the concept of postnatal maturation of ICCs, (2) the importance of the conservative management of children with neonatal megacolon or pseudoobstruction, and (3) the importance of ICCs to the overall peristaltic function of the colon. Little is known about the transmitters expressed by ICCs in disease. However, immunoreactivity to NK1 has been detected in ICCs and may be used as a marker of the ICCs at the deep muscular plexus; these cells may participate in the actions exerted by tachykinins on muscle cells. [401]

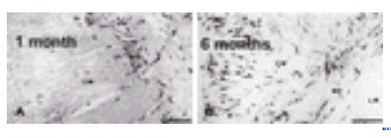

FIGURE 73-29. Full-thickness biopsy specimens from the colon of an infant with neonatal chronic colonic pseudoobstruction demonstrating delayed maturation of interstitial cells of Cajal at 1 month and subsequent expression of the cells at 6 months of age. (From ref. [400].)

Megacolon in an adult has also been associated with abnormal morphology and ultrastructure of ICCs. Faussone-Pellegrini and colleagues [402] demonstrated ICCs with several branches in the dilated transverse colon, but abnormal ICCs with a paucity of mitochondria, filaments, and caveolae in the nondilated descending colon.

In patients with acquired slow transit constipation not associated with colonic dilation, the number of ICCs in the different layers of the sigmoid colon is lower (Fig. 73-30) than in controls (specimens resected for other indications). Moreover, the confocal images show irregular surface markings and a paucity of branches of the cells (Fig. 73-31). [403] Staining of myenteric plexus cells with c-kit is reduced, consistent with a reduction of ICCs or their tyrosine kinase content.

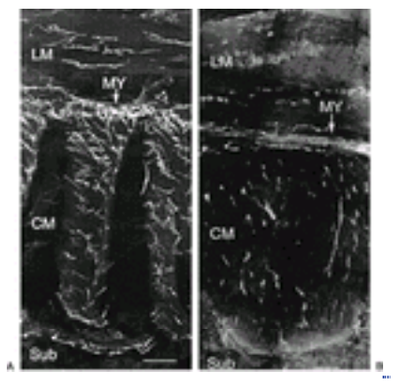

FIGURE 73-30. Distribution of interstitial cells of Cajal in whole transverse mounts of a normal-appearing disease control section of the sigmoid colon (**A**) and the sigmoid colon of a patient with slow transit constipation (**B**). (From ref. 403 .)

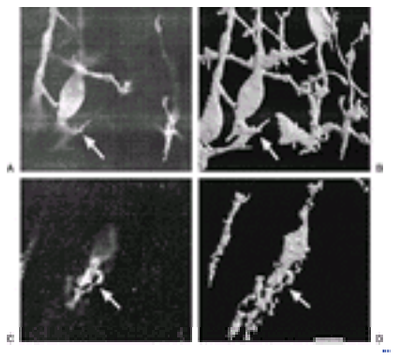

FIGURE 73-31. High-magnification confocal microscopy of the interstitial cells of Cajal in human sigmoid colon. **A** and **C** are single slices; **B** and **D** are reconstructions of 20 consecutive single slices. **A** and **B** are from a healthyappearing disease control colon; note the multiple fine processes and the network of interconnecting interstitial cells of Cajal. **C** and **D** are from a patient with slow transit constipation. Note the irregular markings and loss of fine processes. *Bar* = 10 µm. (From ref. 403 .)

Syndromes Generally Attributed to Disorders of Colonic Motility

Constipation Patients consider themselves to be constipated when they pass stools more infrequently, require more effort for passage (“straining”), or experience more pain or discomfort during passage than they think appropriate. Difficult evacuation of feces, especially when the consistency of stools is softer than normal, is more likely to be caused by disorders of the pelvic floor or anorectum than by slow colonic transit. Disorders of the pelvic floor are disturbances of evacuation (dyschezia, obstructed defecation) and are not be considered here (see Chapter 43 and Chapter 92). Slow transit through some or all segments of the colon leads to the formation of hard fecal masses that are passed infrequently and often with great difficulty. This condition, slow transit constipation (STC), should be considered as separate from IBS and should be diagnosed only if abdominal pain is not a prominent feature. On the other hand, STC certainly merges with IBS when pain, abdominal distention, excessive rectal mucus, and intermittent episodes of frequent, looser stools also occur (see Chapter 86). STC is considered in the next section.

Slow Transit Constipation Figure 73-23 shows radiopaque markers retained predominantly in the distal colon (rectosigmoid segment) 96 hours after ingestion. 325 This technique is simple, inexpensive, and of proven value in the documentation of STC. 325 , 326 , 327 , 328 and 329 Gamma scintigraphy 330 offers another means of testing, which can be made shorter (24 or 48 hours). Whatever method is used, the implications for therapy are potentially important. Most patients with STC respond to laxative programs, suppositories, or enemas. Resective surgery of the colon (usually subtotal colectomy with ileorectostomy) is occasionally necessary for severe STC. When tests of pelvic floor function identify a clinically relevant abnormality, colectomy is not indicated, even in the presence of slow transit. Retraining programs for the pelvic floor should first be used to correct the defect in expulsion, after which transit can be retested.

Manometry. In STC, the normal high-amplitude pressure (peristaltic) waves in the colon are reduced. Hirschsprung disease, or congenital megacolon (see section “ Hirschsprung Disease: Congenital Megacolon”), is a special case in which the pathophysiological abnormality is absence of relaxation of the internal anal sphincters, manifested by absence of the rectoanal inhibitor reflex.

Myoelectric patterns. Myoelectric patterns have confirmed the concept of “paradoxical colonic motility”: patients with diarrheal disease often have a colon that demonstrates relatively little overall myoelectric activity, whereas those with constipation often have very active motor patterns that favor “holding up” contents.

Histopathology. Many patients with STC severe enough to warrant subtotal colectomy display histological changes in the ENS of the resected colon on silver staining; Table 73-9 summarizes the information derived from a number of studies in the literature. 403 , 404 , 405 , 406 , 407 , 408 , 409 , 410 , 411 , 412 and 413 In general, it appears that reduced substance P and increased nitrergic neurons are associated with constipation that leads to surgical resection of the colon. In Parkinson disease, evidence is found of a reduction in the dopamine content of the myenteric plexus and a significant reduction in the dopamine-positive neurons of whole mounts of the plexus. 414

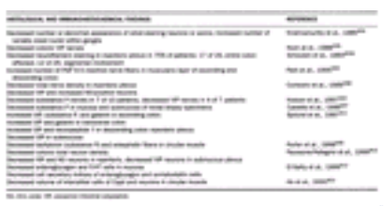

TABLE 73-9 Colonic Neuropathology in Slow Transit Constipation

Ultrastructural quantitative studies have demonstrated abnormalities of the morphology and numbers of ICCs. 403 It is assumed, therefore, that these patients have a morphologic abnormality of the neural control of colonic motility. These clinical and histopathological features appear to merge with the syndromes of intestinal pseudoobstruction (see section “ Colonic Pseudoobstruction and Megacolon”). The treatment of constipation is addressed in Chapter 43.

Colonic Pseudoobstruction and Megacolon

Megacolon (Table 73-10) and *megarectum* are descriptive terms, without etiologic or pathophysiological implications. *Megacolon* has been defined as a diameter of the rectosigmoid region or descending colon, on x-ray film, of more than 6.5 cm, of the ascending colon of more than 8 cm, or of the cecum of more than 12 cm. 415 Megacolon can be caused by aganglionosis (Hirschsprung disease), may be idiopathic (complicating chronic constipation of any cause), or may be a manifestation of diffuse gastrointestinal dysmotility (intestinal pseudoobstruction). *Acute megacolon* is often designated as *Ogilvie syndrome*. Rectal dilation, or *megarectum,* may be an isolated finding or, more often, associated with megacolon or simply prolonged chronic constipation, particularly in children with functional fecal retention. Note that megacolon does not include simple elongation of the colon (dolichocolon).

Congenital Megacolon (Hirschsprung Disease)
"Classical" type
Short segment
Ultrashort segment
Total colonic aganglionosis, zonal loss of ganglia, and other variants
Acquired Megacolon (Associated with Constipation)
Idiopathic
In children (associated with encopresis)
Acute form in adults (Ogilvie syndrome)
Secondary to neurological diseases
Chagas disease
Parkinson disease and central nervous system dysfunction; myotonic dystrophy
Diabetic neuropathy; others (ganglioneuromatosis, familial autonomic dysfunction)
Intestinal pseudoobstruction ("neurogenic" forms)
Secondary to diseases of intestinal smooth muscle
Scleroderma and other "collagen diseases"; amyloidosis
Intestinal pseudoobstruction ("myogenic" forms)
Secondary to metabolic diseases
Hypothyroidism, hypokalemia, porphyria, pheochromocytoma (with ganglioneuromatosis)
Drugs
Mechanical obstruction

TABLE 73-10 Clinical Classification of Megacolon

In *congenital megacolon* (Hirschsprung disease), colonic dilation results from functional obstruction (usually of the rectum) caused by a congenital absence of the intramural neural plexuses that mediate relaxation (aganglionosis). This leads to a narrow segment of the large intestine—that is, one that fails to relax.

Acquired megacolon can complicate any of the many causes of constipation, and it can be assumed that megacolon is acquired when it can be ascertained that colonic dilation was not present at some earlier examination. A common background for acquired megacolon is colonic inertia, which occurs frequently at both extremes of life. In children, this form can be confused with the congenital condition.

Worldwide, infection with *Trypanosoma cruzi* (Chagas disease) is the most common form of acquired megacolon. In this condition, the dilated segment of colon is abnormal because of destruction of the ENS by the neurotoxin of the organism. Although infection was originally confined to the South American continent, it is now estimated that there are 350,000 seropositive persons in the United States; among these, one third are thought to have chronic Chagas disease. [416] Some patients acquire megacolon as part of a generalized intestinal pseudoobstruction.

When colonic pseudoobstruction is acute and associated with another medical condition (abdominal or orthopedic surgery, spinal cord injury, serious cardiovascular or other medical problems), the term *Ogilvie syndrome* is often applied. Toxic megacolon is a life-threatening complication of inflammatory bowel disease and infectious colitides (see Chapter 83 and Chapter 88).

Hirschsprung Disease: Congenital Megacolon

Pathophysiology. Aganglionosis is caused by the arrested migration of cells caudad from the neural crest; these are the cells destined to develop as the intramural plexuses of the gut. In Hirschsprung disease, the aganglionic segment always extends from the internal anal sphincter for a variable distance proximally, but in most instances it remains *within the rectum and sigmoid colon*. The involvement of very short segments, affecting only the anal sphincters, has also been described. The aganglionic segment is permanently contracted, causing dilation proximally. Longer aganglionic segments occur in fewer than 20% of individuals; involvement of the entire colon is infrequent, and aganglionosis extending proximally into the small intestine is rare. Thus, the hallmark of diagnosis is the absence of ganglion cells from the myenteric and submucosal plexuses, as seen on a full-thickness or suction (mucosal-submucosal) biopsy specimen of the rectum. Proximal contents fail to enter the unrelaxed aganglionic segment. Morphologically, ganglion cells are absent from the narrowed segment and for a short distance (usually 1–5 cm) into the dilated segment. In contrast, the nerve fibers are hypertrophic, with abundant, thickened bundles. Specific stains for acetylcholinesterase highlight the abnormal morphology. Adrenergic denervation of the dilated segment is another inconsistent finding, as is a decreased supply of peptidergic nerves (containing VIP, substance P, enkephalins, and other peptides). The most characteristic functional abnormality of aganglionosis is a failure of the internal anal sphincters to relax following rectal distention. [417] Transient distention of a balloon in the rectum causes the intralumenal pressure at the level of the internal anal sphincter to drop; the drop is often accompanied by a reflex contraction of the external sphincter. Up to 20% of normal children may have a falsely absent reflex, especially if they are premature or of low birth weight, but *a positive response is strong evidence against Hirschsprung disease*.

Incidence and genetics. The defect occurs once in each 5000 live births and is in some cases familial, with an overall incidence of 3.6% among siblings of all index cases. [418] Because the disease was highly lethal until the introduction of curative surgery in the 1950s, accurate assessment of the incidence in the offspring of successfully treated patients is incomplete. Consanguinity of parents is exceptional, and the condition is reported to be discordant in dizygotic twins and concordant in monozygotes. The association of congenital aganglionosis of the colon with Down syndrome is ten times more frequent than would be expected by chance; [418] approximately 2% of patients with congenital megacolon have Down syndrome. A number of other congenital anomalies have been reported: hydrocephalus, ventricular septal defect, cystic deformities and agenesis of the kidney, cryptorchidism, diverticulum of the urinary bladder, imperforate anus, Meckel diverticulum, hypoplastic uterus, polyposis of the colon, ependymoma of the fourth ventricle, the Laurence-Moon-Bardet-Biedl syndrome, and congenital central hypoventilation syndrome (Ondine curse). The genetic disorders resulting in disordered development of the neural crest in Hirschsprung disease are discussed in detail above (see section "Ontogeny of the Enteric Nervous System").

Clinical features. Hirschsprung disease should be suspected shortly after birth when the infant passes little meconium and the abdomen is distended. Digital examination of the rectum, insertion of a rectal tube, or administration of a small enema causes retained fecal material to gush forth, with apparent relief of the symptoms. However, the respite is often short-lived; signs of partial intestinal obstruction return, with persistent vomiting and distention as the major features. In about 20% of patients, diarrhea persists; it is caused by pseudomembranous enterocolitis, which develops as a complication of the obstruction. Later in life, the presentation is often less dramatic and may not mimic an acute intestinal obstruction. Severe constipation and recurrent fecal impactions are more common. Children occasionally show evidence of anemia, malnutrition, and even hypoproteinemia resulting from protein-losing enteropathy; their resistance to infection can also be impaired. Although difficulties develop in most children before the second month of life, very-short-segment aganglionosis may not cause severe symptoms until after infancy.

Differential diagnosis. Hirschsprung disease must be distinguished in the neonate from other developmental causes of intestinal obstruction, such as atresias and imperforate anus. Later in life, acquired (secondary) megacolon is the other major consideration. The diagnosis of congenital megacolon is usually not difficult beyond the immediate neonatal period, and the better diagnostic methods now available allow a positive diagnosis in most cases. Obstipation, with infrequent spontaneous passage of stool, dates from infancy, and the rectal examination reveals an empty ampulla. Overflow incontinence is not a feature of Hirschsprung disease. A barium enema x-ray film (Fig. 73-32) confirms the diagnosis if the characteristic transition from the narrowed, distal rectum or rectosigmoid to the dilated proximal colon is seen. However, when the aganglionic segment is very short, a narrowed segment is not seen radiologically. In patients with acquired megacolon, encopresis is common, dilation extends all the way to the anus, and a narrowed zone is not seen.

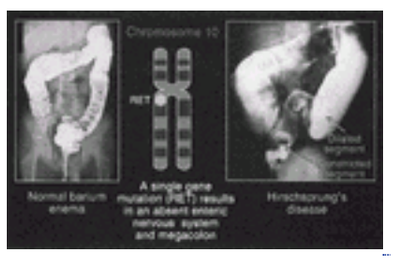

FIGURE 73-32. Barium enema in a normal child contrasted with a study showing megacolon and a narrow segment affected with Hirschsprung disease. The genetic defect involves a mutation of the RET protooncogene on chromosome 10q11.2.

Proctosigmoidoscopy reveals a normal but empty rectum. The dilated proximal bowel, if within range of the scope, is easily traversed except for abundant feces in the lumen; occasionally, stercoral ulcers are noted. The key findings are the empty lower segment and the absence of evidence of organic obstruction. The diagnosis is best substantiated by a full-thickness biopsy of the rectum. The presence of normal numbers of ganglion cells excludes the diagnosis. Mucosal suction biopsy, satisfactory in many instances, is the initial procedure of choice because it is performed easily and requires no anesthesia. If the depth of the examination is sufficient to show the presence of ganglia in the Meissner (submucosal) plexus, the classical form of Hirschsprung disease is excluded. However, the absence of ganglion cells does not establish the diagnosis, and a full-thickness biopsy specimen should be obtained at least 3 cm proximal to the pectinate line. A diminution or absence of ganglion cells distal to this point is difficult to interpret. Careful histology proximal to the internal sphincter reveals that myenteric ganglia may be absent from normal infants over a distance of 4 to 5 mm in this segment; ganglia may be absent from the deep and superficial submucosal layers for even longer distances. Immunohistochemical techniques can highlight the morphologic abnormalities,

showing an abundance of hyperplastic axons but an absence of ganglion cells. Several approaches, in which antibodies to acetylcholinesterase, neuron-specific enolase, neurofilament, and neuropeptides are used, have been described. [419], [420] Physiological tests complement the diagnosis in doubtful cases, and they may be crucial when the aganglionic segment is very short. Such cases are less easily detected on x-ray films and are also likely to be missed by biopsy. The most important pathophysiological test is the response of the anal sphincters to distention of the rectum. [417] In contrast to the internal sphincter in normal individuals and in patients with acquired megacolon, the internal sphincter in patients with congenital aganglionosis fails to relax (or contracts even further) after the rectum is distended. The most common cause of a false-positive test result is a capacious rectum in constipation or megarectum; under these circumstances, distension of the rectal balloon does not stimulate the reflex. Therefore, an enlarged rectum should be excluded before Hirschsprung disease is diagnosed.

Treatment of congenital megacolon. Definitive surgical cure is the treatment of choice. Preliminary decompression by colostomy is still sometimes necessary to relieve obstruction, or it may be necessary in some infants when it is decided to postpone definitive surgery. However, the goal should be early diagnosis and a one-stage surgical approach. The main goals are to establish regular and spontaneous defecation, to maintain normal continence, and not to interfere with sexual potency. The surgical procedure should cause essentially no mortality and minimal morbidity. A number of different operations have been used to remove successfully or to counterbalance the obstructing effect of the aganglionic segment. Long-term results are good in the great majority of patients, but 10% to 20% have residual problems, usually with fecal soiling. [421]

Variants of congenital megacolon. The spectrum of Hirschsprung disease has widened considerably. Patients with a compatible clinical picture may have an ultrashort segment of aganglionosis, involving only the internal anal sphincter. [422] Morphologic confirmation of the diagnosis may be difficult, and physiological testing becomes even more important. Patchy or zonal loss of ganglia (ladder pattern) and dysplastic neurons have also been described. Cases classified as acquired aganglionosis have been reported. In these, ganglia were seen in tissues removed at an initial operation, but when clinical failure led to further surgery, an aganglionic segment was clearly demonstrable. Rather than that these were cases of acquired disease, it seems more likely that a short aganglionic segment was missed on the initial evaluation. With greater awareness of the more subtle morphologic and physiological abnormalities, Hirschsprung disease is being detected more often in adults. [423] The clinical, physiological, and morphologic features in adulthood are usually similar to those of the milder form of the disease when recognized earlier in life. Thus, congenital megacolon (Hirschsprung disease) can be subdivided into the classical form, short-segment types, ultrashort-segment types, and other variants (see Table 73-10).

Acute Megacolon Acute toxic megacolon occurs in patients with severe, fulminant inflammatory bowel disease or infectious colitis (see Chapter 83 and Chapter 88); the colon also dilates in response to acute distal obstruction (e.g., volvulus or carcinoma). However, pseudoobstruction and acute megacolon can occur without evidence of intrinsic colonic disease or mechanical obstruction. In this latter instance, the patient has a form of acute colonic pseudoobstruction, named after Ogilvie. [424] In fact, the condition he described in two patients was longstanding and caused by malignant infiltration of mesenteric nerves. Regardless of the misnomer, the syndrome, now given Ogilvie's name, should be considered as a form of pseudoobstruction localized to the colon; the characteristic time course is acute or subacute. Moreover, most cases are clearly associated with an underlying disease; the most common predisposing conditions described in a metaanalysis of 400 cases were trauma, orthopedic surgery, obstetrical procedures, pelvic and abdominal surgery, metabolic imbalance, and neurological conditions. [425]

Pathophysiology. The precise cause of acute colonic pseudoobstruction is unknown. However, Ogilvie syndrome is the clearest example of the human colon dilating in response to nonmechanical factors. Ogilvie proposed that an imbalance of intrinsic and autonomic neural control is the basis for the syndrome. [424] This propensity of the human colon to relax and dilate has been studied experimentally with the barostat. [1] In these experiments, wall tone decreased markedly during sleep and in response to glucagon; a model of colonic dilation during acute distention of the ileum has been described in dogs. [426] This concept, that the wall of the colon is able to relax readily in response to physiological and pharmacological stimuli, may be an important basis for megacolon.

Clinical presentation. The typical patient is a middle-aged or older person who is recovering quite uneventfully from surgery performed a few days previously and who is already on a general diet. In one report, [427] more than half the patients had undergone recent surgery or manipulation of the spine or retroperitoneum. The abdomen becomes grossly distended and breathing becomes labored, but early in the course, no peritoneal signs are present and the white blood cell count is normal. An abdominal film shows massive gaseous distention of the colon with air distributed throughout, including the rectum. Usually, the small bowel is not seen. The diameter of the cecum at this point is often 9 to 10 cm.

Initial management. Oral feedings should be stopped, parenteral fluids started, and a nasogastric tube passed; all nonessential drugs should be discontinued. A Hypaque (water-soluble contrast) enema is administered; in this way, mechanical obstruction can be excluded and pseudoobstruction confirmed. As a side benefit, hyperosmolar Hypaque usually evacuates the colon during the diagnostic maneuvers. Once confirmed, acute colonic pseudoobstruction should be treated aggressively, with a rectal decompression tube and enemas. Any associated metabolic abnormalities or electrolyte disorders (e.g., hypokalemia) must be corrected; these are prominent in 20% to 30% of cases. [427] Efficacy has been reported for pharmacological blockade of ganglia with guanethidine followed by cholinergic stimulation with neostigmine, [428] although it must be emphasized that the condition resolves in many cases with simple measures. [429] Intravenous neostigmine (up to 2 mg) was effective in acute colonic pseudoobstruction in a randomized controlled trial. [430]

Subsequent management. Most of the patients who do not respond to enemas, nasogastric decompression, and drug therapy continue to have a normal white blood cell count, and fever or peritoneal signs do not develop. If the cecum measures more than 11 cm, the next step is colonoscopic decompression. The previous enema often empties the colon, facilitating endoscopy. Gas and liquid stool are aspirated while small amounts of additional air (or carbon dioxide) are insufflated. The mucosal detail is often obscured by the contents, but an obstructing lesion can usually be seen. It is not necessary to reach the cecum to accomplish adequate decompression; positioning the colonoscope at the hepatic flexure with aspiration of the distal contents usually collapses the right colon. An abdominal film should then be obtained; the collapsed cecum can be documented and the patient kept on enemas until stool and flatus pass spontaneously. Although colonoscopic decompression may have to be repeated, more than 80% of patients respond to colonoscopic decompression and require no further management. An operation is advisable for patients with a very large cecum (>14 cm) and for those whose condition remains intractable to medical and endoscopic management. The most useful and efficacious approach is tube cecostomy, now possible by laparoscopic techniques. Moreover, if at any time a patient manifests fever, leukocytosis, or peritoneal signs, abdominal exploration is mandatory. In these situations, the right side of the colon is frequently nonviable or is already perforated. For perforation, right hemicolectomy with ileostomy and a mucous fistula is the operation of choice. In patients with nonviable bowel but without perforation, a right hemicolectomy and primary anastomosis can be performed with little risk for serious complications. For patients with megacolon, a normal-sized rectum, and a normal mechanism of defecation as determined by the newer tests of pelvic floor function, ileorectostomy is the operation of choice; these patients usually establish a relatively normal bowel habit. Patients with megarectum, a normal-sized colon, and a defecation abnormality are candidates for the Duhamel operation or perhaps a coloanal anastomosis. The enlarged rectum is resected in its entirety; therefore, fecaliths in the rectal remnant, so common in patients after Duhamel procedures, are avoided.

Syndromes Partly Attributed to Disorders of Colonic Motility

Chronic Diarrhea Diarrhea is defined as more frequent defecation or the passage of stools that are less well formed than is thought normal by the individual. In patients with IBS and diarrhea, transit through the proximal colon is accelerated, and the rates at which the ascending and transverse portions of the colon empty are related to fecal weight. [431] Stools that are less solid (fragmented, semisolid, or liquid) result from more rapid transit through the colon; however, the most characteristic bowel pattern in IBS is one of wide fluctuations of stool frequency and consistency. Presumably, colonic transit changes dramatically in IBS, from slow to fast (or vice versa), to produce these stool patterns. The scintigraphic method has been used to demonstrate rapid small bowel and colonic transit in the diarrhea of carcinoid syndrome. [432] A fivefold increase in the emptying rate of the ascending and transverse parts of the colon was noted; this was associated with storage of a reduced volume in the ascending colon, as measured by the scintigraphic method. The rapid transit and reduced capacitance of the proximal colon were associated with increased postprandial tone as measured by the barostat. A serotoninergic mechanism has been implicated, and in carcinoid diarrhea, 5-HT$_3$ antagonists reversed the abnormalities. [433]

Irritable Bowel Syndrome: Motor Dysfunction IBS is now defined usually by the criteria of an international panel that evaluated the symptomatic features of this extremely common condition. The major features are altered stool frequency or consistency and abdominal pain that is directly related to a change in the pattern of bowel movements. Thus, it is not surprising that the colon has been incriminated as the origin of these symptoms. Colonic transit was evaluated in patients with IBS and diarrhea, [431], [434] and rapid transit of solids through the proximal colon was documented. It had earlier been reported that small bowel transit also was rapid in IBS with diarrhea. [434] The variable consistency of the stools that is so characteristic of IBS presumably is the result of slow transit of some of the fecal residue and rapid transit of other portions. The constipation experienced by some patients with IBS appears to blend imperceptibly into the syndrome of idiopathic constipation. Not surprisingly, then, the transit of radiopaque markers is prolonged in constipated patients with IBS. In a group of nearly 300 persons referred to a tertiary center with a major complaint of constipation, [435] the majority had only a modest slowing of colonic transit (it was sometimes normal) and were considered to be examples of IBS.

Inflammatory Disease of the Colon The diarrhea of inflammatory colitis is primarily caused by the exudation of fluid and mucus, bleeding, and impaired absorption; however, disordered motility and transit should also be considered. Connell [436] first proposed that the colon in advanced ulcerative colitis may behave as a semirigid tube, showing fewer phasic pressure waves than is normal; moreover, it is well recognized clinically that haustral contractions are absent in the late stage of colitis. These radiologic phenomena (haustra) are thought to be produced by repetitive, nonpropagated, phasic contractions. Reddy and colleagues [437] used combined manometric and scintigraphic techniques to study transit in ulcerative colitis. They confirmed the paucity of phasic pressure activity in the fasting state. Postprandially, however, low-amplitude pressure waves were more frequent in colitis, and when these were propagated, they always moved contents in an antegrade direction. Thus, movement of isotope from the splenic flexure to the sigmoid colon was usually rapid, perhaps reflecting the absence of retarding pressure waves. [437] Another important disorder of motility is seen in ulcerative proctitis, in which a heightened sensitivity of the rectum to distention has been reported. [438], [439] Clinically, such patients are often sensitive to very small amounts of feces or mucus in the rectum. Pressure waves of high amplitude in the rectum have been recorded in proctitis and implicated in the symptom of tenesmus.

Response of the Colon to Drugs

Laxatives The most complete study of laxative agents and drugs that cause diarrhea as a major side effect was that of Karaus and Sarna. [440] They studied the effects of hypertonic glucose, castor oil, neostigmine, and guanethidine in dogs with strain gauges sewn onto the colon. In all instances, when the agents induced diarrhea, powerful contractions migrated around most or all of the colon and led to an evacuation. On the other hand, a local stimulus to the rectum (distention) was able to provoke expulsion of the balloon without participation of the whole colon in the motor event. The motor effects of the local instillation of stimulant laxatives have been recorded from the human colon, [360] and the myoelectric responses of oral senna have been reported. [441] The effects of laxative doses of castor oil on the colon should be similar to those reported for oleic acid; [361] oleic acid and the active principle of castor oil (ricinoleic acid) are both C-18 aliphatic fatty acids. Lactulose has also been used experimentally as a stimulant of colonic transit; when it was administered in doses that induced a modest increase in stool frequency, transit through the right side of the colon was hastened. [442]

Antidiarrheal Agents The most effective antidiarrheal agents currently available are those related to opioids. Opiates are said to augment the mixing contractions that inhibit transit and to increase colonic tone, both of which might be expected to favor absorption. These actions should retard transit and help alleviate diarrhea. The effects of morphine on colonic tone have also been explored in dogs and humans with the electromechanical barostat. Under baseline conditions in the dog, the drug increased tone sharply [362] in association with an increase in phasic contractions. In the human colon, [443] the effects of morphine were more complex; it relaxed a segment showing high postprandial tone and caused a late (40 minutes after injection) decrease in spontaneous tone. Thus, the effects of opiates on the colon are complex, and perhaps species dependent.

Colonic Prokinetic Agents New 5-HT$_4$ agonists have been shown to accelerate colonic transit in health and in patients with functional constipation and constipation-predominant IBS. [444], [445], [446], [447], [448] and [449] This may represent a new generation of prokinetic agents for the gastrointestinal tract. However, confirmation of their clinical effectiveness awaits additional studies.

CHAPTER 74

Harry B. Greenberg, Suzanne M. Matsui, and Mark Holodniy

SMALL INTESTINE: INFECTIONS WITH COMMON BACTERIAL AND VIRAL PATHOGENS

Each year, an estimated 4 million children worldwide younger than 5 years of age die as a consequence of diarrheal illness. [1], [2] More than a billion others become ill and are temporarily unable to attend to their normal daily activities. Infants and young children in developing countries with limited medical resources are challenged further by suboptimal sanitary conditions and frequent intestinal infections (10–20 episodes of diarrhea before the age of 3 years) that contribute to a poor nutritional state. [3] Diarrheal disease is also important in developed countries, where surveys indicate it ranks second only to respiratory disease as a cause of illness among the general population (average, 1.2–1.5 episodes per person per year). [4], [5] The incidence of diarrheal disease in industrialized countries has declined through the years, but outbreaks of acute gastroenteritis with a variety of pathogens reflect the continued the importance of this illness. New and emerging pathogens, as well as recognized pathogens, may cause severe, even fatal, illness and have far-reaching implications for the community and economy at large. In addition, international travel, fresh food products imported from developing countries, and changes in dietary habits expand the spectrum of microbial pathogens that an individual may encounter, even in developed countries. [6]

The economic impact of diarrheal illness is also quite substantial. In the United States in the 1980s, there were 99 million estimated cases of acute gastrointestinal illness annually, characterized by vomiting or diarrhea. [7] In 1985, 8.2 million affected individuals sought medical attention for their gastrointestinal illness, and of these, 250,000 required hospitalization. The medical costs of hospitalization were $560 million, whereas costs related to lost productivity were in the range of $200 million. The 7.9 million persons treated as outpatients incurred medical costs of $690 million and lost productivity costs of $2.06 billion. For the more than 90 million persons who did not seek medical attention, lost productivity costs alone were estimated to be $19.5 billion. Although these estimates are based on the 1980 population and 1985 economic statistics, they represent minimum costs and demonstrate the magnitude of the economic impact of diarrheal illness in the industrialized world. The Centers for Disease Control and Prevention (CDC) now estimate that 267 million episodes of diarrhea occur each year among adults in he United States, resulting in 612,000 hospitalizations and 3,000 deaths. [8]

This chapter focuses on the major bacterial and viral pathogens that infect the small intestine. Whether by toxin-mediated effects or direct destruction of intestinal epithelial cells, these microbial pathogens have devised ways to disrupt the normal fluid-handling capabilities of the intestinal tract and cause diarrhea. Normally, the small intestine is presented with approximately 9 L of endogenously secreted (7 L) and ingested (2 L) fluid each day, of which 7 to 7.5 L is absorbed in the small bowel. The remainder is presented to the colon, where all but approximately 200 mL is absorbed and excreted in stool. Diarrhea ensues when the absorptive capacity of either the small bowel or colon is exceeded and unable to accommodate larger fluid loads induced by infection. In general, the diarrhea caused by infection with a small bowel pathogen is characterized by high-volume, less frequent bowel movements, whereas lower-volume and more frequent bowel movements are associated with colonic diarrhea.

FOOD POISONING AND COMMON SOURCE OUTBREAKS

Foodborne disease is a widespread public health problem. [9] A recent estimate indicates that 76 million such illnesses occur annually in the United States, contributing to 325,000 hospitalizations and 5000 deaths. [10] Previous estimates ranged from 6 to 80 million illnesses per year, with the economic impact perhaps being $5 billion or more. [11], [12] Water and food (if improperly cooked or handled or left unrefrigerated before consumption) can easily serve as culture media and vehicles for the transmission of microbial agents.

Foodborne disease results from the ingestion of food or water contaminated with pathogenic microorganisms, microbial toxins, or chemicals. Although this chapter emphasizes gastroenteritis, other foodborne illnesses (e.g., hepatitis A, brucellosis, listeriosis, botulism, diphyllobothriasis) do not cause prominent gastrointestinal symptoms. Risk factors for foodborne illness include misidentification of unsafe foods, chemical contamination of unsafe foods, and faulty preparation practices (poor personal hygiene of food handlers, inadequate storage and cooking).

Although the individual with a foodborne illness may or may not recognize the symptoms as related to the ingestion of a particular contaminated food item, certain established guidelines, used by the CDC, aid in the diagnosis of this syndrome. Foodborne disease can in most cases be established if two or more people have a similar illness after consuming a common meal, if an epidemiologic survey implicates a particular food item(s) as the probable cause of the outbreak, or if microbiologic studies identify the same organism or epidemic strain from a common food, food source sample, or clinical specimens obtained in a suspected outbreak.

The CDC publishes annual summaries of foodborne illness in the United States. From 1993 to 1997, 2751 outbreaks, representing 86,058 cases, of foodborne illness were reported to the CDC. Causes were identified in 878 (32%) of the outbreaks, and of these, bacterial pathogens were the most frequent (75%), followed by chemicals (17%), viruses (6%), and parasites (2%). [13] A cause was not established in most (68%) of the reported outbreaks. The incubation time for nearly half of these outbreaks was 15 hours or longer, suggesting a viral cause, such as Norwalk-like viruses. [14] The incubation period and presenting complaint can be helpful in differentiating among the etiologic agents, as shown in Table 74-1.

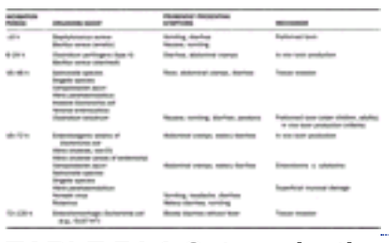

TABLE 74-1 Categorization of Intestinal Infection by Incubation Period and Major Presenting Complaints

Salmonella species caused 357 (55%) of the 655 foodborne diarrheal outbreaks reported. Seven percent of all outbreaks and 22% of outbreaks for which a cause was determined were attributed to *Salmonella enteritidis,* which also was associated with the greatest number of deaths (ten, four of which occurred in nursing home residents). [13]

Because the number of reported foodborne outbreaks is likely a fraction of all foodborne disease, [15] the CDC began an active surveillance program (Emerging Infections Program Foodborne Diseases Active Surveillance Network, or FoodNet) in 1996 to quantify and monitor foodborne illnesses from selected sites in the United States. [16] *Campylobacter, Escherichia coli* O157:H7, *Listeria monocytogenes, Salmonella, Shigella, Vibrio, Yersinia enterocolitica, Cryptosporidium,* and *Cyclospora cayetanensis* are monitored. Most frequently diagnosed during all 5 years of data collection was *Campylobacter* infection. *Salmonella, Shigella,* and *E coli* O157:H7 were commonly found also, but a majority of *Shigella* cases were not acquired through food.

Toxins Associated with Bacterial Food Poisoning

Staphylococcus aureus Staphylococcal food poisoning is one of the most common causes of foodborne illness, accounting for 1.0% to 2.0% of recognized bacterial food poisoning outbreaks reported to the CDC from 1993 to 1997. [13] Staphylococcal food poisoning outbreaks are most common in the summer, reflecting the association between *S aureus* outbreaks and large gatherings, such as picnics. *Bacillus cereus* produces a similar illness; both illnesses are characterized by profuse vomiting that occurs less than 12 hours after a contaminated food has been ingested. *S aureus* colonizes the skin and mucous membranes of 20% to 50% of healthy people, and these persons serve as the most frequent source of food contamination. *S aureus* produces at least seven antigenic types of classical enterotoxin and a delta-toxin, all of which are capable of causing net fluid secretion in the intestine. [17] *Staphylococcus* enterotoxins, purified as small 27- to 30-kd single-chain polypeptides, are resistant to heat, irradiation, pH extremes, and proteolysis. [18], [19] and [20] Assays to detect the enterotoxin in food and its production in vivo are important epidemiologic tools. [21] Phage typing of species can also be used for epidemiologic investigations to trace the source of infection, with phage type III being most often associated with outbreaks of foodborne disease. Foods high in salt, protein, and sugar content select for growth of *S aureus,* with dairy products, salads, and meats often implicated in outbreaks.

Bacillus cereus *B cereus* accounted for fewer than 1% of foodborne outbreaks reported to the CDC between 1993 to 1997. [13] *B cereus* is a ubiquitous aerobic, spore-forming, gram-positive rod organism that is found in soil and water throughout the world and in most raw foods. [22] These bacteria colonize 10% to 40% of humans. Two clinical syndromes are associated with the ingestion of this organism. One, an emetic syndrome characterized by a short incubation period (1–6 hours), presents with vomiting and abdominal cramping. The other, a diarrheal syndrome with a longer incubation period (6–24 hours), is characterized by watery diarrhea, abdominal cramping, and occasionally vomiting. [23], [24] The duration of illness is 2 to 10 hours for the emetic syndrome and 16 to 48 hours for the diarrheal syndrome. The organism can produce either an emetic or diarrheal toxin, depending on the food in which it grows. [25], [26] The emetic syndrome is associated with cooked rice and in 95% of cases is caused by the ingestion of a preformed toxin (5000–10,000 kd) that is resistant to heat. In contrast, the diarrheal syndrome is associated with vegetables, sauces, and puddings and appears to be caused by the ingestion of a heat-labile protein with a molecular weight of 38 to 46 kd. [27], [28] Outbreaks of foodborne illness caused by *Bacillus subtilis, Bacillus licheniformis,* and *Bacillus pumilus* have also been reported. [27]

Clostridium botulinum *C botulinum* is a ubiquitous, gram-positive, spore-forming, anaerobic bacterium that produces a neurotoxin capable of blocking the release of acetylcholine at the neuromuscular junction. The spores are heat-resistant and require anaerobic conditions plus a pH above 4 for production. Home-canned foods and fish products are the most common sources, although any food that meets the criteria for spore germination can become contaminated. Symptoms occur 12 to 36 hours after ingestion of the preformed toxin; the initial clinical features are nausea, vomiting, abdominal pain, and diarrhea. Neurological symptoms include diplopia, dysphagia, dysarthria, dysphonia, ophthalmoplegia, descending bilateral weakness, and respiratory muscle weakness. The case fatality rate remains at 15%. There are seven toxin types, A through G. Type A botulism is more common in the western United States, whereas type B is more common in the eastern parts of the country. Type F is more commonly associated with fish products. Wound botulism is similar, without the gastrointestinal complaints. Botulism is first recognized on the basis of clinical signs and symptoms, with the differential diagnosis including Guillain-Barré syndrome, myasthenia gravis, stroke, and chemical poisoning. Assaying the vomitus, stool, or suspected food for the toxin may lead to the diagnosis. Electromyography may be helpful in distinguishing the diagnosis from Guillain-Barré syndrome. Treatment is supportive, along with early administration of antitoxin. The development of infant botulism requires ingestion of the organism and is seen in children younger than 1 year of age. Antitoxin is given parenterally, but the role of antibiotics is controversial.

TRAVELER'S DIARRHEA

Diarrheal disease has been a well-recognized consequence of travel for many years. Despite advances in public sanitation and water treatment, travel to a less developed country from a developed country is still associated with a substantial risk (~40%) for diarrheal disease. [29], [30] Much has been learned, however, about the specific etiologic agents that cause diarrhea in the traveler and strategies to help reduce the risk for illness.

Pathogenesis and Etiologic Agents

Virtually any microbial pathogen that can cause acute diarrheal disease in the endemic setting is capable of causing traveler's diarrhea. To some degree, the specific agents that cause traveler's diarrhea vary by geographic region and season. For example, the parasitic pathogens *Giardia* and *Cryptosporidium* appear to be common causes of diarrheal disease in visitors to Russia, whereas *Aeromonas* species appear to be very common causes of traveler's diarrhea in visitors to Thailand. [31], [32] Studies of etiologic agents from individual regions have varied in the types of organisms detected and in the sensitivity and specificity of the assay systems employed. In addition to differences in the geographic distribution of various etiologic agents, seasonal variations in the causes of traveler's diarrhea have been noted. For example, toxigenic *E coli* is somewhat more frequently encountered during the warmer summer months, whereas *Campylobacter jejuni* appears to occur more frequently in the winter months. [33], [34]

Although bacteria, viruses, and parasitic organisms have all been linked to traveler's diarrhea, a large number of studies have demonstrated that bacterial pathogens are the most frequent etiologic agents of this syndrome. This conclusion has been reached from the results of studies that tried to identify all agents, and studies showing that antibiotic (antibacterial) treatment or prophylaxis is very efficient in reducing most episodes of traveler's diarrhea. Of the wide array of bacterial pathogens encountered, enterotoxigenic *E coli* (ETEC) appears to be the most common worldwide (Table 74-2). These organisms, which produce enterotoxins (heat-labile toxin [LT] or heat-stable toxin [ST]), account for between 5% and 50% of all episodes of traveler's diarrhea. Other forms of pathogenic *E coli,* including enteroadherent *E coli* (EAEC) and enteropathogenic *E coli* (EPEC), account for fewer illnesses. [35] *Shigella* species and *C jejuni* are perhaps the next most important groups of pathogens, accounting for between 10% and 15% of cases. *Shigella* infection is frequently associated with fever and a dysentery-like illness. Other bacteria, such as *Salmonella, Aeromonas* species, and *Plesiomonas shigelloides,* usually account for fewer than 10% of cases, as do the viral pathogens, such as Norwalk virus and other caliciviruses and rotavirus. Traveler's diarrhea resulting in a prolonged illness (>1 month) is most frequently associated with the parasitic pathogens *Giardia* and *Cryptosporidium*. Of note, an etiologic agent cannot be identified in about 20% to 30% of all cases of traveler's diarrhea. Chronic diarrhea of travelers without a detectable etiologic agent may be classified as Brainerd diarrhea. [36]

ETIOLOGIC PATHOGEN	UNITED STATES (%)	DEVELOPING COUNTRIES (%)	TRAVELERS (%)
Rotavirus	20–45	15–40	<10
Astroviruses, Norwalk-like viruses, enteric adenoviruses	5–20	5–10	0
Campylobacter jejuni	5–10	5–10	5–15

Aeromonas species, *Plesiomonas shigelloides*	<5	5–10	5–10
Giardia	<5	<5	<5
Unknown and other	40	30	20

TABLE 74-2 Etiology of Infectious Watery Diarrhea in Children in Various Geographic Locations and in U.S. Travelers to Developing Countries

The mechanisms by which each pathogen causes diarrhea are extremely varied and range from the secretion of a soluble enterotoxin, which stimulates intracellular cyclic adenosine monophosphate (cAMP) levels and subsequent chloride secretion, to destruction of mature villus tip cells and loss of absorptive epithelium.

Epidemiology

An increased incidence of diarrhea is associated with all forms of international travel, including travel from one developed country to another, travel from a less developed country to a more developed country, and, most commonly, travel from a developed country to a less developed country. [37] The third scenario is the most frequent cause of traveler's diarrhea (30%–50% of cases), whereas the first is the least common (<5% of cases). Other than microbial agents, traveler's diarrhea is most probably caused by, or exacerbated by, a variety of factors, such as stress, sleep deprivation, and excessive alcohol consumption.

The source of microbial contamination can vary. The commonly held notion that tap water is the most frequent culprit is inaccurate. Tap water in many large cities in less developed countries is safe, although contamination can occur during the rainy season and in more rural areas. [38] Food is the most common vehicle for the spread of microbes that cause diarrhea. [39] Fruit and vegetables may become contaminated by fertilization with human waste, preparation by food handlers who are ill, or inadequate washing or cooking; prepared food that remains at room temperature for long periods may also become contaminated.

Host factors also influence the incidence and severity of traveler's diarrhea. Travelers from developed countries tend to have lower levels of immunity to many enteric pathogens, especially ETEC, and are more susceptible to infection and illness. [40] Gastric acid is a general barrier to almost all enteric pathogens; people with lowered levels of stomach acid, either as a consequence of prior surgical therapy or of pharmacological treatment, are at increased risk. [41] Immunosuppressed individuals, irrespective of the cause, may be at some increased risk. Younger persons have higher rates of traveler's diarrhea than older travelers, presumably because of more adventurous eating habits. In some cases, known genetic characteristics, such as blood group O antigen, increase the risk for specific infections, such as cholera. [42]

Although the risk for traveler's diarrhea is highest when travelers from developed countries travel to less developed areas, a geographic spectrum of the relative risk for acquiring diarrhea during travel to less developed countries has been noted. The highest risk is associated with travel to most countries in Latin America and Africa and to many countries in Asia. Travel to the Mediterranean countries of Europe, eastern Europe, Russia, and China is associated with a somewhat lower risk.

Clinical Features

Traveler's diarrhea usually occurs within the first 14 days of travel. It can also occur within a week or more after return from a foreign country. The diarrhea is usually characterized as watery, with the passage of three to ten bowel movements a day for 2 to 5 days. [30] Abdominal cramps and pain often accompany the illness. Fewer patients experience fever, chills, vomiting, and dysentery-like symptoms. Fewer than 10% of patients have an illness that lasts longer than a week, and about 2% of patients have illness lasting a month or more. [43] Acute disease is severe enough to warrant bed rest in fewer than one fourth of patients. [44] Prolonged disease (>1 month) or dysentery-like symptoms help to narrow the potential etiologic agents (to *Giardia* and *Cryptosporidium,* or to *Shigella* and *Campylobacter,* respectively). It is not possible to determine the etiologic agent with any degree of certainty if the illness is characterized by watery diarrhea and cramps, however. Rarely is diagnosis required or available in the setting of acute watery traveler's diarrhea. For cases of dysentery, a diagnosis, if available, is more useful. Given that traveler's diarrhea occurs in the traveling patient, it is almost always reasonable to initiate treatment without an etiologic diagnosis. Stool examination for parasites is warranted only in cases of prolonged illness.

Prevention

One of the simplest and most effective means of preventing traveler's diarrhea is the utilization of safe eating practices. [45] Food should be thoroughly cooked. Peeled fruits and vegetables are safe, whereas salads and uncooked vegetables are high risk. Bottled water, carbonated drinks, and beer are low risk, whereas tap water and ice are associated with an increased risk for illness. Cooked foods that sit at room temperature or on a buffet table for long periods of time should be avoided. Food obtained from street vendors is frequently associated with traveler's diarrhea.

Traveler's diarrhea can also frequently be prevented by the prophylactic use of antibiotics or other medicines. Antibiotic prophylaxis is not without risk, however; side effects, including minor and major drug allergies, do occur. Prophylaxis should probably be recommended only for travelers engaged in very important activities, or for those with decreased gastric acid or immunosuppression that increases their risk for the development of illness. Antibiotics, including doxycycline, trimethoprim-sulfamethoxazole (TMP-SMX), and the fluoroquinolones (FQs), have been shown to be highly effective in preventing traveler's diarrhea. Because of widespread antibiotic resistance, both doxycycline and TMP-SMX are no longer reliably effective, and the FQs are generally the agents of choice (Table 74-3). [46], [47] Traveler's diarrhea can also be prevented with reasonable efficacy by prophylactic treatment with bismuth subsalicylate (BSS). [48], [49] A dose of two 262-mg tablets, chewed four times a day at mealtime and at bedtime, is more than 60% effective in preventing illness. Side effects include a black tongue and occasional tinnitus. *Lactobacillus* species have been shown to have some efficacy in preventing traveler's diarrhea. [50]

TABLE 74-3 Recommendations for Antimicrobial Treatment of Diarrhea Caused by Small Bowel Pathogens

Treatment

In most cases, the treatment of traveler's diarrhea is quite effective and preferable to prophylactic regimens. Several nonspecific therapies are available. Two tablets

of BSS every 30 minutes up to eight times per day has been shown to hasten recovery in mild to moderate illness. [51] This effect is probably mediated through both antisecretory and antibacterial activities. Antimotility agents, such as the synthetic opiates loperamide and Lomotil (diphenoxylate hydrochloride with atropine), are generally more effective than BSS and are most effective when taken shortly after the onset of symptoms. [52] Loperamide is preferable to Lomotil because it does not contain atropine. Loperamide is generally given in a dose of 4 mg (two capsules) initially, followed by 2 mg after each loose bowel movement; up to eight capsules can be taken per day. Lomotil or loperamide, although effective in reducing the frequency and persistence of diarrhea, may enhance disease by impairing intestinal motility, delaying clearance of the infectious agent, and facilitating infection, particularly when illness is caused by highly invasive organisms like *Shigella*. [53] Drugs such as Lomotil and loperamide should be avoided if infection by an invasive organism is suggested by the presence of bloody diarrhea, fever, fecal leukocytes, or substantial systemic symptoms.

Antibiotic therapy is the most effective intervention for traveler's diarrhea. Antibiotics substantially shorten the duration of illness as well as the number of bowel movements per day. [54], [55] An indications for antibiotic use is the passage of two or more unformed stools in 24 hours, diarrhea with abdominal distress or fever, or the passage of bloody diarrhea. Various antibiotics have proved effective, but given increasing drug resistance and the high incidence of illness caused by *C jejuni* in some areas, FQs are now the treatment of choice for adults (see Table 74-3). Because of the potential of FQs to damage articular cartilage, TMP-SMX is still recommended for children, although drug resistance is becoming more widespread. In areas where FQ-resistant *C jejuni* is prevalent, azithromycin is the treatment of choice. [56] Therapy for 3 days is probably sufficient in virtually all cases, and a single dose may be adequate in most. [57]

Vaccines for several of the bacterial and viral causes of traveler's diarrhea are under development (see later sections) and are likely to become available for travelers in the next decade.

BACTERIAL INFECTION

Pathogens such as *Shigella, Salmonella,* and *Campylobacter* are often spread through contaminated foods. *Shigella* and *Campylobacter* usually are colonic pathogens, and as such are discussed in Chapter 88. *Salmonella* and other organisms, including *Clostridium perfringens, L monocytogenes,* diarrheagenic *E coli, Yersinia* species, *Vibrio* species, *Aeromonas, Edwardsiella,* and *Plesiomonas,* are discussed in the following sections. As mentioned previously, the length of the incubation period and the presenting complaint help to distinguish among etiologic agents (see Table 74-1). A more detailed summary of the key features of specific agents is provided in Table 74-4.

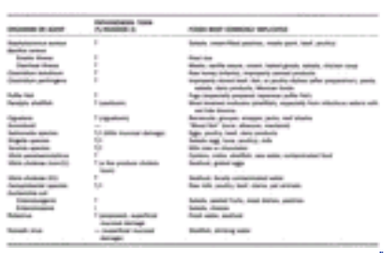

TABLE 74-4 Clinical and Epidemiologic Features of Agent-Specific Foodborne Diseases

Clostridium perfringens

Epidemiology *C perfringens* most commonly causes a mild foodborne illness. [22] Approximately 2% of all foodborne cases reported to the CDC are caused by *C perfringens* food poisoning. [13] This organism is an obligate anaerobe, but it can tolerate exposure to oxygen for up to 72 hours, and it is the only nonmotile species of *Clostridium*. Spores are heat-resistant and survive cooking to germinate. The organisms grow rapidly at temperatures of 15° to 50°C and can double in number in 10 minutes. Illness requires the ingestion of food heavily contaminated with more than 10^8 bacteria per gram. Most of the foodborne *C perfringens* cases are caused by type A strains, which are found in the soil throughout the world and in the intestinal tracts of all vertebrate animals. *Clostridium* types B, C, D, and E are found only in animals, not in soil. Most *C perfringens* outbreaks occur during the fall and winter months (unlike outbreaks caused by *Salmonella* species and *S aureus*), and typically involve the foods listed in Table 74-4. When implicated, these foods usually have been prepared in advance and allowed to cool without prompt refrigeration. In this fashion, heat-resistant spores that survive the cooking process germinate within the food during the cooling period (reduced redox potential within the food favors this process). On reheating before consumption, not all viable cells are killed, and heat-induced sporulation of the cells and enterotoxin production within the intestine cause diarrhea.

Pathogenesis The pathogenesis of *C perfringens* food poisoning is based on the ability of the organism to elaborate enterotoxins. Only 5% of the global *C perfringens* population possesses the *C perfringens* enterotoxin (CPE). CPE is a heat-labile, 35-kd protein toxin that is capable of causing fluid accumulation in animal ileal loop models. It is elaborated by *C perfringens* types A and, less commonly, C and D. CPE causing foodborne illness has been found to be the product of a chromosomal cpe gene, whereas CPE related to antibiotic-associated diarrhea is caused by clostridria isolates containing a plasmid cpe gene. [58] CPE appears to cause clinical symptoms by cytotoxic action in the intestinal epithelial cells. [59] Intralumenal CPE binds to mucosal cell surfaces, where it causes structural damage to these cells with subsequent loss of intracellular substances, primarily sodium, chloride, protein, and fluid. This effect probably leads to impaired macromolecular synthesis, further structural damage, and eventual cell death. [60] CPE also acts as a superantigen reactive with human T lymphocytes. [61]

Clinical Features *C perfringens* causes a watery diarrhea (two to four stools per day) that frequently is accompanied by pronounced abdominal cramping and pain; symptoms characteristically develop 8 to 24 hours (mean, 12 hours) after ingestion of the contaminated food. Attack rates during epidemics usually are high, and in the United States, the median percentage of people affected in an outbreak ranges between 23% and 35%. Constitutional symptoms (e.g., vomiting, fever, chills, malaise) are uncommon. The disease is self-limiting, and full recovery is expected within 24 hours. A fatal outcome is rare and usually associated with an older age and secondary dehydration. Although serum antibody to CPE has been demonstrated in asymptomatic adults and in some but not all volunteers challenged with CPE, the development of protective immunity has not been shown. Local production of anti-CPE antibody in the gut, however, may confer immunity in previously exposed people. [62] Several reports have implicated *C perfringens* as the cause of antibiotic-associated diarrhea and of prolonged and recurrent infectious diarrhea in the elderly and patients in long-term care settings. [63], [64] Although the incidence of carriage of *C perfringens* within the colon can be high, symptoms are associated with the presence of enterotoxin-producing strains. In addition, a significant association with sporadic cases of diarrhea has been reported in patients in whom symptoms of enterocolitis develop, and whose stools contain *C perfringens* and its enterotoxin but no other identifiable common pathogen. [65] The illness thus resembles that associated with *Clostridium difficile,* and although pseudomembranous enterocolitis per se has not been demonstrated in any of the patients in whom endoscopic examination has been performed, the presence of fecal blood and biopsy-proven mucosal hemorrhage and edema in some patients speaks in favor of a colitis. Although many experts do not recommend antimicrobial treatment for this enterotoxin-associated disorder, a favorable clinical and microbiologic response to oral metronidazole (400 mg three times a day for 7–10 days) has been demonstrated. [66] B-toxin is produced by types B and C strains and is associated with the disease pig-bel or, more aptly, necrotic enteritis, which is still reported from isolated parts of the world such as Papua New Guinea. Proteolytic enzymes in the intestine usually inactivate the B-toxin. Underlying diseases such as diabetes mellitus, [67] malnutrition, and a sudden change in the dietary intake of protein may place people at risk, with children and the elderly primarily affected. They may lack the necessary proteolytic enzymes to inactivate the toxin. [27] Bowel resection frequently has been required to treat this disease, but accumulated data indicate that passive immunization with *C perfringens* type C antiserum (beta-antitoxin) [68] and active immunization with pig-bel toxoid vaccine significantly reduce both morbidity and mortality from this illness. [69]

Diagnosis *C perfringens* food poisoning cannot be distinguished easily from other noninfectious, enterotoxigenic intoxications, such as those caused by *B cereus* and *S aureus*. Confirmation of an outbreak relies on the quantification of organisms in food (i.e., >10^5 organisms per gram) or the excreta (>10^6 spores per gram) of ill people. Simple-to-perform assays that are highly sensitive and specific for CPE (reverse passive latex agglutination and slide-latex agglutination) have proved very useful in accurately diagnosing illness caused by *C perfringens*.

Listeria monocytogenes

Epidemiology *L monocytogenes* is a relatively heat-resistant, non–spore-forming, gram-positive bacillus that has been isolated from the intestinal tracts of humans and animals, sewage, and well water. It also has been isolated from many different foods, including meats, fruits, vegetables, seafood, and dairy products. The organism inhabits the gastrointestinal tract of 1% of asymptomatic humans. [70] *L monocytogenes* is an uncommon cause of foodborne infection (0.1% of foodborne

outbreaks reported to the CDC between 1993 and 1997), [13] but several outbreaks have been reported from a variety of food sources. [71], [72] In 1985, Mexican-style soft cheese made from inadequately pasteurized milk was implicated in 142 cases of *Listeria* food poisoning and 45 deaths; 66% of these involved pregnant women and their infants. The remaining cases had a predisposing health problem. [73] *Listeria* produces a number of virulence factors that facilitate cell invasion and cell-to-cell spread. Cell-mediated immunity appears to play an important role in combating infection with *Listeria*. [74] A humoral response develops against several *Listeria* proteins, the clinical significance of which is not clear. [75] Both IgM, which is absent in neonates, and classical complement, which is low in neonates, appear to be important for the efficient opsonization of *L monocytogenes*. [76] Patients with altered cell-mediated immunity are clearly at risk for infections with this intracellular organism. Populations at risk include predominantly pregnant women and their infants, the latter acquiring *Listeria* through vertical transmission. Other populations at risk include immunocompromised persons, such as those who have hematologic malignancies, cirrhosis, diabetes mellitus, acquired immunodeficiency syndrome (AIDS), or renal failure, and those who are receiving corticosteroids. In addition, the elderly, veterinarians, and laboratory workers are at risk; the disease also occurs in persons with no recognizable predisposing or underlying conditions.

Clinical Features The gastrointestinal tract is the primary portal of entry in all cases except fetal and neonatal infections. The clinical syndromes caused by *L monocytogenes* can range from a mild febrile illness to frank bacteremia, meningitis, and sepsis. Pregnant women generally have a mild illness with flulike features of fever and myalgias. The incubation period may be as long as 2 to 3 weeks. [77] Cases of nonperinatal listeriosis are more likely to present with bacteremia, meningitis, or sepsis. Diarrhea and other gastrointestinal symptoms can precede the onset of systemic listeriosis.

Diagnosis The diagnosis of listeriosis depends on isolation of the organism from a normally sterile site or other site in the setting of an appropriate epidemiologic history. Successful therapy has been associated with early diagnosis and initiation of treatment; however, the optimal agent for therapy has not been defined by controlled clinical trials. Ampicillin is the most commonly recommended therapy, often in combination with an aminoglycoside. Other agents suggested are TMP-SMX, a macrolide, or a tetracycline, but cephalosporins should not be used because they have been associated with clinical failures. The optimal duration of therapy is also unknown, but at least 2 weeks seems to be prudent; longer courses, up to 6 weeks, are recommended for patients with endocarditis and brain abscess.

Escherichia coli Enteropathogens

E coli is a common inhabitant of the gastrointestinal tract in both humans and animals. Although most *E coli* strains do not possess known virulence characteristics, a subset exists that can be pathogenic to humans, specifically through the induction of gastroenteritis. The *E coli* organisms that induce intestinal derangement are named according to their pathogenic mechanisms. In the interest of simplicity, these pathogens are herein collectively referred to as *diarrheagenic E coli,* and the particular syndromes caused by each are discussed in the following sections.

Classification The members of the species *E coli* belong to the family Enterobacteriaceae and are characteristically facultative, aerobic, non–spore-forming, mostly motile gram-negative bacteria that grow well at 37°C in nonenriched media. *E coli* bacteria are distinguished from other members of the Enterobacteriaceae by the demonstration of characteristic biochemical reactions; however, different strains of the species of *E coli* are identified by serologic and virulence testing. Serologic markers are found on different parts of the organism. The H-antigen (H-Ag), or flagellar protein, is located on the peritrichous flagellum; the O-antigen (O-Ag), or lipopolysaccharide antigen, and the K-antigen are located on the cell wall and capsule or envelope (when present), respectively. Fimbria or pili and other attachment factors of these organisms also can be determinants of pathogenicity. Four syndromes of *E coli*–induced intestinal dysfunction have been well defined that show specific clinical and epidemiologic features: those caused by enterotoxigenic (ETEC), enteropathogenic (EPEC), enteroinvasive (EIEC), and enterohemorrhagic (EHEC) organisms. [78]

Enterotoxigenic Escherichia coli

Pathogenesis. ETEC produces disease by elaborating enterotoxins without invading or damaging intestinal epithelial cells. [79] One (or more) of at least three enterotoxins may be produced, which differ in their susceptibility to heat: LT (heat-labile toxin), STa, and STb (heat-stable toxins). The characteristics of LT are remarkably similar to those of cholera toxin (see section “ Vibrio Species”): a molecular weight of 84 kd, five identical binding B subunits, and an enzymatically active A subunit, which activates adenylate cyclase in a nicotinamide adenine dinucleotide (NAD)–dependent reaction. [80], [81] The homology between the A and B subunits of LTI and cholera toxin is approximately 80%. [82] In addition, the action of LTI is neutralized by cholera antitoxin. LTs that are not neutralized by cholera antitoxin are designated LTII. STa toxins are small, methanol-soluble peptides that activate the transmembrane guanylate cyclase system and lead to intestinal secretion. [83] STb toxins do not stimulate the guanylate cyclase system. [84] To be fully pathogenic, ETEC must express the virulence factors for adherence and enterotoxin elaboration. The bacteria first colonize the small intestine with the aid of specific CFA (colonization factor antigen) [coli surface (cs) antigens] attachment factors, namely CFA I, CFA II, CFA III (subdivided into CS 1–3), CFA IV (subdivided into CS 4–6), and additional higher-numbered CSs. [79] The plasmids that encode these attachment factors often, but not always, encode ST or LT. [85], [86] There are several major O serogroups. The serogrouping of ETEC has made possible the epidemiologic investigation of outbreaks. Most, but not all, traditional serogroups are associated with at least one CFA. [87] Prevalence studies indicate a relationship between CF type and the presence or absence of ST or LT. [88]

Epidemiology. ETEC has worldwide distribution and is a major etiologic agent of diarrhea affecting children in the developing world (10%–40%). Although ETEC is a rare cause of diarrhea in the United States, it accounts for most cases of illness in travelers to developing countries. The incidence of ETEC infection is equal to, or greater than, the incidence of rotavirus infection, and these two agents are the predominant cause of diarrheal disease throughout the developing world, although rotavirus more frequently causes severe dehydrating diarrhea. ETEC is acquired primarily through the ingestion of contaminated food or water. Person-to-person transmission is rare because a large inoculum (10^8 organisms) is required to cause illness in healthy people. [89], [90]

Clinical features. The illness is characterized by watery diarrhea, ranging from very mild to cholera-like. Other symptoms may include cramping abdominal pain, rarely low-grade fever, headache, arthralgias, myalgias, vomiting, and chills. The illness usually is self-limiting, lasting 3 to 5 days if untreated; those affected pass an average of 8 to 12 unformed stools per day. The stools are watery, yellow, and devoid of mucus, pus, and fecal leukocytes. Dehydration tends to be severe only in the very young and very old. Fatalities are rare, and treatment with antimicrobials (see “ Prevention” and “ Treatment” in section “Traveler’s Diarrhea”) shortens the duration of disease. Fluid and electrolyte replacement is emphasized, especially in the populations at risk.

Vaccine therapy. A number of approaches have been tried in an effort to develop effective vaccines against ETEC. The major problem is that ETEC organisms are antigenically diverse—that is, they are found in a number of O serogroups and possess one of several different CFAs. In addition, ST is not immunogenic because of its small size.

Enteropathogenic *Escherichia coli*

Pathogenesis. EPEC organisms lack *Shigella*-like invasive properties and fail to produce classical ETEC-type enterotoxins. [91] The mechanism of pathogenesis appears to reside primarily in the ability of the bacteria to attach intimately to and efface the microvilli of enterocytes, leading to the destruction of microvilli and cytoskeletal disruption beneath the adherent organisms. The linkage between the effects of EPEC on the epithelial cells and diarrhea remains unknown.

Epidemiology. EPEC is an endemic diarrheal pathogen among infants in developing countries, with person-to-person spread through the fecal-oral route the most likely mode of transmission. Our knowledge of the clinical aspects of EPEC infection remains incomplete, but infants (<2 years of age) are primarily infected, particularly those in day care centers and hospitals, where several outbreaks have been described. Older children and adults may serve as reservoirs for this organism; EPEC strains have been isolated from the oropharynx and the excreta of asymptomatic contacts of ill cases during several outbreaks.

Clinical features. Illness with EPEC is marked by watery diarrhea, which may become profuse and protracted. EPEC enteritis is one of the few identifiable causes of prolonged diarrhea in infancy. A variable percentage of patients display vomiting, fever, failure to thrive, and metabolic acidosis. Dehydration can be severe and life-threatening if the disease is allowed to progress without fluid and electrolyte replacement.

Diagnosis. The diagnosis of EPEC infection is usually based on slide agglutination of suspected colonies with the use of commercial polyvalent antisera for the O-Ag, which are considered to be more specific for EPEC. This method of screening is neither sensitive nor specific, but complete serotyping for all O-Ag and H-Ag is impractical. Stool culture, serotyping, the documentation of characteristic tissue culture adherence, or the detection of adherence factor by DNA probe if *E coli* is identified are the only ways to incriminate EPEC strains in a particular diarrhea episode.

Therapy. Treatment of EPEC infection usually is not required, given the self-limiting nature of the illness; however, attention should be paid to the replacement of fluids and electrolytes through oral or intravenous routes. In addition, consideration should be given to therapeutic measures to relieve diarrhea. The use of antimicrobial agents is advocated in severe illness and in cases of prolonged diarrhea, but which ones and for how long remain to be firmly established (see Table 74-3). [92] In vitro antimicrobial susceptibilities should be routinely determined in isolated strains because these organisms tend to have a surprisingly high rate of antimicrobial resistance. [93]

Enteroinvasive *Escherichia coli*

EIEC organisms are primarily colonic pathogens and are discussed only briefly here. Strains of *E coli* that display the ability to invade the intestinal mucosa are rare causes of diarrhea, although large outbreaks associated with the ingestion of soft cheeses and in the setting of a cruise ship have been reported. [94], [95] EIEC does not appear to be spread from person to person, and although food does appear to play a major role in transmission, the epidemiology of this illness is unclear. EIEC organisms have been associated with specific somatic antigens (O-Ag), and by definition, they are Sereny test positive (production of keratoconjunctivitis in guinea pigs). EIEC organisms possess the same 140-megadalton (Md) plasmid that is associated with invasiveness in *Shigella* strains. The Sereny test and tissue culture invasion were previously the only methods available to detect EIEC. Polymerase chain reaction (PCR) tests and enzyme-linked immunosorbent assays (ELISAs) developed for EIEC may prove useful in detecting these strains in the near future. The illness is indistinguishable from the dysentery-like disease caused by *Shigella*. Treatment with TMP-SMX is recommended for severe infection (see Table 74-3).

Enterohemorrhagic Escherichia coli

Infection with EHEC is characterized by hemorrhagic colitis and bloody diarrhea. Investigations of foodborne outbreaks of

diarrhea in 1982 in Oregon and Michigan incriminated *E coli* serotype O157:H7 as the etiologic agent in this syndrome. [96], [97] Since then, studies have shown that this particular organism is responsible for both sporadic and epidemic cases of hemorrhagic colitis. Epidemiologic studies point to transmission of this organism in food and water, and person-to-person transmission among household members has been documented. [96], [98] Bloody diarrhea caused by *E coli* O157:H7 can be complicated by the hemolytic uremic syndrome and thrombotic thrombocytopenic purpura, with a resultant high mortality rate. [96], [99] EHEC strains such as *E coli* O157:H7 do not invade the epithelium, do not produce STs or LTs, and do not display CFA I or CFA II (adherence factors). The primary virulence factor of these organisms appears to be the production of at least two toxins with properties similar to those of the toxin elaborated by *Shigella dysenteriae* type 1. These two toxins are called *Shiga-like toxin (SLT) I,* or *verotoxin I,* and *SLT II,* or *verotoxin II*. [100] It is known that SLT I has the same biologic properties as, and is immunologically and genetically indistinguishable from, Shiga toxin. EHEC organisms have two well-recognized virulence attributes—namely, the production of one or more SLTs and attachment and effacement. In addition, all isolates of *E coli* O157:H7 possess a 60-Md plasmid that appears to play an important role in adherence. [101] As has been well established, Shiga toxin and SLTs are lethal to certain cells in culture and are enterotoxic, mediating fluid accumulation in ligated ileal loops. They also can cause limb paralysis when injected parenterally into animals. [102], [103] Bacterial lipopolysaccharide and SLT may stimulate the production of interleukin-1 and tumor necrosis factor from macrophages, which may increase the sensitivity of endothelial cells to SLT by increasing the expression of globotriaosylceramide (Gb3) on the cell surface. [100], [104], [105] and [106] The Shiga toxin then inhibits protein synthesis and the endothelial cells may detach, exposing platelets to the subendothelium and initiating coagulation. [104] It is perhaps through this vascular endothelial damage that infection with *E coli* O157:H7 is capable of producing hematologic abnormalities (i.e., hemolysis and thrombosis). SLT production is not limited to the O157:H7 strain of *E coli,* and non-O157:H7 SLT-producing *E coli* have been isolated from both bloody and nonbloody diarrhea. In addition, culture-confirmed infections with *E coli* O157:H7 can produce a nonbloody diarrhea and can also cause asymptomatic infection. Infections associated with nonbloody diarrhea are less likely to be complicated by hemolytic uremic syndrome. It is likely that the amount, the site of production, and the chemical structure of the toxin, and perhaps the organism's ability to adhere to the intestinal mucosa, all play a role in the development of the particular clinical syndromes. The clinical illness caused by SLT-producing *E coli* is described in Chapter 88.

Salmonella Species

Classification Currently, all *Salmonella* isolates are classified in a single species, *Salmonella choleraesuis,* based on DNA sequence similarity. [107] The species *S choleraesuis* can be subclassified into seven subgroups, of which subgroup I contains almost all the serotypes and isolates pathogenic for humans. The correct taxonomic names for *Salmonella typhi* and *S choleraesuis* are *S choleraesuis* (group I), serotype *typhi,* and *S choleraesuis* (group I), serotype *choleraesuis,* respectively. There are more than 2000 *Salmonella* serotypes, all of which, with the exception of *S typhi* and the paratyphoid strains, have nonhuman reservoirs and are widely dispersed in nature. The classification scheme for the different species and particular biotypes/serotypes within each species is similar to that described for *E coli*. The somatic or polysaccharide O-Ag, the flagellar H-Ag, and the Vi-Ag are markers of *Salmonella* serotypes displaying varying degrees of host-specific adaptation and the ability to cause different clinical syndromes. *Salmonella* organisms are gram-negative, non–spore-forming, motile, facultatively anaerobic bacilli.

Nontyphoid Salmonellosis

Epidemiology. Nontyphoid *Salmonella* species have been, and continue to be, one of the most frequent causes of foodborne enteric infection in the industrialized world. *Salmonella* is estimated to cause more than 1.5 million cases of foodborne illness in the United States annually, [10] with most caused by *S enteritidis*. *Salmonella* also was the most frequently reported cause of foodborne disease outbreaks between 1993 and 1997, accounting for 13% of all outbreaks. [13] In addition, *Salmonella* caused more deaths (44.8%) than any other pathogen in these outbreaks reported to the CDC. The incidence of nontyphoid salmonellosis still continues to be a major problem in the United States. *S enteritidis* and *Salmonella typhimurium* are the most commonly isolated *Salmonella* serotypes. Nontyphoid *Salmonella* is widely distributed among different animal species and is particularly prevalent among animals raised for food. *Salmonella* serotypes, particularly those belonging to *S enteritidis,* have been isolated from a wide variety of animals, including poultry and all types of farm animals. Food and milk are commonly associated with diarrhea outbreaks, but many notable outbreaks have been traced to numerous other sources (e.g., pet turtles, marijuana). The major reservoirs for *Salmonella* organisms that cause human illness, however, are poultry and domestic livestock. One study found 50% of poultry in retail stores to be contaminated with viable *Salmonella* species. [108] An increase in the incidence of the nontyphoid *Salmonella* serotypes associated with reptiles and an overall decrease in the incidence of those associated with meat, poultry, and eggs have been noted. [109] This may in part be the result of programs that focus on reducing the risk for *Salmonella* exposure in food products to consumers. Eggs and egg products often have been identified as sources of epidemic salmonellosis. mall cracks may allow passage of the organism into the interior of an egg while it is being laid (contact with feces) or cleaned, or vertical contamination in utero before the shell calcifies. In the United States, an estimated 0.01% of intact eggshells contain *S enteritidis*. [110], [111] Person-to-person transmission of salmonellosis is thought to be minor, but it may be important in institutional settings (including day care centers), where fecal contamination of the environment and inadequate hygiene are common. About 85% of all outbreaks, however, occur through the consumption of contaminated food or drink, and only 10% through cross-infection. Both *S typhi* and nontyphoid *Salmonella* species show a seasonal variation, and the frequency of illness reaches a peak in the summer and fall, when picnics and barbecues are common and the cooking practices necessary to kill the *Salmonella* organisms (>150°F for 12 minutes) are often not followed. There is no sex preponderance, and attack rates are greatest in children younger than 5 years of age, followed by persons 20 to 30 years of age and older than 70 years. If one household member becomes infected, the probability that another will become infected is 50% to 60%. [112] Patients with malignancies, immunosuppression, alcoholism, sickle cell disease, an abnormal cardiovascular system, hemolytic anemia, schistosomiasis, or a major underlying disease are predisposed to progressive salmonellosis with bacteremia, as are postsurgical patients. A case fatality rate of 0.2% has been reported in epidemics, but the overall mortality rate averages 2% to 3% if any of the predisposing factors are present. The case fatality rates are highest in nursing home residents and infants in nurseries (7%–9%).

Pathogenesis. The development of salmonellosis hinges on the number of organisms ingested (10^3–10^8) and on predisposing host factors. The most important factor that allows a smaller dose to cause infection is a lack of gastric acidity (e.g., neonatal period, achlorhydria, gastric surgery, antacid use). [113] For diarrhea to develop, viable organisms must reach the small intestine and invade the intestinal mucosa. *Salmonella* organisms must traverse the acid barrier of the stomach and the mucous layer of the intestinal epithelium while evading intestinal, pancreatic, and gallbladder secretions. After crossing the small bowel mucous layer, *Salmonella* organisms interact with both enterocytes and microfold (M) cells. On contact with M cells, the organisms are rapidly internalized and transported into the submucosal lymphoid tissue, where they may enter the systemic circulation. Unlike *Shigella* species, *Salmonella* organisms usually do not cause epithelial damage by invasion. Salmonellae induce nonphagocytic cells to internalize them by means of fimbrial adhesins. [114] Salmonellae are internalized within membrane-bound vacuoles of epithelial cells. [115] After the organisms penetrate the epithelial barrier, they rapidly interact with macrophages and lymphocytes in Peyer patches in the small intestinal submucosa. [116] The ability of *Salmonella* organisms to delay lysosomal fusion and to attenuate the acidification of phagosomes likely contributes to their survival within macrophages. Rarely, nontyphoid *Salmonella* species can produce more extensive lesions, consisting of an intense colitis with small hemorrhages and ulcerations of the surface epithelium and multifocal microabscesses. Some nontyphoid *Salmonella* serotypes, especially *S choleraesuis,* show a much greater ability to invade. Invasion of the bloodstream by nontyphoid *Salmonella* species occurs in just under 10% of cases. The pathogenic mechanism of *Salmonella* gastroenteritis is poorly understood. Many of the genes that are important to the virulence of *S typhimurium* are regulatory proteins that control the synthesis of multiple proteins at the level of gene transcription. The *Salmonella* virulence plasmid appears to be important in pathogenesis, as do the major surface carbohydrate-containing molecules of *Salmonella,* such as the lipid A component of lipopolysaccharide. Host factors appear to be very important in contracting and warding off disease caused by *Salmonella* organisms. The increased incidence of nontyphoid bacteremia in AIDS patients and transplant hosts suggests that cell-mediated immunity is important in controlling these organisms. As mentioned previously, alterations in the gastric acid barrier predispose individuals to infection.

Clinical features. *Salmonella* infection in humans comprises four clinical syndromes: gastroenteritis, enteric fever, bacteremia, and asymptomatic carriage. The features of *Salmonella* gastroenteritis are indistinguishable from those of gastroenteritis caused by many gastrointestinal pathogens. Symptoms usually develop within 48 hours after the ingestion of contaminated food or water. At one end of the spectrum of disease is a very mild illness characterized by the passage of one to a few loose stools and only minimal symptoms; at the opposite end is a cholera-like illness with profuse diarrhea and significant dehydration. A dysentery-like syndrome is also occasionally seen. Fecal leukocytes are usually present. Fevers, abdominal cramping, nausea, vomiting, and chills are frequently reported. The diarrhea usually lasts 3 to 7 days, and the fever usually resolves within 2 to 3 days. Improvement is expected after the initial 36 hours. Bacteremia is uncommon with this type of illness (6%–8%), but it is seen more frequently in children and in people with underlying health defects (15%), in whom the mortality rate is also higher. Serious complications (e.g., osteomyelitis) can occur in association with underlying disorders such as sickle cell disease and other hemolytic diseases. Bacteremia and focal abscesses, which can result in septic shock, are complications seen in patients with AIDS and patients who have malignancies or are undergoing therapy for malignancies. Finally, infected aortic or iliac aneurysms in patients with preexisting atherosclerotic vascular disease can result in mortality rates higher than 60%. After the gastroenteritis resolves, the mean duration of carriage of nontyphoid *Salmonella* in the stool is 4 to 5 weeks and varies by *Salmonella* serotype. [117]

Therapy. Antimicrobials should not be used routinely in mild to moderately ill patients with gastroenteritis because their use may prolong the intestinal carriage of nontyphoid *Salmonella* species and may increase the incidence of bacteriologic relapse. [118], [119] Indications for antimicrobial therapy are predisposing factors that can complicate salmonellosis, including extremes of age, an immunodeficiency condition, signs and symptoms of sepsis, infection with organisms likely to produce bacteremia (e.g., *S typhi, Salmonella paratyphi, S choleraesuis*), focal infections (e.g., osteomyelitis, abscesses), and chronic typhoid carrier states. Drug resistance among *Salmonella* species (including *S typhi, S typhimurium,* and certain serotypes of *S enteritidis*) is increasing. A multidrug-resistant strain of *S typhimurium,* referred to as *definitive type 104 (DT104),* has emerged as a significant problem in United States and elsewhere. [120] DT104 and other multidrug-resistant *Salmonella* species demonstrate resistance to such antimicrobials as chloramphenicol, tetracycline, ampicillin, TMP-SMX, and the aminoglycosides. This resistance is mediated by large complex plasmids. [121], [122] In seriously ill persons with nontyphoid *Salmonella* infection, it is reasonable to administer two antimicrobial agents from different classes until the sensitivities are known. Agents that can be used (see Table 74-3) are ampicillin, amoxicillin, TMP-SMX, cefotaxime or ceftriaxone, chloramphenicol,

and FQs. Low-grade bacteremia, not involving the vascular structures, should be treated with 7 to 14 days of intravenous antimicrobial therapy, with 6 weeks of therapy reserved for documented or suspected intravascular infection. Persons with AIDS and a first episode of *Salmonella* bacteremia should be given 1 to 2 weeks of intravenous therapy followed by 4 weeks of an oral FQ to eradicate the organism and lessen the risk for recurrent bacteremia. Those with recurrent bacteremia may require suppressive therapy. Amoxicillin and TMP-SMX given for 6 weeks have a success rate of more than 80% in eradicating the chronic carriage state of *Salmonella*. [123], [124] FQs are also recommended in the treatment of the chronic carrier state. Antimicrobial agents, however, are not very effective in eradicating the carrier state in persons with anatomic abnormalities (e.g., biliary or renal stones).

Typhoid (Enteric) Fever

Clinical features. Enteric fever can occur with any *Salmonella* serotype, but most commonly with *S typhi* and *S paratyphi*. The hallmarks of enteric fever are prolonged fever and abdominal symptoms. The symptoms are often nonspecific and may be insidious in onset. The diagnosis should be considered strongly in a traveler with fever who has returned from a subtropical or tropical area. *S typhi* usually is transmitted through the ingestion of material contaminated by human feces, either from ill people or asymptomatic carriers. Because humans are the only reservoir of *S typhi,* the factors that directly relate to the prevalence of this organism in the environment are a lack of water sanitation and the number of carriers. In the United States, the rate of typhoid has dramatically decreased (in contrast to the rate of nontyphoid salmonellosis), but typhoid continues to be a prevalent endemic problem in developing nations. The incubation period of *S typhi* is approximately 1 week (range, 5–21 days). Following ingestion of the organism, enterocolitis may develop with diarrhea lasting several days, which usually resolves before the onset of fever. After this initial phase, the clinical features of typhoid are those of an acute febrile illness, lasting an average of 3 to 5 weeks and accompanied by specific and nonspecific signs and symptoms. The nonspecific symptoms appear early, are usually insidious, and include frontal headache, general malaise, prostration, mental confusion (at times delirium), anorexia, and abdominal discomfort and bloating. Upper respiratory tract symptoms, particularly dry cough, coryza, and sore throat, can be prominent presenting complaints and may lead the physician to misdiagnose the illness. Constipation is common initially but may give way to diarrhea in the late phase of the illness. During the initial phase of fever and nonspecific symptoms, blood cultures are positive in more than 90% of patients, and characteristic clinical signs develop. The liver and spleen frequently are enlarged, and abdominal tenderness can be observed, particularly over the lower quadrants (at times mimicking appendicitis) and over the liver. Thirty percent of patients have typical rose spots, a faint salmon-colored maculopapular rash on the trunk. These occur in the first 1 to 2 weeks and last only 3 to 4 days, but they are not specific for typhoid (i.e., they have been reported with psittacosis, shigellosis, brucellosis, and other illnesses). Relative bradycardia (pulse relatively slow for degree of fever) can be seen in fewer than 50% of patients. Symptoms usually begin to abate after the third week of untreated illness in the 90% who survive. In 3% to 13% of untreated patients (and about 20% of treated patients), relapse can occur, usually after a variable period of time (average, 2 weeks). Relapse tends to be a milder and shorter illness than the full-blown syndrome. Many of the complications of untreated enteric fever develop in the third and fourth weeks of infection. Complications include intestinal hemorrhage and perforation related to hyperplasia of the lymphoid tissue in the ileocecum, in addition to focal infections such as pericarditis, orchitis, and splenic or liver abscesses. Hematologic abnormalities include leukopenia and anemia. The chronic carrier state (excretion for 1 year or longer) is seen in 1% to 4% of patients with *S typhi* and *S paratyphi* infection and is commonly associated with an age younger than 1 year or older than 60 years, concomitant biliary tract disease, and schistosomiasis (important in urinary tract carriage of *Salmonella* species). Chronic carriage is also seen in 0.2% to 0.6% of patients with nontyphoid salmonellosis. The biliary tract commonly serves as a focus of *Salmonella* organism multiplication in typhoid carriers, especially if concomitant derangements are present (e.g., stones, obstruction).

Diagnosis. The diagnosis of enteric fever requires the isolation of *S typhi* or *S paratyphi* from the patient. Cultures of blood, stool, urine, rose spots, blood mononuclear cells, and bone marrow may be useful in making the diagnosis. The diagnosis is established in more than 90% of cases if blood, bone marrow, and intestinal secretions are all cultured. The sensitivity of blood culture alone is 50% to 70%, and of bone marrow alone is 90%.

Therapy. Chloramphenicol is a tried and true treatment for enteric fever, reducing mortality from 20% to 1% and reducing the duration of fever from between 14 and 28 days to between 3 and 5 days. Because of resistance, a high rate of relapse and chronic carriage, and potential bone marrow toxicity, however, chloramphenicol has been replaced as the intravenous antimicrobial of choice. Third-generation cephalosporins and FQs are effective in the treatment of typhoid fever.

Vaccine therapy. Enteric fever can be prevented by immunization. Parenteral whole-cell and purified capsular polysaccharide vaccines (Typhim Vi; Aventis Pasteur, Swiftwater, Pennsylvania) and an oral live attenuated vaccine (Ty21a, Vivotif Berna; Berna Products Corporation, Coral Gables, Florida) have been developed. Typhim Vi and Ty21a are available in the United States. Ty21a must be administered in four doses, given every other day for 4 days. Typhim Vi is given as a single injection. These vaccines confer only limited protection for a few years. [125] Efficacy studies indicate that the whole-cell vaccine has a significantly greater efficacy rate than Typhim Vi or Ty21a, but its toxicity profile is much greater. [126], [127] Boosters are recommended for the Ty21a vaccine every 5 years and for Typhim Vi every 2 years.

Yersinia species

Classification *Yersinia* species, members of the Enterobacteriaceae family, are gram-negative, non–lactose-fermenting coccobacilli that are motile at 25°C but not at 37°C. *Yersinia* species have been classified according to surface antigens, somatic (O-Ag) and flagellar (H-Ag), and on this basis, more than 50 serotypes of *Y enterocolitica* and six serotypes of *Yersinia pseudotuberculosis* have been recognized, with specific geographic distributions.

Epidemiology Most reported cases of gastrointestinal illness caused by *Yersinia* species have been in European children. However, *Yersinia* can infect people of all ages [128], [129] and [130] and is distributed widely throughout the world. The incidence of *Y enterocolitica* infection in the United States is unknown, but it accounts for approximately 0.1% of reported foodborne diarrheal illness. [13] *Y pseudotuberculosis* is uncommon in the United States but is more frequently isolated in Europe. Disease in humans presumably occurs through contact with animals, particularly swine. *Y enterocolitica* disease is mainly transmitted by the fecal-oral route, and foodborne outbreaks caused by this pathogen have been reported. Contact with dogs, ingestion of outbreak-associated foods (e.g., chocolate milk, ice cream, tofu), contact with contaminated surface water, and person-to-person transmission have been documented in *Y enterocolitica* infections.

Pathogenesis The virulence of *Yersinia* organisms depends on a heat-stable enterotoxin (Yst) and surface antigen (Myf). [131] Furthermore, V and W antigens confer dependency on calcium for growth at 37°C. Pathogenic strains are resistant to complement, penetrate epithelial cells, are lethal to mice, and demonstrate cytotoxicity. Some of these characteristics are mediated by plasmids. In particular, the 70-kb plasmid encodes virulence determinants that include a secreted protein kinase and an outer membrane protein with protein tyrosine phosphatase activity. [132], [133] *Y enterocolitica* grows better in the presence of iron because it does not have its own siderophore. Patients with iron overload syndromes may be at great risk for *Yersinia* infections. [134]

Clinical Features *Y enterocolitica* infection is usually a self-limiting febrile diarrheal illness. Vomiting occurs in 50% of cases, and abdominal pain is a very prominent symptom. The abdominal pain may be localized to the right lower quadrant, mimicking acute appendicitis to the extent that many unnecessary appendectomies are performed in patients with this illness. Localized right lower quadrant pain rarely is seen in children younger than 5 years of age. Most patients experience a *Shigella*-like illness, with the passage of a few watery stools per day, often blood-streaked, accompanied by abdominal pain, low-grade fever, and constitutional symptoms. The diarrhea and constitutional symptoms tend to diminish by the second or third day of illness, but in some cases the diarrhea may last up to 45 days. Other common symptoms, in order of decreasing frequency, include fever, dysentery, and arthritis, or the patient may have no symptoms. Pharyngitis can occur in 50% of children and 10% of adults. Chronic diarrhea persisting for months is observed in a small number of patients, usually children, but in the vast majority of cases, complete recovery is achieved by the second week of illness. Complications are rare but include appendicitis, intestinal perforation, ileocolic intussusception, peritonitis, toxic megacolon, and cholangitis. These features are seen almost exclusively in children and young adults. Septicemia caused by *Y enterocolitica* is uncommon but may develop in patients with a predisposing illness, particularly iron overload states such as hemochromatosis, cirrhosis, and hemolytic processes. Similarly, *Y enterocolitica* infections can lead to extraintestinal focal suppurative lesions that may involve any region of the body; infants younger than 6 months of age are particularly prone to the development of extraintestinal disease. Postinfectious complications can lead to thyroiditis, glomerulopathy, Reiter syndrome, carditis, reactive arthritis, erythema nodosum, skin rashes, ankylosing spondylitis, and inflammatory bowel disease. Except for patients with thyroiditis and glomerulopathy, these patients tend to be HLA-B27 antigen–positive, and their disease may be precipitated by an acute *Yersinia* infection. Molecular mimicry between HLA-B27 and *Yersinia* antigen has been postulated as a mechanism for reactive arthritis. Superantigenic activity has been found in cultures of *Y enterocolitica* and may be a mechanism for reactive arthritis. [135]

Diagnosis Examination of the stool reveals many white blood cells, and frequently red blood cells. The diagnosis can be made by using both bacteriologic and serologic techniques. The laboratory personnel should be alerted if *Yersinia* infection is suspected because standard processing of stool specimens may overlook this organism, and special media may be necessary.

Therapy No evidence has been found that antimicrobial therapy for *Yersinia* enteritis alters the course of this usually self-limiting illness, and therefore treatment is not commonly advocated. In sharp contrast, antibiotics should be administered for septicemic illness; however, mortality rates of 50% for *Y enterocolitica* and 75% for *Y pseudotuberculosis* infection are the rule despite antibiotic therapy. Antibiotics have no effect on the postinfectious complications. Aminoglycosides, tetracycline, chloramphenicol, TMP-SMX, piperacillin, and third-generation cephalosporins usually are effective, although resistance to ampicillin and other antibiotics has been reported (see Table 74-3). [136] A 3-week (or longer) course of antibiotic therapy is recommended for the treatment of extraintestinal disease. *Y pseudotuberculosis* usually is susceptible to ampicillin in addition to the antimicrobials already listed.

Vibrio Species

An estimated 5.5 million cases of cholera occur worldwide each year, with more than 100,000 deaths. [137] The illness is caused by *Vibrio cholerae* O-group 1, a member of the Vibrionaceae, which also includes *Aeromonas* species and other *Vibrio* species. Non-O1 strains, such as O139, have also been associated with epidemic cholera. [138] Cholera is endemic in southern Asia, Africa, and Latin America, where the disease results in high mortality. The risk for cholera acquired in the

United States is small. The ingestion of contaminated seafood from the Gulf Coast or contaminated imported food and travel to areas of endemicity have led to an increase in reported cases of both serogroup O1 and serogroup O139. More antimicrobial resistance is also being reported. [139]

Classification Gastroenteritis can be caused by seven of ten known pathogenic *Vibrio* species (*V cholerae, V parahaemolyticus, V fluvialis, V mimicus, V hollisae, V furnissii,* and perhaps *V vulnificus*), of which *V cholerae* and *V parahaemolyticus* are the most important. *V cholerae* is divided into 139 serotypes on the basis of the O-Ag of the cell surface lipopolysaccharide. The organism is a motile, monoflagellated, short, curved, gram-negative rod. It grows best in thiosulfate citrate bile salts (TCBS)–sucrose agar and is inhibited by the selective media commonly used in routine stool cultures. [140], [141] Strains associated with endemic or epidemic cholera are designated as O1, and the rest are commonly described in general as non-O1 *V cholerae*. *V cholerae* O1 is divided into two biotypes, classical and El Tor. Both the classical and the El Tor biotypes can be subdivided according to subspecificity of the O1 antigen as Ogawa, Inaba, or Hikojima.

Vibrio cholerae

Epidemiology. *V cholerae* O1 is a free-living inhabitant of brackish water and estuaries. Survival is prolonged in cold, saline conditions; the organism has the ability to change from a viable, culturable form to a nonculturable form under certain conditions. [142] Water, specifically fecally contaminated water, is the major vehicle of transmission for *V cholerae* O1, although food is increasingly implicated in disease transmission. The previous exposure of a population is an important factor in the risk for contracting cholera. Patients who recover from *V cholerae* O1 infection have long-lasting immunity. Person-to-person transmission is not thought to play a major role in the propagation of cholera, and chronic human carriage is rare. Persons with low levels of gastric acidity resulting from malnutrition, gastritis, surgery, or antacids are at increased risk for cholera infection. Bottle feeding may also be a risk factor for cholera in infants. Where endemic, cholera affects primarily children between the ages of 2 and 9 years, with a second peak occurring in women of childbearing age. In areas of endemicity, attack rates are higher in women than in men, perhaps because of cultural norms whereby women may have greater exposure to the organism through domestic chores, such as washing and caring for small children. All age groups and both sexes are affected equally when cholera is introduced into a previously uninfected area. For as yet undiscovered reasons, people with blood type O tend to experience clinically more severe cholera.

Pathogenesis. Pathogenesis requires colonization followed by the elaboration of numerous toxins, the best known being an enterotoxin. The cholera toxin of *V cholerae* O1 and its effect on the surface epithelial cells of the gut has been well studied and has contributed much to our understanding of the pathophysiology of diarrhea. [143] After ingestion, *V cholerae* O1 must pass through the gastric acid of the stomach to colonize the small intestine. The organism must then penetrate the mucous gel, adhere to the intestinal epithelial cells, and produce a number of extracellular proteins, such as cholera toxin, neuraminidase, and hemolysin. [144] Pili are important factors in the adherence of vibrios to the small intestine. The classical biotype of *V cholerae* O1 produces a pilus, the toxin-coregulated pilus, that is necessary for human colonization. [145], [146] Cholera toxin is a protein with a molecular weight of 84,000 d and six structural subunits: five binding B subunits and one active A subunit composed of two peptides (A1 and A2). The B-subunit pentamer binds holotoxin to the enterocyte surface receptor, the ganglioside GM_1. The A1 fragment catalyzes the ADP ribosylation of a GTP-binding protein and causes persistent activation of adenylate cyclase. The resultant increase of cAMP within the intestinal epithelial cells stimulates chloride secretion and decreases sodium reabsorption, leading to a loss of fluid and electrolytes and the production of watery diarrhea. Although the pathogenesis of the classical cholera syndrome has long been attributed to the effects of an elaborated enterotoxin, *Vibrio* can produce illness even if the bacteria do not possess the cholera toxin gene. Some strains of *V cholerae* appear to produce other enterotoxins, such as zonula occludens toxin and accessory cholera toxin, that may play a role in pathogenesis.

Clinical features. The clinical symptoms present a spectrum ranging from subclinical gastroenteritis to severe cholera (cholera gravis). The mild to moderate illness caused by cholera cannot be distinguished from other forms of enterotoxigenic diarrhea, and many affected persons do not seek medical attention. By contrast, severe, complicated cholera, now relatively rare if oral fluid therapy is made available, can lead to hypovolemic shock within 1 hour and death within 2 to 3 hours if left untreated. The key feature is that fluid and electrolyte loss leads to serious complications in children, including severe metabolic acidosis, hyponatremia, hypokalemia, lethargy, altered sensorium, and seizures. Clinical signs of such profound dehydration include wrinkled skin with minimal turgor, sunken eyes, cold extremities, restlessness, dry mucous membranes, depressed fontanels in infants, weakened voice, thready pulse, and systolic hypotension. Severe cholera starts abruptly with diarrhea, which becomes the classical rice water (watery stools with flecks of mucus) of cholera. The incubation period ranges from a few hours to 7 days, with some patients experiencing premonitory symptoms of abdominal cramping and anorexia. In most cases, however, the onset of the illness is sudden. The rate of diarrhea production, which can exceed 1 L/hour, usually peaks within the first 24 hours and slowly declines thereafter. Vomiting may complicate and exacerbate dehydration, but it usually abates when the patient is properly hydrated. Fever is rare, as is abdominal pain. Malnutrition in children places them at higher risk for the development of severe dehydration and prolonged diarrhea despite antibiotics. Full recovery without antibiotics can be expected in 1 to 6 days if rehydration is administered. If rehydration strategies are delayed, prolonged hypotension can lead to acute renal tubular necrosis. Hypoglycemia in children can result in grand mal seizures. Hypoglycemia and altered consciousness are risk factors for death. Paralytic ileus, muscle cramping, weakness, and cardiac arrhythmias may herald hypokalemia, the most common electrolyte abnormality of children in the tropics. Pulmonary edema has been reported in severely acidotic children rehydrated with normal saline solution not containing base, unless augmented with standard oral rehydration salts.

Diagnosis. The diagnosis can be made presumptively based on the clinical manifestations and the laboratory identification of toxigenic *V cholerae* O1 or *V cholerae* O139 Bengal. Stool Gram stain may help identify vibrio-like organisms. *V cholerae* organisms display a typical shooting-star motility that can be seen under dark-field or phase microscopy, but unless specific antisera (Ogawa or Inaba) are added to the stool preparation, a diagnosis of cholera cannot be made with certainty. When cholera is suspected, the laboratory should be alerted to use the proper media and identification techniques.

Therapy. The simple rule of thumb in the treatment of cholera is to replace lost elements and reduce the amount of purging. The first goal is easily accomplished in 92% to 95% of cases with the early institution of oral rehydration solutions endorsed by the World Health Organization (WHO; see section “ Oral Rehydration Therapy” and Chapter 53). [147] Severe dehydration (>10% body weight), incessant vomiting, or a change in mental status requires intravenous rehydration therapy, such as with lactated Ringer solution supplemented with potassium (Table 74-5). Hypoosmolar solutions, or those containing rice, may be more efficacious than standard oral solutions. [148], [149]

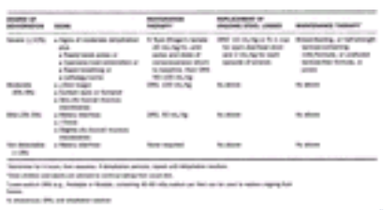

TABLE 74-5 Fluid Therapy for Dehydration

Although rehydration is the only treatment needed, antibiotics can shorten the period of excretion of *V cholerae* and reduce the volume and duration of diarrhea, thereby diminishing the cumulative fluid loss. Tetracycline and doxycycline have proved effective, as have alternatives (streptomycin, chloramphenicol, TMP-SMX, nalidixic acid, and ampicillin). A single 1-g dose of ciprofloxacin was more effective than a 300-mg dose of doxycycline in one study. [150]

Vaccine therapy. Currently, only a parenteral inactivated vaccine is available in the United States. An oral killed whole-cell and oral live attenuated vaccine are available outside the United States. Vaccines in general provide about a 50% rate of protection from disease for only 24 months, do not reduce the rate of asymptomatic infections, and do not prevent disease transmission (see section “ Enteric Vaccines”). [151], [152] Vaccines are not effective against non-O1 strains. Apart from *V cholerae* O1, a number of other *Vibrio* species can produce illness in humans. These pathogenic noncholera vibrios are encountered frequently in the marine environment or associated with seafood, and are known to cause or are suspected of causing gastroenteritis. [153]

Vibrio parahaemolyticus *V parahaemolyticus* is a halophilic (i.e., salt-loving) vibrio. It is commonly isolated from marine waters, their sediment, their inhabitants (fish, crustaceans, and shellfish), and, less commonly, from soft tissue infections of people who have come in contact with seawater. Isolation of the organism from asymptomatic people is rare. *V parahaemolyticus* is a major etiologic agent of bacterial diarrhea in Japan and has been implicated frequently as causative agent of outbreaks of food poisoning in the United States. Nearly all confirmed cases have been associated with either the consumption of raw or improperly stored (after cooking) seafood or the contamination of food with seawater. Disease presentation is variable, ranging from a mild, watery diarrhea to a dysentery-like syndrome. Typically, most cases present with an acute onset of diarrhea after an incubation period of less than 24 hours (range, 4–96 hours) resembling that of nontyphoid salmonellosis. Nausea, vomiting, headache, and low-grade fever are common, but severe dehydration is rare. Mortality rates are low, and the elderly and very young are at greatest risk, particularly if they have concomitant underlying illness. The diarrheal effluent is most commonly watery, but it may contain a few leukocytes and, less often, frank blood (<15%). The diagnosis is confirmed by culturing the organism from stool, a procedure that usually requires the use of selective media (i.e., TCBS agar). Treatment should be directed at the prompt replacement of lost fluid and electrolytes, usually orally but intravenously if the clinical situation so requires. The use of antibiotics has not been shown to shorten the natural course of the illness or duration of pathogen excretion. Some experts, however, suggest that tetracycline may be used in those rare instances when illness is severe (see Table 74-3). As with any organism involved in food poisoning, prevention lies in proper food preparation technique (i.e., appropriate cooking and storage temperatures and avoidance of raw or poorly cooked seafood, including oysters and clams).

Non-O1 Cholera Vibrios Non-O1 cholera vibrios are known as such because despite their biochemical resemblance to *V cholerae,* they do not agglutinate in antiserum against the O-group 1 (somatic) antigen. Non-O1 *V cholerae* have been found to cause gastroenteritis in many parts of the United States. They grow well in waters with increased salinity and are commonly found in the estuarine environment during the warm months and in marine animals, particularly filter feeders such as oysters but also other shellfish, in which they may be concentrated. Other foods, including grated eggs and potatoes, have been implicated in disease outbreaks. The

clinical manifestations of the illness range from a cholera-like syndrome to frank dysentery. Non-O1 *V cholerae* organisms have the capacity to produce cholera toxin or another LT that is active in biologic assays. Most organisms in the United States, however, are not enterotoxigenic, and illness tends to be less severe than typical cholera. Epidemiologic studies show that up to 25% of patients in the United States infected by non-O1 vibrios manifest bloody diarrhea. [154] The illness, which usually begins with diarrhea followed by abdominal cramping, fever, nausea, and vomiting after a 12-hour incubation period (range, 6 hours–3 days), lasts 1 to 6 days. The diagnosis is made by culturing the stool on TCBS agar. Antimicrobial treatment has not been shown to reduce the course or severity of the disease, but, as with *V parahaemolyticus,* tetracycline seems a logical choice in cases of severe diarrhea. The other pathogenic vibrios, including *V fluvialis, V furnissii, V hollisae,* and *V mimicus,* are associated with diarrheal illness more frequently than their counterparts, *V damsella* and *V vulnificus*. The epidemiology and features of the diarrheal illness caused by these organisms resemble those of *V parahaemolyticus* and non-O1 *V cholerae* infection; the organisms are found commonly in the marine environment, and illness is associated with seafood consumption.

Aeromonas, Plesiomonas, and Edwardsiella

Aeromonas Aeromonads are gram-negative, oxidase-positive bacteria that are members of the family Vibrionaceae. Aeromonads are commonly identified and isolated from fresh water fish and shrimp. [155] The role of *Aeromonas* as a cause of wound infection and septicemia is well recognized, but controversy still surrounds its role as a cause of gastroenteritis. *Aeromonas hydrophila, Aeromonas veronii* biotype *sobria,* and *Aeromonas caviae* account for more than 85% of all human infections caused by aeromonads. [156] During the acute phase of the diarrheal illness, the isolation of aeromonads in a diagnostic setting should not be difficult because moderate to large numbers of these bacteria are present in fecal samples. In cases of subacute or chronic diarrhea, however, *Aeromonas* may be overlooked if enrichment procedures are not included. *Aeromonas* infections at any site are more likely to occur during the warmer months of the year, but unlike outbreaks caused by other waterborne and foodborne pathogens, clearly defined outbreaks of diarrheal illness caused by *Aeromonas* have never been reported. Some studies have suggested that *Aeromonas* may simply be a nonpathogenic fellow traveler. In several studies, it has been isolated with almost equal frequency from stools of control patients without diarrhea. [157] Alternatively, a study of 1000 children with diarrhea in Australia demonstrated *Aeromonas* strains in 10% of children with diarrhea, as opposed to an incidence of only 1% in age- and sex-matched controls. [158] Furthermore, treatment of gastrointestinal symptoms with antibiotics directed against *Aeromonas* species has resulted in clinical improvement, and serologic conversions have been demonstrated after clinical infection. Infection with *A hydrophila* is commonly associated with exposure to water, and the organism has been demonstrated as a pathogen in both immunocompromised and otherwise healthy adults. The pathogenesis of *A hydrophila* infection is incompletely understood, but virulence probably relates to the ability of the organism to attach to epithelial cells and to the production of heat-labile enterotoxins. [159] Enteric illnesses caused by *Aeromonas* species range from acute watery diarrhea and dysentery to subacute or chronic diarrhea. Symptoms of the former include watery diarrhea that may contain blood and mucus in up to 22% of cases, mild fever, and vomiting. The clinical symptoms of illnesses caused by various *Aeromonas* species do not appear to differ. The symptoms usually last less than 1 week, but they may persist as long as 2 weeks or more in the case of short-term illness, and more than 1 year in the case of chronic illness. Most *Aeromonas* species are normally susceptible to tetracyclines, aminoglycosides, TMP-SMX, third-generation cephalosporins and their analogs, and FQs, but most are resistant to ampicillin. The treatment in *Aeromonas*-associated gastroenteritis is rehydration. Although most disease is self-limiting, it seems reasonable to treat those patients who have stool cultures positive for *Aeromonas* and who have had symptoms for at least 7 to 10 days (see Table 74-3). TMP-SMX is perhaps the drug of choice in cases of *Aeromonas* gastroenteritis. Other agents that may be used include doxycycline or tetracycline, FQs, and aminoglycosides in septic patients.

Plesiomonas The classification of *P shigelloides* is unresolved, with some studies suggesting that this organism be classified with the Enterobacteriaceae rather than the Vibrionaceae. [160] *P shigelloides* is a non–lactose-fermenting, facultatively anaerobic, gram-negative rod that grows on commonly used enteric media. Features associated with *Plesiomonas* enteric infection include travel to the tropics, abdominal pain, and gastrointestinal illness of more than 14 days' duration. The prevalence of *P shigelloides*–associated diarrhea appears to be increasing, probably as a result of migration and travel. [161] In a controlled study from Nigeria, *P shigelloides* accounted for 8% of cases of diarrheal illness in nonurban areas. [162] *P shigelloides* gastroenteritis affects both children and adults, and 70% of identifiable cases are associated with an underlying illness or risk factor, such as the consumption of contaminated food (e.g., seafood) or foreign travel. Virulence factors have not been clearly established. The features of this illness can vary; it may have an invasive character, similar to the illness caused by *Shigella* species, or manifest as an enterotoxigenic diarrhea. Severe abdominal pain and cramping are commonly seen. The untreated illness can last from 2 to 14 days; antimicrobial therapy has been associated with elimination of the organism from stool and concomitant improvement in clinical symptoms. [163], [164] Most strains are resistant to ampicillin in vitro but sensitive to tetracyclines, TMP-SMX, cephalosporins, chloramphenicol, and FQs. The susceptibility of the plesiomonads to the aminoglycosides varies. [165] FQs and TMP-SMX may be the best oral agents for the treatment of uncomplicated plesiomonad diarrhea.

Edwardsiella The genus *Edwardsiella* comprises gram-negative, oxidase-positive rods that are facultatively anaerobic. Three major species are included, but only *Edwardsiella tarda* is thought to cause human disease. *E tarda* is found primarily in water sources and aquatic animals. *E tarda* can cause wound infections, systemic illnesses, and gastroenteritis. [166] It most commonly causes a diarrheal illness that takes either of two forms—a benign secretory diarrhea or a more invasive process resembling dysentery. *Edwardsiella* strains penetrate nonphagocytic cells, produce hemolysins, and are cytotoxic. [167] The nature of the gene associated with this cytotoxicity has been described. [168] Culture remains the diagnostic method of choice. Based on antimicrobial susceptibility patterns but limited available patient data, ampicillin, TMP-SMX, and ciprofloxacin are all reasonable therapeutic choices. [169]

VIRAL PATHOGENS

Viruses from four distinct and diverse nonenveloped viral families are known to cause acute gastroenteritis in humans. Rotaviruses are the most important cause of severe diarrhea in young children worldwide and are members of the Reoviridae, with a segmented, double-stranded RNA genome. Enteric adenoviruses, by contrast, have a double-stranded DNA genome and belong to a unique subgroup of the Adenoviridae. Norwalk and Norwalk-like viruses, referred to in the older literature as *small round structured viruses* according to their morphologic features, and human caliciviruses, with classical calicivirus morphology, are members of the Caliciviridae, a family of positive-strand RNA viruses. Finally, human astroviruses, which are also positive-strand RNA viruses, belong to a separate and distinct viral family, the Astroviridae. These gastroenteritis viruses are shed fecally to varying degrees by symptomatically infected patients and can be identified by electron microscopy. Despite their genetic and morphologic diversity, the viruses cause diarrheal diseases that are virtually indistinguishable, and infection by these agents is generally limited to the gastrointestinal tract. The patient's history and the setting in which the illness has occurred may help to distinguish among these agents clinically. For example, a child with diarrhea who is younger than 5 years of age and from a developed country is most likely to be infected with rotavirus, but infection with enteric adenovirus, classical calicivirus, or astrovirus is also possible. By contrast, Norwalk and Norwalk-like caliciviruses are well-established causes of large outbreaks of foodborne or waterborne gastroenteritis among older children and adults.

Rotavirus

Pathogenesis Rotaviruses are triple-layered icosahedral viruses approximately 100 nm in diameter. [170] The outer protein layer of the triple-layered virion is composed of two viral proteins, VP4 and VP7. [171] These proteins are responsible for attachment and entry of the virus. Antibodies to both VP7 and VP4 neutralize the virus and are felt to be important mediators of protective immunity. A variety of serotypically distinct VP4s and VP7s have been identified, but most human isolates have one of four principal VP7 types and one of three principal VP4 types. [172] Although the precise role of rotaviral serotype in modulating protective immunity is not yet clear, it is generally felt that serotype-specific immunity is important for protection. [173] The second layer of the rotaviral virion is made up of VP6, which constitutes more than 50% of the mass of the virus. This protein is antigenically cross-reactive among various isolates and is the most immunogenic protein during natural infection or immunization. Antibodies to VP6 do not neutralize rotavirus in vitro but may play a role in protective immunity in vivo. [174] The innermost layer of the virion is composed of VP1, VP2, and VP3. These proteins are components of the viral transcription and replication machinery. [175] The three protein layers surround the genome of the virus, which is composed of 11 segments of double-stranded RNA. [176], [177] Most pathogenic human rotaviruses fall into a single genogroup, group A. The genomes of group A rotaviruses share substantial sequence similarity and are able to undergo gene reassortment with one another. Two other genogroups, groups B and C, also infect humans, although less commonly than group A strains. Group B strains have been primarily identified in China, where they have caused large waterborne epidemics of diarrheal disease in adults, whereas group C strains occur sporadically around the world. [172], [178] Rotavirus replication occurs exclusively in the cytoplasm of infected cells. The replication cycle has several interesting features, including a multiple-step binding and entry phase, a high frequency of gene reassortment during mixed infections, and intracellular budding through the endoplasmic reticulum during virion assembly. [179] Rotaviruses are common enteric pathogens in many mammalian and avian species. In most cases, host range barriers appear to restrict rotavirus strains to a single host. Genetic studies indicate that the basis of host range restriction is likely to be multigenic. [172], [180] Rotaviruses exhibit tropism for tissue as well as host. In immunologically intact animals, rotavirus replication appears to be restricted to the mature villus tip cells of the small intestine, [181] with infection occurring from the duodenum to the ileum. The basis for this tissue tropism is not known, but the restriction of infection to the intestine implies that local immune mechanisms are likely to be the primary determinants of protection. [182] In at least some animal models, rotavirus infection is lytic, and infected mature enterocytes are rapidly killed. It is generally felt that diarrhea is caused by the loss of mature villus absorptive cells and the resultant loss of absorptive capacity for water and sodium, in addition to the loss of brush border hydrolases such as lactase. [183] A rotavirus nonstructural protein, NSP4, has been shown to have enterotoxin-like activity in a variety of experimental circumstances [184], [185] and may

play a role in causing diarrhea. [184] Studies have also implicated activation of the enteric nervous system as a mechanism by which rotavirus causes diarrhea. [186] Because of the importance of rotaviruses, much attention has been devoted to the study of viral immunity. In animal model systems, it appears that both humoral and cellular immune mechanisms are responsible for the resolution of primary infection, [187] and children and animals with severe defects of both cellular and humoral immunity become chronically infected. Antibody appears to be the most important determinant of protection from reinfection, and a good correlation has been found in model systems between the level of antibody in the gastrointestinal tract and the degree of immunity. [188] As mentioned, it seems likely that both homotypic and heterotypic forms of humoral immunity exist, and both forms probably play a role in protection following primary infection. [189]

Epidemiology Rotaviruses are the single most important cause of severe dehydrating diarrhea in young children in virtually all areas of the world. Rotaviruses play a less critical role as a cause of milder diarrheal disease in young children. It is estimated that worldwide, rotavirus infections account for 125 million cases of diarrheal disease, 8 million of which are severe, and cause more than 600,000 deaths. [190] The high mortality rate in less developed countries is caused by a lack of readily available treatments, such as oral rehydration therapy. Even in highly developed countries such as the United States, however, rotavirus infection commonly leads to substantial morbidity. [191], [192] and [193] Studies indicate that approximately 1 million cases of rotavirus infection occur in the United States annually, leading to about 65,000 hospitalizations. The overall medical costs, both direct and indirect, have been estimated to exceed $1 billion annually. The annual death rate ascribed to rotavirus infection in the United States has fallen and is now less than 20 cases per year. [191], [192] and [193] Rotaviruses cause illness primarily in young children between the ages of 3 months and 3 years. [194] Although rotavirus infection has its greatest impact on the very young, illness can occur throughout life. Hence, immunity to reinfection is only partial and not long-lived. Rotavirus disease has also been described in elderly and immunocompromised populations. [195], [196] Studies of diarrhea among otherwise healthy adults indicate that rotavirus infection may be more common and more variable in severity than was appreciated previously. [197], [198] Although most patients are managed as outpatients, many require hospitalization. [198] Unlike rotavirus infection in childhood, infection among adults is not restricted to the winter season. [197] Rotavirus infection is generally spread by the fecal-oral route, although in some less developed areas it appears that waterborne transmission can occur. Transmission is highly efficient, even in developed countries, because of the very large load of viruses shed in the feces. Foodborne infection has also been described. [199], [200] In temperate climates, rotavirus infection generally occurs in the cooler, wetter winter months, whereas in tropical countries, infection tends to occur year round. In the United States, a wave of rotavirus illnesses spreads annually across the country, starting in the Southwest in the fall. [201] A similar sequential wave of spread also has been observed in Europe. [202]

Clinical Features Like many viral infections, most rotavirus infections are asymptomatic. This is especially true in children younger than 3 months of age, in whom maternal antibody may protect against illness, and older than 3 years of age, in whom prior exposure provides partial or complete protection. [203], [204] Symptomatic infection usually follows an incubation period of 1 to 3 days. Illness is characterized by the rapid onset of fever, malaise, vomiting, and watery diarrhea. Illness usually lasts between 3 and 8 days. [205], [206] In comparison with other acute enteric infections of children, rotavirus illness is characterized by significantly more vomiting and dehydration. Laboratory tests can show a mild elevation of the blood urea nitrogen and a mild metabolic acidosis. Stools are watery but do not contain red or white blood cells. If appropriate rehydration and other supportive therapy is instituted, recovery is uneventful in 3 to 10 days. In severely immunocompromised children, disease can be prolonged, and spread of infection to the liver has been reported. Rotavirus infection has been associated with a wide variety of other syndromes, including necrotizing enterocolitis and intussusception, but a causal relationship with these diseases has not been established. [172]

Diagnosis The clinical syndrome caused by rotavirus is relatively nonspecific. To make an accurate etiologic diagnosis, it is essential to use one of the numerous available diagnostic assays. However, it is debatable whether, in any individual case, it is necessary to determine the etiologic agent of an acute diarrheal illness in young child in a developed country. The original diagnostic assay for rotavirus detection was immune electron microscopy. This had the advantage of detecting a wide variety of etiologic viral agents in one test but the disadvantage of being labor-intensive, expensive, and relatively insensitive. Numerous solid phase immunoassays for rotavirus detection have been developed during the last 15 years, and these tests generally have sensitivities and specificities in excess of 90%. [207] Many are commercially available. Other tests include nucleic acid hybridization assays of one form or another, sometimes carried out in conjunction with reverse transcriptase-PCR (RT-PCR) assays. These tests can be even more sensitive than the solid phase immunoassays and can be used to determine the serotype of isolates as well. However, they are generally more difficult to perform and more expensive. [208] Rotavirus can also be readily detected by electrophoretic analysis of RNA isolated from stool specimens. [209] This assay is inexpensive and sensitive. Finally, rotavirus can now be cultivated with reasonable efficiency directly from fecal specimens. [210]

Treatment/Prevention The treatment of rotavirus infection is supportive. In most cases, oral rehydration therapy, as recommended by the WHO (see Table 74-5), is entirely sufficient. [211], [212] and [213] Only in the case of very severe vomiting or frank shock is parenteral hydration required. Current dietary recommendations are to begin refeeding with a complete diet as soon as rehydration is complete. Despite secondary lactase deficiency caused by rotavirus infection, restriction of milk intake is usually not required. Breast-feeding should be continued throughout the oral rehydration process. Currently, no effective antiviral medication is available for rotavirus infection. Several experimental studies have indicated that passive, orally administered immunotherapy has a beneficial role in treating acute or chronic infection and in preventing primary infection. [214], [215] Although nonspecific antidiarrheal treatment with opiates does not appear to be indicated, recent preliminary studies demonstrate a potentially useful therapeutic effect of an enkephalinase inhibitor in the treatment of rotavirus diarrhea. [216] The major approach to rotavirus disease is through vaccination, which is discussed in detail in the section “Enteric Vaccines.” Briefly, several live attenuated vaccine candidates currently are being studied and appear promising. [190], [217], [218] A reassortant rotavirus vaccine derived from a simian rotavirus parent was shown to be highly efficacious, but postlicensing analysis disclosed that this vaccine appeared to cause rare cases of intussusception. [219] This vaccine has been withdrawn.

Norwalk and Norwalk-like Caliciviruses

Norwalk virus is the prototype of a group of viruses that are the primary cause of epidemic gastroenteritis throughout the world. [8] In the United States, an estimated 23 million persons become ill with Norwalk-like virus infections each year. [10], [220] Most of the viruses in this group are named for the location of an outbreak (e.g., Hawaii, Snow Mountain, Taunton). Norwalk virus is named for a 1968 outbreak of epidemic gastroenteritis at an elementary school in Norwalk, Ohio, in which half of the teachers and pupils became ill. [221] The identification of Norwalk virus by immune electron microscopy in 1972 was the first proof of a viral cause of diarrhea. [222] Despite this early success, Norwalk virus proved difficult to study because it could not be propagated in cell culture, no animal models were available, and only small numbers of viral particles were shed in the feces of infected individuals. Newer methods for detecting Norwalk and related viruses became available in the early 1990s after cloning and sequencing of the viral genome [223], [224] and [225] and expression of the single capsid protein as viruslike particles (VLPs). [226]

Pathogenesis Human volunteer studies have helped to elucidate the pathogenesis of illness aused by Norwalk and Hawaii viruses. [227], [228], [229], [230] and [231] Jejunal biopsy specimens from symptomatically infected patients showed broad and blunted villi, crypt cell hyperplasia, cytoplasmic vacuoles, and infiltration of the lamina propria with polymorphonuclear and mononuclear cells. Specimens from the stomach and colon were unremarkable histologically. Jejunal specimens taken after resolution of the symptoms showed a return of the normal villus architecture. Viral particles were not evident in electron micrographs of intestinal biopsy specimens. [227] Functional studies showed a decrease in intestinal brush border enzyme activities [227] and delayed gastric emptying [232]; the latter may contribute to the nausea and vomiting experienced by infected persons. Immunity to infection with Norwalk virus is not well understood. [233], [234], [235] and [236] Various studies indicate that individuals who have been infected with Norwalk virus and in whom an immune response develops (measured by a rise in serum antibody level) are protected from reinfection for a few weeks to a few months (short-term immunity). However, the level of serum antibody does not predict an individual’s susceptibility to infection or illness in the long term. Issues such as the type of antibody (neutralizing versus nonneutralizing) and the role of genetically determined factors in long-term immunity require further study. Immune responses to purified recombinant Norwalk VLPs fed to human volunteers [237] or such VLPs expressed in plants fed to mice (edible vaccine) [238] and the possible utility of these reagents for vaccination are under investigation.

Epidemiology Outbreaks of gastroenteritis caused by Norwalk and related viral strains have occurred year round in a variety of settings, including homes, schools, hospitals, cruise ships, swimming pools, and military facilities. [239] Epidemiologic investigation has shown associations with the ingestion of contaminated food, particularly raw or poorly cooked shellfish, and uncooked or previously cooked foods, including frosting, salads, and sandwiches, that require manual preparation and handling by food service workers. Contaminated water and ice have also been implicated as causes of outbreaks. Primary attack rates of 50% or higher and secondary attack rates of 30% or higher are typical. Transmission is primarily through the fecal-oral route, but person-to-person, airborne, or fomite transmission has been suggested in certain outbreaks in which fecal-oral transmission was unlikely. [240], [241], [242] and [243] In most studies from developed countries, antibody acquisition curves (determined by older [244] and newer [245], [246] and [247] diagnostic methods) show a precipitous rise that begins in the teen years and reaches a plateau of 50% or higher by middle age. Most people in developing countries acquire antibody to Norwalk virus in childhood. It should be noted, however, that Norwalk-like viruses such as Toronto virus (previously called *minireovirus*) infect infants and produce a diarrheal illness of sufficient severity to warrant hospitalization in many cases. [248] With the refinement and broader use of molecular detection assays has come the recognition that Norwalk-like viruses are a significant cause of childhood diarrhea. [249], [250] Common features of Norwalk virus outbreaks that can be used to make a tentative diagnosis in outbreaks of viral gastroenteritis include the following [251]: (1) Bacterial or parasitic pathogens are not identified; (2) nausea, vomiting, diarrhea, and abdominal cramping with an acute onset are prominent symptoms, with fever and malaise in some cases; (3) illness lasts 12 to 60 hours; and (4) the incubation period is 12 to 36 hours. Newer methods for detecting viral antigen or nucleic acid or immune responses to the virus are used in research studies to identify the viral pathogen involved in the outbreak.

Clinical Features The full spectrum and distribution of symptoms in human volunteers reflect what is seen in natural infections. The incubation is 10 to 50 hours, and

symptoms last 12 to 72 hours with no long-term sequelae. Infected patients with symptoms most frequently reported nausea, abdominal cramps, or headache/body ache (96% each), whereas diarrhea was reported by 86%, vomiting by 57%, and temperature above 37.8°C by 32%. [235] Newer methods of viral antigen detection indicate that viruses may be shed for days to 2 weeks after the resolution of symptoms. [235], [252]

Diagnosis Toronto virus, a Norwalk-like virus that was originally found in diarrheal stool from children, was detected by direct electron microscopy (EM). By contrast, adults infected with Norwalk virus tend to shed more soluble antigen than viral particles, and their stool may not contain the concentration of 10^6 viral particles per gram required for visualization by direct EM. Immune EM can circumvent this problem, [222] but it is not available in all medical centers. Newer methods that can detect viral antigen (by ELISA with antibody to recombinant VLPs), the presence of viral RNA (by RT-PCR), or the serologic response to infection (by ELISA with VLPs as the antigen) are very promising but available only in certain research laboratories. [253] These tests are highly sensitive. With regard to specificity, the ELISA designed to detect viral antigen (based on antibody to recombinant VLPs) detects only Norwalk-like viruses that are closely related to the particular VLP to which the antibody was produced. [235], [254] By contrast, the ELISA that uses VLPs as the antigen can detect serum antibody to a broader range of Norwalk-like viruses. [255] For example, if recombinant Norwalk virus VLPs are used as antigen in the ELISA, antibodies to Snow Mountain virus, a Norwalk-like virus of a distinct genogroup, can also be detected. The success of RT-PCR depends on selecting the appropriate primer set(s) and removing substances in stool that may be inhibitory to RT or PCR. [253] Some strains of Norwalk-like virus may not be detectable with currently available primer sets. However, primers based on sequences from one of the more conserved regions of the genome encoding the viral RNA-dependent RNA polymerase have been helpful in obtaining initial sequences for several Norwalk-like viruses. RT-PCR is a powerful technique that has been applied to outbreak investigations and has helped to establish links between outbreaks and also links to contaminated vehicles of transmission.

Treatment/Prevention No specific therapy is available for this generally mild and self-limiting illness. In a study of young children in the community, acute gastroenteritis caused by Norwalk-like viruses was noted to be more severe than illness caused by Sapporo-like viruses (human caliciviruses with classical ultrastructural features). [256] Hospitalization and intravenous fluid resuscitation are rarely necessary. [249] Oral rehydration (see Table 74-5) and other supportive measures may be helpful during the acute phase of the illness. [257] BSS may decrease abdominal cramping. [258] Prevention starts with good hand washing and hygienic food preparation techniques. The public should be made aware of the risks of eating raw shellfish. The common practice of steaming clams until their shells just open (<1 minute) does not achieve the internal temperature of 100°C (4–6 minutes) required to inactivate viruses. [259] Public health efforts should be directed at properly chlorinating drinking water, developing methods to identify accurately shellfish and foods that are contaminated with enteric viruses, and identifying infected food handlers who may be asymptomatic.

"Classic" Human Calicivirus

The genome organization of the morphologically typical caliciviruses (or Sapporo-like viruses) more closely resembles that of animal caliciviruses (e.g., rabbit hemorrhagic disease virus) than that of the Norwalk-like viruses discussed previously. [260], [261] and [262] Differences in the nucleic acid and amino acid sequences of these caliciviruses have placed them in a distinct genogroup. [239]

Pathogenesis The virus is believed to replicate in the small bowel, but limited information is available.

Epidemiology Infection with caliciviruses was first described in infants and young children who had acute gastroenteritis, but it is not restricted to this age group. [263] Infection in adults, particularly elderly individuals, has been documented. [264] Outbreaks in a variety of institutional settings also occur, but less frequently than outbreaks caused by the Norwalk-like caliciviruses described previously. Seroepidemiologic studies of calicivirus strains isolated from infants in the United Kingdom indicate that this is a common infection among infants. [265], [266] and [267] Antibodies are acquired early in life, and high titers of antibodies can be seen in nearly all children (69%–100%) by the age of 12 years. In contrast to Norwalk virus antibodies, antibodies to the morphologically typical caliciviruses appear to be associated with long-term resistance to illness. [268] Infected children tend to excrete large numbers of viral particles that can be readily recognized by EM. Although the mode of transmission has not been clearly established, the fecal-oral route is likely. Oysters and cold foods have been identified as vectors of transmission. [269]

Clinical Features Vomiting and diarrhea are the most common symptoms associated with calicivirus infection. Patients may also experience abdominal pain, fever, and respiratory symptoms. Illness lasts 1 to 2 days and is preceded by an incubation period of 1 to 3 days. Calicivirus illness in infants and young children resembles a mild form of rotavirus illness. [270]

Diagnosis Because these viruses are shed in relatively large quantities in stool and have a distinctive appearance, direct EM is useful in diagnosing infection. An ELISA that detects all classic human caliciviruses has been developed but is not available commercially. [266], [271] Nucleic acid sequence data should hasten the development of molecular detection tests and VLPs. [262]

Treatment/Prevention The recommendations for treatment and prevention are similar to those enumerated for rotavirus and Norwalk virus in the previous sections.

Astrovirus

Pathogenesis Limited information is available on the pathogenesis of human astrovirus infection. The finding of astrovirus particles in intestinal epithelial cells of two patients who were shedding astrovirus in their stool suggests that astrovirus replicates in these cells. [272] The significance of this observation is not clear, however, because both children had severe underlying gastrointestinal pathology and chronic diarrhea. When immunocompetent lambs were infected with an outbreak strain of ovine astrovirus, diarrhea developed in the animals and astrovirus was found in mature enterocytes and subepithelial macrophages. [273], [274], [275] and [276] Viral aggregates were observed in some enterocytes, along with villus atrophy and crypt cell hyperplasia.

Epidemiology Astrovirus infection of humans occurs worldwide. Although astrovirus is primarily a pediatric pathogen, [277], [278] and [279] illness has occurred among institutionalized elderly patients [280], [281] and [282] and immunocompromised individuals. [283], [284], [285] and [286] Symptomatic illness tends not to develop in most otherwise healthy adults, except when they are exposed to contaminated food or water with high viral titers. Antibody acquisition begins in childhood, and antibody prevalence rates of 70% by school age have been reported. [286] Antibody to five of the eight serotypes of human astrovirus are detectable in gamma globulin pools from the United States [287] and Japan [277] (reagents to test for antibody to the three more recently described serotypes were not available at the time of these studies). Large-scale epidemiologic studies based on an ELISA capable of detecting all serotypes of human astrovirus have demonstrated the medical importance of astrovirus infection. [288], [289] Astrovirus was shown to be second only to rotavirus as a cause of viral gastroenteritis among children attending outpatient clinics in Thailand.

Clinical Features Gastroenteritis caused by astrovirus is usually characterized by a mild, watery diarrhea that lasts for 2 to 3 days and may be accompanied by vomiting, fever, and abdominal pain. [290] The incubation period varies from 1 to 4 days. In children, the symptoms of astrovirus gastroenteritis may be indistinguishable from those attributable to rotavirus infection. Although most cases of gastroenteritis that require hospitalization are caused by rotavirus, in a study from Australia, [291] hospitalization rates for gastroenteritis caused by astrovirus (4.2%) and adenovirus (3.7%) were comparable. Astrovirus was found to be a common pathogen among patients infected with human immunodeficiency virus (HIV) [283] and recipients of bone marrow transplants [284], [292] who had diarrhea. In some immunocompromised patients, prolonged infection and more severe illness may be seen. [285], [293], [294] In normal individuals, the production of serum antibody [295] and lamina propria $CD4^+$ T cells that recognize astrovirus antigens in an HLA-restricted manner [296] are important host defenses against repeated astrovirus infections. Protracted infection with astrovirus has been reported in patients with $CD4^+$ T cells depleted by chemotherapeutic agents, such as fludarabine. [285], [297], [298]

Diagnosis Shedding of up to 10^{14} astrovirus particles per gram of stool has been reported, [285] although shedding of 10^8 to 10^{10} particles per gram is more typical. [293] Since the identification of astrovirus in 1975, direct EM has played a prominent role in the diagnosis of astrovirus gastroenteritis. However, accurate diagnosis by EM may require an experienced microscopist because typically only about 10% of the particles display the characteristic surface star. [263] Astroviruses have been mistakenly identified as small round featureless viruses (e.g., parvovirus and picornavirus) and as Norwalk-like viruses. [299] An ELISA based on a monoclonal antibody that reacts with all eight types of human astrovirus [300], [301] is available as a commercial kit abroad, but not in the United States. This ELISA should facilitate the rapid diagnosis of human astrovirus infection.

Treatment/Prevention Issues regarding treatment and prevention are very similar to those discussed for Norwalk virus and rotavirus in the previous sections. In immunocompromised patients, the treatment of protracted astrovirus diarrhea with immunoglobulin administered intravenously, [285] orally, [292] or by a combination of both routes [302] has met with variable success. Experience with this treatment is limited, and it has not yet been studied systematically in controlled clinical trials.

Enteric Adenovirus

Adenoviruses are a large family of DNA viruses that have been associated with a variety of illnesses. Adenoviruses of subgroup F, specifically serotypes 40 and 41, are also known as *enteric adenoviruses* because of their consistent association with gastroenteritis in infants and young children. [303] Other types of adenovirus have also been identified in stool, but they do not fulfill Koch's postulates, and their role as gastrointestinal pathogens is not established.

Pathogenesis Adenoviruses replicate in the intestinal tract. Up to 10^{11} viral particles per gram of stool are excreted during infection. In one report of a fatal case of

gastroenteritis attributable to adenovirus, viral particles were observed in the nucleus of small intestinal mucosal cells. [304] Nonenteric types of adenovirus have been found in AIDS patients with acute and chronic diarrhea. [283], [305], [306] and [307] Their precise role in this disease entity is not well established. [308], [309]

Epidemiology Enteric adenovirus infections occur worldwide and primarily affect children younger than 2 years of age. [303] In developed countries, where the incidence of adenovirus infection is 4% to 10%, these viruses were formerly considered to be second to rotavirus in importance, but the application of newer assays for virus detection has led to the identification of astroviruses and Norwalk-like viruses more often than enteric adenoviruses. In most developing countries where studies have been conducted, an incidence of 2% to 3% typically has been found. A study from Guatemala, however, detected enteric adenovirus in 14% of patients with diarrhea, whereas rotavirus was identified in 4.7%. [310] With few exceptions, adenovirus infections appear to occur throughout the year and do not peak in any particular season. Infection is transmitted from person to person.

Clinical Features Infection with enteric adenovirus may cause an illness indistinguishable from that caused by other viral agents. The infection is generally mild, but the full spectrum of severity can be seen. An incubation period of about 7 days precedes the symptomatic phase, which is characterized primarily by watery diarrhea and vomiting. [311] Virus is shed in the stools for 10 to 14 days, significantly longer than in rotavirus infections. Respiratory symptoms and low-grade fever may accompany adenovirus gastroenteritis. Young children are most commonly affected. Protracted lactose intolerance and malabsorption have been observed following symptomatic infection with enteric adenovirus. [312], [313] It has also been speculated that adenovirus infection may be related to the development of celiac sprue. [314]

Diagnosis A commercially available, sensitive, and specific ELISA kit, based on monoclonal antibodies to each enteric type of adenovirus, is the preferred method for detecting enteric adenovirus antigen in stool. [315] Adenovirus particles are generally shed in large quantities in infected feces (=10^{11}/g) and can be readily identified by EM, but discerning the enteric serotypes requires immune EM. [316] Molecular methods, including PCR strategies, have been developed in research laboratories to detect minute quantities of enteric adenovirus DNA. [303]

Treatment/Prevention No specific antiviral agents are available. Mild to moderate dehydration may be treated with oral rehydration solutions or intravenous fluids, as indicated. The goal of therapy is to prevent severe dehydration and maintain nutritional intake.

THERAPEUTIC CONSIDERATIONS

Oral Rehydration Therapy

Of all the therapeutic modalities available to treat diarrheal disease, none has been more important than the discovery and development of oral rehydration solutions. [3], [317] These formulations are based on careful pathophysiological studies that characterized precisely the fluid and electrolyte losses in stools of cholera patients. The solutions take advantage of the glucose and sodium cotransport mechanism, in which sodium absorption is stimulated by the entry of glucose or other small nutrient molecules into intestinal epithelial cells. This mechanism of absorption is generally not affected by the infecting microbial agents.

The oral rehydration solution recommended by the WHO is slightly hypertonic and is prepared by mixing in 1 L of water sodium chloride (3.5 g), potassium chloride (1.5 g), sodium bicarbonate (2.5 g) or sodium citrate (2.9 g), and glucose (20 g). These components are available in packets that can be mixed with clean water as needed. Replacement of the glucose with other nutrients, such as amino acids and cooked cereals, does not interfere with the cotransport mechanism. [147] An alternative solution that can be prepared at home consists of 3/4 tsp of table salt, 1 tsp of baking soda, 1 cup of orange juice or two bananas, and 4 tbsp of sugar (or 50–60 g of cooked cereal flour from rice, maize, sorghum, millet, wheat, or potato) in 1 L of clean water. [318] Commonly recommended clear liquids, such as apple juice, carbonated beverages, and chicken soup, do not appropriately replace electrolyte losses and may precipitate osmotic diarrhea. [147], [319]

Despite its salutary features, treatment with an oral rehydration solution does not reduce stool volume. [3] Thus, the patient's hydration status should be monitored by measuring the heart rate, blood pressure, and urine output. It is imperative that the parents of infants with watery diarrhea understand that this life-saving treatment will not eliminate the diarrhea.

The fluid management of patients with diarrhea consists of (1) rehydration, (2) replacement of ongoing fluid losses in stool, and (3) maintenance therapy. A clinical assessment of the patient's degree of dehydration is used to guide management in each of the three areas, particularly the rehydration phase. [320] The approach is summarized in Table 74-5. It is important to note that these parameters were established for infants, but the utility of oral rehydration therapy extends beyond infant patients. Elderly adults are also quite susceptible to dehydration, but it may be more difficult to assess the level of volume depletion accurately, short of a catastrophic event such as circulatory collapse. [321] More reliable objective criteria, such as plasma specific gravity, [322] may help with this assessment.

Antimicrobial Therapy

Decisions regarding treatment with antimicrobial agents [323] frequently must be made at the time of the encounter with the patient on the basis of the history, physical examination, and epidemiologic setting, usually without the benefit of diagnostic test results. These decisions also must weigh the potential risks of treatment, which include side effects, the possible occurrence of superinfection when the normal bacterial flora is eradicated, the contribution to the development of infections that are resistant to common antimicrobials, and the possible induction of disease-producing phage with antimicrobials. Table 74-3 summarizes the indications for antimicrobial therapy and the recommended treatment of specific infections. Such treatment is clearly indicated for only two of the bacterial pathogens of the small intestine discussed in this chapter.

Antidiarrheal Drugs When the use of opiates or intralumenal agents is under consideration, it is important to remember that most cases of acute diarrhea are self-limiting and likely to resolve regardless of the use of these medications. The benefit of relieving the patient's symptoms must be weighed against the potential risks associated with medications that may adversely affect intestinal motility or interact with other drugs the patient is taking.

Opiates and opioids. Opiates and opioids [324] inhibit intestinal motility and thereby provide symptomatic relief of mild to moderate diarrhea. Diphenoxylate and loperamide are synthetic congeners of morphine that, in general, have little potential for abuse. Diphenoxylate (2.5 mg) is combined with atropine (0.025 mg) in a tablet (Lomotil); atropine causes discomforting anticholinergic effects if more than 10 tablets are taken in a day and is included to deter abuse of the diphenoxylate. Loperamide is poorly absorbed from the intestinal tract and poses no potential for abuse because it does not cross the blood-brain barrier. It is available over the counter and is safe for children. It may be as effective as BSS in curbing the symptoms of mild to moderate traveler's diarrhea.

Intralumenal agents. Bismuth, marketed as BSS, has antibacterial properties that are not fully characterized and stimulates fluid absorption. BSS is useful in preventing and treating traveler's diarrhea in adults. [325] It has also been shown to be effective in treating acute diarrhea in children. [326] Because salicylate intoxication is a potential problem, however, caution should be exercised in giving the drug to children with known salicylate sensitivity, patients taking other salicylate-containing medications, and patients with bleeding disorders. [327] Patients should be informed that their stools may turn black as the drug is converted to bismuth sulfide in the colon. Because the salicylate portion of the compound may interfere with the renal excretion of organic acids, the patient's medication list should be reviewed and the patient advised accordingly. A bismuth encephalopathy can develop in HIV-infected patients. [328] Adsorbents, such as kaolin-pectin compounds, alter stool consistency and have been touted as potential toxin binders, but controlled trials have failed to show an effect on stool weight [329] or efficacy comparable with that of loperamide. [52] Other antidiarrheal agents, including a-adrenergic agonists (e.g., clonidine), somatostatin and its analogs (e.g., octreotide), calcium channel blockers, nonsteroidal antiinflammatory drugs, and cholestyramine, have no role in the treatment of acute infectious diarrhea.

Enteric Vaccines Although many etiologic agents can cause diarrheal illness as a consequence of infection of the small bowel, the great majority of illnesses, especially in the young, are caused by a relatively limited array of pathogens. ETEC, EPEC, *Shigella, V cholerae* O1, and *S typhi* represent the critical bacterial pathogens, and rotaviruses are clearly the most important viral pathogens. Progress has been made toward developing vaccines for most of these agents.

Rotavirus. Animal studies have demonstrated that a variety of vaccine strategies, including parenteral immunization with inactivated virus, VLPs, and recombinant viral proteins, are all potentially efficacious. [330], [331] and [332] These vaccination approaches have not been tested in people, however. Other animal studies indicate that oral immunization with attenuated homologous virus, inactivated virus administered in microcapsules, and host range–restricted live viruses also effectively induces protective immunity. [333], [334] Human studies have focused on the effectiveness of animal viruses themselves or reassortant animal viruses containing human VP7 or VP4 as an immunogen. These approaches have been termed *jennerian* and *modified jennerian vaccination,* respectively. Other potential candidates that have been investigated in preliminary studies include homologous human strains repeatedly passed in cell culture or isolated from asymptomatic newborns. [335] In a variety of human trials of a tetravalent monoreassortant vaccine in which a simian virus was used as the genetic backbone, this modified jennerian vaccine was immunogenic and more than 80% effective in preventing severe disease. [336] The results of preliminary studies based on a similar approach involving a bovine/human reassortant vaccine are very encouraging. [218] A modified jennerian rotavirus vaccine, based on a simian rotavirus backbone, was licensed for use in the United States. Unfortunately, following licensure, the vaccine was associated with an excess rate of intussusception and was removed from the market by the manufacturer. [337], [338] Ongoing research is directed at clarifying the precise risk associated with the vaccine, which may be quite small. Future studies will be required to determine if the host range–restricted reassortant vaccines are highly effective in less developed countries and whether other approaches to vaccination, such as parenterally administered VLP or DNA immunization or homologous vaccination with attenuated human strains, are more effective or associated with less risk. Epidemiologic and

immunologic data are not yet sufficient that it can be determined whether vaccines for astroviruses and the human caliciviruses are either necessary or feasible. However, the Norwalk virus is serving as a very interesting model system to determine whether plant expression systems can be used to produce a low-cost “edible vaccine.” [339]

Enterotoxigenic Escherichia coli. Various approaches have been used to construct vaccines against ETEC. [340], [341] and [342] Because immunity to these agents appears to be mediated by local antibody against bacterial surface structures, LT, or ST, most vaccine strategies have focused on local immunization. Major problems in this area include the diversity of the O, H, and fimbrial antigens of the toxigenic strains and the difficulties involved in producing immune responses to the ST. Vaccination approaches that have been investigated to date include a *V cholerae* killed-vibrio/B-subunit vaccine, [340], [341], [343] the administration of purified *E coli* fimbriae or inactivated whole *E coli* in microcapsules, and the use of enteric bacterial expression vectors derived from *E coli, Shigella flexneri,* or *S typhi* to express ETEC LT/ST and colonization factors. [342], [344], [345] These various strategies have shown some success in experimental volunteer challenge systems but have not yet been tested extensively in the field.

Enteropathogenic Escherichia coli. Advances in our understanding of EPEC have accelerated progress toward vaccination in this area. [346], [347] Live bacterial vaccines, in which key virulence factors are deleted, are in the early stages of evaluation in human volunteers. It is too early to know if these approaches will be successful in the field, and it is not entirely clear that a vaccine against EPEC would have a substantial effect on infantile diarrhea.

Vibrio cholerae. Great progress has been made in the field of cholera vaccination since the early 1990s. The existing inactivated whole-cell parenteral vaccine is only modestly effective for just several months. A new approach involves the oral administration of a killed whole-cell preparation together with a purified preparation of the B subunit. This vaccine was shown to be moderately (85%) effective during a 6-month follow-up in Bangladesh [348] and demonstrated varying efficacy in a trial in Peru. [349], [350] Perhaps the most promising studies involved a genetically attenuated live vibrio called *vaccine candidate CVD 103-HgR*. The toxin gene has been removed from this strain. [351] In experiments in volunteers, the vaccine was highly effective in generating protection against challenge. [352] However, the efficacy of this strain in a very large field trial was minimal. [353]

Shigella. Progress toward an effective *Shigella* vaccine has been slow. Studies are under way to determine if conjugate O polysaccharide vaccines may be effective against *Shigella*. [354] The identification of two new enterotoxins [355], [356] offers hope that deletion of these virulence factors may lead to an attenuated but immunogenic live bacterial vaccine candidate. Several promising approaches to developing a live attenuated *Shigella* vaccine with recombinant techniques are being evaluated. [357], [358] and [359]

Salmonella typhi. Several approaches to vaccination against typhoid fever have been quite successful. Ty21a is a licensed orally administered *S typhi* vaccine produced by chemical mutagenesis of *S typhi*. It has been widely tested and has proved safe and 60% to 90% effective. [360], [361], [362] and [363] New live bacterial vaccine candidates, prepared by more precise genetic modification, offer the promise of increased immunogenicity and a reduced dosage requirement in comparison with Ty21a. [364], [365] and [366] In addition, parenteral immunization with *S typhi* Vi polysaccharide conjugated to carrier protein has been shown to provide considerable protective efficacy in human volunteer studies. [367] The Vi polysaccharide vaccine demonstrated more than 90% efficacy in a large field trial of young children. [368]

CHAPTER 75

George T. Fantry, Lori E. Fantry, and Stephen P. James

CHRONIC INFECTIONS OF THE SMALL INTESTINE

WHIPPLE DISEASE

Whipple disease is an uncommon, chronic, systemic bacterial disease first described in a classical paper by George Hoyt Whipple in 1907. [1] Before 1985, it was estimated that 2000 patients had been afflicted since 1907. [2] Even with the advent of sensitive and specific diagnostic tests, the disease appears to be rare. Whipple disease may involve virtually any organ system in the body, with the predominant pathological changes occurring in the gastrointestinal tract and central nervous system. In most cases, the small intestine is involved, resulting in malabsorption. The clinical presentation is widely variable. Patients may present with classical symptoms of malabsorption; however, extraintestinal symptoms, such as chronic seronegative arthritis or fever of unknown origin, may predominate or predate the gastrointestinal symptoms by many years. Because Whipple disease is uncommon, with a varied presentation and insidious onset, it is often diagnosed late in its course. Before the availability of antibiotics, Whipple disease uniformly progressed to a fatal outcome.

In the early 1950s, further advances were made in our understanding of the histopathological findings associated with Whipple disease and the systemic nature of the disorder when periodic acid-Schiff (PAS)–positive macrophages were demonstrated in biopsy specimens of the small bowel [3], [4] and other organs. [5], [6] and [7] In 1952, the first report of antibiotic therapy resulting in a remission of Whipple disease was published. [8] Subsequently, patients exhibited a dramatic clinical response after treatment with a variety of antibiotic regimens. [9], [10], [11], [12], [13], [14], [15] and [16] In the early 1960s, the characteristic rod-shaped bacillus was found in the mucosa of untreated patients with Whipple disease, [17], [18] but the organism could not be reproducibly cultured. Eventually, these bacilli were identified in nonintestinal tissues. [12], [19], [20], [21], [22] and [23] In 1992, an exciting advance was made when a polymerase chain reaction (PCR)–based molecular genetic approach was used to identify the uncultured bacillus of Whipple disease, which was named *Tropheryma whippelii*. [24] In 2000, the bacterium was successfully subcultured, with establishment of a strain that can be used for further study. [25] These findings have provided a basis for more specific diagnostic testing for this organism. [26], [27]

Epidemiology

Although data are limited because of the low incidence of Whipple disease, a number of interesting features help define its epidemiology. The disease is most common between the fourth and sixth decades of life, the mean age of patients at onset being 50 years, [15], [16], [28], [29] but it can occur at nearly any age. Males are more frequently affected, with a male-to-female ratio of approximately 8:1. [15], [28], [29], [30] and [31] Whipple disease occurs predominantly in Caucasians and has rarely been described in persons of African descent and other ethnic groups. Although the disease occurs sporadically and no clearly defined geographic or environmental risk factors have been established, it appears to be more common in farmers and individuals involved in farm-related trades. [15] This may be an important trend because phylogenetic analysis reveals that *T whippelii* is closely related to aerobic soil organisms. However, *T whippelii* DNA has been found in samples of waste water [32] and in the gastric juice and saliva of persons with no clinical evidence of Whipple disease, [33], [34] and [35] suggesting that *T whippelii* may be an environmental or commensal organism that is ubiquitous. Direct person-to-person transmission has not been documented, although the disease was reported in brothers on two occasions [36], [37] and in a father-daughter pair. [38]

Etiology and Pathogenesis

For many years, Whipple disease was thought to be caused by bacteria. This notion was supported by the finding of gram-positive bacilli in involved tissues, and clinical improvement after treatment and disappearance of the organisms. In addition, the bacteria in infected individuals and involved tissues had a uniform electron microscopic appearance. Unfortunately, culture data were conflicting, and the Whipple bacillus could not be reproducibly cultured.

In the early 1990s, major advances were made when PCR was used to identify genes from the uncultured bacillus of Whipple disease. Bacteria have 16S ribosomal RNA genes that are highly conserved in nature but undergo random mutations with time. The sequences of ribosomal genes can be used to construct evolutionary trees of microorganisms, and the ribosomal gene sequences of new, unidentified microorganisms can be used to estimate their phylogenetic relatedness to known microorganisms. [39] Taking advantage of the fact that bacterial ribosomal genes are conserved and readily distinguished from human sequences, and the fact that human tissue should contain no bacterial genes other than those associated with infiltrating bacteria, Wilson and colleagues [40] were able to amplify a 645–base pair bacterial 16S ribosomal RNA sequence from the duodenal tissue of a patient with Whipple disease. Based on the sequence obtained, the authors suggested that the unidentified bacillus was most closely related to the nocardioforms. Subsequently, Relman and colleagues [24] used the same approach to amplify a unique 1321-base pair bacterial 16S ribosomal RNA sequence from the duodenal tissue of five patients with Whipple disease. This sequence was not detected in tissue from ten control patients without Whipple disease. Phylogenetic analysis of the sequence obtained suggested that the Whipple disease bacillus is a gram-positive bacterium more closely related to the actinobacilli than to the nocardioforms, and the bacterium was given the designation *T whippelii*. Actinobacilli, as well as nocardioforms, are actinomycetes; these are a diverse group of bacteria, most of which are aerobic soil organisms. Detailed analysis of sequences has more precisely placed the organism in the phylogenetic position of the actinomycetes. [41] Further independent evidence for the identity of the Whipple bacillus was obtained when RNA

sequences of *T whippelii* were identified by PCR in peripheral blood mononuclear cells and pleural effusion cells in a patient with Whipple disease, which confirmed the systemic nature of the disease. [42] In two subsequent cases, the Whipple bacillus was identified by PCR in peripheral blood. [43] Interestingly, in those patients who had undergone splenectomy, the bacillus was associated with erythrocytes. Finally, *T whippelii* was detected by electron microscopy and PCR in the vitreous aspirate of a patient with uveitis whose intestinal biopsy specimens had appeared normal by light microscopy. [44] These important discoveries illustrate the usefulness of molecular methods to identify uncultured organisms and the feasibility of developing specific diagnostic tests without having cultured the organism.

In 1997, the Whipple bacillus was isolated and grown in human macrophages inactivated with interleukin-4. [45] Subsequently, Raoult and colleagues [25] successfully propagated *T whippelii* in a human fibroblast cell line (HEL) using an isolate obtained from the aortic valve of a patient with endocarditis secondary to Whipple disease. In addition, these investigators were able to subculture the bacterium and establish a strain of the Whipple bacillus. Furthermore, serologic assays revealed that a significantly larger number of patients with Whipple disease had IgM antibody titers specifically against the bacterium of 1:50 or more than did controls. These critical advances will make it possible to undertake future investigations, such as developing serologic tests for Whipple disease and tests for antibiotic susceptibility, and to define the potential role of this pathogen in other human illnesses.

Because the distribution of *T whippelii* in the environment is unknown, it is uncertain to what extent the disease may be caused by exposure to an unusual pathogen. However, the finding of *T whippelii* DNA in the gastric juice and saliva [33], [34] and [35] of people without Whipple disease and the striking clinical features of the disease, with the persistence of intracellular bacteria in macrophages, strongly suggest that an abnormal host response defect may play a central role in pathogenesis. Dobbins, [46] collecting information on HLA phenotypes through literature searches and personal communications, found that the frequency of HLA-B27 (28%) was higher than would be expected in the ethnic groups affected by Whipple disease. This observation is of interest because it is known that the HLA-B27 phenotype is a host factor strongly predisposing to spondyloarthropathies that may be caused by abnormal interactions of the host with enteric bacterial flora. Despite this observation, the incidence of spondyloarthritis does not appear to be increased in patients with Whipple disease. One study even questioned whether the observed correlation is correct; in a study of 14 patients with Whipple disease in Argentina, the frequency of HLA-B27 (one patient, 7.7%) was no higher than that in a control population. [47] However, other observations suggest the presence of host defects. Patients generally exhibit lymphopenia, diminished skin test responses, and decreased mitogen-induced lymphocyte responses in vitro, and these changes may persist after treatment. [48] The abnormality of cellular skin test responses was confirmed and extended. [49] In a study of 20 patients with Whipple disease, none had skin test responses to streptococcal antigens, whether they were untreated or in remission. Because it is known that streptococcal antigens may cross-react with bacterial antigens of actinomycetes, the authors suggested that patients with Whipple disease may have selective defects in their ability to respond to certain types of bacterial antigens. It has been shown that the expression of CD11b, a complement receptor involved in bacterial phagocytosis on circulating lymphoid cells, [50] is decreased in patients with Whipple disease, suggesting that there may be a molecular basis for defective macrophage function in this disease. Subsequently, decreased monocyte interleukin-12 production leading to reduced T-cell production of interferon-? was demonstrated in patients with Whipple disease. [51] This finding provides confirmatory evidence that an underlying defect of monocyte/macrophage function may lead to the inability of the host response to eliminate the causal bacteria. In addition, it may have important clinical implications in resistant Whipple disease, in which immunomodulating therapy with interferon-? may be beneficial. [52]

Histopathology

The histopathological appearance of the small bowel mucosa in Whipple disease is distinct, unique, and usually diagnostic. The lamina propria is infiltrated by large foamy macrophages that grossly distort normal villus architecture, so that the villi take on a blunted, clublike appearance. The cytoplasm of these macrophages is filled with large glycoprotein granules that stain with PAS (Fig. 75-1). The lymphatic channels in the mucosa and submucosa are dilated, and fat droplets may be seen in the extracellular spaces within the lamina propria, reflecting lymphatic obstruction by enlarged mesenteric lymph nodes.

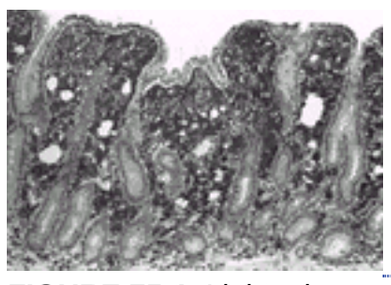

FIGURE 75-1. Light microscopic appearance of the intestinal mucosa in a patient with Whipple disease. The villi are clubbed, and the lamina propria is extensively infiltrated with periodic acid-Schiff (PAS)–positive macrophages. PAS and hematoxylin stain; original magnification ×250. (From ref. [15].)

With electron microscopy, many of the characteristic rod-shaped bacillary bodies can be seen in the lamina propria; they are most abundant just beneath the absorptive epithelium. The fine structure of the bacilli is identical in different patients. The bacilli are 0.25 µm wide and 1 to 2.5 µm long, with a characteristic cell wall and pale central nucleoid. [10], [17], [18], [53], [54] and [55] The bacilli are often seen within the PAS-positive macrophages (Fig. 75-2). Most of the PAS-positive glycoprotein within the macrophages likely represents remnants of the cell wall of the phagocytosed bacilli. Unlike the *Mycobacterium avium* complex, the Whipple bacillus is acid-fast–negative.

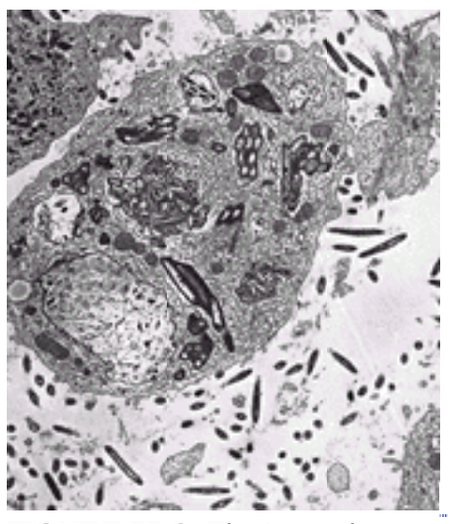

FIGURE 75-2. Electron micrograph showing numerous bacilli in the extracellular spaces and ingested bacilli in varying stages of breakdown within a macrophage. Original magnification ×11,000. (From ref. [15].)

PAS-positive macrophages and the characteristic bacilli have been identified in many nonintestinal tissues, including heart, [19], [56] lung, [20] liver, [12] and brain, [21] documenting the systemic nature of the disease.

The histology of intestinal Whipple disease was revisited in a study of 48 patients. [57] During treatment, several alterations in the histopathological findings were noted. In addition to the continuous decrease in PAS-positive macrophages, the pattern of mucosal infiltration changed from diffuse to patchy. The cytologic aspects of the PAS-positive macrophages changed substantially, leading to the proposal of four different subtypes. Finally, as had been previously shown, a few PAS-positive macrophages commonly persisted at long-term follow-up of treated patients. Because of this finding, it is recommended that during biopsy, undertaken either to

determine a response before treatment is discontinued or to confirm a clinical suspicion of relapse, sufficient samples be obtained so that electron microscopy can be performed to look for the characteristic bacillus, not just light microscopy alone.

Clinical Manifestations

The clinical features and presentation of Whipple disease are highly variable. Many patients present with gastrointestinal symptoms suggestive of malabsorption, such as steatorrhea, abdominal bloating, and weight loss. However, occasionally the diagnosis is made in patients with extraintestinal symptoms, such as arthritis and fever, but no significant gastrointestinal complaints. Symptoms are often present for several months to years before the diagnosis is made. Extraintestinal symptoms may precede gastrointestinal symptoms by many years.

The gastrointestinal symptoms associated with Whipple disease are nonspecific and may be seen in patients with other malabsorptive states (Table 75-1). Diarrhea is the most common presenting complaint. In a study of 29 patients with Whipple disease, diarrhea was the chief complaint in 39%. [16] In this group, 75% of the patients had diarrhea, a frequency similar to that found in other studies. [28], [29] and [30] It is noteworthy that 25% of the patients did not have diarrhea before the initial evaluation. This finding emphasizes that although diarrhea affects most patients with Whipple disease, it is not essential for the diagnosis of malabsorption or Whipple disease. The diarrhea is usually suggestive of steatorrhea; multiple large, watery, or semiformed stools are passed daily. Other intestinal symptoms that are often present include abdominal bloating, cramps, or distention, anorexia, and occasionally intestinal bleeding, which may be manifested by occult blood [30]; less common symptoms are melena and hematochezia. [7], [58], [59] Weight loss is the second most common presenting complaint in patients with Whipple disease and is present before the initial evaluation in 89% to 100% of them. [16], [28], [29] and [30] Severe cachexia may result from anorexia and malabsorption. Fatigue and generalized weakness are common. Continued malabsorption may result in specific nutritional deficiencies. With the loss of albumin into the intestinal lumen as a consequence of lymphatic obstruction, significant ascites and peripheral edema may develop.

GASTROINTESTINAL	EXTRAINTESTINAL	NEUROLOGICAL
Common	**Common**	**Common**
Diarrhea	Arthritis	Central nervous system
Weight loss	Arthralgias	Dementia
Anorexia	Fever	Myoclonus
Less Common	**Less Common**	Insomnia
Abdominal bloating	Pulmonary	Lethargy
Abdominal cramps	Chronic cough	Headache
Hematochezia	Pleuritic pain	Muscle weakness
	Cardiac	Ataxia
	Congestive heart failure	Cranial nerves
	Symptomatic pericarditis	Deafness
	Symptomatic valvular disease	Dysarthria
	Ocular	Facial numbness
	Decreased visual acuity	Diplopia

TABLE 75-1 Symptoms in Patients with Whipple Disease

Extraintestinal symptoms are very common in Whipple disease and may precede the gastrointestinal symptoms by many years (see Table 75-1). Arthritis is the most common extraintestinal symptom and affects the majority of patients. [16], [28], [29] and [30] It often develops several months to years before the initial diagnosis of Whipple disease and is typically an intermittent migratory arthritis of both the large and small joints. Some patients may have arthralgias only. Permanent joint deformity is rare. Fever is the second most common extraintestinal symptom of Whipple disease. [16] The fever is usually low-grade and intermittent. Because of the systemic nature of Whipple disease, numerous other extraintestinal symptoms develop that reflect involvement of other organ systems. Pulmonary involvement is often manifested by chronic cough or pleuritic chest pain. [1], [16], [20], [60] Cardiac involvement [61], [62], [63] and [64] may be manifested as congestive heart failure, valvular lesions, [61], [62] or pericarditis. [16], [19], [60], [64] Numerous reports of endocarditis secondary to *T whippelii* infection in the absence of overt gastrointestinal disease have been published. [65], [66], [67] and [68]

Although central nervous system (CNS) involvement is thought to be common, symptoms related to CNS Whipple disease may be present in only 10% to 20% of patients (see Table 75-1). [69], [70], [71], [72], [73] and [74] Neurological symptoms may occur in association with gastrointestinal symptoms or as isolated symptoms. [15], [21], [75], [76] The most common CNS symptoms are dementia, paralysis of gaze, and myoclonus. [15] Hypothalamic symptoms such as insomnia, hyperphagia, and polydipsia are also frequently present. [15]

The physical findings in patients with Whipple disease are variable, depending on the organ systems involved (Table 75-2). Frequently, the findings are related to severe malabsorption and the loss of fluid and electrolytes, such as emaciation, muscle wasting, peripheral edema, purpura, glossitis, muscular irritability, and peripheral neuropathy. Hyperpigmentation and peripheral lymphadenopathy are the most common physical finding, [16], [29], [30] seen in more than 50% of patients with Whipple disease. The palpable lymph nodes are usually firm, nontender, and mobile. Abdominal findings often include mild distention and tenderness. Abdominal fullness or mass may be caused by marked enlargement of the mesenteric lymph nodes. Ascites is uncommon but may be seen in association with severe hypoalbuminemia. Hepatomegaly and splenomegaly are uncommon. [16], [30] Additional well-recognized physical findings in patients with Whipple disease include fever, peripheral arthritis, heart murmurs, pleural or pericardial friction rubs, and ocular abnormalities. The neurological examination may reveal findings suggestive of CNS or cranial nerve involvement, such as dementia, ataxia, muscle weakness, sensory loss, and ophthalmoplegia.

COMMON	UNCOMMON
Weight loss	Ascites
Lymphadenopathy	Peripheral edema
Hyperpigmentation	Hepatomegaly
Abdominal distention	Splenomegaly
Fever	Pleural friction rub
Arthritis	Ocular findings
Heart murmurs	
Neurological findings	

TABLE 75-2 Physical Findings in Patients with Whipple Disease

Laboratory Findings Laboratory abnormalities, usually related to severe malabsorption, are very common in patients with Whipple disease. Most have steatorrhea, [16], [30] in addition to low serum carotene levels [16], [30] and hypoalbuminemia. [16], [29], [77] In patients with severe diarrhea and malabsorption, electrolyte disturbances such as hypokalemia, hypomagnesemia, and hypocalcemia may be seen. Anemia is a very common finding. [15], [16], [28], [29] and [30] The anemia is usually normochromic-normocytic, suggestive of chronic disease. Occasionally, it is hypochromic-microcytic, related to iron deficiency; however, macrocytosis secondary to folate or vitamin B_{12} deficiency is unusual. Many patients have an elevated erythrocyte sedimentation rate, and the prothrombin time is often prolonged secondary to malabsorption of vitamin K. [16]

Radiologic and Endoscopic Findings Radiologic evaluation can be helpful, particularly a barium contrast study of the small intestine, the results of which are abnormal in most patients with Whipple disease. [16], [30], [78] The most characteristic finding is marked thickening of the mucosal folds, suggestive of an infiltrative process. This finding is usually more prominent in the duodenum and proximal jejunum, with decreased involvement distally and sparing of the ileum. In addition to the marked thickening of the proximal small bowel, abdominal computed tomography (CT) often reveals massive paraaortic and retroperitoneal adenopathy. [16], [79] Gross endoscopic lesions in the duodenum have been described in Whipple disease. [80], [81] The characteristic finding is pale, shaggy, yellow mucosa in the postbulbar duodenum. Yellow plaques or erosions may also be seen. Although involvement of the esophagus and colon is unusual in Whipple disease, endoscopic lesions similar to those seen in the duodenum, consisting of pale, white, plaquelike nodules, have been described. [82]

Diagnostic Evaluation

Most important in the evaluation of Whipple disease is a high index of suspicion. The diagnosis should be considered in patients with diarrhea, weight loss, arthritis,

adenopathy, and fever. However, it is important to remember that the gastrointestinal symptoms related to malabsorption may not be the prominent complaint and, on occasion, may be absent. In addition, extraintestinal symptoms, particularly arthritis and fever, may be present years before gastrointestinal symptoms develop. Therefore, the diagnosis of Whipple disease should be considered in patients with seronegative arthritis in whom symptoms suggestive of malabsorption develop, such as diarrhea or unexplained weight loss, and in patients with culture-negative endocarditis.

Although the clinical presentation, laboratory findings, and x-ray studies may suggest Whipple disease as a diagnosis, small intestinal mucosal biopsy with histological examination is the diagnostic test of choice and is required for a definitive diagnosis. The histological finding of infiltration of the lamina propria of the small intestine by PAS-positive macrophages containing gram-positive, acid-fast–negative bacilli accompanied by lymphatic dilation is specific and diagnostic of Whipple disease (Fig. 75-3). Electron microscopy should also be routinely performed on the biopsy specimens to verify the presence of the characteristic bacillus. This is particularly important during the follow-up of patients treated for Whipple disease in which PAS positivity persists, often for many years; electron microscopy in successfully treated patients shows disappearance of the Whipple bacillus. [10], [16], [51], [83]

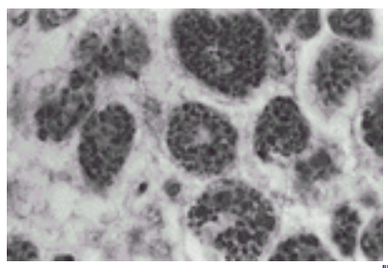

FIGURE 75-3. Light microscopic appearance of macrophages in the intestinal lamina propria in Whipple disease. Note that most of the periodic acid-Schiff (PAS)–stained inclusions are round or sickle-shaped. This appearance is virtually diagnostic, especially in the intestinal mucosa. PAS and hematoxylin stain; original magnification ×1000. (From ref. [15].)

Very rarely, the diagnosis of Whipple disease is established in the absence of intestinal involvement. The diagnosis in such cases is made by the identification of bacilli in involved tissues, including the brain and lymph nodes. Although the colonic mucosa may occasionally be involved in Whipple disease, caution is required in the interpretation of rectal biopsy specimens. PAS-positive macrophages may be seen in the rectal and colonic mucosa of healthy individuals. [84] Therefore, this finding, without demonstration of the bacilli, is not diagnostic of Whipple disease.

With the characterization of *T whippelii* by PCR and sequencing of the bacterial 16S ribosomal RNA gene in tissue from infected patients, [24], [40], [42], [43] and [44] a PCR-based diagnostic assay has become useful in confirming the diagnosis of Whipple disease and in monitoring the response during antibiotic treatment. A PCR assay for *T whippelii* was applied diagnostically to intestinal biopsy specimens in two retrospective studies that showed that PCR is a highly sensitive and specific test to confirm the diagnosis of Whipple disease. [26], [27] In the first study, *T whippelii* DNA was detected in all 30 patients with Whipple disease and in no controls. Despite negative findings of intestinal PCR studies after treatment, symptomatic cerebral Whipple disease appeared in three patients, suggesting that PCR assay may be less useful for monitoring the effects of treatment. [26] In the second study, none of the patients who had negative PCR findings after treatment experienced a clinical relapse, whereas most of the patients with positive PCR findings after treatment either never responded to treatment or experienced a clinical relapse during the follow-up period. [27] In contrast to the first study, [26] this study suggests that PCR may be useful to monitor therapy, with a negative PCR result predicting a low likelihood of clinical relapse. Additional studies have also demonstrated that PCR assay is a very useful diagnostic tool to confirm the diagnosis of Whipple disease and to monitor bacterial elimination during therapy. [85], [86] and [87] Furthermore, PCR assay has been shown to be a valuable aid in diagnosing extraintestinal Whipple disease and in differentiating Whipple disease from other diseases with similar histological features. [88], [89], [90] and [91] Although previous reports suggested that a PCR-based diagnosis of Whipple disease may be accomplished by the detection of *T whippelii* DNA in peripheral blood mononuclear cells or whole blood, [42], [43] this appears to be of limited diagnostic value. Multiple investigators have found no evidence of *T whippelii* 16S ribosomal DNA (rDNA) in peripheral blood monocytes in patients with active Whipple disease, suggesting that PCR of peripheral blood mononuclear cells is not a sensitive test for the diagnosis of Whipple disease and cannot be used as a substitute for the analysis of duodenal biopsy specimens. [85], [92]

Differential Diagnosis

Because the gastrointestinal symptoms in Whipple disease are nonspecific, other malabsorptive diseases with diffuse small intestinal involvement, such as celiac disease, may present in a similar manner. Infiltrative diseases of the small intestine, such as intra-abdominal lymphoma, can cause similar gastrointestinal symptoms and account for many of the x-ray findings associated with Whipple disease. These diseases can be easily and reliably differentiated by small intestinal mucosal biopsy.

Of particular importance, given the increasing incidence of acquired immunodeficiency syndrome (AIDS), Whipple disease must be distinguished from *Mycobacterium avium* complex (MAC) infection. Patients with AIDS are at risk for the development of intestinal infection with MAC, which can cause symptoms of diarrhea and weight loss. The histological lesion in MAC infection reveals infiltration of the lamina propria with PAS-positive macrophages, as in Whipple disease. [93], [94] These diseases can be differentiated by performing an acid-fast stain on the biopsy specimen (Fig. 75-4). MAC bacilli are acid-fast, whereas the Whipple bacillus is not. In addition, MAC organisms can be cultured and have an electron microscopic appearance quite different from that of Whipple bacilli. PAS-positive macrophages in the intestinal lamina propria can also be seen in systemic histoplasmosis and macroglobulinemia; however, each has histological features that should readily differentiate it from Whipple disease. In systemic histoplasmosis, large, PAS-positive, rounded, encapsulated *Histoplasma* organisms are easily seen in macrophages, and the faintly staining, homogeneously PAS-positive macrophages of macroglobulinemia should be readily recognized.

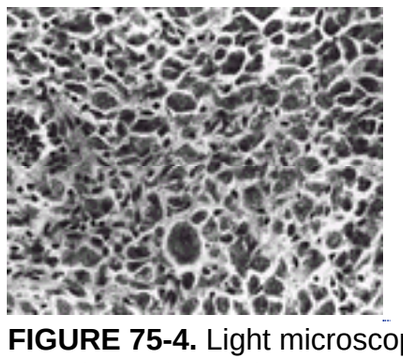

FIGURE 75-4. Light microscopic appearance of macrophages in the intestinal lamina propria of a patient with acquired immunodeficiency syndrome and *Mycobacterium avium* complex involvement of the gut. Note the easily identified bacilli within the macrophages. Acid-fast stain; original magnification ×500. (From ref. [15].)

Treatment and Prognosis

Whipple disease usually responds dramatically to antibiotic therapy. Numerous antibiotic regimens effective against gram-positive organisms and given for variable lengths of time have been used successfully, including penicillin, penicillin and streptomycin, erythromycin, ampicillin, chloramphenicol, tetracycline, and trimethoprim-sulfamethoxazole (TMP-SMX). [8], [9], [10], [11], [12], [13], [14], [15] and [16] Because Whipple disease is uncommon, no controlled trials have compared antibiotic regimens. Therefore, the best regimen and the optimal duration of treatment have not been established. Despite the initial response to antibiotic therapy, relapses are

common. Relapses can occur during treatment or months to years after completion of treatment. [10], [14], [15] and [16], [72] In a review of the long-term follow-up of 88 patients with Whipple disease who had initially responded successfully to antibiotic therapy, 31 patients eventually relapsed. [14] The mean time to relapse was 4.2 years. Of the 31 patients who relapsed, 21 had received initial therapy with tetracycline alone. Clinical relapses consisting of a recurrence of gastrointestinal symptoms and arthritis occurred both early and late and responded favorably to further antibiotic treatment, whereas CNS relapses tended to occur late and responded poorly to additional antibiotic therapy.

Given the concern about CNS relapses, [14], [64], [72], [75] it is reasonable to assume that all patients may have CNS involvement and to treat initially with an antibiotic that readily crosses the blood-brain barrier. One double-strength tablet of TMP-SMX (160 mg of TMP and 800 mg of SMX) given twice daily for 1 year is the best long-term option (Table 75-3). [14] TMP-SMX penetrates the blood-brain barrier and should effectively eradicate CNS involvement. Although shorter courses of antibiotic therapy may be effective, because of the concerns about CNS relapse and its poor response to additional therapy, it is appropriate to treat patients for 1 year. [14], [16], [95] Experts have suggested that initial therapy with parenteral penicillin G (1.2 million U/d) and streptomycin (1.0 g/d) for 10 to 14 days may be of additional benefit, [14], [16], [95] resulting in the lowest relapse rate. This should be considered in all patients with Whipple disease, particularly because compliance with the prescribed regimen is often limited (see Table 75-3). In patients who are allergic to or cannot tolerate TMP-SMX, parenteral penicillin and streptomycin for 10 to 14 days followed by oral penicillin VK or ampicillin for 1 year is reasonable. In these patients, if the development of CNS symptoms is a concern, chloramphenicol is an option. Oral chloramphenicol, like TMP-SMX, achieves relatively high CNS concentrations. In addition to antibiotic treatment, in patients with severe malabsorption and malnutrition, appropriate supplementation of specific nutrients, such as folic acid, vitamin B_{12}, fat-soluble vitamins, and iron, should be given to prevent deficiency.

	MEDICATION	DURATION
Treatment of Choice	Trimethoprim-sulfamethoxazole *or*	1 year
	Procaine penicillin G_1/ streptomycin (parenteral) *plus*	2 weeks
	Trimethoprim-sulfamethoxazole	1 year
Alternatives	Penicillin or ampicillin*	1 year
	Chloramphenicol†	1 year

*May be used in patients with sulfa allergy without central nervous system symptoms.

†May be used in patients with sulfa allergy with central nervous system symptoms.

TABLE 75-3 Treatment of Whipple Disease

At the conclusion of 1 year of antibiotic therapy, a small intestinal mucosal biopsy should be repeated to document the absence of residual bacilli before treatment is discontinued. Although PAS-positive macrophages may be present in the lamina propria for many years in patients treated for Whipple disease, the presence of bacilli on electron microscopy suggests inadequate treatment. PCR for *T whippelii* in intestinal biopsy specimens is not routinely recommended at this time; however, if available, it may provide useful information regarding the adequacy of therapy and the likelihood of relapse. PCR positivity suggests inadequate treatment, and PCR negativity predicts a low likelihood of clinical relapse but does not guarantee an absence of future CNS relapse. [26], [27]

The prognosis for patients with Whipple disease who receive appropriate effective antibiotic therapy is excellent. Gastrointestinal symptoms frequently resolve within 1 month. Extraintestinal symptoms such as fever and arthritis often disappear within a few days. Most patients are asymptomatic within a few months. After therapy has been discontinued, patients must be carefully observed for symptoms suggestive of relapse. They should be followed with clinical evaluation and laboratory studies. After endoscopy with intestinal biopsy at 1 year to confirm the response to treatment, routine invasive diagnostic studies, such as annual endoscopy with intestinal biopsy, are not warranted. Relapse may be signaled by a recurrence of gastrointestinal symptoms or by symptoms suggesting extraintestinal involvement. If relapse is suspected, small intestinal biopsy should be repeated and the specimen examined for the presence of free bacilli. The treatment of a relapse of Whipple disease is more complex but consists of a repetition of the initial therapy. Gastrointestinal relapse responds well to further antibiotic therapy. If the patient does not respond to TMP-SMX, then a trial of oral penicillin VK or tetracycline is reasonable. Patients with CNS relapse have a relatively poor prognosis. If the patient does not respond to a repeated course of the initial therapy, then a course of chloramphenicol is warranted. Combination therapy with antibiotics and interferon-? may be beneficial in patients with refractory Whipple disease. [52]

TROPICAL SPRUE

Tropical sprue, a syndrome occurring in individuals residing in certain tropical locations, is characterized by chronic diarrheal illness and malabsorption that gradually lead to the development of severe nutritional deficiencies. The typical clinical description of tropical sprue was first reported in 1759 in Barbados. [96] The cause is presumed to be bacterial overgrowth of the small intestine. The essential clinical features of the disease are chronic diarrhea and malabsorption, with resultant weight loss. Megaloblastic anemia secondary to folate and vitamin B_{12} deficiency is usually present. When clinically suspected, the diagnosis is made by small intestinal biopsy and confirmed by prompt clinical and laboratory response to treatment with folic acid and broad-spectrum antibiotics.

Epidemiology

Tropical sprue is endemic in many tropical locales. The disease is common in India, is relatively frequent among the indigenous populations of Cuba, the Dominican Republic, Haiti, and Puerto Rico, and may be seen in northern South America, Venezuela, and Colombia. Tropical sprue has also been described in a number of other countries, including the Philippines. Although the disease has been described in all age groups, it is primarily a disease of adults, occurring only rarely in children. Tropical sprue seems to occur mostly as sporadic isolated cases, but epidemics have been described among British forces serving in Burma during World War II, American military personnel serving in the Philippines, and villagers living in southern India. [97], [98] and [99] Several reports have indicated that in both sporadic cases and epidemics, a peak seasonal occurrence of tropical sprue is observed that is unrelated to the rainy season. [100]

Although tropical sprue can afflict visitors within weeks or months after their arrival in a region of endemicity, it rarely occurs in short-term travelers, usually developing in persons who have lived in a region for more than 6 months to 1 year. [101] The prevalence of tropical sprue among residents of developed countries visiting areas of endemicity for long periods of time appears to be decreasing, possibly related, in part, to the frequent use of self-medication with antibiotics for episodes of acute diarrheal disease. Tropical sprue also appears to occur more often among native and nonnative residents and those who live where sanitary conditions are poor. [102] In rare instances, tropical sprue does not become clinically apparent among native or nonnative residents until months or even years after they have moved to a temperate climate. [103]

Etiology and Pathogenesis

Tropical sprue is presumed to be an infectious disease that results from chronic bacterial overgrowth of the small intestine by toxigenic strains of coliform bacteria, but no unique organism has been identified. The epidemiology of the disease, with documented epidemics and seasonal variation, supports the possibility of an underlying infectious etiology. In addition, the disease often occurs after an acute diarrheal illness and usually responds to antibiotic treatment, lending further support for an infectious etiology for tropical sprue.

Although extensive studies have failed to identify a single specific infectious agent as the causative factor, most individuals with tropical sprue, including both native and nonnative residents, exhibit bacterial overgrowth of the jejunum with strains of *Klebsiella pneumoniae* or, less often, *Enterobacter cloacae* or *Escherichia coli*. [104], [105] and [106] Eradication of these bacteria with antimicrobial therapy results in cure of the intestinal abnormalities. [104], [106] In addition, among foreigners who have acquired tropical sprue after their return to a temperate climate, the bacterial overgrowth persists until they receive antibiotic treatment. [106]

The organisms that overgrow the small bowel of patients with tropical sprue are facultative anaerobes, typically consisting of only one or a few species, serotypes, or biotypes in each individual patient. [105] There are no anaerobes as classically seen in diseases manifested by small bowel stasis and resultant bacterial overgrowth, such as blind loop syndrome. These coliform bacteria have pathogenic properties that are not shared by similar isolates obtained from the small bowel of patients with blind loop syndrome. [107] The organisms isolated from patients with tropical sprue were found to have a secretory effect and to induce structural damage, presumably

by toxin production, in the small intestine of rabbits and rats. [107], [108] However, these studies were performed before current techniques and assays, such as DNA probes and ELISA, were available to identify and characterize any of these presumed toxins precisely.

In most nonnative residents, tropical sprue develops after an attack of acute watery diarrhea. Acute infectious diarrhea, caused by a variety of enteric pathogens, may be associated with transient jejunal contamination by coliform bacteria. [109] This event may be the precipitating factor in tropical sprue. Subsequently, the coliform bacteria are able to colonize the small intestine permanently. Eventually, prolonged exposure of the small bowel intestinal mucosa to the organisms and their toxins precipitates a series of events leading to progressively worsening abnormalities of intestinal structure and function.

The factors responsible for the persistent bacterial colonization in tropical sprue are unknown. Some evidence suggests that these coliforms may be unusually adherent to the intestinal mucosa [110]; however, light and electron microscopic studies of jejunal biopsy specimens obtained from patients with untreated tropical sprue have failed to show bacteria adherent to the intestinal lumenal surface. [111] No evidence has been found of intestinal immunologic dysfunction that might predispose to abnormal bacterial colonization in tropical sprue. [112], [113] and [114] It has been postulated that dietary fat, specifically long-chain fatty acids such as linoleic acid, may play a role in the development of tropical sprue. [100], [115], [116] In addition to altering intestinal motility and delaying intestinal transit time, long-chain fatty acids can alter intestinal physiology and contribute to the production of tropical sprue by a number of other mechanisms, [115], [117], [118] and [119] but it remains to be determined whether this is clinically relevant.

The unique role of folate deficiency in the pathogenesis of tropical sprue is not completely understood, but it is likely that whatever the initial insult to the small intestine may be in tropical sprue, the resulting folate malabsorption and deficiency contribute to ongoing pathogenesis. Folate deficiency leads to a decreased number of intestinal epithelial cells and atrophy of villi and is associated with a number of intestinal structural and functional alterations, including crypt hypertrophy, blunting of villi, and less efficient absorption of water, electrolytes, and carbohydrates. Treatment with pharmacological doses of folic acid results in structural and functional improvement in the small bowel of patients with tropical sprue. [101]

Although the available data suggest that tropical sprue is a syndrome of postinfectious malabsorption caused by chronic bacterial overgrowth of the small intestine with toxigenic coliform bacteria, it is important to emphasize that this is perhaps an oversimplification, and a number of questions remain. For example, coliform bacteria have been isolated from the proximal small intestine in healthy asymptomatic controls in tropical locations such as India and South Africa. [120], [121] Furthermore, these bacteria have not been found in all patients with tropical sprue. In addition, a single causative infectious agent has not been identified. The reasons for the rarity of this disease among children and its scattered geographic distribution are unclear.

Histopathology

The classical histopathological finding in patients with tropical sprue is partial atrophy of the villi in the small intestine. A completely flat mucosa, as is seen in untreated celiac sprue, is found in fewer than 10% of patients with tropical sprue. The histological changes consist of lengthening of the crypt area, broadening and shortening of the villi, chronic infiltration of the lamina propria by inflammatory cells, and variable degrees of abnormality of the surface epithelium (Fig. 75-5). [111], [122] The basement membrane usually appears thickened, staining as collagen on light microscopy. [122] Electron microscopy shows that the thickening represents an accumulation of dense material, of unknown composition, subjacent to a normal basal lamella. [111] Structural abnormalities are more prominent in the jejunum during the early phase of tropical sprue; however, eventually the entire small bowel is equally affected. These histological changes are nonspecific and may also be seen in a number of other clinical entities, including severe folate deficiency, bacterial overgrowth, and human immunodeficiency virus (HIV) enteropathy. Functional changes in the small intestine in tropical sprue reflect the morphologic changes and are most prominent in the jejunum and ileum, resulting in malabsorption and the associated clinical features.

FIGURE 75-5. A: Light microscopic appearance of the moderate villus abnormality of tropical sprue acquired by a North American during a 2-week visit to the Philippines. Note the broadened villi, infiltration of the lamina propria by plasma cells and lymphocytes, and lymphocytic infiltration of the epithelium. Periodic acid-Schiff and hematoxylin stain; original magnification ×80. **B:** Enlargement of a portion of **A** reveals the epithelial changes. Original magnification ×132.

Clinical Manifestations

Many individuals can identify the onset of their disease as an episode of acute diarrhea. After about a week, the symptoms become milder and chronic. Less commonly, the onset of tropical sprue is insidious. The chronic symptoms, including prolonged diarrhea, abdominal cramping, nausea, and anorexia with associated weight loss, are nonspecific and related to malabsorption. Fever may be present at the onset of the disease but rarely persists. Lactose intolerance often develops early in the course of tropical sprue, caused by a reduction in brush border disaccharidase enzyme activity. Within a few months, malabsorption results in folate deficiency. After a variable period of time, usually about 6 months but sometimes earlier in poorly nourished native residents in whom the disorder develops, severe depletion of folate coupled with the development of vitamin B_{12} deficiency causes symptoms associated with megaloblastic anemia, such as fatigue and weakness. Later in the course of the disease, peripheral neuropathy and confusion may occur. If the anemia is severe enough, symptoms of high-output heart failure may appear. These deficiencies and their manifestations can develop in about 10% of patients with tropical sprue who have never experienced any gastrointestinal symptoms.

The findings on physical examination are manifestations of nutritional deficiencies and therefore typically appear late. These include pallor, glossitis, and edema. [123], [124] Stomatitis, hyperpigmentation, and neurological manifestations of vitamin B_{12} deficiency may occur but are rare.

Laboratory Findings Megaloblastic anemia, caused by combined deficiencies of folate and vitamin B_{12}, is the hallmark of tropical sprue. Steatorrhea and reduced xylose absorption are frequently present. Malabsorption of fat-soluble vitamins often occurs, resulting in low serum concentrations of vitamin A (and ß-carotene), 25-hydroxyvitamin D, and calcium. Marked elevation of the prothrombin time is unusual. Hypoalbuminemia and hypocholesterolemia are also seen.
Radiologic and Endoscopic Findings A small bowel series may reveal findings suggestive of tropical sprue. These include prominent, thickened mucosal folds with a coarsened or irregular contour involving the jejunum and ileum. Lumenal dilation and flocculation of the barium may also be seen. [125] Although these findings are nonspecific, ileal involvement is characteristic of tropical sprue and relatively uncommon in celiac sprue, Whipple disease, and other small bowel enteropathies. Upper gastrointestinal endoscopy may reveal scalloping of the valvulae conniventes and a mosaic pattern of the mucosa, [126] findings frequently described in celiac sprue.

Diagnostic Evaluation

The clinical presentation of tropical sprue is nonspecific. The diagnosis should be considered in patients who present with chronic diarrhea, weight loss, and evidence of malabsorption. A history of recent travel to, residence in, or immigration from a tropical location is essential. Depending on the duration and severity of the disease, important physical findings may be detected that are related to anemia and nutritional deficiencies, and laboratory abnormalities, such as megaloblastic anemia caused by folate and vitamin B_{12} deficiency, can be important clinical clues. Stool culture is of no diagnostic value in tropical sprue, but the stool should be examined for ova and parasites to rule out other infectious causes of chronic diarrhea, such as *Giardia*.

When the diagnosis of tropical sprue is suspected, endoscopy with small bowel biopsy should be performed. The demonstration of characteristic changes in the architecture of the villi, including partial atrophy, supports the diagnosis. The diagnosis of tropical sprue is confirmed by a prompt clinical and laboratory response to the institution of appropriate treatment.

Differential Diagnosis

The differential diagnosis includes a number of other malabsorptive diseases and enteropathies. In temperate climates, the presentation of celiac sprue be similar to that of tropical sprue. In celiac sprue, the ileum tends to be minimally involved, and vitamin B_{12} deficiency is uncommon. In addition, more severe histological abnormalities are seen in celiac sprue, with flattening of the villi, and the clinical response to a gluten-free diet is dramatic. As in celiac sprue, significant involvement of the ileum and vitamin B_{12} deficiency is uncommon in Whipple disease. Whipple disease can easily be distinguished histologically by the presence of PAS-positive macrophages and the detection of organisms on electron microscopy. HIV enteropathy is manifested by chronic watery diarrhea in the absence of an identifiable infectious agent, and the intestinal histology may be very similar to that of tropical sprue. Therefore, it is important that a thorough history be taken, including questions relating to possible HIV exposure; for individuals at risk for AIDS, the appropriate diagnostic tests are indicated. Infection of the small intestine with parasites such as *Cryptosporidium, Giardia,* and *Strongyloides* can cause chronic diarrhea and malabsorption. However, the malabsorption is usually less severe, without significant malnutrition and weight loss. The diagnosis can often be made by stool examination for ova and parasites. Bacterial overgrowth caused by intestinal stasis may be seen in diseases that alter intestinal motility, such as amyloidosis, pseudoobstruction, scleroderma, and blind loop syndrome, resulting in chronic diarrhea. In addition to the presence of these underlying diseases, bacterial overgrowth can be distinguished from tropical sprue by the presence of anaerobes rather than coliforms in the small intestine and by the mild nonspecific findings on the small bowel biopsy specimen. Primary intestinal lymphoma may present with chronic diarrhea, often with significant associated abdominal pain. Intestinal TB may occur in some tropical countries but it is much less common than tropical sprue.

Finally, tropical sprue occurs in areas such as Haiti, where the frequency of an entity usually referred to as *tropical enteropathy* is high. [127] Tropical enteropathy is generally associated with milder abnormalities of intestinal structure and function, and clinically significant malabsorption or nutritional deficiencies do not develop in affected persons. Unlike the abnormalities of tropical sprue, the intestinal abnormalities of tropical enteropathy resolve within a year after return to a temperate climate, even without specific therapy. [128] It is thought that the intestinal abnormalities of tropical enteropathy are a manifestation of repeated, transient episodes of intestinal infection caused by various enteric pathogens.

Treatment and Prognosis

Although spontaneous remissions occurred rarely, tropical sprue was usually a fatal disease before the 1930s. This changed after treatment with liver extract was introduced in 1931, followed a decade later by folic acid treatment and subsequently by antimicrobial therapy in the 1960s.

Treatment with pharmacological doses of folic acid alone promptly relieves the megaloblastic anemia, and a return of appetite is accompanied by weight gain in the ensuing weeks. As intestinal morphologic abnormalities regress, gastrointestinal symptoms become less severe. Although this therapy alone may be curative for those in the early stage of the disease, treatment for up to 2 years may be required if intestinal structure and function are to return completely to normal. [101] In chronic disease, folic acid relieves the intestinal abnormalities and gastrointestinal symptoms; however, it does not completely reverse the intestinal abnormalities, and chronic symptoms often persist. [129]

Treatment with antimicrobials eradicates the contaminating coliform bacteria. [104], [106] Tetracycline and nonabsorbable sulfonamides are equally effective. [130], [131] Given alone, antimicrobial therapy results in a reduction of the gastrointestinal symptoms within weeks along with a slow, progressive regression of the intestinal abnormalities. Improved folate absorption results in a hematologic response and a return of appetite within several weeks.

Combination therapy with tetracycline and folate is the most logical approach to the treatment of tropical sprue. This consists of 250 mg of tetracycline four times a day and 5 mg of folic acid once daily. Although 1 month of therapy has been effective in travelers with tropical sprue, treatment for up to 6 months is often required for those with chronic disease to achieve complete remission of the malabsorptive syndrome and to prevent recurrence. [130], [131] Although not necessary for the acute phase of therapy, vitamin B_{12} (1000 µg), administered parenterally once a week for several weeks, should also be given to replete tissue stores. Despite treatment with combination therapy for 6 months, intestinal abnormalities may persist, and clinical relapse, requiring additional courses of therapy, may occur in 10% to 20% of patients who remain in tropical locations of endemicity. [132]

TUBERCULOSIS

Mycobacterium tuberculosis, the primary cause of tuberculosis (TB), infects a third of the world's population and causes more deaths per year than any other infectious agent. [133] It is found primarily in developing countries of the world, where overcrowding and poor sanitation contribute to its spread. Twelve countries in the world account for nearly three fourths of all cases. In the United States, the number of reported TB cases reached an all time low of 7.4 per 100,000 persons in 1997, and 39% of these were among foreign-born persons. Although pulmonary manifestations predominate in most cases of TB, gastrointestinal involvement can be part of a disease process affecting multiple organs; less commonly, gastrointestinal involvement in the absence of other identifiable sites of infection (so-called primary gastrointestinal TB) may be associated with symptoms and even be the primary cause of death. [134], [135] and [136] This diagnosis is rarely considered before death, and as a result the opportunity for effective therapy is often missed.

Epidemiology

Before the development of effective anti-TB chemotherapy, gastrointestinal TB was seen in about 70% of persons with advanced pulmonary disease. [137] Since the advent of effective chemotherapy, gastrointestinal TB has become much rarer, and in the United States and Canada, it is reported in fewer than 1% of all cases. [138], [139] In developed countries, it is most commonly found in association with immunosuppression, especially in patients with AIDS. [140] In developing countries, AIDS and immunosuppression, in combination with limited access to anti-TB therapy and inadequate sanitation, appear to have increased the incidence of gastrointestinal TB. In one series from South Africa, 46% of patients with smear-positive, cavitating pulmonary TB had gastrointestinal involvement. [141] In India, TB remains the most common granulomatous disease of the intestinal tract. [142]

Some data suggests that the risk for gastrointestinal disease is directly related to the severity of pulmonary disease, although not all persons with gastrointestinal TB have evidence of current or past pulmonary disease. [141], [142] Rare cases of congenital necrotizing enterocolitis have been reported in infants born to mothers with miliary TB. [143]

Etiology and Pathogenesis

Gastrointestinal TB is usually caused by *M tuberculosis,* but it may also be caused rarely by a closely related species of bacteria, *Mycobacterium bovis*. [133] In the United States, *M bovis,* an organism that can cause TB in cattle and in humans, is only of historical interest because the pasteurization of milk and the screening of cattle for infection have eliminated it as a cause of TB. It still may be rarely seen in other parts of the world, however, where these public health measures are not practiced. *M tuberculosis* is an acid-fast, curved bacillus that can infect certain primates, including humans, but humans are the only known reservoir. It spreads from human to human by aerosolization. It is thought that gastrointestinal disease arises when organisms are swallowed and survive destruction by gastric acid; the source of the organisms can be either dietary, such as infected milk in the rare cases of *M bovis* infection, or more commonly pulmonary secretions. Lesions may also occur as a result of disseminated miliary disease.

Infection of the upper gastrointestinal tract is very uncommon, and lesions are more often found in areas characterized by high lymphoid density and stasis, such as the distal small bowel, cecum, appendix, and, less commonly, colon and rectosigmoid. [144], [145] Gastrointestinal TB is thought to arise by the same pathophysiological sequence as pulmonary infection; initial infection of macrophages is followed by multiplication of the organisms in macrophages, caseation necrosis, and a secondary host immune response. The immune response is characterized by either cell-mediated immunity, with a marked influx of activated myeloid and lymphoid cells, or a delayed hypersensitivity reaction accompanied by cell death and caseation necrosis. [146] The defects of cell-mediated immunity seen in patients with AIDS and other immunocompromised hosts result in failure to contain the organism, so that these patients are predisposed to the development of clinical disease once infected.

Pathology

The pathological lesions of gastrointestinal TB have classically been divided into an acute ulcerative stage and a chronic hypertrophic stage of disease that is characterized by granulomata and extensive fibrosis. The ulcerations presumably develop as a result of infection of gastrointestinal macrophages, with subsequent caseation necrosis and intense inflammatory changes. The lesions are most often located in the distal small bowel and cecum. Multiple focal areas of involvement are typical. The ulcers may be deep; typically, they are circumferential, in contrast to the linear ulcerations of Crohn's disease. The ulcers are typically irregular with a necrotic base, and pseudopolyps may be found. Perforation may occur. Fistulae and anorectal lesions may form. Histologically, the ulcerative lesions are characterized by granulomata, usually with caseation and larger numbers of acid-fast organisms than in the later, fibrotic stages. Involvement of draining lymph nodes is common. In HIV-infected patients, inflammatory and ulcerating lesions are typical, with perforation reported. With more chronic inflammation, the bowel wall may become markedly fibrotic and stenotic, with the formation of mass lesions (tuberculomas). Strictures are typically short and may be multiple. The numbers of organisms may be markedly diminished in the fibrotic stages or absent in patients who have received treatment.

Clinical Manifestations

The symptoms of gastrointestinal TB are nonspecific, and in the absence of pulmonary TB, the diagnosis may be difficult. The most common symptom of gastrointestinal TB is abdominal pain. [142], [144], [147] Others include fever, anorexia, diarrhea, weight loss, constipation, bloating, and hemorrhage. [135], [137], [142], [144], [147] If disease is limited to the duodenum, the symptoms may be primarily those of peptic ulcer disease. [148] The physical findings may include cachexia and, in patients with an acute pulmonary process, pulmonary manifestations. [149], [150] and [151] The abdominal examination may reveal a palpable mass, which in various series is the abnormality most commonly found. [142], [144], [147] Other physical examination findings include evidence of complications such as perforation, obstruction, fistulae, massive hemorrhage, and malabsorption. [134], [145], [147], [148]

Diagnostic Evaluation

Barium contrast studies may demonstrate ulcerations, strictures, fistulae, and thickening, deformity, and incompetence of the ileocecal valve; evidence of mass lesions similar to those of Crohn's disease may be seen (Fig. 75-6). [152], [153] CT and ultrasonography both show mural thickening of the bowel at sites that correlate with the pathological findings at colonoscopy. [154] Mesenteric lymphadenitis, omental thickening, and ascites are frequently associated with tuberculous enterocolitis. [154] Peritonitis is found in about 20% of patients. [155] Lesions may also be found in liver, spleen, or pancreas. CT-guided or ultrasonographically guided fine-needle aspiration has been used successfully for diagnosis. [156]

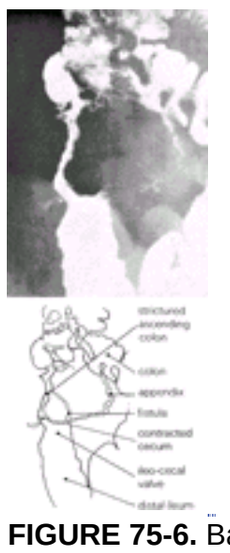

FIGURE 75-6. Barium study in a patient with hypertrophic tuberculosis shows a dilated distal ileum leading into a contracted cecum and strictured ascending colon. (From Misiewicz JJ, Forbes A, Price A, et al. Atlas of clinical gastroenterology, 2nd ed. London: Wolfe, 1994:5.4.)

Because tissue is required for histological confirmation and culture, and because the most common site of involvement is the ileocecal region, the diagnostic procedure of choice is usually colonoscopy with biopsy. [142], [143], [149] Upper gastrointestinal endoscopy with jejunal or duodenal biopsy is indicated less commonly, when disease at these sites is suspected. [135], [148] Visual inspection of the involved bowel most commonly reveals multiple areas of nodular mucosa with areas of ulceration. [144], [147]

Biopsy material, obtained either endoscopically or surgically, must be submitted for histological examination and the detection of mycobacteria. Histological studies showing caseating granulomata or Ziehl-Neelsen or Kinyoun stain showing acid-fast, beaded, slightly bent rods may provide immediate answers, but often the results of these tests are negative. In one series, the yield of acid-fast bacilli from colonic biopsy was zero. [147] In addition, typical caseating granulomata are found less frequently in biopsy material from lymph nodes than from the intestine and may be found in only half of specimens. [147] PCR has the potential to provide a rapid diagnosis with enhanced sensitivity and specificity, but studies of biopsy material from the gastrointestinal tract have shown sensitivities of only 40% to 75%. [142], [157] Culture remains the gold standard but requires 1 to 2 weeks for results with the Bactec radiometric system (Bactec Corporation, Houston, Texas) and 4 to 6 weeks when standard detection systems are used. However, even the results of culture are often negative, and a presumptive diagnosis is based on endoscopic findings in combination with a response to anti-TB therapy. [142], [147]

Differential Diagnosis

TB should always be considered in the differential diagnosis of patients with obscure abdominal symptoms or physical findings, especially those who are immunocompromised. Other entities that may present clinically and pathologically similarly to TB include Crohn's disease, lymphoma, carcinoma, diverticular disease, appendicitis, and other infections of the gastrointestinal tract. [137], [151], [154] The latter include histoplasmosis and, in AIDS patients, MAC enteritis and, less closely, cryptosporidiosis (Table 75-4). Cytomegalovirus infection is another diagnostic consideration when the colon is involved. *Yersinia* enteritis may also present with similar clinical manifestations and pathology in the terminal ileum, but its shorter course usually distinguishes it from TB. Despite the extensive tuberculous dissemination frequently associated with TB enteritis, the diagnosis is often delayed, and TB enteritis is most frequently discovered unexpectedly at exploratory laparotomy or autopsy. [134], [140]

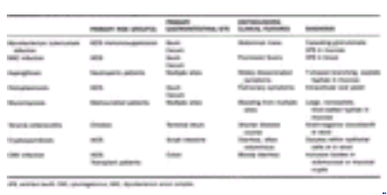

TABLE 75-4 Infectious Diseases Mimicking Tuberculous Enteritis

It seems paradoxical that Crohn's disease was recognized in the early part of the last century, when it was distinguished from gastrointestinal TB. The distinction remains a problem in countries in which TB is endemic. However, in most developed countries, Crohn's disease is now much more common, and intestinal TB is rare. The clinical challenge is to recognize TB in a patient thought to have Crohn's disease. Helpful distinguishing features are that Crohn's disease more commonly begins

earlier in life, ulcerations are more typically linear, and granulomata, when present, do not contain caseation necrosis or organisms. Severe active Crohn's disease is usually not found in patients with advanced HIV infection.

Treatment and Prognosis

The prognosis of a patient with gastrointestinal TB depends primarily on the immune status and the institution of the appropriate therapy in a timely manner. In untreated HIV-infected patients, the disease progresses rapidly and is almost always fatal. [140] However, the results of therapy are usually satisfactory, even in immunocompromised hosts, when it is started sufficiently early in the course of disease. The difficulty lies in making a timely diagnosis, and in many series, significant numbers of patients die before the disease is diagnosed. [136], [141]

If any indication of TB is noted, such as a compatible clinical picture in a high-risk patient, a positive acid-fast stain, or histological evidence of granulomata, therapy should be started immediately pending the results of culture and susceptibility testing. If the patient is immunocompetent and lives in a community where the rate of resistance is known to be less than 4%, the regimen of choice is 300 mg of isoniazid, 600 mg of rifampin, and 1.5 to 2.5 mg of pyrazinamide. [158] If the person is immunocompromised or lives in an area with high rates of drug resistance, then either 15 mg of ethambutol per kilogram or 15 mg of streptomycin per kilogram once daily should be added to the previously mentioned regimens. If the patient does not show evidence of malabsorption, we prefer ethambutol to streptomycin because it can be administered orally instead of by intramuscular injection.

If susceptibility testing reveals that the organism is sensitive to all drugs, then ethambutol or streptomycin can be stopped immediately and pyrazinamide continued for only 2 months. Isoniazid and rifampin must be continued for an additional 4 months, for a total of 6 months of therapy. In a randomized controlled trial, 6 months of therapy for gastrointestinal TB was equivalent to 12 months, the previous standard duration. [159] Alternative regimens for patients who cannot tolerate all three drugs include isoniazid and rifampin for 9 months and isoniazid and ethambutol for 18 months. [160]

If the organism is resistant to isoniazid (the most common form of resistance), then treatment can be with rifampin, pyrazinamide, and either ethambutol and streptomycin for 6 months or rifampin and ethambutol for 12 months. [160] In cases with a more complicated resistance pattern, alternative drugs are required for at least 1 year after cultures become negative.

Surgical intervention, although it was frequently used in the past for diagnosis, is usually not necessary and is reserved for complications such as obstruction, perforation, fistula, or a mass that does not resolve with medical therapy. [136], [145], [149] In most cases, a trial of medical therapy should be undertaken before surgical intervention. Complications can be fatal, even with surgical intervention, and may occur after the initiation of anti-TB medications. [134], [135] and [136], [161]

MYCOTIC INFECTIONS

Mycotic infections are most often a result of dissemination from a pulmonary source and usually occur in immunocompromised hosts, although they may also occur in normal hosts. The etiologic agents of aspergillosis, candidiasis, histoplasmosis, cryptococcosis, and mucormycosis have all been cultured from the small intestine. Although *Cryptococcus* has been cultured from the small intestine of patients with AIDS, it has not been associated with clinical disease and is not discussed further here. [162]

Histoplasmosis

Epidemiology Histoplasmosis is a very common infection in the midwestern and south central regions of the United States, where 80% of the inhabitants are infected. [163] Infection, however, rarely equates with disease. When symptoms do occur, they most commonly involve the lungs, the primary portal of entry. Gastrointestinal disease occurs usually, but not always, as a result of widespread dissemination in an immunocompromised host. Infants and children, the elderly, patients on immunosuppressive therapy, including steroids, and persons with immunosuppressive diseases (especially AIDS) are all at higher risk than the general population.
Etiology and Pathology Histoplasmosis is an infection caused by *Histoplasma capsulatum,* a fungus that exists in the mycelial form at ambient temperature (30°C) and in the yeast form at body temperature (37°C). [163] This dimorphic fungus produces both macroconidia and microconidia in clinical isolates. Visual inspection of the involved bowel may reveal entirely normal tissue or a variety of lesions. The most common lesions are single or multiple ulcers and tissue necrosis. [164], [165] Other lesions include flat elevations and polypoid protrusions. Microscopic examination of pathological specimens, after staining with methenamine silver, PAS, or Wright-Giemsa stain, reveals tiny (2–3 μm in diameter) oval yeast forms inside macrophages (Fig. 75-7). [163] Pathological specimens may also show granulomatous inflammation if the patient is not severely immunocompromised. [163] Culturing for the organism should be performed but is difficult, and up to 6 weeks may be required for a positive result. [163]

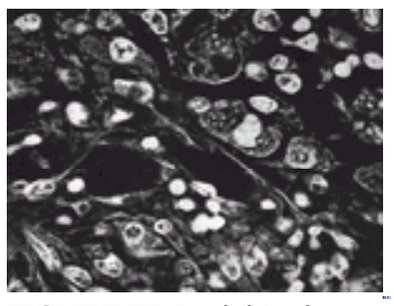

FIGURE 75-7. Light microscopic appearance of oval yeast forms of *Histoplasma capsulatum* within macrophages from a patient with disseminated histoplasmosis. High-power magnification. (From Shull HJ. Human histoplasmosis: a disease with protean manifestations, often with digestive system involvement. Gastroenterology 1953;25:389.)

Clinical Manifestations Although involvement of the small and large bowel is quite common in disseminated disease, symptomatic disease is much less common. In one series, only 50% of persons with gastrointestinal ulcerations had diarrhea or abdominal pain. [165] In addition, persons with disseminated disease who have little or no gastrointestinal pathology may have diarrhea or abdominal pain. Furthermore, even when gastrointestinal symptoms are present, they are often overshadowed by systemic or pulmonary complaints. [166] Occasionally, however, gastrointestinal complaints predominate. [166] The symptoms most commonly associated with small intestinal histoplasmosis include diarrhea, weight loss, fever, abdominal pain, nausea, vomiting, lethargy, and fatigue. [164] The stools are typically liquid or semiliquid and on occasion are bloody, especially if the colon is also involved. Weight loss of up to 30 lb has been reported. The abdominal pain is usually cramping and may be diffuse or localized, depending on the underlying pathology. Other reported presentations include edema of the legs and eyelids caused by protein-losing enteropathy [164] or malabsorption with steatorrhea. [166], [167] The most frequent complication and often a cause of death is perforation of the small bowel. [164], [168] In one series, this was the terminal event in 11% of persons with disseminated histoplasmosis. [164] Obstruction by ileocecal masses or enlarged retroperitoneal lymph nodes can also occur, as well as intussusception in association with pseudopolypoid or polypoid lesions. [164], [165]
Diagnostic Evaluation Involvement of the gastrointestinal tract should be suspected in the setting of blood cultures positive for *H capsulatum,* a fourfold rise in titer or a titer equal to 1:32 of *H capsulatum* serum complement fixation tests or higher, or a positive result of testing for *H capsulatum* in the blood or urine. For a definitive diagnosis of gastrointestinal involvement, upper gastrointestinal endoscopy with duodenal or jejunal biopsy or colonoscopy with terminal ileum biopsy is necessary. The choice of biopsy site should be guided by the symptoms and the knowledge that the ileocecal region is most commonly involved. [164], [165] If abdominal surgery is necessary, the specimens should be cultured to ascertain a diagnosis.
Differential Diagnosis Elongated constricting lesions, abnormally thickened loops of bowel, and lymphadenopathy can all be found on upper gastrointestinal contrast studies and abdominal CT and can mimic Crohn's disease of the terminal ileum, mycobacterial enteritis, other mycotic infections, and carcinoma. [164], [166]
Treatment and Prognosis The natural course of small intestinal histoplasmosis is difficult to determine because in many cases the disease is not diagnosed before death. Cases of disseminated disease, in which small intestinal involvement is frequent, have gone on for more than 10 years without specific therapy. [164] However, this situation is less likely today because of the increased association of the disease with immunosuppression—in particular, AIDS. Immunosuppressed persons often have more severe disease that progresses relatively rapidly, and death is inevitable without treatment. In the normal host with mild or moderate disease, the agent of choice is itraconazole; 200 to 400 mg is given per day, depending on the severity of illness. [169] Therapy should be continued for 6 to 18 months. If itraconazole cannot be taken, 400 mg of fluconazole per day is an alternative, but fluconazole is not as active against *H capsulatum.* Amphotericin B is usually reserved for patients who

have life-threatening disease or are severely immunocompromised. Adults with AIDS and those with life-threatening disease should be given 0.7 to 0.8 mg of amphotericin B deoxycholate per kilogram per day intravenously until clinical improvement occurs, usually after 1 to 2 weeks, and then they can be switched to itraconazole for the remaining course of therapy. Although only a few case reports of the successful use of lipid formulations of amphotericin to treat histoplasmosis have been published, [170], [171] experience in other disseminated fungal infections suggests that lipid formulations of amphotericin, given in higher doses than amphotericin deoxycholate, can be used for patients who have renal impairment or who fail to respond to amphotericin deoxycholate. [172] AIDS patients require maintenance therapy for life with 200 mg of itraconazole per day. [169]

Aspergillosis

Epidemiology Unlike histoplasmosis, which can develop in immunocompetent hosts, aspergillosis affects only severely immunocompromised patients. AIDS, organ transplantation, immunosuppressive chemotherapy, and the improved survival of premature infants have all contributed to an increase in the prevalence of aspergillosis. [173] In addition, the development of new oral antifungal agents, which have little or no activity against *Aspergillus* and are often used for prophylaxis and treatment in transplant, oncology, and AIDS patients, has resulted in the more frequent isolation of *Aspergillus*. [173] The small intestine is involved in about 5% of patients with disseminated aspergillosis. [173], [174]
Etiology and Pathology Aspergillosis is an infection caused by *Aspergillus,* a mold that grows by branching and longitudinal extension of wide (2- to 5-μm), Y-shaped, branching, septate hyphae. [175] The most common clinical isolate is *Aspergillus fumigatus,* followed by *Aspergillus flavus*. Clinical disease is produced by vascular invasion and necrosis. Lesions seen in pathological specimens or during endoscopy include linear ulcers, hemorrhagic infarcts, and necrotic mucous plaques. [173], [174], [176]
Clinical Manifestations The data on the clinical manifestations of aspergillosis of the gastrointestinal tract are sparse because much of the information has been derived from autopsy series. The most commonly reported symptom is gastrointestinal bleeding. [173], [174] Small intestinal perforation may also occur. [177]
Diagnostic Evaluation The diagnosis is especially difficult because *Aspergillus* is not easily cultured in the laboratory, and even when it is cultured, the culture may signify only contamination or colonization. [173], [175] Biopsy with histological evidence of tissue invasion is essential to verify that *Aspergillus* is the cause of the disease process (Fig. 75-8). *Candida* may also be seen on histological specimens and may contribute to the disease process (Fig. 75-9). [174], [176]

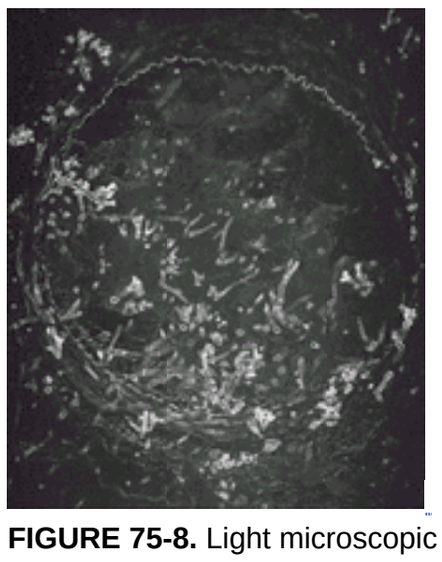

FIGURE 75-8. Light microscopic appearance of *Aspergillus* organisms showing vascular invasion. (From ref. [176].)

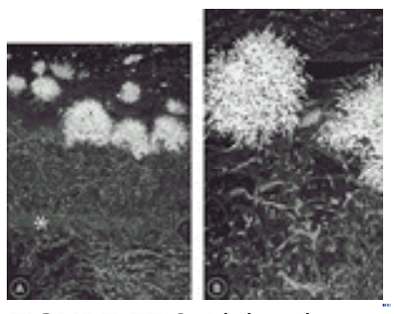

FIGURE 75-9. Light microscopic appearance of *Candida* organisms on the surface of infarcted bowel mucosa with *Aspergillus* hyphae in the underlying mucosa and submucosa. **A:** Low magnification. **B:** High magnification. Grocott-Gomori methenamine-silver stain. (From ref. [176].)

Differential Diagnosis The differential diagnosis includes mycobacterial enteritis, bacterial typhlitis, ischemic bowel, and other mycotic infections.
Treatment and Prognosis Disseminated aspergillosis, regardless of whether or not small intestinal involvement is present, carries a uniformly poor prognosis unless the underlying immunosuppression can be reversed. [175] It is critical for successful treatment that antibiotic therapy be started early in the course of disease. The recommended treatment for small intestinal aspergillosis is at least 1 mg of amphotericin B per kilogram per day for 2 weeks, continued until a clinical response occurs. If the patient is temporarily neutropenic, treatment should be continued until the marrow recovers. [175] Lipid formulations of amphotericin, at higher doses, can be used for patients who have renal failure or in whom renal failure develops during therapy or who do not respond to amphotericin deoxycholate. Salvage therapy for intolerance or failure to amphotericin B has been reported with itraconazole.

Candidiasis

Epidemiology *Candida* species are the fourth most common organisms isolated from the blood of hospitalized patients and are normal colonizers of the gastrointestinal tract. [178] The organisms are commonly associated with esophageal disease in immunocompromised patients but rarely cause disease of the small intestine. Persons at highest risk include those with AIDS, chronic mucocutaneous candidiasis, or malignancies, and those taking immunosuppressive agents.
Etiology and Pathology *Candida* is a yeastlike fungus that reproduces by budding small (4- to 6-μm), thin-walled, ovoid cells. Yeast forms, pseudohyphae, and hyphae can all be found in tissue specimens. *Candida albicans* is the species most often associated with disease of the small intestine. The most common lesions associated with *Candida* are single or multiple ulcerations. [176], [178] Superficial erosions, bloody masses, and pseudomembranes also occur, but with less frequency. White plaques and thickened mucosal folds may also be seen on endoscopy. [176]
Clinical Manifestations Candidiasis of the small bowel is rarely diagnosed antemortem, so which symptoms are attributable to fungal invasion is often unclear. The most common symptom associated with intestinal candidiasis is diarrhea. [176] Other reported symptoms include nausea, vomiting, flatulence, abdominal pain, abdominal distention, melena, and hematochezia. [176], [178] Complications include perforation and penetration of intestinal ulcers. [176]
Diagnostic Evaluation Because *Candida* is a normal colonizer of the entire gastrointestinal tract and even more abundant in persons at risk for disease because of decreased immune function and antibiotic treatment, a diagnosis of small intestinal candidiasis is not easily made. The mere presence of the organism on stain or culture of specimens from the small intestine does not establish the diagnosis. A biopsy specimen of the small intestine with histologic evidence of invasion is necessary. *Aspergillus* may also be found on histological sections and may be part of the disease process. [174], [176]
Differential Diagnosis The differential diagnosis includes diseases that involve the small bowel, particularly those seen in immunocompromised hosts, and includes other mycoses, TB enteritis, ischemic bowel, typhlitis, and MAC infection.
Treatment and Prognosis Therapy for *Candida* infection continues to evolve with the increased use of azoles. We now recommend, based on the results of both randomized trials in immunocompetent hosts and observational trials in immunocompromised hosts, [179] 400 mg of fluconazole per day for gastrointestinal candidiasis in stable patients who have not received recent azole therapy. For unstable patients or those who have previously been given therapy with azoles, 0.6 to 0.7 mg of amphotericin B per kilogram per day is recommended. As in other cases of disseminated fungal disease, lipid formulations of amphotericin B can be used if the patient does not respond to therapy or concerns about renal toxicity arise. Therapy should continue be continued for at least 2 weeks and until a clinical response occurs. In patients with temporary neutropenia caused by chemotherapy, treatment should not be stopped until the neutrophil count rises above 500/mm $_3$. Resection

of the diseased bowel or maintenance therapy may be required, especially in patients who are permanently immunosuppressed.

Mucormycosis

Epidemiology Like aspergillosis and candidiasis of the small intestine, small intestinal mucormycosis is most commonly found in persons with impaired defenses, such as patients on steroids or other immunosuppressive medications and patients with diabetes mellitus, malnutrition, chronic renal insufficiency, burns, aplastic anemia, leukemia, lymphoma, or AIDS. [180], [181] Premature infants may also have significant gastrointestinal mucormycosis, which is rapidly fatal within days to weeks after birth. [182], [183] Small intestinal infection is usually acquired through dissemination from a pulmonary source, although some authors have suggested that fungi can enter the body with food. [180]

Etiology and Pathogenesis The usual pathogens, *Rhizopus, Absidia,* and *Mucor,* are ubiquitous in nature and are inhaled as spores that produce infectious particles called *sporangiospores*. Organisms produce disease by invading blood vessel walls, causing infarction and necrosis. [181] They can be identified by their large, nonseptate, thick-walled hyphae with right-angle branching in tissue sections. [181] In culture, they grow as fluffy molds. Mucormycosis has a predilection for certain anatomic sites, including the sinuses, orbits, brain, and lungs. Isolated gastrointestinal lesions are uncommon. Involvement of the gastrointestinal tract may occur as a part of disseminated disease. Mucormycosis may cause mass lesions resembling carcinoma, cause infarction and perforation, or involve the ileocecal region in a pattern resembling perforated appendicitis. Small bowel infarction in neonates resembling necrotizing enterocolitis has also been reported. Mucormycosis can lead to superinfection of preexisting lesions of the gastrointestinal tract, including peptic ulcers, penetrating wounds, and TB. [184]

Clinical Manifestations Fever, abdominal pain, and distention are the most common symptoms. [180], [181] Nausea, vomiting, hematemesis, hematochezia, diarrhea, and melena are seen less commonly. Because multiple sites of the gastrointestinal tract are often involved, it is difficult to determine which symptoms are attributable to small intestinal involvement. In one reported case with only small intestinal involvement, the only symptom was abdominal distention. [180] The physical findings may include abdominal mass lesions or signs of bowel necrosis or perforation. Intestinal perforation is the most common complication. [180], [181]

Diagnostic Evaluation As in other small intestinal mycoses, disease is more commonly diagnosed postmortem than antemortem. [181] A definitive diagnosis requires biopsy for culture and histological examination for evidence of tissue invasion. [185] Endoscopy may reveal ulcerations, especially in the ileum. [180], [186] Culture is frequently unsuccessful, and even when it is successful, it may signify only colonization because the agents of mucormycosis are saprophytic and ubiquitous in nature.

Differential Diagnosis The differential diagnosis includes carcinoma, ischemic bowel, other intestinal mycoses, and TB enteritis.

Treatment and Prognosis The prognosis is usually poor, and the mortality rate is high regardless of therapy. [181] The treatment of choice is 1.0 to 1.5 mg of amphotericin B deoxycholate per kilogram per day with surgical resection. [187] Lipid formulations of amphotericin B can be used in higher doses to treat patients with renal insufficiency or those not responding to initial therapy. Once a clinical response to amphotericin B occurs, dosing can be decreased to every other day. The duration of therapy is unknown and may be lifelong. Fluconazole and itraconazole are not active, as they are in other mycotic infections.

CHAPTER 76

Paul J. Ciclitira and H. Julia Ellis

CELIAC DISEASE

DEFINITION

Celiac disease is a condition in which an abnormal small intestinal mucosa reverts toward normal when patients are treated with a gluten-free diet and relapses when gluten is reintroduced. The disorder is sometimes called *celiac sprue* or *gluten-sensitive enteropathy*. It was previously termed *nontropical sprue, celiac syndrome, idiopathic steatorrhea,* or *primary malabsorption*.

Dermatitis herpetiformis is a related disorder characterized by an itchy, blistering skin eruption that frequently affects the knees, elbows, buttocks, and back. Patients with dermatitis herpetiformis invariably have some degree of related gluten-sensitive small intestinal enteropathy.

HISTORY

Celiac disease was mentioned by Aretaeus the Cappadocian in the second century [1]; the term denoted an illness associated with the abdominal cavity. “If diarrhoea does not proceed from a slight cause of only one or two days duration and if, in addition, the patient’s general system be debilitated by atrophy of the body, the celiac disease of a chronic nature is formed.” Samuel Gee, [2] who in 1888 described the condition, reported that the disorder affects all age groups. He recognized that “if the patient can be cured at all it must be by means of the diet.”

Dicke, during the early 1930s, became convinced that the consumption of bread and wheat flour had an adverse effect on patients with this condition. His first report appeared in *Het Nederlands Tijdschriftvoor Geneeskunde* in 1941, and his observations were expanded in his doctoral thesis, submitted to the University of Utrecht in 1950. During World War II in The Netherlands, food, particularly cereals used to make bread, was scarce. During this time, the condition of children with celiac disease improved, only to relapse following supply, by the Swedish Air Force, of bread at the end of the war. It was this serendipitous observation that led to the finding that wheat exacerbates celiac disease. [3]

EPIDEMIOLOGY

Celiac disease affects a large number of ethnic groups, but mostly people of European origin, including those living in North America and Australia. The prevalence throughout Europe was previously thought to be about 1 in 1000, with only 1 in 6000 affected in North America. However, serologic testing of blood donors indicates that the actual number in both Europe [4] and America [5] may be closer to 1 in 250. The condition may be even more common in Celtic populations. A report from Ireland suggests a prevalence of 1 in 120. [6]

Celiac disease occurs in non-Caucasians, although the incidence is probably lower. It has been reported in the wheat-consuming population of Bengal and the Punjab rather than the predominantly rice-consuming population of southern India. The condition has been reported in Arabs, Hispanics, Israeli Jews, and Sudanese of mixed Arab and Negro stock. The condition rarely, if ever, affects people from a purely Afro-Caribbean or Chinese background. [7]

The disorder has been reported to affect women more often than men; some authors have suggested a sex (female-to-male) ratio of 2:1, but others think that equal numbers of persons of both sexes are affected.

The survival of persons with untreated celiac disease before the description of a gluten-free diet was poor, with an estimated mortality rate of 20%; reports varied between 10% and 30%. The introduction of a therapeutic gluten-free diet greatly reduced mortality. However, the latest information suggests that the mortality rate for patients with celiac disease may still be twice that of the population without celiac disease, the excess risk being mainly a consequence of non-Hodgkin lymphoma. [8] The risks for neoplasm in patients with celiac disease who continue to ingest gluten were reported by Holmes and colleagues in 1989. [9] These authors reported an increased number of deaths from all cancers; the greatest increase in relative risk was for intestinal lymphoma when celiac patients ingesting gluten were compared

with both normal subjects and celiac patients on a strictly gluten-free diet.

CEREAL CHEMISTRY

The precise structure of the gluten proteins that exacerbate celiac disease remains unknown, although significant advances have been made in this area. Wheat grains comprise three major constituents, which are separated by milling: the outer husk, or bran; the germ; and the endosperm, or white flour, the last of which constitutes 70% to 72% of the whole grain by weight. Cereal storage proteins fall into four groups: the minor albumins, the globulins, the glutenins, and an ethanol-soluble fraction, the prolamins, termed *gliadins* in wheat. The prolamins from other cereals are termed *secalins* (from rye), *hordeins* (from barley), *avenins* (from oats), and *zeins* (from celiac nontoxic maize). The taxonomic relationship of the major cereal grains (*gramina*) is shown in Figure 76-1. Wheat glutenins give this cereal its characteristic baking quality by entrapping carbon dioxide in the dough, which then rises when it is left to prove. The gliadins provide the lubrication required for the glutenin proteins to slide over one another when the dough rises. The term *gluten* denotes the ethanol-soluble fraction and the glutenins.

FIGURE 76-1. Taxonomic relationships of the major cereal grains. (From Kasarda DD, Okita TW, Bernardin JE, et al. Nucleic acid [cDNA] and amino acid sequences of a-type gliadins from wheat [*Triticum aestivum*]. Proc Natl Acad Sci U S A 1984;87:4712.)

The initial separation of wheat proteins depends on their relative solubility characteristics: Gliadins are soluble in 40% to 90% ethanol, and glutenins are insoluble in neutral aqueous solution, saline solution, and ethanol. The gliadins can be subdivided further either according to their relative electrophoretic mobility into a, ß, ?, and ? subfractions or according to their N-terminal amino acid sequence into a, ß, and ? subfractions, the previously described ß subfraction being reclassified as a type of a-gliadin. [10] The molecular weights of these proteins increase from 32 kd for the a-gliadins to 58 kd for the ?-gliadins.

PATHOGENESIS

Enzyme Deficiency and Lectin Binding

Three main hypotheses for the pathogenesis of celiac disease have been proposed. According to the first, a small intestinal peptidase deficiency results in an inability to digest gluten, which in turn damages the small intestine. This theory has now been largely discounted, [11] although the possibility still exists that lack of an enterocyte intracellular enzyme may in some way affect gliadin peptide transport or processing. In the second, an enterocyte membrane defect allows lectin-like binding of gliadin to the small intestinal enterocytes, altering cell function and resulting in premature cell death. This hypothesis has fallen from favor. [12] It is now generally accepted that celiac disease is mediated by the cells of the immune system, with the normal oral tolerance to food antigens bypassed in a manner not yet understood. Considerable evidence is available to support this hypothesis.

Immune Hypersensitivity

A dense infiltration of the lamina propria with lymphocytes and plasma cells is found in the jejunal biopsy specimens of patients with untreated celiac disease. Furthermore, the ratio of intraepithelial lymphocytes to surface enterocytes is increased; most intraepithelial lymphocytes express the suppresser/cytotoxic phenotype and have the appearance of immunoblasts. [13] Splenic atrophy is known to occur, and a strong association with the histocompatibility antigen HLA-DQ2 has been noted, which is linked with autoimmune disorders. Patients with untreated celiac disease have high titers of circulating antibodies to gluten and antibodies to reticulin and endomysium. [14] The titers of these antibodies are known to decline when gluten is excluded from the diet, so that investigators have assumed that their presence is secondary to pathogenesis. However, the discovery that the antigen for antiendomysial antibody is tissue transglutaminase (tTG) [15] has opened a new chapter in our understanding of the condition. [16]

The action of this small intestinal enzyme on gliadin peptides has been shown to be crucial for T-cell activation in vitro. It appears that within antigenic gliadin peptides, certain glutamine residues are specifically targeted by tTG and deamidated to glutamic acid. This process greatly increases binding of the peptides to DQ2 and DQ8 molecules and facilitates T-cell activation. It has further been suggested that tTG may generate additional antigenic T-cell neoepitopes by cross-linking extracellular matrix proteins with gliadin (16).

The presence of a high proportion of T cells bearing the ?/d T-cell receptor in the epithelial compartment of the small intestinal mucosa of patients with untreated celiac disease has long been noted. As our understanding of the role of these primitive lymphocytes has increased, the concept has emerged that these cells may act to protect the mucosa from damage during chronic exposure to antigens such as gluten in those individuals in whom normal development of tolerance has failed. [16]

The finding of increased numbers of cells expressing the proinflammatory cytokines interferon-? (IFN-?) and tumor necrosis factor-a (TNF-a), but not interleukin-4 (IL-4), [17] supports the immune-mediated hypothesis. The isolation of gluten-sensitive T cells from both the peripheral blood and small intestinal biopsy specimens of patients with celiac disease, [18] , [19] the HLA-DQ2 restriction of most of these cells, and their production of proinflammatory cytokines when stimulated with wheat gliadin [20] provide further evidence, as does the phenomenon of “gliadin shock,” or “gluten shock.” This condition, which occurs in only a few treated patients with celiac disease after gluten challenge, is characterized by vomiting, tachycardia, and cardiovascular collapse; it responds to treatment with corticosteroids.

We previously proposed that gliadin is absorbed initially across and between the small intestinal enterocytes and reaches the dendritic cells in the lamina propria. These cells process the antigen and present it in conjunction with HLA-DQ2 to sensitized T cells (afferent limb). The sensitized cells generate immune products that damage the epithelial cells (efferent limb). The lymphocyte products, most notably IFN-?, induce HLA class II gene product expression in the small intestinal enterocytes, which can then present further antigen to the sensitized lymphocytes. This process is shown schematically in Figure 76-2. The reason for the breakdown in normal oral tolerance is not known.

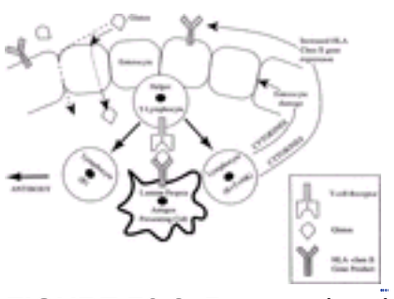

FIGURE 76-2. Proposed pathogenetic mechanisms of celiac disease. Gluten is absorbed into the lamina propria and presented in conjunction with human leukocyte antigen (HLA)–DQ2 or HLA-DQ8 cell surface antigens by dendritic cells to sensitized T lymphocytes expressing the a/ß T-cell receptor (afferent limb). These lymphocytes then activate other lymphocytes to generate immune products that damage the enterocytes (efferent limb). The induction of aberrant HLA class II cell surface antigens on the enterocytes permits additional antigen presentation by these cells to the sensitized lymphocytes.

Toxicity Studies

Initial work attempting to characterize the “fraction” within cereals that exacerbates celiac disease involved separation of the proteins according to the method described by Frazer and colleagues. [21] This method entailed the physiological digestion of wheat proteins with pepsin and trypsin, followed by separation according to their solubility properties. Six fractions were produced, all of which were toxic to celiac patients with the exception of fraction 6, which was studied in only one subject.

Hekkens and associates [22] purified a-gliadin to 60% purity and investigated the toxicity of this fraction in a single subject with celiac disease who was in remission. They concluded that a-gliadin was toxic to the subject, based on a decrease in small intestine brush border enzyme levels in several biopsy specimens taken over 55 hours. They did not report the results of assessments of the other gliadin fractions.

Both Howdle and colleagues [23] and Jos and associates [24] studied the celiac toxicity of gliadin fractions using a celiac in vitro jejunal biopsy organ-culture technique. They independently assessed the effects of the a, ß, ?, and ? subfractions of gliadin, and both groups concluded that all the gliadin subfractions are enterotoxic to celiac small intestinal mucosa. The subject remains controversial, but in vivo studies indicate that all four gliadin subfractions exacerbate celiac disease. [25]

Kagnoff and colleagues [26] suggested that environmental factors may initiate celiac disease. They conducted a computer analysis of a bank of protein sequences in search of potential sharing of amino acid sequence homologies with aggregated A-gliadin, a type of a-gliadin; the analysis revealed shared amino acid residues in a span of 12 amino acid residues and an identical pentapeptide with the 54-kd E1b coat protein of adenovirus 12, an adenovirus usually isolated from the gastrointestinal tract. Cross-reactivity of an antibody to the adenovirus with A-gliadin was seen, implying shared immunogenicity. These authors proposed that in susceptible persons, an encounter of the immune system with this adenovirus may be important in the pathogenesis of celiac disease. [26], [27]

The fraction of wheat that exacerbates celiac disease is a protein because defatted a-gliadin, which contains less than 0.007 mol of carbohydrate per mole of protein, exacerbates the condition. [28] All four gliadin subfractions share epitopes that also are found in rye secalins, as demonstrated by both polyclonal and monoclonal antibody studies. Detoxification of wheat gluten proteins by deamidation implies that glutamine, which contributes more than 35% of the amino acids within gliadin, may be involved, although the method used also may have altered the structure of other amino acid residues. [29]

It is possible to isolate and clone gliadin-sensitive T cells from both the peripheral blood [19], [30] and small intestinal mucosa [18] of patients with celiac disease. The first of these clones isolated from the peripheral blood [30] of a patient with celiac disease was restricted by HLA-DQ2 and responded to a peptide corresponding to amino acids 31 through 49 of A-gliadin. Removal of any residues from the C-terminal and more than two residues from the N-terminal abrogated the sensitivity of the cloned T cells to these smaller peptides. [30] More recently, a number of T-cell clones have been isolated from the small bowel of patients with celiac disease. The antigen specificity of some of these has been elucidated and may be summarized as follows [31]: three DQ2-restricted epitopes, of which one originates from ?-gliadin and two from a-gliadin, and two DQ8-restricted epitopes, of which one arises from a-gliadin and one from a glutenin protein. The two DQ2-restricted a-gliadin epitopes are of particular interest in that they comprise overlapping sequences, [18] and when they were tested with a panel of clones from DQ2-positive Norwegian patients, between them they stimulated all clones. A very similar peptide was found to stimulate interferon-? production in peripheral blood T cells of patients with celiac disease following gluten challenge. [19] It has been suggested [18], [19] that these peptides may represent the immunodominant epitopes in celiac disease. An in vivo challenge study has recently confirmed the toxicity of these peptides in four celiae patients. [32] however, this awaits confirmation. A preliminary celiac small bowel organ-culture study has suggested that a similar but not identical peptide does indeed cause in vitro damage to the celiac duodenal mucosa. [32] However, in this study, only one histological variable was measured. Further data are required to confirm this finding.

An earlier feeding study with peptides corresponding to amino acid residues 31 through 49 (peptide A), 202 through 220 (peptide B), and 3 through 21 (peptide C) of A-gliadin concluded that the peptide corresponding to amino acids 31 through 49 of A-gliadin is enterotoxic in celiac disease, whereas the other peptides are not. [33], [34] However, although one report of a peripheral blood clone that responds to peptide A has been published, [30] to date no small intestinal T-cell line or clone has been shown to respond to this peptide. It is possible that peptide A represents a minor epitope.

Several groups are independently studying the binding of sequenced gliadin proteins to the product of HLA-DQ2, the inheritance of the encoding alleles for which is closely linked to celiac disease. Two approaches are being used; one involves the binding of radioactive iodine–labeled peptides to affinity-purified HLA-DQ2 molecules, [35] and the other involves a cell-binding assay using biotinylated peptides and subsequent analysis by flow-activated cell-sorter analysis (FACS). [36] The initial results show binding of gliadin peptides, including a peptide corresponding to amino acid residues 31 through 49 of A-gliadin, to HLA-DQ2. This finding has permitted computer-aided modeling of the binding of gluten proteins to HLA-DQ2, an antigen-presenting molecule thought to be involved in the pathogenesis of celiac disease. [35], [36]

Genetics

The precise means of inheritance of both celiac disease and dermatitis herpetiformis is unknown, although 10% of first-degree relatives of probands may be similarly affected. The concordance rates are 70% to 100% for identical twins but only 30% for nonidentical twins, which supports a genetic etiology for celiac disease. Efforts to understand the mechanisms and genetics of polygenic human diseases have focused on identifying DNA or protein products and protein molecules that segregate with diseases in both populations and families.

The most significant observation is the increased frequency of specific serologically defined lymphoid cell surface proteins, termed *HLA class II molecules,* in persons with celiac disease. These are glycosylated transmembrane heterodimers consisting of both a and ß chains, the genes for which are organized into three related subregions: DR, DP, and DQ. These subregions are shown in Figure 76-3. [37] The genes are encoded within the HLA class II region of the major histocompatibility complex on the short arm of chromosome 6. The association of particular HLA-DR and -DQ types with both celiac disease and dermatitis herpetiformis is well established. [38], [39] Associations with the HLA-DP region and TNF-a genes have been reported but are thought to be secondary to linkage disequilibrium with HLA-DR and -DQ haplotypes. The genes most strongly associated with celiac disease are *DQA1*0501, DQB1*0201;* 98% of northern Europeans with celiac disease have these alleles in *cis* (DQ2), whereas in southern Europe, a third of the population with this disease express the same class II molecule from these alleles in *trans* (DR5, DR7). [38] Italian and Argentinian populations with celiac disease also are reported to have an increased frequency of the DR5, DR7 genotype. [40] In Israel, an association has been found between the HLA-DR4, -DQ8 genotype and celiac disease. This genotype encodes a class II molecule with considerable similarities in the peptide-binding groove configuration to that produced by the DQ2 genes, supporting a central role for the HLA class II molecule in an immune-mediated model of celiac disease. [41]

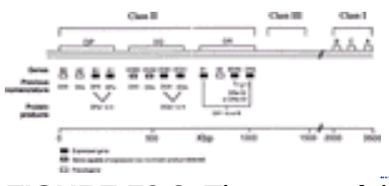

FIGURE 76-3. The gene of the human leukocyte antigen class II region. (From Trowsdale J, Campbell RD. Physical map of the human HLA region. Immunol Today 1988;9:2.)

It is estimated that the HLA associations account for only 30% of the genetic susceptibility to celiac disease, as evidenced by the prevalence of the susceptibility DR3, DQ2 haplotype in up to 25% of the general British and American populations. Segregation analyses propose an oligogenic model involving both the HLA-DQ alleles and the involvement of one or more other genes located elsewhere on the genome. [42], [43] To narrow the search for these non-HLA susceptibility loci, three genome-wide linkage studies using either sibling pairs or extended pedigrees from multiply affected celiac families have so far been published. These have produced largely conflicting results, and four follow-up studies of candidate regions suggested by the genome-wide studies have mostly failed to replicate linkage to celiac

disease in these regions. At present, no linkage to any single region has been consistently replicated between populations. The current state of our knowledge in this rapidly changing field has been reviewed by King and Ciclitira. [44]

PATHOLOGY

Celiac Disease

Celiac disease affects primarily the mucosa of the small intestine; the abnormalities are most marked proximally and decrease in severity with distal progression through the small intestine. In severe cases, however, the lesion can extend to the ileum and also may affect the stomach and colon.

The characteristic histological appearance of the jejunal mucosa in normal subjects is shown in Figure 76-4 and can be compared with that of a biopsy specimen from a patient with untreated celiac disease, shown in Figure 76-5. In the classical flat mucosa, no villi are seen; the normal architecture of the villi is lost, and the normal ratio of villus height to crypt depth (between 5:1 and 3:1) is reduced. The appearance of the mucosa can range from mild flattening through partial atrophy of the villi to a total absence of villi. The total thickness of the mucosa usually is increased because of crypt hyperplasia and cellular infiltration of the lamina propria with plasma cells and lymphocytes. The surface epithelial cells become pseudostratified, as opposed to their normal tall columnar shape, and surface enterocyte height is reduced. Crypt mitotic activity is no longer confined to the base, and although the histological appearance of the crypt is otherwise normal, crypt abscesses have been described. Cell migration time from the base of the crypt to the tip of the villus is reduced in untreated celiac disease to between 12 and 24 hours; the normal time is 3 to 5 days. The ratio of intraepithelial lymphocytes to surface enterocytes is increased in patients with active disease; the normal ratio of lymphocytes is 10 to 30 per 100 epithelial cells.

FIGURE 76-4. Histological appearance of the jejunal mucosa of a normal subject.

FIGURE 76-5. Histological appearance of the jejunal mucosa of a patient with untreated celiac disease. Note the absence of villi, expanded mononuclear cell population, and increased number of intraepithelial lymphocytes.

Isaacson [45] has suggested that the crypt abscesses and small ulcers represent underlying T-cell lymphoma. These ulcers can become troublesome and occasionally develop into a frank small intestinal lymphoma that was formerly thought to complicate 6% to 10% of cases of celiac disease. This figure may, however, be an overestimate, given the more recently described increased prevalence of celiac disease in various populations. Goblet cells are evident throughout the crypt and along the epithelial surface. Paneth cells in untreated celiac disease may discharge their contents into the crypts more readily, so that they are difficult to recognize and appear to be reduced in number. The numbers of endocrine-secreting cells in the small intestine of patients with untreated celiac disease may be both increased and decreased. In some cases, the basement membrane changes—that is, it develops the staining characteristics of collagen rather than reticulin, although this abnormality is frequently patchy.

Chronic inflammatory cells infiltrate the mucosa of the small intestine in untreated celiac disease. Also, the number of plasma cells in the lamina propria increases. Most intraepithelial lymphocytes express the common leukocyte antigen CD3, 70% express the suppressor/cytotoxic phenotype CD8, 5% express the helper/inducer CD4 phenotype, and 20% are $CD3^-$, $CD4^-$, and $CD8^-$. Most of these cells express the more primitive ?/d rather than the more usual a/ß T-cell receptor; as a result, the number of ?/d T-cell receptor–positive lymphocytes in the surface epithelium of the small intestine is significantly increased in both untreated and treated celiac disease.

Dermatitis Herpetiformis

In addition to dermatitis herpetiformis, several other skin disorders are associated with celiac disease: psoriasis, eczema, pustular dermatitis, cutaneous amyloid, cutaneous vasculitis, nodular prurigo, acquired ichthyosis, epidermal necrolysis, pityriasis rubra pilaris, and mycosis fungoides. Atopic eczema in celiac patients may respond to a gluten-free diet.

Dermatitis herpetiformis is the skin disorder most commonly associated with celiac disease, gluten-sensitive enteropathy being common to both conditions. Dermatitis herpetiformis is, however, relatively rare compared with celiac disease. Because figures for the prevalence of gluten sensitivity, as judged by serologic screening tests, have changed considerably in recent years, [4], [5] and [6] it is impossible to estimate the number of patients with celiac disease who also have dermatitis herpetiformis.

Dermatitis herpetiformis is characterized by an itchy papular vesicular eruption, usually symmetrically distributed on the elbows, knees, buttocks, sacrum, face, neck, and trunk and occasionally within the mouth. The predominant symptoms include itching and burning, which may become sufficiently severe to cause considerable pain. Rupture of the blisters results in a rapid relief of symptoms.

Only 10% of patients have symptoms attributable to malabsorption, although nearly 100% have some abnormality of the jejunal mucosa. Gastrointestinal symptoms, when present, are similar to those of celiac disease, although usually milder. The small intestinal lesion is patchy, and several biopsy specimens may be needed to demonstrate it. [46], [47] The risk for gastrointestinal lymphoma and malignancy is increased, as in celiac disease, [9] if a gluten-free diet is not adhered to strictly. Lowered circulating levels of IgM, raised levels of IgA, and variable changes in IgG occur in dermatitis herpetiformis, similar to the pattern observed in celiac disease.

The diagnosis of dermatitis herpetiformis requires the demonstration of granular IgA at the dermoepidermal junction in an area of skin not affected by blistering. This permits discrimination of the condition from another disorder, termed *linear IgA disease,* with a similar presentation but not associated with gluten-sensitive enteropathy.

The precise pathogenesis of dermatitis herpetiformis remains unknown, although it has been suggested that the formation of antibodies in the small intestinal mucosa is stimulated by the presence of gluten. The antibodies are carried through the circulation and bind at the dermoepidermal junction, causing the classical skin lesions.

Dermatitis herpetiformis is treated with dapsone, which should be given at a dosage of 1 to 2 mg/kg daily. All patients with dermatitis herpetiformis should be advised

to adhere to a gluten-free diet, although symptoms may not diminish significantly for 6 to 12 months. The dose of dapsone usually can be lowered, and in many cases it can be stopped. The problem is that it frequently takes months or even years for the full effect of the diet to be evident, by which time the patient may be unwilling to continue to maintain a gluten-free diet. [48]

Grades of Enteropathy

The classical celiac lesion of the small bowel has been described. However, it has become apparent that grades of enteropathy exist within the gluten-sensitive spectrum. Marsh [49] has classified them as follows: Grade 1 is an infiltrative lesion without any change in the architecture of villi but with an excess of lymphocytes in the epithelium. This lesion is typically found in patients with dermatitis herpetiformis and is not associated with symptoms. The hyperplastic, or grade 2, lesion is similar to the grade 1 lesion, but the crypts are hypertrophic, and the epithelium is also infiltrated with lymphocytes. The destructive, grade 3 lesion is the typical flat mucosa of untreated celiac disease. These changes are not exclusive to celiac disease; they may also occur in a number of other conditions, such as tropical sprue, giardiasis, and short-term food sensitivities in infants (see section " Differential Diagnosis "). Two further lesions occur, one at each end of the spectrum. The grade 0, or preinfiltrative, lesion is seen in some cases of dermatitis herpetiformis and is characteristic of latent celiac disease. The biopsy specimen appears totally normal but can be shown in the laboratory to be producing antibody to gluten and endomysium. At the time of this writing, patients with the grade 0 lesion are not treated with a gluten-free diet, but this may change. The grade 4 lesion, at the other end of the spectrum, is a hypoplastic lesion and is unresponsive to gluten withdrawal. It is seen in cases of intestinal ulceration, jejunoileitis, and enteropathy-associated T-cell lymphoma. It appears that the clonal expansion of malignant T cells renders the mucosa unresponsive to antigen withdrawal, resulting in hypoplasia and progressive atrophy of the entire lining of the intestinal wall.

Differential Diagnosis

A number of conditions may cause enteropathy similar to that of the celiac spectrum, so that it is essential to demonstrate that a lesion is gluten-dependent. Giardiasis may cause grades of enteropathy from infiltrative to destructive, as may tropical sprue, marasmus, and sensitivity to cows' milk protein. Other enteropathies associated with food proteins, such as those in egg, soy, chicken, or fish, tend to result in a destructive-type lesion. Other conditions causing some form of atrophy of the villi include acute bacterial or viral infection, bacterial overgrowth, human immunodeficiency virus (HIV) infection, histoplasmosis, and tuberculosis. Noninfectious causes are starvation (including anorexia nervosa), Whipple disease, nonsteroidal antiinflammatory agents, radiation, disorders of the immune response (e.g., hypogammmaglobulinemia), and Crohn's disease.

The grade 4 hypoplastic lesion is seen in unresponsive sprue and is associated with a number of interrelated conditions, including refractory sprue, collagenous sprue, ulcerative jejunitis, autoimmune enteropathy, and lymphoma. Refractory sprue is discussed in a later section.

Involvement of Other Parts of the Gut

It has become apparent that although primarily the small bowel is affected in celiac disease, other parts of the gastrointestinal tract are also sensitive to gluten. Local challenge of the buccal mucosa in patients with treated celiac disease leads to an increase in the numbers of $CD4^+$ cells in the lamina propria. [50] Results of studies suggest that gastric atrophy and achlorhydria are fairly common in patients with gluten sensitivity. [49] About 10% of patients with celiac disease may also have a lymphocytic gastritis, [51] defined by the presence of 25 or more intraepithelial lymphocytes per 100 gastric columnar cells. The intraepithelial lymphocytes are of T-cell lineage. In one series, the patients with celiac disease who did not have lymphocytic gastritis, as defined above, did nonetheless have significantly more intraepithelial lymphocytes than the patients in a control group.

Microscopic colitis is characterized by mucosal inflammation of an endoscopically normal colon. Depending on whether or not a thickened subepithelial collagen band is present, two separate terms are used to describe the condition: *collagenous colitis* and *lymphocytic colitis*. A feature of the colonic inflammatory reaction is intraepithelial lymphocytosis, suggesting that an immunostimulating agent may be presented to mucosa-associated lymphoid tissue. Potential agents include dietary antigens. [52] Microscopic colitis can be diagnosed only by rectal biopsy, although a full colonoscopy should then be undertaken. [53] Gluten challenge of the rectal mucosa of patients with treated celiac disease causes an increase in the number of intraepithelial lymphocytes, and this has been suggested as a possible means of diagnosis. [54], [55]

CLINICAL FEATURES

The classical description of Samuel Gee, [2] with its evocative account, was concerned largely with gross manifestations of the disorder. This florid presentation is unusual in the Western world, and although some patients have severe illness, many others have few or no symptoms at diagnosis. Such cases can be found by screening the relatives of patients during research studies or screening patients with associated disorders, such as diabetes mellitus or Down syndrome. Abnormalities encountered in routine hematologic or biochemical profiles or knowledge of HLA class II profiles may provide diagnostic indicators of celiac disease.

Infancy and Childhood

Classically, celiac disease in infancy appears shortly after weaning, when cereals are first introduced into the diet. Failure to thrive is associated with apathy, pallor, anorexia, and abdominal distention. Developmental delay, with particular retardation of motor skills, sometimes occurs in more extreme cases, in which muscle wasting and hypotonia may be features. Because of numerous other symptoms, the patient may be brought to medical attention. Presenting complaints can include behavioral problems and rectal prolapse, which is much more common in cystic fibrosis.

The child with untreated celiac disease typically passes soft, bulky, clay-colored stools with an offensive odor, but watery diarrhea or constipation is occasionally reported. Young children may present with effortless vomiting, which can be of large volume and usually is associated with abdominal distention but little or no diarrhea. Abdominal pain is sometimes so severe that the child undergoes laparotomy because of a mistaken diagnosis of intestinal obstruction. Older children tend to have more varied symptoms and present with anemia, rickets, or failure to thrive, so that they fall below the third percentile for weight. Height also may be affected, although usually less than weight. Unexplained short stature should be an indication for jejunal biopsy, even when gastrointestinal symptoms are mild or absent. Catch-up growth, once a gluten-free diet is commenced, is well documented. [56] Biochemical vitamin D deficiency or even clinical rickets is not uncommon, especially among Asian children with untreated celiac disease. This situation improves with the introduction of a gluten-free diet, although supplements may be required in the short term.

Considerable debate continues about why celiac disease now tends to be diagnosed later and with milder signs and symptoms than previously. The impact of changes in infant feeding practices remains unclear, and the total amount of gluten presented to the immature gastrointestinal system, in addition to the age of the child at introduction, may be important factors. [57]

Adulthood

It is not uncommon for adults and adolescents with celiac disease to have had illness for many years, but with symptoms insufficiently severe for them to seek medical advice. An individual may come to accept chronic ill health as normal. Sometimes, an additional illness or surgery precipitates symptomatic diarrhea and a clinical presentation. The presentation that leads to a diagnosis may be with varied symptoms and to almost any hospital department. [58] The patient usually, but not always, has diarrhea at diagnosis, and constitutional symptoms (e.g., unexplained lassitude, weight loss, glossitis, angular stomatitis, cheilosis) and symptoms pertaining to anemia are common. Aphthous stomatitis may be the only presenting symptom, so that it is important to exclude celiac disease in all cases of severe recurrent, unexplained aphthous mouth ulceration. Nausea and vomiting usually are associated only with severe bouts of diarrhea, and although anorexia can occur, some younger adults and pediatric patients have an increased appetite. Failure to gain weight despite the ingestion of 7000 to 8000 calories a day has been reported.

Typically, the patient with untreated celiac disease has diarrhea, passing three to four times a day loose movements that are pale, often foul-smelling, occasionally frothy, and sometimes difficult to flush away; some patients report that they have to keep a bucket of water near the toilet to flush the stools. Specific questioning about stool color and frequency is essential because some patients may regard this type of bowel habit as normal, particularly when the diagnosis has been delayed. Normally formed and colored stools do not preclude a diagnosis of celiac disease, and the bowel habit fluctuates depending on gluten intake.

Abdominal pain with borborygmi, visible peristalsis, and symptoms of increased flatulence are reported, but severe pain is uncommon in celiac disease and should

alert the clinician to other forms of intra-abdominal pathology, such as volvulus, intussusception, cholelithiasis, peptic ulcer, and pancreatitis.

Bleeding into the skin may reflect vitamin K deficiency or scurvy complicating celiac disease, which was common at one time but is rarely seen today. Purpura was reported in l0% of patients and was the presenting feature in 20% of cases before the therapeutic effect of a gluten-free diet was discovered.

Amenorrhea and spontaneous abortions occur more commonly in untreated patients with celiac disease than in normal persons or patients with celiac disease who are on a gluten-free diet. [59] Female infertility or male impotence is the mode of presentation for some adults with celiac disease. In some women, the condition may be unmasked by the metabolic demands of pregnancy. Untreated celiac disease can be associated with an abnormal psychological state or frank psychiatric symptoms, including schizophrenia and depression, which usually diminish when the patient is on a gluten-free diet.

It is important to remember that frequently the symptoms are nonspecific, and the index of suspicion should be high when significantly abnormal immunologic, hematologic, or biochemical profiles are encountered. In particular, the finding of an unexplained mild macrocytic anemia with a persistently low serum or red cell folate level should be an indication for further investigations, including an investigation of possible celiac disease. A common problem is a previous diagnosis of celiac disease in childhood that has been forgotten by both patient and doctor, so that the patient incorrectly resumes a normal diet during adolescence but does not immediately experience symptoms. Careful inquiry should therefore be made regarding previous medical problems, such as childhood diarrhea, short stature, recurrent anemia, and rickets. It should not be forgotten that the prevalence of the condition among first-degree relatives of affected subjects is high. It is in such relatives that latent celiac disease is most likely to appear—that is, persons who have normal jejunal biopsy findings while on a gluten-containing diet but who at some time have had or will have a gluten-sensitive enteropathy. [60], [61] These individuals may be detected by screening tests that reveal the presence of serum antibodies to gliadin and endomysium, but on biopsy, their architecture is normal (Marsh grade 0). [49]

Osteomalacia, rickets, and bone pain, although common in children, may lead to a diagnosis of celiac disease, reflecting poor calcium and vitamin D absorption. Symptoms pertaining to low levels of calcium and vitamin D are frequently insidious and may become severe before they are recognized. Vitamin D deficiency or osteopenia may be the presenting problem when celiac disease is diagnosed in adults.

The ages at presentation of a group of adults who were found to have celiac disease are shown in Figure 76-6.

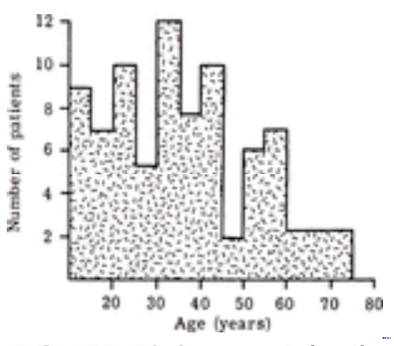

FIGURE 76-6. Age at the time of diagnosis of celiac disease in 84 adults. (From Ferguson A. Coeliac disease [gluten hypersensitivity]. J Hum Nutr 1976;30:193.)

Physical Signs

Psychological abnormalities are not uncommon in newly presenting patients. Affected children are usually irritable and unhappy; these signs, combined with a history of diarrhea, should alert the clinician to the diagnosis. Adults may present with depression, Korsakov syndrome, neurasthenia, or frank symptoms of schizophrenia. Although most patients with celiac disease do not appear psychologically abnormal in comparison with their peers, many affected subjects report a striking improvement in mood shortly after commencing a gluten-free diet. [62], [63]

Patients with celiac disease frequently are of short stature. Growth retardation is common in children, but when they start a gluten-free diet before puberty, a compensatory growth spurt usually occurs, so that the effect on adult height is minimized. Persons with celiac disease are on average 8 cm shorter than their peers. Tall patients are seen, however, and a height of more than 1.8 m does not preclude the diagnosis. Weight loss is common in celiac disease in both children and adults. Sixty percent of children with newly diagnosed disease fall below the third percentile for weight. The average loss of weight in one series of adults was 124.5 kg, and 10% had lost more than 12 kg since the onset of symptoms. It is common for adults with celiac disease to experience a weight gain of more than 6 kg following institution of a gluten-free diet. Edema and ascites are rare but can occur secondary to hypoproteinemia. Abdominal distention and general dilation of the intestinal tract are common in celiac disease, so that the abdomen has a doughy feel, which makes the detection of ascites difficult.

Clubbing of the fingers may occur. Koilonychia may develop and is associated with long-standing iron deficiency anemia. Tooth eruption may be delayed in children, and hypoplasia of dental enamel has been described. [64]

Gynecologic and obstetrical problems are common in women with untreated celiac disease. [59] Delayed menarche (typically by a year) is frequent in untreated subjects. Amenorrhea may occur, and menstrual loss is frequently less than normal. The average age at menopause is 53 years in women with celiac disease who are on a gluten-free diet. Women with untreated celiac disease may present with infertility, [65] and the mean time required for female patients with celiac disease to conceive on a normal diet is 19 months, compared with 12 months for those on a gluten-free diet. It is common for infertile women with celiac disease to become pregnant shortly after commencing a gluten-free diet. Spontaneous abortion or miscarriage is common in female patients with untreated celiac disease. [66] Reduced potency and an abnormally low sperm count are common in adult men with untreated celiac disease. Levels of plasma testosterone, free testosterone, and plasma 5-dihydrotestosterone are low; the level of plasma luteinizing hormone is often raised, which may explain the frequently observed delay in puberty and late development of secondary sex characteristics in untreated male patients with celiac disease. All these abnormalities disappear following prolonged treatment by exclusion of gluten from the diet.

Some untreated persons have a low-grade fever associated with anemia; this finding may indicate a concurrent complication, such as malignancy and, in particular, lymphoma. Peripheral lymphadenopathy is uncommon in celiac disease, and if significant lymphadenopathy is found, the clinician should suspect complicating lymphoma. Rarely, lymphadenitis is seen that disappears during treatment with a gluten-free diet. Cavitating abdominal mesenteric lymph nodes that resolve with a gluten-free diet also have been reported. Computed tomography (CT) sometimes reveals low-grade lymphadenopathy that frequently is associated with hyposplenism. [67]

ANTIBODY TESTS FOR SCREENING

If a diagnosis of celiac disease is being considered, serologic antibody screening tests can be informative, but they do not replace the need for small intestinal biopsy. In patients with celiac disease, levels of antibody to gliadin of both the IgG and IgA classes are raised. The sensitivity and specificity of IgA antigliadin antibody were recently reported as 83% and 82%, respectively, whereas those of IgG antigliadin antibody were 86% and 76%. [68] It has been our observation that when these tests are performed in laboratories not experienced in this area, the sensitivity can fall to as low as 50%. Raised titers alone should not be used to make a definitive diagnosis because titers of antibodies to gliadin can be elevated in other disorders, such as inflammatory bowel disease and hepatic disease. These antibodies were previously used routinely to screen for celiac disease, but although they are still considered to be of some value, they have been largely superseded by other, more specific tests.

Patients with untreated celiac disease have serum IgA antibodies directed against the connective tissue endomysium. These can be detected on sections of monkey esophagus or, more recently, human umbilical chord. The method requires use of a fluorescence microscope and considerable expertise in interpreting the results. However, a sensitivity of 90% and a specificity of 99% have made antibody measurement the test of choice. [68]

The discovery that tTG is the antigen for antiendomysial antibody [63] has made it possible to develop a cheap and simple enzyme-linked immunosorbent assay (ELISA) for this antibody. IgA anti-tTG has a reported sensitivity of 93% and a specificity of 95%. [68] Concerns have been raised that the quality of the enzyme used as the ELISA coating antigen may vary between centers. The use of human recombinant tTG may help to overcome this problem.

It must be remembered that about 2.5% of patients with celiac disease have selective IgA deficiency, and in such cases, the results of tests for either antigliadin, antiendomysial, or anti-tTG antibody will be falsely negative. To attempt to overcome this problem, some authors have investigated the use of IgG anti-tTG and IgG1 antiendomysial antibody. [69], [70] Measurement of these antibodies appears useful in persons with selective IgA deficiency.

The European Society of Paediatric Gastroenterology and Nutrition (ESPGAN) considers elevated titers of these antibodies to be important both in follow-up and in support of the diagnosis. [71] Estimates of the antibody titers can be useful in detecting intentional or inadvertent ingestion of gluten by patients with celiac disease, particularly children, when they are unwell.

Despite reports of the high sensitivity rates of antiendomysial antibodies in patients with celiac disease, some authors have reported disappointing results of antibody measurement in clinical practice, especially in patients with a minor degree of villus atrophy. [72] When malabsorption is suspected, the absence of celiac antibodies should not be a reason to delay biopsy. Equally, the presence of celiac antibodies should be followed by a small bowel biopsy because serologic tests are not 100% specific.

DIAGNOSIS

Laboratory Tests

A bone marrow evaluation in adults usually reveals megaloblastic erythropoiesis. Forty-five percent of bone marrow aspirates from adults with untreated celiac disease have a pure megaloblastic appearance, 55% exhibit megaloblastosis with a lack of iron, and a small number have a pure iron deficiency.

The characteristic hematologic profile is one of a mild hypochromic macrocytic anemia. Patients with mild disease may present only with anemia secondary to iron or folate deficiency and without gastrointestinal symptoms. [73], [74] Iron deficiency is common in celiac disease as a consequence of impaired absorption and increased losses into the gastrointestinal tract, either because of rapid epithelial cell turnover or associated blood loss. Treatment with a gluten-free diet or corticosteroids increases iron absorption. Severe anemia occurs uncommonly, usually in patients with extensive disease, and should arouse suspicion of a superimposed complication, such as malignancy. The exception is during pregnancy, when patients often present with a combined iron and folic acid deficiency anemia and hemoglobin levels as low as 4 to 6 g/dL. Persistent iron deficiency anemia in treated patients should alert the clinician to the possibility of continued long-term inadvertent gluten intake.

The peripheral blood film may reveal target cells, Howell-Jolly bodies, siderocytes, irregular and crenated red cells, Heinz bodies, microspherocytes, acanthocytes, occasional erythroblasts, and thrombocytosis. [75], [76] An erythroblastic appearance with circulating nucleated red cells, pale ring cells, and Howell-Jolly bodies is suggestive of splenic atrophy, which invariably occurs in celiac disease. [77] When both folate and iron deficiency patterns of anemia are superimposed, variations in the size and shape of the erythrocytes and the degree of hemoglobin may give rise to the characteristic appearance of dimorphic anemia. Serum iron, ferritin, and folic acid levels are invariably low. A macrocytic megaloblastic anemia may occur in both children and adults, although in children, a hypochromic macrocytic anemia that slowly responds to oral iron therapy is more typical. Sometimes, the patient has a remote history of a previous requirement for parenteral iron injections.

The serum folate level is low in most untreated patients with celiac disease. Red cell folate is a better indicator of total body stores, and the level is reduced in 85% of patients with untreated celiac disease. The mean serum levels of vitamin B_{12} of untreated patients with celiac disease are lower than those of controls, although only 14% have levels lower than normal. Moreover, the low values are usually close to the normal range, suggesting that some low levels of vitamin B_{12} are secondary to folate deficiency. Rarely do untreated patients exhibit an anemia secondary to a combined deficiency of vitamin B_{12} and folic acid, which requires combined therapeutic replacement. Normally, vitamin B_{12} levels rise spontaneously when patients are treated with a gluten-free diet. Rarely, pernicious anemia may be present, which is linked to the DR3, DQ2 haplotype.

Patients with persistent, frequent loose stools are at risk for the development of sodium and potassium depletion, which results in fatigue and a loss of muscle power and may present with symptoms resembling those of a peripheral neuropathy. Potassium depletion can simulate a renal disorder, but oral potassium or sodium replacement will reverse this problem. Untreated patients with celiac disease frequently have hypocalcemia and hypomagnesemia, although the latter rarely occurs independently. Symptoms are unlikely to develop unless the serum calcium level falls below 1.5 mEq/L. These include personality changes, limb tremors, uncoordinated movements, convulsions, increased limb reflexes, nausea, vomiting, abdominal pain, and paralytic ileus. Malabsorption and insensitivity to vitamin D can occur, the latter causing resistant osteomalacia and elevated serum levels of parathyroid hormone. Rickets, bone pain, or pathological fractures may be presenting features; symptoms pertaining to low levels of calcium and vitamin D are frequently insidious and may become severe before they are recognized. Cramps and tetany also can be associated with low serum calcium and magnesium levels, but calcium and magnesium replacement therapy usually is effective treatment for all the symptoms of deficiency. [78]

Albumin levels are low in up to one third of subjects with untreated celiac disease. Unexplained hypoalbuminemia should be considered an indication for investigating for celiac disease. Severe hypoalbuminemia in a patient receiving active treatment suggests a complication, such as gastrointestinal lymphoma. Zinc deficiency is likely to occur in celiac disease, and if it does, it should be treated by replacement. Rarely, zinc therapy has been reported to induce anemia, apparently as a result of the induction of concomitant copper deficiency. [79] Early reports of elevated circulating immune complex levels in patients with celiac disease have not been confirmed, so their presence is not of diagnostic significance. [80]

Most patients with untreated celiac disease have steatorrhea at some time, but fat excretion is normal in up to 30% at diagnosis. A customary Western diet usually contains 60 to 100 g of fat per day, but patients with untreated celiac disease often discover that they can reduce their diarrhea by decreasing their fat intake. It is therefore recommended that subjects ingest a diet that contains at least 100 g of fat for 2 days before and during the study. All stools should be collected during a 3-day period to eliminate day-to-day variations. The accepted upper limit of normal for fecal fat excretion is 5 or 6 g/d. [81] The estimate is a relatively crude test that is liable to errors of collection or measurement and not specific to celiac disease. Fecal fat estimation no longer has a place in routine investigations for celiac disease. Results of hydrogen and ^{14}C-bile acid breath tests may be mildly abnormal, reflecting a degree of bacterial overgrowth in the small intestine, which usually regresses during treatment of the celiac disease.

Patients with celiac disease characteristically have a flat glucose tolerance test result, although this finding is not of diagnostic value because a significant proportion of normal persons exhibit a similar pattern. Measurement of the excretion of L-rhamnose and lactose after the ingestion of a hypertonic solution containing both these sugars may prove a valuable diagnostic adjunct when obtaining a small intestinal biopsy is difficult. The result is invariably abnormal. One study reported the lactulose–to–L-rhamnose urinary excretion ratio to be sevenfold higher in patients with untreated celiac disease than in controls; no overlap between the two groups was found. [82] These tests can be useful for diagnostic management when other tests are contraindicated, such as during pregnancy, and can be used for research purposes. [83] They should not, however, replace biopsy of the small intestine, which remains the diagnostic investigation of choice.

The xylose absorption test is not useful because urinary excretion values can be normal in up to 20% of patients with untreated celiac disease. This test is now rarely used.

Most patients with celiac disease have a degree of lactose and sucrose intolerance; this usually disappears during treatment with a gluten-free diet. A small percentage of patients, however, exhibit concomitant lactase or sucrase deficiency that does not normalize during treatment with a gluten-free diet, and they usually have persistent diarrhea despite treatment with a gluten-free diet. It is important to identify these patients because appropriate dietary restriction usually causes their symptoms to resolve.

Pancreatic function testing frequently reveals low intralumenal trypsin and lipase concentrations in resting samples. Following stimulation with secretin and pancreozymin, the pancreas is able to respond normally in patients with untreated celiac disease. Similarly, results of the pancreolauryl test are invariably normal in

this condition. Pancreatic function should be assessed only to exclude underlying concurrent pancreatic insufficiency if the patient does not respond to a strict gluten-free diet. Reduced cholecystokinin levels following a fatty meal have been recorded in celiac disease, which may explain the observed gallbladder inaction and diminished pancreatic response to oral challenge observed in patients with untreated celiac disease. [84] A generalized reduction in many gut hormones may be present; levels tend to normalize following the introduction of a gluten-free diet. The exception is a poor rise in plasma gastric inhibitory peptides following an oral stimulus. Grossly elevated levels of enteroglucagon and abnormal responses to oral glucose have been reported to be unique to celiac disease. [85], [86]

Small Bowel Biopsy

The diagnosis may be suspected on clinical grounds or on the basis of various screening tests results. For confirmation, however, it is mandatory to proceed to a small intestinal biopsy. A biopsy of the small intestine should be undertaken in anyone with a history suggestive of celiac disease, including patients with mild symptoms, particularly relatives of probands, and all patients with dermatitis herpetiformis. Even when multiple specimens are taken, some symptomatic relatives may have a normal mucosa even though their serum contains antiendomysial antibodies. [60], [61] The most common indications in childhood are diarrhea, failure to thrive, anemia, and short stature.

Biopsy of the small intestine can be undertaken either endoscopically or with a small intestinal suction (Watson or Crosby-Krugler) biopsy capsule. The hemoglobin level, platelet count, and prothrombin time should be checked before the biopsy is performed because the prothrombin time is increased in a significant number of patients with untreated celiac disease; this can be corrected with parenteral vitamin K.

Endoscopic biopsy specimens should be taken from the second part of the duodenum with the largest forceps, frequently termed *jumbo forceps*. At least three specimens should be taken to avoid difficulties in interpretation resulting from the presence of mucosa without villi that normally overlies Brunner glands. The macroscopic appearance of the duodenum at endoscopy should be noted because duodenal ulcer or patchy duodenitis can produce a pattern of inflammation similar to that found in celiac disease. In severe cases, a loss of the normal circular folds in the second part of the duodenum is seen. This loss, and the loss of normal villi, can be visualized more easily if india ink is injected into the duodenal lumen and the pattern that forms is observed. [87] Typically, in mucosa without villi, a mosaic rather than the usual velvety appearance is seen. The specimen should be retrieved quickly from the capsule or endoscopic forceps and oriented before fixing so that on sectioning the villi are cut in a plane parallel to their longitudinal axis. The cut surface of the specimen should be placed on a small square of absorbent paper (e.g., Millipore filters) with a dissecting microscope and the whole specimen immediately placed in fixative.

It is important that the specimens be correctly oriented before embedding because tangentially cut biopsy specimens make subsequent histological interpretation difficult. [88] Placing the sample mucosa side up on a piece of cellulose nitrate/acetate filter paper provides the correct orientation for cutting because the filter can be included in the paraffin block and processed with the tissue. It is now appreciated that the classical appearance of mucosa without villi is not seen in all cases of gluten-sensitive enteropathy. Marsh [49] has identified a spectrum of gluten-sensitive lesions that may merely represent an increase in the number of intraepithelial lymphocytes of a patient on a gluten-containing diet. A decrease in their number toward normal while the patient is on a gluten-free diet can be taken as evidence of celiac disease.

If larger and better samples are needed, and certainly if the interpretation of an endoscopic biopsy specimen is doubtful, a proximal jejunal suction biopsy should be undertaken with a Crosby-Krugler or Watson biopsy capsule. [89] A Quinton or Rubin biopsy capsule can be used to obtain multiple specimens from the esophagus, stomach, small intestine, or colon [90] and has been used in research studies. [33] The patient fasts overnight. Sedation and local anesthesia to the throat may make the procedure easier for the patient to tolerate but are not mandatory. The patient swallows the capsule, which is attached to a flexible radiopaque tube within a semisoft polypropylene outer tube measuring 4 mm in diameter; a brass ring at the end facilitates manipulation of the capsule into the pyloric antrum. Metoclopramide can be given intravenously to increase intestinal motility. The patient is asked to turn onto the right side, and use of the outer tube permits the capsule to be passed into the duodenum. Radiographic screening can be used to visualize passage of the capsule into the proximal jejunum, where it is fired. In the case of the Watson or Crosby-Krugler capsule, rapid suction is applied through the peroral connecting tube with either a 50- or 20-mL syringe. Inexperienced operators can check the position of the capsule before firing by injecting 15 to 20 mL of water-soluble contrast solution through the connecting tube to outline the jejunum. If this is done, however, the oral tube should be washed through with 20 mL of tap water followed by 30 mL of air to ensure removal of fluid from the capsule, so that it can fire.

Radiology

Dilation of the colon was noted to be an early radiologic sign, although the most common feature is dilation of the small intestine. The upper limit for the diameter of the normal proximal small bowel on barium follow-through is 30 mm in adults, 24 mm in children 2 years of age, and 14 mm in children up to the age of 6 months. The ileum does not exhibit much distention and measures up to 24 mm in normal adults. In normal adults, the diameter of the small intestine may increase to 50 mm during enteroclysis or small bowel enema.

Barium follow-through examination of the small intestine reveals a loss of the fine, feathery mucosal pattern with thin mucosal folds in 85% of subjects (Fig. 76-7). The normal appearance of an enteroclysis examination does not include this feathery pattern. Usually, some straightening of the valvulae conniventes, thickening of the mucosal folds, and an increase in their separation are seen. Superimposed on dilation and thickening of the mucosal folds are varying degrees of flocculation, segmentation, and clumping, which are more relevant when they occur early in the examination. These changes are, however, not specific to celiac disease.

FIGURE 76-7. Small bowel follow-through showing dilated loops of jejunum with the characteristic appearance of untreated celiac disease.

The radiologic findings of most patients with untreated celiac disease suggest the condition, but in other cases, the findings resemble those of Crohn's disease or scleroderma, the latter of which should readily be differentiated on screening by the presence of decreased motility. The findings may also be suggestive of tropical sprue and occasionally chronic pancreatitis. A dilated and often redundant colon is a feature that renders the untreated patient susceptible to the development of volvulus, with resultant abdominal pain. Intussusception can complicate celiac disease and may be diagnosed by the classical radiologic appearance.

Although 25% of patients with untreated celiac disease do not have any radiologic abnormality, radiology remains an important tool in cases with abdominal pain to exclude complicating lesions, such as jejunal ulceration, stricture, lymphoma, and carcinoma. Abdominal CT and nuclear magnetic resonance imaging of the abdomen may provide a diagnostic clue to the presence of celiac disease by revealing hyposplenism, which is invariably associated with the disorder, and abdominal lymphadenopathy.

DISEASE ASSOCIATIONS

The numerous diseases reported to be associated with celiac disease are listed in Table 76-1. [91] In particular, an association with autoimmune disorders has been noted, in which the prevalence of the genes encoding HLA-DR3 and HLA-DQ2 is also high. The relationship to dermatitis herpetiformis has been described.

FACTOR/DISEASE	APPROXIMATE REPORTED INCIDENCE (%)
First-degree relative of celiac patients	10
Dermatitis herpetiformis	U
IgA deficiency[132]	2.5
Hyposplenism[133–136]	100
Aphthous ulceration	5
Down syndrome[100–101]	U
Small intestinal T-cell lymphoma[10]	10
Thyroid disease[137]	6
Diabetes mellitus[92–95]	6
Cutaneous vasculitis[138–140]	U
Liver disease[103–105]	U
Fibrosing alveolitis[106,107]	U
Sjögren syndrome[141]	U
Polymyositis[142]	U
Addison disease	U
Systemic lupus erythematosus[143]	U
Ulcerative colitis/Crohn's disease[108–111]	U
Rheumatoid arthritis	U
Idiopathic pulmonary hemosiderosis[144]	U
Glomerulonephritis[145]	U
Schizophrenia	U
Sarcoidosis	U
Histocompatibility antigens HLA-DQ2 or HLA-DQ8[37–40]	99

U, incidence unknown; HLA, human leukocyte antigen.

TABLE 76-1 Factors and Diseases Associated with Celiac Disease

Diabetes Mellitus

Celiac disease is associated with diabetes mellitus in both children and adults, and the prevalence of diabetes mellitus in patients with celiac disease is between 4% and 6%. [92], [93], [94] and [95] Diarrhea is a symptom of both disorders. The presentation of celiac disease in a diabetic patient often is preceded by poor diabetic control. Anemia, finger clubbing, glossitis, recurrent oral ulceration, abdominal discomfort or distention, and a poor nutritional state or unexpected episodes of hypoglycemia with exacerbations of diarrhea should alert the clinician to the diagnosis. The dietary treatment of concomitant celiac disease improves diabetic control and usually makes possible a reduction in insulin dosage. It has become apparent that individuals in whom celiac disease is diagnosed early in life, particularly before the age of 2 years, are at no greater risk for the development of autoimmune disease, such as insulin-dependent diabetes mellitus, than the general population. This protection is partially abrogated if a gluten challenge is used as part of the diagnostic process. [96]

Neurological Disorders

Patients with celiac disease may have a number of neurological disorders. [97], [98] A strong association has been found between celiac disease and epilepsy, which may or may not involve cerebral calcification. [99] In one series, 5% of adults with celiac disease had epilepsy. Although the seizures of some patients can be controlled by gluten restriction and folate supplementation, drug-resistant seizures develop in others despite these measures (see ref. [97] for review).

The incidence of celiac disease is greatly increased in patients with Down syndrome. [100], [101] This finding prompted investigators to examine a possible association between celiac disease and chromosome 21; however, none was found. [102]

Liver Disease

The incidence of chronic hepatitis, primary biliary cirrhosis, and sclerosing cholangitis is higher than expected in patients with celiac disease. [103], [104] and [105]

Lung Disease

Chronic fibrosing alveolitis and other interstitial lung diseases, including idiopathic pulmonary hemosiderosis, have been reported in association with celiac disease. [106], [107]

Inflammatory Bowel Disease

Celiac disease is associated with inflammatory bowel disease, particularly ulcerative proctitis, which affects up to 20% of patients. [108], [109], [110] and [111] The proctocolitis is usually relieved by a gluten-free diet; therapy with sulfasalazine (Salazopyrine), mesalamine, or corticosteroid enemas is also effective. The demonstration of an inflammatory infiltration of the rectal mucosa following a rectal gluten challenge suggests that the cause of proctocolitis may be similar to that of small intestinal enteropathy. [54], [55] Microscopic colitis, another chronic diarrheal syndrome, is characterized by mucosal inflammation of an endoscopically normal colon. Depending on whether or not a thickened subepithelial collagen band is present, two separate terms are used to describe the condition: *collagenous colitis* and *lymphocytic colitis*. A feature of the colonic inflammatory reaction is intraepithelial lymphocytosis, suggesting that an immunostimulating agent may be presented to mucosa-associated lymphoid tissue. Potential agents include dietary antigens. [52] Microscopic colitis can be diagnosed only by rectal biopsy, although a full colonoscopy should then be undertaken. [53] The therapeutic alternatives have been discussed by Zins and colleagues. [112]

Intestinal Pseudoobstruction

Symptoms of intestinal obstruction without any evidence of an organic lesion obstructing the lumen of the intestine rarely can be associated with celiac disease; if so, the symptoms are relieved by treatment with a gluten-free diet. [113]

Nonceliac Gluten Intolerance

This condition has been described in infants and children, usually in association with intolerance to cows' milk. [71], [114] The ingestion of gluten-containing cereals causes diarrhea, vomiting, and occasionally rhinitis and bronchitis. Other symptoms include vomiting, headaches, and recurrent oral aphthous ulceration. The disorder also affects adults, whose symptoms are usually abdominal pain and diarrhea. Investigation reveals a normal jejunal mucosa with a normal intraepithelial lymphocyte count and disaccharidase activity. Results of immunologic tests, including measurement of immunoglobulin and gliadin antibody levels, are normal. The cause of the intolerance is unknown, and treatment with sodium cromoglycate does not help. All patients experience dramatic relief with a gluten-free diet and relapse on challenge, and it is possible that they have a functional bowel disorder exacerbated by wheat starch. [115] A diet that omits cereals, particularly wheat, and replaces dietary fiber with ispaghula husks or ground psyllium seeds usually is effective.

TREATMENT

Celiac disease is treated with a gluten-free diet; products containing wheat, rye, barley, and traditionally oats are avoided. [3] The toxicity of oats is a matter of disagreement. [116] Several studies have indicated that moderate amounts (50 g/d) of oats are not harmful to adult patients with celiac disease, and one study has suggested that children with celiac disease can consume oats, although this must be confirmed. [117] Many commercially available sources of oat flour are contaminated with wheat flour because the mills are not scrupulously cleaned after previous milling of wheat. Oats should therefore be purchased from a dedicated miller.

Holmes and colleagues [9] showed that a gluten-free diet significantly decreases the incidence of T-cell lymphoma of the small intestine in patients with celiac disease.

For this reason, and the need to protect patients with celiac disease from dietary deficiency, even those with relatively mild symptoms should be advised to follow a strict gluten-free diet. The advice must be emphasized because some patients improve significantly on a partially gluten-free diet and may be tempted to take a rather relaxed approach to the gluten-free diet. A small percentage of patients become severely systemically ill with untreated or unresponsive celiac disease, in which case a short course of oral or parental steroids should be given.

Gluten-Free Diet

The gluten-free diet is based on the complete avoidance of wheat, rye, and barley, and products containing these grains. Triticale, which is a hybrid of wheat and rye, must be avoided, as must spelt or “ancient” or “wild” wheat. Attempts have been made to market spelt as suitable for individuals with gluten intolerance. Claims that this cereal is in some way different from wheat are totally spurious. Malted barley products, malt extract or flavoring, and beers and lagers of all types contain residual gluten peptides and must be excluded from the diet.

The distant cousins of wheat, such as maize, rice, and sorghum, contain storage proteins that bear little similarity to gluten, and these cereals can be safely consumed by patients with celiac disease. Buckwheat is a source of confusion; actually, it is a legume rather than a cereal and can thus be safely consumed by individuals with gluten sensitivity. Carbohydrate sources such as chick peas and potato flour are also free of gluten by nature. Thus, a number of flour substitutes that are naturally free of gluten have been used as substitutes for wheat. They do not, however, have the baking qualities of wheat. It is possible to produce a palatable cake or biscuit with, for example, maize flour. However, bread made without wheat is a good deal less successful. This has led manufacturers to use wheat starch, which has a better texture and taste. Despite improvements in manufacturing techniques, small amounts of gluten remain to contaminate the wheat starch, the significance of which is disputed. A study in Scandinavia [118] suggested that the regular use of wheat starch made according to the stringent standards of modern regulations is compatible with good health in patients with celiac disease. Some groups of patients, however, feel that any foods labeled as gluten-free should contain levels of gluten lower than those found in wheat starch. Some patients are exquisitely sensitive to tiny amounts of gluten and must follow a gluten-free, wheat-free diet that excludes wheat starch.

In addition to wheat starch, many other sources can contaminate foods that appear not to contain the protein gluten. Errors during the manufacturing, storage, and handling of foodstuffs can and do lead to the contamination of foods with gluten. [119] Additionally, incorrect or ambiguous food labeling creates further hazards. A number of organizations provide regularly updated information about the contents of manufactured foods. Useful contacts include the Celiac Sprue Association of the United States of America (csaceliacs.org), the Celiac Disease Foundations (celiac.org), the U.K. Coeliac Society (coeliac.co.uk), and a commercial database (www.brandbeach.com/celiac/upc/index.html).

A gluten-free diet contains little fiber, which may cause some constipation. Patients should be encouraged to eat good quantities of fruit and fibrous vegetables, possibly with the addition of regular dietary rice bran and ispaghula. Commercially available gluten-free products, which are available by prescription in many countries, may be useful supplements to a gluten-free diet, particularly for children. Any specific dietary deficiencies that occur, including deficiencies of iron, folic acid, calcium, and rarely vitamin B_{12}, should be corrected.

After 3 or 4 months of treatment with a gluten-free diet, biopsy of the small intestine should be repeated to demonstrate improvement in the appearance of the jejunal mucosal morphology. If improvement has not occurred, other possible causes of atrophy of the small intestinal villi, such as giardiasis, intolerance to cows’ milk, and hypogammaglobulinemia, should be considered and another biopsy performed after an additional 6 to 9 months.

If the patient’s symptoms persist or the jejunal specimen morphology remains grossly abnormal while the patient is on a gluten-free diet, commercial gluten-free products based on wheat starch should be discontinued and the initial diagnosis questioned. The completely wheat-free diet should be organized by a dietitian who is competent and experienced in the field. It should not be forgotten, however, that the most common reason for the lack of a response is either poor patient compliance or the inadvertent ingestion of gluten.

If a clear improvement in the jejunal specimen morphology with complete resolution of the histological abnormalities and symptoms does not occur, further confirmation can be made by a demonstrating a deterioration in the small intestinal morphology after a gluten challenge. Such confirmation is essential in children, in whom conditions such as infectious diarrhea and cows’ milk intolerance may cause similar abnormalities of small intestinal morphology. The most convenient method of gluten challenge is to ask the patient to ingest at least 10 g of gluten in the form of four slices of normal gluten bread each day for 4 to 6 weeks. If severe symptoms result, the date of the biopsy should be brought forward. The ESPGAN suggests that it is not mandatory to repeat the jejunal biopsy following a gluten challenge if a gluten-free diet has been associated with good relief of symptoms and significant improvement in the morphology of a repeated jejunal biopsy specimen. [71] Nearly half of all adult patients have an incomplete histological resolution despite marked symptomatic improvement. Many physicians do not routinely use gluten challenge in patients with celiac disease, reserving it for cases of diagnostic uncertainty.

Patients who do not adhere strictly to a gluten-free diet invariably experience chronic ill health and recurring symptoms, which usually can be traced to dietary lapses that are either deliberate or inadvertent. Difficulty may arise when a given food is thought to be gluten-free but in fact contains gluten, including those with low levels of contamination by wheat flour. An experienced dietitian may have to analyze the diet in detail. Frequent problem foods include malted breakfast cereals, snacks, sauces, and beer.

Rarely, failure to respond to a gluten-free diet is caused by the development of a small intestinal lymphoma or ulcerative jejunitis (see section “ Refractory Sprue”) or the presence of another concurrent disorder, such as chronic pancreatitis. Occasionally, the condition of a patient on treatment will deteriorate, and the patient may die unaccountably.

Pink and Creamer [120] reported that 70% of patients with celiac disease on a gluten-free diet quickly return to normal health, with improvement noted within 2 weeks. The remaining 30% of patients fall into three groups. Patients in the first group experience progressive deterioration, which is halted in some cases by corticosteroids but leads to death in others. Patients in the second group have an associated pancreatic lesion. Those in the third group do not adhere strictly to the diet, but even when this problem is addressed, their minor abdominal symptoms, including diarrhea, persist. [71] It is important to note that dietary failure is not always the cause of persistent symptoms.

REFRACTORY SPRUE

Lymphoma, Jejunal Ulceration, and Autoimmune Enteropathy

Enteropathy-associated T-cell lymphoma (EATL) may occur in patients with a long history of celiac disease, but it is often seen in adults with a short history of celiac disease, which suggests that it is a consequence of long-term ntreated disease. T-cell lymphoma often presents as a gluten-resistant enteropathy also known as *refractory sprue*. [121] Not all cases of refractory sprue progress to EATL.

A related complication of celiac disease is known as *ulcerative jejunitis,* which has clinical features similar to those of lymphoma. Jejunitis is characterized by multiple chronic, apparently benign ulcers that are found most frequently in the jejunum. Both jejunitis and EATL tend to affect persons in the fifth and sixth decades of life and present with fever, lassitude, anorexia, weight loss, abdominal pain, and diarrhea. [122] Anemia, both microcytic and macrocytic, is common, as is steatorrhea and a protein-losing enteropathy. The jejunal ulcers may be complicated by hemorrhage, perforation, or stricture formation, and emergency laparotomy is often required. [45] A flat jejunal mucosa on small intestinal histology is similar to that found in celiac disease. Patients may benefit from a gluten-free diet, but the response to such a diet is frequently suboptimal. The HLA genotype in the few reported cases is identical to that found in celiac disease and supports an association of these disorders. [123] The prognosis is poor, with a third of patients dying of complications, although it is considerably improved if the ulcerated or strictured segment is resected. Some patients with jejunitis progress to EATL, whereas multiple inflammatory mucosal ulcers frequently accompany EATL itself.

Refractory sprue—that is, the loss or lack of response to a gluten-free diet—may also progress to EATL. Both refractory sprue and ulcerative jejunitis are characterized by a nonlymphomatous monoclonal T-cell population in the affected mucosa. In EATL, a similar population that demonstrates clonal identity with the lymphoma itself is seen. Bagdi and colleagues [121] demonstrated that in all three cases, the monoclonal T-cell population consists of cytologically normal noninvasive intraepithelial T lymphocytes that share an identical aberrant immunophenotype with EATL. The authors concluded that patients with refractory sprue or ulcerative jejunitis have a neoplastic T-cell disorder. Others [124] found that a subgroup (16%) of individuals with refractory sprue who did not have aberrant clonal intraepithelial

lymphocytes made a complete recovery when treated with steroids in addition to a gluten-free diet.

Antienterocyte antibodies have been detected in a subgroup of patients with refractory sprue. [125] These antibodies are found in autoimmune enteropathy, a condition originally described in children and diagnosed by histological evidence of enteropathy in the presence of antienterocyte antibodies and the absence of an identified dietary protein trigger. Other organ-specific antibodies are common, whereas antiendomysial antibodies are not usually found. It is suggested that celiac-like enteropathy may be a manifestation of a multisystem autoimmune disorder. Routine searching for the presence of antienterocyte antibodies in all cases of refractory sprue is suggested because they may respond better to immunosuppressive therapy. [125]

Steroids

Celiac disease can be treated with systemic steroids, which induce a rapid cessation of diarrhea, weight gain, and improvement in fecal fat excretion and absorption, although these effects rarely persist once treatment has been stopped. Corticosteroids are not indicated in the routine management of celiac disease but are appropriate in the treatment of acute celiac crisis, manifested by severe diarrhea, dehydration, weight loss, acidosis, hypocalcemia, and hypoproteinemia. Steroids also can be used in the rare condition of gliadin or gluten shock that occurs in occasional treated patients who are subjected to gluten challenge. [126]

Azathioprine or 6-mercaptopurine can be used as a steroid-sparing agent if a dose of 10 mg of prednisolone or more per day is required to keep the condition under control. [127] The role of cyclosporine remains unproved. [128], [129]

The dose of steroids depends on the individual case. If intravenous fluid replacement is required because of vomiting, diarrhea, or surgery, 100 mg of hydrocortisone should be given intravenously every 6 hours. A patient who is eating normally but exhibiting a crisis should be given 40 to 60 mg of prednisolone daily. It should be possible within a few weeks to reduce the dose to that given for celiac disease that has not responded adequately to a gluten-free diet (i.e., 5–10 mg/d). Failure to be able to do so should alert the clinician to the possibility of either a failure to adhere to the diet or a complication, such as lymphoma or ulcerative jejunitis.

COMPLICATIONS

All patients with celiac disease exhibit lactose and sucrose intolerance at the time of diagnosis. Only a small percentage have a persistent disaccharidase deficiency following treatment with a gluten-free diet, and they experience abdominal pain and diarrhea with intake of lactose or sucrose. These conditions can be diagnosed either by enzyme assays of a small intestinal biopsy specimen or, more simply, by an appropriate sugar tolerance test. If concomitant disaccharidase deficiency is present, the relevant disaccharide should be excluded from the diet.

Some patients with treated celiac disease have bacterial overgrowth in the small intestine, which can be diagnosed by an abnormal result of a hydrogen or bile acid breath test or by an elevated urinary or small intestine bacterial count (see Chapter 78). Treatment is with an antibiotic, such as 250 mg of oxytetracycline four times daily, which can be rotated every 2 weeks with another antibiotic, such as ciprofloxacin.

Neurological Complications

Neurological complications, reviewed by Willis, [97] may occur in 10% of patients with celiac disease. [62], [63] These include disorders of the central nervous system, such as epilepsy, myoclonus, ataxia, and dementia, which frequently respond poorly to the exclusion of gluten from the diet. However, peripheral neuropathies of the axonal and demyelinating types may respond to a gluten-free diet. The neurological complications may be related to vitamin deficiencies or may be of immune origin. The suggestion that occult celiac disease may underlie a proportion of cases of neurological dysfunction of unknown cause has not been universally accepted. However, workers in the United Kingdom identified patients with “gluten ataxia,” characterized by the presence of antigliadin antibodies with or without small bowel histological abnormalities. [130] All had gait ataxia, and some had limb ataxia. A large number of the patients had some form of peripheral neuropathy. Some of them responded symptomatically to a gluten-free diet. Two patients who died showed evidence of lymphocytic infiltration of the cerebellum, damage to the posterior columns of the spinal chord, and sparse infiltration of the peripheral nerves. The literature contains a number of case reports. [97] The neuropathological findings have been heterogeneous, some suggesting an immune etiology and others showing only degenerative change.

Osteoporosis

Good evidence has been found of reduced bone mineral density in celiac disease. [131] In persons in whom the disease is not diagnosed until after bone mineral density peaks in the third decade, full mineralization may never be achieved, so that the risk for osteoporosis later in life is very high. Conversely, studies have shown that those who have been on a gluten-free diet since childhood have a normal bone mineral density. Osteoporosis in celiac disease is probably related to calcium malabsorption leading to parathyroid hormone secretion and resultant increases in bone turnover. Vitamin D malabsorption may coexist, requiring vitamin D therapy.

Some sources favor investigating the bone mineral density at diagnosis, although it is recognized that this policy might put undue strain on the densitometry services. [131] In this case, a compromise might be to test the bone mineral density at menopause in woman, with the test repeated 2 years later in those with a normal value at menopause. In men, testing at the age of 55 years is suggested.

The British Society of Gastroenterology has suggested a strategy for the prevention and treatment of this common complication of celiac disease. Patients should be counseled about the importance of a strict gluten-free diet. Adequate dietary calcium should be supplemented, if necessary, to ensure a daily intake of 1500 mg. The importance of exercise and moderate alcohol consumption should be stressed. Smoking is prohibited. Vitamin D deficiency should be sought and treated. Those with osteoporosis should be treated with bisphosphonate or calcitonin and hormone replacement therapy in postmenopausal women.

CHAPTER 77

Denesh K. Chitkara, Adrienne M. Scheich, and Richard J. Grand

DISORDERS OF EPITHELIAL TRANSPORT IN THE SMALL INTESTINE

The intestinal mucosa represents a semipermeable barrier that controls the flux of solutes and fluid into the systemic circulation. It is highly differentiated at the cellular level, and in particular, enterocytes acquire increasing functional capacity as they migrate along the crypt-villus axis. Maximal absorptive activity thus is found along the villus, characterized by the presence of an enzyme-rich brush border membrane [1], [2], [3] and [4] and the expression of mRNA for specific transporters. [5] Secretory function is concentrated at the base of the crypt. [6] Most defects of intestinal transport affect the absorption of a specific nutrient or a group of nutrients. Accordingly, the phenotypic expression varies significantly from none to life-threatening as the result of a wide range of intestinal and extraintestinal effects. Intestinal effects are usually secondary to the presence of excessive amounts of unabsorbed solutes in the lumen, which leads to acute fluid and ionic imbalances; in general, extraintestinal effects reflect the systemic deficiency of a specific nutrient and therefore may be more insidious and progressive. Transport is closely integrated with digestion [7]; therefore, this chapter focuses on specific mucosal transport defects and common hydrolytic enzyme deficiencies (primary or secondary) that may be phenotypically indistinguishable.

DISORDERS OF LACTOSE AND SUCROSE DIGESTION

The clinical symptoms associated with lactose or sucrose malabsorption customarily are ascribed to low intestinal levels of the microvillus membrane disaccharidases required for their hydrolysis: lactase–phlorizin hydrolase and sucrase-isomaltase, respectively. Such reduced levels may be a consequence of genetic alterations in expression of the enzymes or of reductions in enzyme activity as a result of intestinal injury. Depending on the severity of injury, nutritional complications may occur. The average adult ingests about 300 g of carbohydrate daily, 50% as calories, 17% as starch (mainly as cereals and potatoes), 25% as sucrose, 5% as lactose (mainly in milk), and 3% as fructose (in fruit and honey). Glycogen, glucose, and maltose are minor constituents, and cellulose accounts for about 4 g of carbohydrates per day. In contrast, lactose contributes 35% to 55% of the calories ingested daily by infants. As weaning foods are introduced, lactose intake decreases toward quantities commonly ingested by adults.

Lactose Intolerance

Biology and Genetics The human lactase gene, located on chromosome 2q22, comprises 17 exons and covers about 70 kilobases, giving rise to an mRNA of slightly more than 6 kilobases. From the initiation codon to the stop codon, human lactase mRNA encodes 1927 amino acids forming the complete translation product. [8] The nascent protein is heavily glycosylated, so that the final translation product is about 220 kd. [9] This high-molecular-mass glycoprotein undergoes two cleavage events and is then is inserted into the microvillus membrane of the enterocyte as a mature enzyme of approximately 160 kd. [10], [11] The cleaved intracellular portion of the precursor protein is degraded. [12] Analysis of the human lactase gene from subjects with high and low levels of lactase demonstrates interesting single-nucleotide polymorphisms, but their function in lactase expression remains to be delineated. [13], [14] The developmental pattern of expression of lactase in the human fetus is unique. Before week 24 of gestation, the level of intestinal lactase activity is low. It then begins to increase, and during the third trimester, lactase activity increases markedly until levels in term neonates are at or above those of infants ages 2 to 11 months. [15] Unlike the response of sucrase activity to sucrose feeding, [16] lactase activity cannot be increased by lactose feeding, and it is not reduced during periods of lactose elimination in humans. [17] Lactase exhibits a characteristic proximal-to-distal pattern of expression; enzyme activity is greatest in the midjejunum, with decreased activity proximally, especially in the duodenum, and distally, especially in the terminal ileum. [18] Lactase is expressed more distally on the villus, which is said to account for its sensitivity to villus flattening. [19] Within the enterocyte, lactase–phlorizin hydrolase mRNA is colocalized with its encoded protein in the apical enterocyte. [20] In most of the human population, lactase activity decreases during middle childhood (~5 years of age), and levels are low in adulthood. In contrast, in a minority of the human population, especially persons of northern European extraction and a few other racial groups, high levels of activity are retained throughout adult life (Table 77-1). [21] It is important to note that in all placental mammals, intestinal lactase activity is reduced to about 10% of the suckling level around the time of weaning. It is now clear that in all mammals, including humans, the primary mechanism of this decline in lactase activity is regulated by gene transcription, and lactase activity is strongly correlated with the intestinal content of lactase mRNA. There is some evidence that posttranscriptional factors may also be involved in the intestinal lactase decline. [22] A small number of Caucasian persons with a racial/genetic lactase decline have an abnormality of the intracellular processing of newly synthesized lactase protein. [17], [23]

TABLE 77-1 Distribution of Lactose Phenotypes in Selected Populations

Pathophysiology Lactose digestion is slower than that of sucrose, and hydrolysis has been considered the rate-limiting step for the overall process of lactose absorption. [24] Lactose is hydrolyzed to glucose and galactose on the microvillus membrane of the intestinal absorptive cells. Uptake of these monosaccharides is accomplished by the sodium-dependent glucose carrier SGLT1 (see below). When lactose is not absorbed by the small bowel, it passes rapidly into the colon as a consequence of the osmolality of the intralumenal disaccharide. In the colon, lactose is converted to short-chain fatty acids and gas (hydrogen, methane, carbon dioxide) by the bacterial flora, forming acetate, butyrate, and propionate. The short-chain fatty acids are absorbed by the colonic mucosa, and this route salvages malabsorbed lactose for energy utilization. This is the mechanism by which the newborn colon also salvages lactose, and the adult with low intestinal lactase activity may adapt to persistent lactose ingestion. [21] This fermentative process, which conserves nutritionally important carbohydrate, serves as the basis of the lactose breath hydrogen test (see below). Clinical symptoms in persons with lactose intolerance are quite variable. Important factors include the osmolality and fat content of the food

in which the sugar is ingested, the rate of gastric emptying, the individual sensitivity to intestinal distention produced by the osmotic load of unhydrolyzed lactose in the upper small bowel, the rate of intestinal transit, and the response of the colon to the carbohydrate load. The higher the osmolality of the gastric contents and the higher the fat content of the food containing the lactose, the slower the gastric emptying and the fewer the symptoms induced by the sugar.

Clinical Features When clinical symptoms are induced by the ingestion of lactose, the term *lactose intolerance* is applied. [21], [23], [24] Lactose intolerance may be caused by a primary reduction in lactase expression or by the secondary effects of a variety of mucosal diseases. Three clinical phenotypes are associated with primary reductions in lactase activity. Developmental lactase deficiency occurs in preterm infants as a result of relatively low intestinal lactase activity before 32 weeks' gestation. A second phenotype, human congenital lactase deficiency, is an extraordinarily rare condition. It is inherited in an autosomal recessive fashion and results in the complete absence of active lactase enzyme. This condition has been recognized in isolated populations, as in Finland, where most cases have been reported. The locus for congenital lactase deficiency has been linked to a 350-kilobase interval more than 2 megabases away from the lactase–phlorizin hydrolase gene. [25] The most common form of lactose intolerance appears in the majority of the world's population, in which lactase activity declines at about the age of 5 years; thereafter, only low lactase levels persist (see Table 77-1). In Western countries, where patients may be immigrants from developing areas of the world, physicians should be aware of the prevalence and racial distribution of genetically controlled low levels of lactase activity. The occurrence of low lactase levels in patients older than 5 years is most prominent in Asian, African, and all indigenous populations. Most infants and children up to the age of 5 years in every racial and genetic group have preserved lactase levels. Population genetic analysis indicates that a persistently high level of lactase activity in adult life is inherited as a single autosomal dominant gene, whereas a low level of lactase activity is inherited as a recessive trait. Secondary lactase deficiency is the result of mucosal injury. Diseases that can cause mucosal damage or villus flattening include infectious gastroenteritis (rotavirus is the most common cause), parasitic infections (giardiasis), celiac disease, tropical sprue, radiation enteritis, drug-induced enteritis, and Crohn's disease involving the proximal small intestine. The literature is unclear about the prevalence of lactase deficiency in Crohn's disease involving other parts of the small intestine. In one study, the intestinal lactase activity of patients with Crohn's disease reflected their genetic background. [26] In contrast, in another study, patients with Crohn's disease had a higher prevalence of lactose malabsorption than would have been expected for their ethnic group and in comparison to patients with ulcerative colitis. [27] These dichotomous findings remain to reconciled. In many secondary disorders, mucosal damage may be focal or patchy, so that a diagnosis of lactase deficiency by lactase assay in biopsy samples is difficult because lactase levels may vary in different samples. Lactose intolerance is characterized by abdominal pain, cramps or distention, nausea, flatulence, diarrhea, or vomiting. The abdominal pain may be cramping and may develop in the periumbilical region or the lower quadrant. Borborygmi may be audible on physical examination and to the patient. Lactose intolerance generally causes abnormal stools, which are usually bulky, frothy, and watery. In severe cases, mostly in infants, acidosis and dehydration may be a problem. Vomiting after lactose ingestion often is seen in adolescent patients. Different persons appear to be more or less sensitive to the ingestion of lactose and exhibit variable degrees of abdominal distention and variable complaints when ingested lactose stimulates an influx of water into the lumen of the small intestine or when the production of gas distends the colon. Persons with greater tolerance report fewer symptoms. These subjective responses are difficult to quantify. On careful testing, most lactose-intolerant adults who are offered alternatively lactose- and glucose-containing milk experience little difference in clinical symptoms despite differences in gas production. [28], [29] In fact, women proven to be lactose maldigesters were able to tolerate a lactose-containing diet that provided 1300 mg of calcium per day without experiencing significant symptoms, such as bloating, abdominal pain, or diarrhea. [30] Thus, subjective contributions to the clinical symptoms of lactose intolerance are important. Patients with irritable bowel syndrome who are also lactose intolerant may experience increased pain after lactose ingestion. Intestinal transit also is influenced by the quality of the diet and individual motility patterns. Accordingly, some lactose-intolerant persons have a rapid movement of sugar to the cecum, whereas others have slower motility. Fecal flora adapt to ingested carbohydrates. In many intolerant people, therefore, if lactose is provided slowly over a long period, the flora may adapt to the load and the symptoms caused by gas and acid in the colon may be reduced or eliminated. The breath hydrogen excretion and symptoms of African American adolescents who were lactose maldigesters significantly decreased when they were fed a lactose-containing diet over 21 days, presumably because of colonic flora adaptation. [31] This mechanism of lactose tolerance in persons with low lactase levels accounts for the discrepancy between lactase malabsorption, defined by lactose breath hydrogen testing, and clinical symptoms of lactose intolerance. Human adult-onset lactase decline has been correlated with osteoporosis, which can lead to bone fragility and an increased risk for bone fracture. [23] Women with osteoporosis had a significantly higher prevalence of lactose malabsorption than age-matched controls of similar ethnic origin. [32] Lactose avoidance can also lead to bone demineralization in children. In an evaluation of children whose intake of lactose was restricted because of various disorders (genetic lactose intolerance, short bowel syndrome, mild protein allergy, hypercholesterolemia), 50% of the patients had signs of osteoporosis or osteopenia based on bone mineral density measurement. [33] Adequate supplementation of calcium intake is necessary in people with lactose intolerance for the long-term maintenance of bone health.

Diagnosis The confirmation of lactose intolerance depends on reproducing symptoms when lactose is ingested. Alternatively, when the diagnosis of lactose intolerance is strongly suspected, resolution of symptoms after the temporary elimination of lactose from the diet serves as a diagnostic test. The diagnosis of lactose malabsorption is based on the results of appropriate tests that reflect or confirm the inability to absorb lactose. A low fecal pH or the presence of reducing substances in stools indicates lactose malabsorption, but the results of these tests are valid only when lactose has been ingested, intestinal transit time is rapid, stools are collected fresh and assays performed immediately, and bacterial metabolism of colonic lactose is incomplete. In general, lactose malabsorption is best confirmed with a more specific test. The capacity for lactose absorption can be measured with a lactose absorption test. In adults, it has a sensitivity of 75% and a specificity of 96%. In children, however, it is cumbersome, invasive, and time-consuming and has been replaced largely by the lactose breath hydrogen test. [24], [28], [29] The breath hydrogen test really measures lactose nonabsorption rather than lactose hydrolysis and monosaccharide uptake. Its sensitivity and specificity are superior to those of the absorption test, and it is simple and noninvasive. The lactose hydrogen breath test has become the most popular and reliable method for the diagnosis of lactose malabsorption. The test can be performed in patients of all ages. The administered dose is customarily 2 g of lactose in water per kilogram of body weight, not to exceed 50 g. Breath is sampled before lactose is ingested and at 30-minute intervals thereafter for 3 hours and is analyzed for hydrogen content with readily available desktop or portable devices. It is customary to consider a hydrogen value of 10 parts per million as normal, with samples obtained after lactose ingestion compared to the baseline value. Hydrogen values between 10 and 20 parts per million may be indeterminate unless accompanied by symptoms, but hydrogen values higher than 20 parts per million represent lactose malabsorption. False-positive results are caused by inadequate pretest fasting or recent smoking. False-negative results are obtained when patients have recently used antibiotics or are not hydrogen producers (~1% of the population). In children younger than 5 years of age, an abnormal lactose breath hydrogen test result signifies intestinal mucosal injury or bacterial overgrowth, both of which require further definition by appropriate diagnostic tests. A normal breath hydrogen test result does not rule out an intestinal mucosal lesion, and it cannot be used to avoid an intestinal biopsy. The assay of disaccharidase activity in small bowel biopsy samples establishes the presence of disaccharidase deficiency and has been used to define populations at risk for low lactase levels. [21] Although a low level of lactase activity accompanies intestinal injury, the lesion may be focal or patchy; consequently, intestinal biopsy samples may not yield an abnormal result. Clinical and biochemical data always must be compared to obtain the correct diagnosis.

Treatment The treatment of lactose intolerance is based on four general principles (Table 77-2 and Table 77-3): reduction or restriction of dietary lactose, substitution of alternative nutrient sources to avoid reductions in energy and protein intake, regulation of calcium intake, and the use of a commercially available enzyme substitute. When lactose restriction is necessary, patients must be instructed to read labels of commercially prepared foods to identify hidden lactose (see Table 77-2). Complete restriction of lactose-containing foods should be necessary for a limited period only to ascertain the specificity of the diagnosis. Because many patients can tolerate graded increases in lactose intake, small quantities of lactose should be reintroduced subsequently into the diet, with careful attention paid to associated symptoms. Because of its high sugar and fat content, ice cream may be a good way to introduce lactose into the diet. The diet should be reviewed with the patient to ensure that protein, fat, and other nutrients are supplied at appropriate levels. Calcium is supplemented in the form of calcium carbonate; Tums is a popular and effective product. Standard preparations contain 500 mg of calcium carbonate, equivalent to 200 mg of elemental calcium, which is 20% of the U.S. Recommended Dietary Allowance for adults. For infants and young children, liquid calcium gluconate is readily tolerated and available. When complete lactose restriction is recommended, the U.S. Dietary Reference Intake (DRI) for calcium should be provided as a supplement. Commercially available lactase preparations (see Table 77-3) are actually bacterial or yeast ß-galactosidases. When added to lactose-containing foods, or when ingested with meals containing lactose, they effectively reduce symptoms and breath hydrogen values in many lactose-intolerant subjects. These products cannot completely hydrolyze all dietary lactose, however, and the results achieved in individual patients are variable. The commercial lactase preparations can be added to foods, ingested with foods, or sprinkled on food products. Commercially available Lactaid milk comes in 70% and 100% hydrolyzed forms. It should be noted that acidophilus milk is not sufficiently depleted of lactose. Live-culture yogurt, which contains endogenous ß-galactosidase, is a useful alternative source of calcium and calories and should be well tolerated by a number of lactose-intolerant patients. [34] Types of yogurt in which milk or milk products are added back after fermentation may cause symptoms. Whereas the consumption of yogurt alone by persons with low levels of lactose tolerance reduces symptoms, the consumption of yogurt together with additional lactose does not reduce symptoms. The capacity of probiotics to provide lactose digestion in individuals with low lactase levels appears to vary. For example, milk treated with *Lactobacillus bulgaricus* has been shown to decrease both breath hydrogen excretion and clinical symptoms of lactose intolerance in lactose maldigesters. [35] However, *Lactobacillus acidophilus* has not affected these markers significantly. [35], [36]

PRODUCT	UNIT	LACTOSE (APPROXIMATE g/UNIT)
Milk	1 cup (244 g)	11
Low-fat milk, 2% fat	1 cup (244 g)	9–13
Skim milk	1 cup (244 g)	12–14
Nonfat dry milk, instant	1⅓ cup (91 g)	46
Whipped cream topping	1 tbs (3 g)	0.4
Light cream	1 tbs (15 g)	0.6
Cheese		
Cheddar	1 oz (28 g)	0.4–0.6
Cream	1 oz (28 g)	0.8
Parmesan, grated	1 oz (28 g)	0.8
American	1 oz (28 g)	0.5
Swiss	1 oz (28 g)	0.4–0.6
Cottage	1 cup (210 g)	5–6
Ice Cream		
Vanilla, regular	1 cup (133 g)	9
Sherbert, orange	1 cup (193 g)	4
Ice, orange	100 g	0

TABLE 77-3 Some Commercial "Lactase" Substitutes

Sucrase-Isomaltase Deficiency

This rather rare disorder is the consequence of faulty synthesis or processing of the intestinal enzyme sucrase-isomaltase. [17] Typically, patients present in infancy, although sometimes the diagnosis is not made until childhood or, occasionally, adolescence or adulthood. [37]

Biology and Genetics The sucrase-isomaltase gene is located on chromosome 3, and 12.2 kilobases of its promoter have been cloned. The polypeptide sequence deduced from the human cDNA consists of 1827 amino acids, forming the complete translation product. The final form of the protein inserted into the microvillus membrane is heavily glycosylated, such that the molecular mass is about 270 kd. Once it is inserted into the microvillus membrane, the 270-kd form is cleaved by pancreatic proteases into its mature form, an enzyme complex in which sucrase (~120 kd) is noncovalently linked to isomaltase (~140 kd) inserted into the microvillus membrane by a hydrophobic anchor sequence. The development of expression of sucrase-isomaltase in the human fetus differs from that of lactase. Even in the youngest fetuses studied (10 weeks), the activity of sucrase-isomaltase is similar to that in the adult human intestine. Sucrase-isomaltase activity remains unchanged throughout development. [15] The activity of sucrase-isomaltase, however, is responsive to dietary carbohydrate and increases after prolonged fructose and sucrose feeding. [16] Sucrase exhibits a proximal-to-distal expression pattern similar to that of lactase, but with relatively more activity in the duodenum and ileum than is found for lactase. On the vertical axis, sucrase is expressed at the lower villus; in contrast, lactase is expressed at the upper villus. [19] Within the enterocyte, sucrase mRNA is colocalized with encoded protein in the apical side of the cell. [20] Sucrase-isomaltase deficiency is an autosomal recessive disorder characterized by undetectable levels of intestinal sucrase activity and reduced isomaltase activity. Although intestinal histology may show minor degrees of villus atrophy with associated malnutrition, [38] most patients with sucrase-isomaltase deficiency have normal villus architecture. The prevalence of sucrase-isomaltase deficiency is about 0.8% in North Americans and about 10% in the Eskimos of Greenland. The biochemical defects identified indicate that the deficiency state arises from varying allelic mutations of the sucrase-isomaltase gene. [17], [39] At least six different defects have been identified: arrest of prosucrase-isomaltase in the rough endoplasmic reticulum; arrest and degradation of prosucrase-isomaltase in the Golgi apparatus; catalytically altered enzyme in the microvillus membrane and partial missorting to the basolateral membrane; missorting to the basolateral membrane and accumulation in the rough endoplasmic reticulum; intracellular loss of the sucrase subunit and expression of the isomaltase subunit at the microvillus membrane; cleavage and secretion of the mutant sucrase and absent immunoreactive protein. [17], [40] Thus, most genetic defects seem to reflect mutations in the gene that lead to changes in the primary amino acid sequence of sucrase-isomaltase. [39] The resulting mutant proteins display a broad variety of mechanisms of aberrant intracellular sorting or premature degradation.

Clinical Features Sucrase-isomaltase deficiency presents at different ages. [38], [41], [42] In infancy, symptoms may occur when sucrose is introduced into the diet: diarrhea, secondary malabsorption, and failure to thrive. In young children, chronic diarrhea may occur immediately or months after the introduction of sucrose. Because sucrose is not the primary carbohydrate in most infant formulas, malnutrition is less commonly associated with sucrase-isomaltase deficiency. Occasionally, the first manifestations appear in adolescence or adulthood after a gastroenteritis with symptoms of diarrhea, abdominal cramps, and flatulence that are intermittent in nature and mimic the irritable bowel syndrome. The stools of patients with sucrase-isomaltase deficiency often contain nonhydrolyzed sucrose; however, a special technique is needed to hydrolyze the disaccharide before testing for reducing substances because sucrose is not a reducing sugar. The diagnosis of sucrase-isomaltase deficiency is achieved most easily by means of the sucrose breath hydrogen test, which is performed in exactly the same manner as the lactose breath hydrogen test. However, a false-positive rate of 20% to 30% in some studies may suggest the need for confirmation of the diagnosis by small intestinal biopsy with disaccharidase determination. [38]

Treatment The primary approach to the treatment of sucrase-isomaltase deficiency is the elimination or restriction of dietary sucrose, which leads rapidly to resolution of the clinical symptoms. Over time, small quantities of sucrose can be introduced into the diet because colonic fermentation of ingested sucrose does occur (see section " Lactose Intolerance"). The induction of sucrase-isomaltase activity by means of dietary carbohydrate was reported in one patient, whose enzyme activity increased after a diet high in fructose. [15] This approach has not been used widely. Furthermore, depending on the underlying basic defect, substrate induction of enzyme activity would not be expected to occur. A new approach to the treatment of sucrase-isomaltase deficiency involves the use of enzyme supplements. [43] Exogenous enzyme can compensate to produce adequate sucrose hydrolysis. A randomized, double-blinded, placebo-controlled trial demonstrated lower sucrose breath hydrogen values, decreased stools, and resolution of symptoms after affected patients with sucrase-isomaltase deficiency were treated with sacrosidase (a liquid produced from *Saccharomyces cerevisiae*). [44]

DEFECTS IN INTESTINAL CARBOHYDRATE TRANSPORT

D-Glucose, D-galactose, and D-fructose are the end products of lumenal and membrane digestion of ingested carbohydrates. These two processes occur through the activity of various enzymes that are either secreted into the lumen or inserted into the apical membrane of villus enterocytes as integral proteins. In humans, the major route of entry of hexoses into enterocytes is by brush border membrane carrier systems (Fig. 77-1). Whereas fructose is transported by facilitated diffusion by GLUT5, [45] glucose and galactose influx occurs through an apical Na^+-coupled glucose cotransporter (SGLT1), which is the only Na^+-coupled glucose transporter expressed in enterocytes. Differential expression of the *SGLT1* gene may occur along the crypt-villus axis. [46] This mechanism of coupled transport is an example of secondary active transport. [47] At the basolateral membrane, the two hexoses are transferred from the enterocyte into the circulation down their concentration gradient through a facilitated glucose transporter (GLUT2) that bears no homology with the SGLT family. [48] This basolateral carrier is a member of the gene family (GLUT) encoding the facultative glucose transporters present in erythrocytes, hepatocytes, myocytes, and adipocytes. [49], [50]

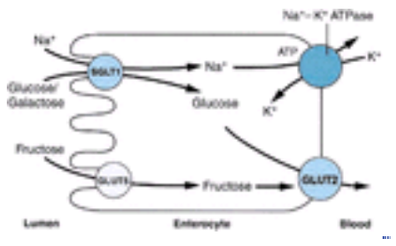

FIGURE 77-1. A model of sugar transport across the enterocyte showing the apical SGLT1 and GLUT5 transporters and the basolateral Na^+/K^+ pumps and sugar transporter GLUT2. (Adapted from ref. [64].)

SGLT1 is a Na^+-dependent cotransporter with a coding sequence of 15 exons distributed along 72 kilobases of DNA localized to chromosome 22q13.1. [51], [52], [53] and [54] The primary protein carrier is a glycosylated integral brush border membrane protein (84 kd) with 14 transmembrane-spanning domains. [55] Specific antibodies raised against extramembranous domains of the rabbit *SGLT1* sequence as well as cDNA probes have been used to identify this protein in a large number of species, indicating that the *SGLT1* DNA and protein sequence are highly conserved throughout evolution. [56], [57] and [58] SGLT1 has been shown to function in the cotransport of 2 Na^+, 1 glucose or galactose, and 200 to 400 water molecules along with urea and glycerol. [59] Through mutational analysis, it has been determined that hexose binding and translocation occur on the C-terminal domain of the protein, whereas Na^+ binding and translocation occur on the N-terminal domain. Expression of *SGLT1* is regulated by both transcriptional and posttranscriptional events. [57], [60]

Glucose-Galactose Malabsorption

The phenotype associated with glucose-galactose malabsorption was first described in the late 1960s. [61] The authors noted an association with consanguineous mating, although 30% of patients with glucose-galactose malabsorption are the result of nonconsanguineous relationships. The disorder is inherited as a autosomal recessive trait and remains rare, with only 200 patients reported worldwide. Glucose-galactose malabsorption is caused by an inability of SGLT1 to absorb hexoses, whereas the digestion of lactose, sucrose, and maltose and the absorption of fructose and xylose occur normally. [46]

Genetics A single missense mutation in the *SGLT1* gene (at position 92) was identified in two sisters carrying the glucose-galactose malabsorption phenotype. [62] Both parents were heterozygotes for the base substitution, pointing to the autosomal recessive mode of inheritance. The protein product revealed an asparagine residue at position 28 instead of aspartate. This report was the first of a genetic disorder correlated with a membrane transport protein mutation, and it definitively established SGLT1 as the principal mediator involved in intestinal glucose transport. More than 20 different types of missense, nonsense, and splice site mutations of *SGLT1* have subsequently been identified in patients with glucose-galactose malabsorption. Most mutations cause either truncated proteins or defects in trafficking between the endoplasmic reticulum to the Golgi complex to the plasma membrane of the enterocyte. [54], [55], [63], [64] and [65] The geographic distribution of reported cases includes regions as varied as Europe (Sweden), North America, Japan, Iraq, Lebanon, Morocco, Syria, Saudi Arabia, and Bangladesh.
Clinical Features Typically, infants carrying the glucose-galactose malabsorption genotype present during the first week of life with profuse watery diarrhea and hyperosmolar dehydration, failure to thrive, abdominal distention, and vomiting. Stool analysis reveals the presence of reducing substances and a low pH. Renal glycosuria has been reported in the absence of hyperglycemia. Symptoms resolve as soon as dietary glucose and galactose are withdrawn and a fructose-based formula is instituted. Cases of glucose-galactose malabsorption diagnosed in adulthood have been reported. [66], [67] The growth and development of children will be normal if symptoms are controlled, demonstrating a direct response to appropriate dietary management and individual tolerance. The most reliable diagnostic test for glucose-galactose malabsorption is the hydrogen breath test. [64] The presence of reducing substances in neonatal diarrheal stools without another cause strongly suggests glucose-galactose malabsorption. If the elimination of dietary glucose and galactose is not accompanied by resolution of symptoms and normal weight gain, however, other causes of carbohydrate malabsorption must be ruled out.
Pathophysiology Glucose-galactose malabsorption is characterized by gastrointestinal losses of electrolytes and fluids. Unabsorbed carbohydrates contribute to an increase in osmotic pressure in the intestinal lumen, with secondary fluid secretion. [68] The transit time is reduced as a result of the increased flow rate. Diarrhea develops because the osmotic load and increased flow rate exceed the colonic capacity for water reabsorption. [69] The fecal osmolality may be reduced in the colon as the colonic flora converts malabsorbed carbohydrates to short-chain fatty acids. [70], [71] These are in turn oxidized by bacteria or absorbed, allowing for some caloric salvage and decrease in the osmotic load as transit progresses distally. [68], [72] In contrast to what occurs in secretory diarrhea (see below), the contribution of electrolytes to stool osmolality is minimal, as revealed by a high osmolal gap. Also, the adaptive changes observed in the colon may explain the variable degree of carbohydrate tolerance observed in adults with glucose-galactose malabsorption. The absorption patterns of these patients are consistent with the selective malabsorption of glucose and galactose in the small intestine secondary to the genetically defective transporter SGLT1.
Treatment As outlined above, the therapeutic response to a fructose-containing formula establishes the diagnosis and subsequent management. It is important to note that oral rehydration solutions, such as Pedialyte, must be avoided during the treatment of acute dehydration because they contain glucose. Galactomine 19 (Nutricia, Zoetermeer, Holland), which is free of glucose and galactose, may be used in the first few months of life; alternatives are the carbohydrate-free formula RCF (Ross Laboratories, Columbus, Ohio) and Product 3232A (Mead Johnson, Evansville, Indiana). Fructose must be added to the formula to increase the calories by 3 kcal/oz per day to an end point of 20 kcal/oz to ensure gastrointestinal tolerance. [73] Compliance usually decreases with age, but gastrointestinal tolerance increases with the introduction of meats, eggs, and fats into the diet. The dietary load of glucose and galactose tolerated symptomatically varies from individual to individual, but malabsorption of both sugars is lifelong. Patients should avoid foods in which the disaccharide or glucose content represents more than 45% of the total carbohydrate, and alternative sweeteners (i.e., honey) should be used. [73] New foods should be introduced every 5 to 7 days to ensure tolerance in children. In most cases, growth and development are normal during childhood, [74] as is adulthood. [66], [67]

DISORDERS OF AMINO ACID ABSORPTION

Amino acid transport defects were described as early as 1889. Epidemiologic studies based on the screening of newborns have shown that the prevalence varies greatly, depending on the populations studied. Cystinuria, in particular, is one of the most commonly inherited disorders; its overall prevalence has been estimated at 1 in 7000 (ranging from 1 in 100,000 in Sweden to 1 in 2000 in England). [75] Most of these defects affect both the renal and intestinal epithelia, but concomitant phenotypic expression may not be seen.

L-Isomers of amino acids, like glucose, are normally absorbed at the brush border membrane through carrier-mediated mechanisms. Accordingly, the influx of peptides into enterocytes is a Na^+-dependent secondary active transport mechanism that carries either single amino acids or oligopeptides (dipeptides, tripeptides). Peptide efflux into the systemic circulation occurs through distinct carrier systems at the basolateral membrane. The hallmark of intestinal and renal amino acid transporters is their multiplicity and overlapping specificities. Certain L-amino acids compete for one specific carrier system. Conversely, neutral amino acids are transported by four different processes with variable specificity.

The clinical relevance of the complexity and interaction of these carrier systems becomes apparent in disease states. It should be emphasized that the final phenotypic expression of each of these defects is largely variable (Table 77-4). The disparity between genotype (identified by urinary excretion patterns and intestinal malabsorption) and clinical phenotype (overt symptoms) has been noted often, particularly since the introduction of newborn screening. Clinical protein malnutrition and essential amino acid deficiency are rare in most of these defects.

DISORDER	SUBSTRATES	CLINICAL ASSOCIATIONS
Hartnup disease	Neutral amino acids	Pellagra-like rash Neuropsychiatric symptoms
Cystinuria	Dibasic amino acids Cystine	Renal calculi Chronic pancreatitis
Lysinuric protein intolerance	Dibasic amino acids	Failure to thrive Growth retardation Hepatosplenomegaly Hyperammonemia
Blue diaper syndrome	Tryptophan	Bluish, discolored diapers Hypercalcemia Nephrocalcinosis
Oasthouse urine disease	Methionine	Mental retardation Seizures
Lowe syndrome	Lysine Arginine	Mental retardation Cataracts Renal failure
Joseph syndrome (iminoglycinuria)	Glycine Proline Hydroxyproline	Aminoaciduria

Data from Freeman HJ, Sleisinger MH, Kim YS. Human protein digestion and absorption: normal mechanisms and protein-energy malnutrition. Clin Gastroenterol 1983;12:357, and Silk DBA. Disorders of nitrogen absorption. Clin Gastroenterol 1982;11:47.

TABLE 77-4 Disorders of Intestinal Amino Acid Transport

Cystinuria

In classical cystinuria (dibasic aminoaciduria), the renal and intestinal lumenal reabsorption of cystine and cationic amino acids (lysine, arginine, ornithine) is decreased. Cystinuria is inherited in an autosomal recessive fashion. The three types of cystinuria are classified according to the amount of cystine present in the urine and plasma after oral loading. [76] In 1993, the gene encoding the transporter for cystine and dibasic amino acids was identified on chromosome 2p21 and was designated *SLC3A1.* Patients with type I cystinuria had various mutations in this gene sequence. [75] The type III cystinuria gene defect has been linked to chromosome 19q13.1. [77] The gene *SLCA9* encodes a b $^{o,+}$ amino acid transporter that is expressed in the kidney, liver, and small intestine. utations have been found in this gene in patients with non–type I cystinuria. [76] The diagnosis is made in patients who excrete more than 250 mg of cystine per gram of creatinine in 24 hours. Urolithiasis is the only clinical manifestation resulting from the excretion of poorly soluble cystine and accounts for 10% of cases of nephrolithiasis in children. The treatment of cystinuria consists of managing stone disease, preventing stone formation with hydration, ingesting sodium bicarbonate to maintain the urinary pH at about 7.5, limiting dietary sodium and methionine, and using sulfhydryl reagents to solubilize cystine. The recognition of several genetic subtypes led to the conclusion that cystinuria is caused by allelic mutations with a complex mode of inheritance. [76]

Lysinuric Protein Intolerance

Lysinuric protein intolerance (familial protein intolerance or hyperdibasic aminoaciduria type II) results from a transport defect at the basolateral membrane of the enterocyte, renal tubular cell, fibroblast, and probably also the hepatocyte. The mode of inheritance is autosomal recessive, and the prevalence is higher in Finland and southern Italy. [78], [79] The influx of peptides into enterocytes is normal, but the transcellular flux is impaired at the level of amino acid efflux into the systemic circulation. The defect affects cationic amino acids (lysine, arginine, ornithine). The diagnosis is established by the detection of high rates of urinary excretion and low plasma concentrations of these amino acids, which accumulate within the enterocyte. The gene causing lysinuric protein intolerance was assigned to chromosome 14q11.2 after linkage analysis of affected patients. [80] Mutational analysis, along with functional oocyte expression models, revealed mutations in the gene *SLC7A7,* which encodes a y+L amino acid transporter-1. [81] These studies have made possible molecular diagnosis, genetic counseling, and prenatal diagnosis. The clinical signs of lysinuric protein intolerance consist of failure to thrive, vomiting, growth retardation, and muscular hypotonia. Hyperammonemia following a protein-containing meal contributes to postprandial nausea and vomiting; secondary protein aversion further contributes to systemic protein deficiency. The pathophysiology of hyperammonemia is incompletely understood, but data point to a defect in the intramitochondrial transport of ornithine. [82] Because patients may limit their protein intake spontaneously, they may remain phenotypically silent. It is worth noting that breast-fed infants typically present later, during weaning or the introduction of other foods, because human milk is relatively low in protein in comparison with commercial formulas. Progressive hepatosplenomegaly and osteoporosis are other prominent features. Late complications, which at times may be the only manifestation of this defect, include alveolar proteinosis and glomerulotubular disease leading to renal failure. Treatment includes a low-protein diet to prevent hyperammonemia (children, 1–1.5 g/kg daily; adults, 0.5–0.7 g/kg daily) but may not always ensure adequate caloric intake, particularly in children. Citrulline supplementation (2.5–8.5 g) normalizes the urea cycle by restoring its pool of intermediates.

Hartnup Disease

Hartnup disease (neutral aminoaciduria and indolic aciduria) is an autosomal recessive disorder. The phenotypic expression results from intestinal and renal wasting of tryptophan. [83] Most subjects in whom neutral hyperaminoaciduria is identified are phenotypically normal; however, clinical symptoms such as a pellagra-like rash, cerebellar ataxia, mental retardation, and psychotic behavior have been reported. [84] The symptoms are caused by an absence of nicotinamide, the metabolized product of tryptophan. The dissociation between genotype and phenotype most likely is a consequence of superimposed polygenic and environmental factors. The diagnosis is established by the detection of an increased amount of urinary neutral amino acids and indican in the absence of intestinal bacterial overgrowth. Treatment with nicotinamide (50–150 mg daily) relieves the skin lesions and any neurological manifestations that are present. A protein-enriched diet also is recommended. [85]

DISORDERS OF ELECTROLYTE AND MINERAL TRANSPORT

See also Chapter 14.

Specific intestinal defects affecting ionic transport have been described for copper (Menkes disease), chloride (congenital chloride diarrhea), and sodium (congenital sodium diarrhea). The two latter present invariably with significant gastrointestinal symptoms. Other selective deficiencies of minerals such as magnesium (familial hypomagnesemia) [86] and zinc (acrodermatitis enteropathica) [87] have been reported as recessively inherited disorders. Sandstrom and associates [88] suggested a cellular defect of zinc metabolism rather than impaired absorption in a patient with acrodermatitis enteropathica. Gastrointestinal symptoms may be present, although extraintestinal signs usually prevail. With the exception of Menkes disease, these deficiencies can be corrected with oral supplementation, which suggests that distinct uptake processes may occur in the intestine.

The pathophysiology of cystic fibrosis is linked to abnormal cyclic AMP–dependent chloride conductance in the apical chloride channel, which leads to disturbances of mucus and electrolyte secretion in the pulmonary and gastrointestinal tract. The electrolyte defect and the clinical features are discussed in Chapter 98.

Menkes (Steely Hair) Disease

Copper is an essential nutrient for eukaryotes and prokaryotes, [89], [90] being an integral component of a multitude of key enzymes. [91] It is thus not surprising that a primary defect of copper transport, such as occurs in Menkes disease, leads to a fatal clinical picture involving a multitude of organs if copper is not provided. [92] As the molecular genetics of Menkes disease have been increasingly refined, however, it has become clear that the same gene is involved in clinically milder forms, such as occipital horn syndrome.

Genetics Menkes disease is a genetically transmitted, X-linked disorder that is the result of defective copper homeostasis. The incidence of Menkes disease has been estimated at between 1 in 100,000 and 1 in 250,000, with an estimated 15 to 35 patients affected in the United States per year. [93] The gene for Menkes disease was isolated in 1993 by positional cloning within Xq13 in an affected female subject bearing a balanced t(X;2) translocation. [94], [95] and [96] The gene product was found to be a transmembrane P-type adenosine triphosphatase (ATPase7A). [95] More than 150 different mutations that lead to Menkes disease have been identified in the ATPase7A gene, and it appears that distinct splice sites underlie the various phenotypes, which range from the lethal form to a milder form called *occipital horn syndrome*. [97], [98]

Clinical Features The clinical features of Menkes disease are summarized in Table 77-5. Affected patients are usually in good health for the first 8 to 10 weeks of life. At 2 to 3 months of age, typical signs include loss of previously acquired milestones, hypotonia, and seizures, along with the scalp hair characteristics. Of note, affected infants may present with vomiting, diarrhea, and failure to thrive, with or without a protein-losing enteropathy. The long-term prognosis is poor because

cerebral degeneration persists despite copper supplementation; death usually occurs during childhood.

	NEONATAL PERIOD	INFANCY TO EARLY CHILDHOOD
Prematurity	+	
Hypothermia	+	+/-
Hyperbilirubinemia	+	
Growth retardation		+
Abnormal facies	+/-	
Depigmentation (skin, hair)		+
Trichorrhexis, monilethrix	+/-	+
Pili torti		+
Developmental delay/neurodegeneration (seizures, ataxia)		+
Vascular complications		+
Osteoporosis		+
Death		+

TABLE 77-5 Clinical Features of Menkes Disease According to Age

The diagnosis is clinical, although confirmation can be sought by measuring serum levels of copper and ceruloplasmin. During the newborn period, a plasma catecholamine analysis and measurement of the placental copper concentration are more reliable tests to make the diagnosis. [93] Copper in the intestinal mucosa and liver and in cell cultures should be measured if the diagnosis remains uncertain (particularly in the milder forms). Cell cultures reveal intracellular copper accumulation resulting from defective transport and cellular copper toxicity. [99], [100]

Pathophysiology Dietary copper is normally absorbed in the stomach and small intestine. Within the enterocyte, high-affinity copper transporters (hCTR1) transport copper into the cell. Copper is then transported to the trans-Golgi network and delivered by ATPase7A into the secretory pathway. The secretory pathway involves the production of copper-dependent enzymes such as lysyl oxidase, dopamine ß-hydroxylase, and tyrosinase. [101] When cellular copper concentrations increase, ATPase7A relocalizes to the plasma membrane and functions to transport copper out of the cell by the efflux pathway. [101] In Menkes disease, abnormality or absence of ATPase7A prevents the function of both these pathways. Copper is trapped at the intestinal level, resulting in severe deficiency at the tissue level. Impaired function of key enzymes ensues, leading to the observed clinical features (see Table 77-5).

Treatment Therapy includes parenteral copper histidine supplementation (up to 600 ng/kg weekly), although it does not appear to arrest cerebral degeneration. [102] Copper adducts are needed that cross the blood-brain barrier and might restore brain copper levels toward normal; these are not currently available. It has been suggested that the neuropathology is of early onset, linked to prenatal copper deficiency during the critical period of central nervous system development. [103] These findings are corroborated by the fact that copper deficiency secondary to malnutrition [104] is not usually associated with neurological complications.

Congenital Chloride Diarrhea

In 1945, two infants presented with severe diarrhea during the newborn period. Their feces was characterized by a high chloride content, hence the term *congenital chloride diarrhea*. Since then, nearly 100 cases have been described. [105], [106] A high proportion of cases have been reported from Finland, Poland, Saudi Arabia, and Kuwait; however, the distribution is worldwide. [107]

Genetics Congenital chloride diarrhea is inherited as an autosomal recessive trait, with a high prevalence found in the children of consanguineous relationships. By genetic linkage in Finnish families, the gene was localized to chromosome 7q31, proximal to the cystic fibrosis transmembrane regulator (CFTR). [108], [109] A candidate gene known as *DRA* ("down-regulated in adenoma") because of its reduced expression in colonic adenoma was identified in this position. The product of this gene is expressed in the brush border of normal ileum and colonic epithelial cells. [108] In a *Xenopus* expression model, *DRA* encodes a transporter with properties of Cl^-/OH^- exchange. [110] Twenty different mutations of the *DRA* gene have been identified in patients with congenital chloride diarrhea. [108]

Clinical Features One of the pathognomonic features of congenital chloride diarrhea is the fetal onset of diarrhea, evidenced by the development of maternal polyhydramnios. [106], [111] Other clinical features may include prematurity, absence of meconium, hyperbilirubinemia, abdominal distention, and failure to thrive. Radiographic studies of newborns reveal fluid-filled intestinal loops with or without ascites, again pointing to an intrauterine onset of the disease. If these early signs are absent, the diagnosis should be strongly suspected in any neonate in whom profuse watery diarrhea develops that is unresponsive to fasting and is often mistaken for urine. Without treatment, life-threatening dehydration and electrolyte imbalance may ensue as a result of persistent osmotic diarrhea. Fecal electrolyte analysis reveals an elevated chloride content (>90 mmol/L), a negative anion gap ($Na^+ + K^+ < Cl^-$), and a low fecal pH. The serum electrolyte levels and acid-base status may reveal hyponatremia and hypochloremia in the newborn period, although isosmolal dehydration is common; metabolic acidosis also has been reported. Metabolic alkalosis and hypokalemia develop progressively as a result of both intestinal and renal abnormalities. [111], [112] Not uncommonly, the condition is diagnosed in early infancy or early childhood if affected children survive the newborn period. They often carry another diagnosis related to their prevailing symptoms. [106], [111], [113] If congenital chloride diarrhea is diagnosed early and treated appropriately, adult patients are healthy but require lifelong supplements because of continued diarrhea (1.5–2 L/24 h). [112] The development of renal disease (i.e., hypertensive arteriopathy, juxtaglomerular hyperplasia, glomerular hyalinosis) has been described in a group of patients whose diagnosis and treatment were delayed or whose therapy consisted solely of potassium chloride supplements without sodium replacement. [114], [115]

Pathophysiology Intestinal perfusion studies [116], [117] have revealed a single defect in ileal and colonic sodium/hydrogen exchange. In subjects with congenital chloride diarrhea, the active exchange of anions (Cl^-/HCO_3^-) is absent, whereas cation exchange (Na^+/H^+) occurs normally. From the dietary NaCl delivered to the small intestine, Na^+ is absorbed in exchange for H^+ (equivalent of $Na^+HCO_3^-$ reabsorption) and excreted in the urine either as $Na^+HCO_3^-$ or with an organic anion (high urinary anion gap and pH). [106], [118] Chloride influx, however, in exchange for HCO_3^- does not occur; chloride-rich, acidic fecal fluid is excreted, the volume of which correlates with the osmotic load. [112] It is important to note that chloride influx takes place in patients with congenital chloride diarrhea by distinct pathways, most likely passive as revealed by all perfusion studies. [116], [117], [118] and [119] Strictly speaking, chloride is not actively secreted. Overall, affected subjects are unable to maintain a positive chloride balance in view of the daily obligate losses (intestinal and extraintestinal). Metabolic alkalosis is maintained by a combination of renal mechanisms; hypovolemia-induced aldosterone secretion promotes renal reabsorption of $NaHCO_3$ in the proximal tubule [120] and K^+ excretion in the cortical collecting duct, particularly in light of bicarbonaturia, [121], [122] leading to excessive K^+ losses. More importantly, hypokalemia itself stimulates renal bicarbonate sparing, as shown in micropuncture studies of euvolemic rats, thus contributing to persistent alkalosis. [120]

Treatment The mainstay of therapy is adequate replacement of Na^+, K^+, and Cl^-. [106] This implies that other mechanisms of intestinal chloride reabsorption (possibly passive) must be effective to render the defect compatible with life, [116] further allowing enteral electrolyte supplementation. As noted, NaCl replacement alone is not appropriate because hypokalemia contributes to the maintenance of metabolic alkalosis. Multiple drugs have been tried without success. [118] A report described a beneficial effect of omeprazole, [118] with reduction of stool frequency and volume. The authors proposed that inhibition of gastric chloride secretion (i.e., HCl) allowed a reduction of distally unabsorbed chloride. Indeed, fecal Na^+ and Cl^- losses decreased significantly, as did renal K^+ excretion in light of a drop in the bicarbonaturia, the latter most likely reflecting the decrease in gastric HCl loss; however, KCl supplementation had to be maintained to avoid hypokalemia. Of note, fecal K^+ losses decreased proportionally less than Na^+ and Cl^- losses during omeprazole therapy.

Differential Diagnosis The hallmarks of secretory diarrhea are twofold. First, Na^+, K^+, and their accompanying anions account for most osmoles excreted in the feces; the osmotic gap is thus small. Second, stool volume generally does not diminish with fasting. The differential diagnosis of secretory diarrhea is extensive, and the reader is referred to Chapter 42. One defect that is indistinguishable on clinical grounds from congenital chloride diarrhea is congenital sodium diarrhea.

Congenital Sodium Diarrhea

In four reports, neonatal watery diarrhea was ascribed to a defect of Na^+ reabsorption in the small intestine. [123], [124], [125] and [126] The clinical presentation was similar to that of congenital chloride diarrhea. In all three cases, the prenatal onset of watery diarrhea led to polyhydramnios, neonatal abdominal distention, and lack of meconium. A number of patients had choanal atresia, which has been associated with congenital secretory diarrhea. [126] In contrast to the infants with congenital chloride diarrhea, these infants had hyponatremia and metabolic acidosis. The fecal chloride was significantly lower than in congenital chloride diarrhea, the fecal Na^+ was high (100–200 mmol/L), the anion gap was positive (fecal $Na^+ + K^+ > Cl^-$), and the fecal pH was high. In brush border membrane vesicles obtained from their patient, Fell and colleagues [125] demonstrated a defect in the jejunal Na^+/H^+ exchange mechanism. Of interest, several Na^+/H^+ exchanger isoforms have been cloned to date, [127], [128] in particular NHE-3, which appears to be an epithelial brush border exchanger confined to the intestine and kidney. However, multifocal linkage analysis of patients excludes NHE-1, -2, -3, and -5 as potential genes for congenital sodium diarrhea based on their chromosomal location. [126] Therapy includes Na^+

and K^+ supplementation in the form of bicarbonate or citrate salts.

PRIMARY BILE ACID MALABSORPTION

Thaysen and Pedersen [129], [130] were the first to coin the term *idiopathic bile acid malabsorption* in their report of patients with chronic diarrhea of unknown cause who had concomitant fecal bile acid wasting. Several reports confirmed abnormal bile acid absorption in a number of patients with long-standing idiopathic diarrhea, [131], [132] and [133] as assessed by the elimination of 23-seleno-25-homotaurocholic acid (SeHCAT), a gamma-emitting synthetic analog of taurocholic acid. [134], [135] Bile acid malabsorption in general is associated with increases in intestinal fluid loss as the spillover of dihydroxy bile acids (i.e., chenodeoxycholic acid and deoxycholic acid) from the ileum into the colon leads to cyclic AMP–mediated sodium secretion. [136], [137] and [138] Interestingly, in some studies, numerous affected patients carried the diagnosis of functional diarrhea or irritable bowel syndrome before their bile acid absorption was evaluated, and their symptoms resolved after the administration of cholestyramine. The fact that some patients do not respond to cholestyramine [133] would indicate that another pathophysiological process is involved in the development of diarrhea with secondary bile acid malabsorption. Accordingly, some reported cases did have altered intestinal transit times, [131] although it is unclear whether these times were a cause or an effect of bile acid malabsorption. Analysis of the bile acid composition revealed normal concentrations of dihydroxycholic acids in the duodenal fluid of patients with bile acid malabsorption in comparison with controls. [139] Bile acid malabsorption has been classified into three distinct types. [138], [140] Type I is secondary to ileopathy or ileal resection; type II is an idiopathic entity with normal histological findings; type III occurs in association with a variety of other gastrointestinal disorders, such as chronic pancreatitis, cholecystectomy, and diabetes mellitus, and after peptic ulcer surgery. [131], [138], [141]

Pathophysiology

The absorption of bile acids in the small intestine is a highly efficient process whereby more than 95% of the bile acid pool secreted into the gastrointestinal tract is conserved. The major site of the intestinal conservation of bile acids is the terminal ileum. [142] The mechanisms participating in the enterohepatic recirculation of bile acids include both active and passive processes, the latter involving simple diffusion and possibly a facilitated, protein-mediated, Na^+-independent uptake process. [143] A specific Na^+-dependent transporter has been characterized in rabbit ileal enterocytes, [144] and membrane bile acid–binding polypeptides have been identified in rats. [145], [146] and [147] When transport rates of both conjugated and unconjugated bile acids in the jejunum and ileum were compared in intestinal perfusion studies performed in rabbits as well as in brush border membrane vesicles, the active Na^+-dependent uptake of conjugated bile acids was confined to the ileum. [148] Passive diffusion, although it occurs in both jejunum and ileum, appeared to be greater in the ileum in light of decreased membrane fluidity and a higher cholesterol-to-phospholipid ratio at that level. These membrane properties would contribute to the prevention of Na^+ backward flux in a segment containing multiple other Na^+-dependent transport mechanisms, which emphasizes the highly specialized functional character of the ileum in intestinal absorption processes. Data indicate that homeostasis of the circulating bile acid pool is achieved not only at the level of bile acid synthesis in the liver but also at the level of intestinal conservation. Following expression cloning of the sodium-dependent bile acid transporter of the rat liver basolateral membrane [149] and the hamster ileum brush border, [150] a 48-kd glycoprotein was demonstrated and expressed at the brush border membrane of the ileal villus enterocyte [151] that was highly homologous to the ileal hamster transporter. [150] The developmental regulation of this transporter appears to be mostly transcriptional at the time of weaning, with marked increases in mRNA and protein levels, similar to those of other brush border enzymes. [152] These data corroborate the results of earlier studies of the ontogeny of ileal bile acid transport in brush border membrane vesicles whereby carrier-mediated bile acid transport was absent at birth, only to appear abruptly in the early weaning period. [153] The expression of ileal bile acid transport appears to be initiated in part by the presence of lumenal substrate because expression of ileal bile acid transport can be induced with bile acid feedings during the suckling period. [151]

Considering the growing body of molecular data on ileal bile acid uptake, the hypothesis of a defect in the ileal sodium-dependent transporter as a cause of chronic diarrhea becomes more plausible, particularly if the onset is early in life. The human ileal Na^+/bile acid cotransporter gene (*SLC10A2*) was cloned and used for single-stranded conformational polymorphism analysis to find possible causative mutations in a family with primary bile acid malabsorption. Mutations were identified and shown to inhibit bile acid transporter function in transfected COS cells. [154] This report linked a mutation in a bile acid transporter to primary bile acid malabsorption. However, it did not explain adult-onset idiopathic bile acid malabsorption.

Clinical Features

Typically, patients present with a history of long-standing, at times intermittent, watery diarrhea and increased stool volume. Abnormal secretion of mucus, as well as increased colonic motility with urgency, may be caused by the presence of lumenal bile acids. Abdominal cramping usually resolves with defecation, and occasionally irritable bowel syndrome is diagnosed. As mentioned, bile acid malabsorption can be documented by using ^{75}SeHCAT to measure either fecal radioactivity or retained abdominal radioactivity. Increased levels of serum 7-a-hydroxy-4-cholesten-3-one were positively correlated with an abnormal ^{75}SeHCAT pattern in 19 of 23 patients studied. [155] The diagnosis of primary bile acid malabsorption remains one of exclusion; an increase in fecal bile acids in itself, even in the absence of other findings, does not imply a decrease in ileal uptake. [140] Similarly, a positive response to cholestyramine does not confirm that bile acid malabsorption is the primary defect; at most, it points to the fact that increased intralumenal bile acids may be contributing to the patient's symptoms. However, symptoms commonly recur without therapy.

DISORDERS OF LIPID MALABSORPTION

The assimilation of dietary fat is a complex process in which the enterocyte plays a pivotal role. Following digestion, solubilized fatty acids and monoglycerides are taken up by the enterocyte and rearranged into apolipoprotein-containing particles necessary for their transfer into the systemic circulation. A defect in the formation of these particles impairs the assimilation of dietary fats and leads to severe deficiencies, as is the case in abetalipoproteinemia.

Abetalipoproteinemia

Abetalipoproteinemia is an autosomal recessive disease characterized by the virtual absence of apolipoprotein B (apo B) and apo B–containing lipoproteins in the plasma of affected subjects. Triglycerides accumulate in the cytoplasm of hepatocytes and enterocytes secondary to abolished secretion.

Genetics Since abetalipoproteinemia was first reported in 1950, fewer than 100 cases have been reported with the abetalipoproteinemia phenotype. The pedigrees described show a recessive mode of inheritance, and some reports have suggested that consanguinity is as high as 50% in affected families. The phenotype is linked to a defect in the microsomal triglyceride transfer protein (MTTP), a neutral lipid transfer heterodimeric enzyme that includes a protein disulfide-isomerase (PDI) and a 97-kd subunit. The relationship between apo B and MTTP is discussed below. The human gene encoding the 97-kd subunit of MTTP has been cloned and sequenced [156], [157], [165], [166] and localized to chromosome 4q22-24. [158] Genetic studies were undertaken in subjects carrying the abetalipoproteinemia phenotype. [159], [160] All were carriers of a homozygous or compound heterozygous mutation of both alleles. Most subjects demonstrated a truncated form of the MTTP large subunit (97 kd) that impeded its interaction with PDI and rendered the complex nonfunctional in its role of shuttling lipids between membranes of the endoplasmic reticulum. [161]
Pathophysiology The major lipids found in tissues and cells, triglycerides and cholesteryl esters, are secreted into the extracellular fluid in particles in association with the large hydrophobic protein apo B, which is the product of a single gene and occurs in two distinct forms, apo B-48 (264 kd) and apo B-100 (550 kd). The former is essential for chylomicron formation in enterocytes, in which dietary free fatty acids and cholesterol are esterified to triglycerides and cholesteryl esters, respectively. These esters are incorporated into apo B–containing particles (chylomicrons) before they are transferred into the extracellular space. A similar process occurs in hepatocytes, in which apo B-100 is secreted in association with triglycerides to form very-low-density lipoproteins (VLDLs), lipid (triglyceride)–rich particles exporting long-chain fatty acids synthesized in the liver. Apo B is also the major protein component of low-density lipoprotein (LDL) particles carrying cholesteryl esters to peripheral tissues by means of LDL receptors. [162] Apo B, which contains insufficient quantities of lipids that enhance its stability within these particle structures, undergoes intracellular degradation by binding to heat shock protein 70, which disposes of misfolded proteins by the ubiquitin-proteosome pathway, in keeping with the findings that its secretion is regulated posttranscriptionally. [163] The binding of heat shock protein 70 to apo B is increased in cells depleted of lipids to regulate the amount of lipoprotein formed. [163] The discovery that abetalipoproteinemia is not the result of defective apo B synthesis, [164], [165] and [166] as initially contended, and that no genetic linkage exists between the disorder and the apo B gene [167] has not only allowed a basic understanding of the defect but also has shed new light on the mechanisms of triglyceride-rich particle assembly. Wetterau and colleagues [156], [168], [169] first isolated and characterized MTTP, a protein complex, from microsomal membranes of bovine liver. MTTP is a heterodimeric enzyme composed of PDI, a ubiquitous multifunctional resident endoplasmic reticulum protein, and a unique 97-kd subunit that confers lipid transfer activity to the complex. Studies in subjects with abetalipoproteinemia have shown that the assembly of apo B–containing lipoproteins is defective as a result of a nonfunctional MTTP. [156], [170], [171] The process whereby lipids are transferred to apo B, allowing apo B to form a

secretion competent particle, is thus abolished. Accordingly, the concomitant expression of MTTP and apo B in CO8-1 cells and HeLa cells is sufficient to mediate the secretion of triglyceride-rich lipoproteins. [172], [173] Furthermore, mRNAs for apo B and apo B protein are present in the intestinal mucosa and liver of affected subjects. [174], [175] The exact relationship between MTTP structure and its function in apo B lipidation has been only partly elucidated. Data extracted from studies of lipid-binding sites on MTTP [176] and from studies of the regulation of expression by dietary fat content [177] point to distinct mechanisms leading to particle assembly. MTTP functions in the initial transfer of lipids from the endoplasmic reticulum during apolipoprotein translation and translocation into the rough endoplasmic reticulum. After translocation, apo B is initially folded into a compact globular structure of a-helices supported by disulfide bonds. The subsequent amphipathic ß-sheet domain of apo B binds lipid that is transferred by MTTP. [163] This forms a framework for the lipoprotein molecule that would otherwise misfold and be degraded though interaction with heat shock protein 70. The particle then fuses to triglyceride droplets at the junction of the rough and smooth endoplasmic reticulum to form mature chylomicrons and VLDL. [163] Further involvement of MTTP in the formation of chylomicrons and VLDL remains to be elucidated. Abetalipoproteinemia may not be the only phenotype caused by a defect in the MTTP gene.

Clinical Features The clinical expression of this disorder depends on the age at onset. Symptoms of malabsorption and failure to thrive secondary to steatorrhea are the hallmarks of early onset in infancy and childhood. [178] Poor growth may precede overt gastrointestinal symptoms, and affected children are frequently thought to have celiac disease. The steatorrhea may diminish with time if dietary fat is avoided. [178] In addition, polyunsaturated fats appear to be better tolerated than saturated fats. If the disease is unrecognized as patients enter their second and third decades of life, neurological and ophthalmic symptoms become apparent, along with their progressively debilitating effects. [178] Spinocerebellar axonal degeneration and pigmented retinopathy result from a chronic deficiency of fat-soluble vitamins E and A, respectively, mimicking Friedreich ataxia. Clinically, early signs include the loss of deep tendon reflexes, followed by a decrease in proprioceptive and vibratory senses in the lower extremities. Cerebellar signs, such as sensory ataxia (Romberg sign), dysmetria, and spastic gait, ensue. Typically, these central nervous system abnormalities are devastating and lethal. A sensory peripheral neuropathy also has been described that is a result of the degeneration and demyelination f large nerve fibers. Ophthalmic symptoms of retinitis pigmentosa (night and color blindness) develop first. Nystagmus and ophthalmoplegia are frequent. Progression to macular involvement in untreated patients leads to blindness, usually in the fourth decade of life. The diagnosis of abetalipoproteinemia is based on hematologic, biochemical, and histopathological findings, the last of which depend on which organs are involved. Hematologically, mild to moderate anemia results from chronic hemolysis. Severe vitamin E deficiency causes autohemolysis. The presence of predominantly spiculated acanthocytes within the red blood cell population (50%–70%) further contributes to the anemia. Their abnormal membrane lipid composition shortens the life span of erythrocytes. Vitamin K deficiency may increase the prothrombin time. The biochemical hallmark in affected patients reflects the lack of lipoprotein secretion by enterocytes. Plasma lipid and lipoprotein profiles include hypocholesterolemia (0.5–1.30 mmol/mL), low triglyceride levels, and virtually undetectable levels of chylomicrons (including postprandially), VLDLs, LDLs, and apo B. Plasma levels of vitamin A and both plasma and tissue levels of vitamin E are significantly decreased. [178] Histopathology of the gastrointestinal tract reveals normal villi, distinguishing the condition from celiac disease, but enterocytes are lipid laden. Their cytoplasm contains free lipid droplets, whereas the Golgi apparatus is devoid of lipoprotein-containing particles. Elevation of hepatic enzymes and hepatic steatosis have been observed but are extremely rare. Other clinical abnormalities have been described in isolated cases, such as aminoaciduria, hypogammaglobulinemia, and physical anomalies of digits, but it is unclear whether these findings are related to abetalipoproteinemia.

Treatment Restriction of fats, in particular long-chain fatty acids, alleviates the gastrointestinal symptoms. Medium-chain fatty acids may be used temporarily if severe malnutrition is present, but their routine use should be avoided because they can worsen hepatic steatosis. [179] Appropriate vitamin supplementation must be the basis of therapy because the inability to form chylomicrons leads to a deficiency of fat-soluble vitamins. [179] Vitamin E supplementation is beneficial in both preventing and potentially reversing the neurological and ophthalmic features of the disease. [180] Because it is one of the most nonpolar lipids known, the assimilation of vitamin E is affected not only by decreased intestinal absorption but also by the absence of LDL and VLDL particles involved in its hepatic secretion and systemic transport, respectively. [181] These negative effects can be overcome by administering large doses of vitamin E (100–200 mg/kg daily) polyethylene glycol 1000 succinate (Liqui-E). [180] Monitoring the plasma levels of vitamin E alone is unreliable, but quantification of the vitamin E levels in adipose tissue does reflect the vitamin E status of these patients; however, this method is not practical for routine clinical use. The hydrogen peroxide hemolysis test does serve as a good screening test for increased vitamin E stores. [180] When the total serum lipids are reduced, the ratio of vitamin E to total lipids is not a reliable measure of the vitamin E status. [180] Clinically, improvement in tissue vitamin E levels may be reflected in improved visual or somatosensory evoked responses. Vitamin A (200–400 IU/kg per day or 25,000 IU daily or every other day) and vitamin K (5–10 mg/d) are given in their water-miscible forms (Aquasol A and Mephyton, respectively) to normalize the levels of vitamin A in plasma as well as the prothrombin time. Disorders of lipid metabolism that may clinically mimic abetalipoproteinemia include chylomicron retention disease (Anderson disease), caused by the inability of enterocytes to secrete chylomicrons, and familial hypobetalipoproteinemia, caused by truncations of apo B. The homozygous form of familial codominant hypobetalipoproteinemia is clinically and biochemically indistinguishable from homozygous recessive abetalipoproteinemia. Anderson disease also may present in early childhood with severe steatorrhea and growth failure [182]; in contrast to the fasting triglyceride levels in the two former disorders, however, the fasting triglycerides in Anderson disease are normal. The exact defect is not known; apo B-48 is present in enterocytes, which are filled with fat, but not in plasma, suggesting that a defect may be present at several steps involving lipidation, translocation, or secretion of apo B-48 (see Chapter 18).

DEFECTS IN INTESTINAL COBALAMIN ABSORPTION

The intestinal absorption of cobalamin (vitamin B_{12}) occurs in the ileum and is receptor mediated. [183] Dietary cobalamin undergoes proteolytic release from food sources and then is complexed with haptocorrin in the presence of a low gastric pH. Exposure of this complex to pancreatic proteases permits the release of cobalamin and its binding to intrinsic factor (IF), which is synthesized in the gastric parietal cells. These initial steps require intact gastric function for acid secretion, proteolytic activity, and IF secretion. Only IF-bound cobalamin binds to the ileal receptor, allowing endocytosis of the complex. Other ligands for cobalamin include transcobalamins I, II, and III (TCI, TCII, and TCIII). TCII, which is synthesized in most tissues as well as in the ileal mucosa, is required for the uptake of cobalamin into tissues. It is thought that after internalization of the IF-cobalamin complex bound to its ileal receptor, cobalamin is transferred intracellularly from IF to TCII. This secondary complex then enters the systemic circulation. Cobalamin also may be transported systemically bound to TCI and TCIII, which are circulating haptocorrins in the plasma. Their precise role in the homeostasis of cobalamin is not known, but they are cleared by the liver, and the cobalamin is secreted in the bile as one arm of an enterohepatic circulation.

Congenital defects affecting intestinal vitamin B_{12} uptake include congenital IF deficiency (congenital pernicious anemia) and congenital vitamin B_{12} malabsorption resulting from an ileal defect (Imerslünd-Grasbeck syndrome). TCII deficiency affects cellular uptake and is unique in that serum levels of cobalamin are normal. TCI (R binder) deficiency also has been described. [184], [185] Clinical signs are absent despite low levels of serum cobalamin, and affected subjects do not require vitamin B_{12} supplementation. Addisonian pernicious anemia, in contrast to congenital pernicious anemia, presents in adulthood and is characterized by the presence of anti-IF antibodies (types I and II), antiparietal cell antibodies, atrophic gastritis, and achlorhydria (Table 77-6).

TABLE 77-6 Vitamin B_{12} Malabsorption Syndromes

Pathophysiology

The biochemical abnormalities associated with the disorders of cobalamin deficiency reflect dysfunction of the cobalamin coenzymes adenosylcobalamin and methylcobalamin, which are involved in the synthesis of succinyl-CoA from L-methylmalonyl-CoA and methionine from homocysteine, respectively. Hence, methylmalonic aciduria, homocystinuria, or both have been observed in cobalamin-deficient patients. The clinical manifestations, of which megaloblastic anemia is the hallmark, result from disruption of the folate cycle, which depends on the conversion of homocysteine to methionine by methylation; this, in turn, allows the regeneration of tetrahydrofolate. The accumulation of methyltetrahydrofolate ensues, leading to functional folate deficiency. It has been suggested that the neurological effects of cobalamin deficiency may be secondary to demethylation of myelin basic protein. [186]

Congenital Pernicious Anemia

A juvenile form of pernicious anemia has been reported in a number of children presenting with megaloblastic anemia and developmental delay. [187] The age at onset

is typically between 1 and 5 years. The delay in the clinical expression of vitamin B_{12} deficiency compared with TCII deficiency generally is explained by replete body stores in early infancy. These depend on maternal vitamin B_{12} stores. Because the transplacental transfer of cobalamin to the fetus occurs in the third trimester, infants who received inadequate vitamin B_{12} in utero express clinical symptoms earlier. In humans, IF has been detected in fetal gastric extracts from 11 weeks onward [188] in the corpus and pylorus. Solubilized IF receptor (IFR) activity has been found in both small intestine and colon between 10 and 25 weeks' gestation but only in ileum thereafter. The exact mechanism of this proximal-to-distal gradient of IFR expression requires further elucidation. From a functional point of view, the early expression of all components of the vitamin B_{12} entry pathway demonstrates the potential for uptake of the receptor-IF-B_{12} complex during fetal life. [188]

Congenital pernicious anemia differs from the ileal defect syndrome (see below) by the absence of functional IF. IF may be immunologically undetectable because of decreased synthesis, [184] or it may be present but nonfunctional. [189] Reports of nonfunctional IF have included a low affinity of IF for either cobalamin or the ileal receptor. In addition, Levine and colleagues [190] described three siblings who presented in their second year of life with megaloblastic anemia and abnormal Schilling test results (<1%), corrected with exogenous IF. The native IF demonstrated increased susceptibility to gastric acid and proteolysis, with loss of its normal structure and function. A cDNA for IF in both rats and humans has been cloned, [191], [192] and the IF gene has been localized to chromosome 11. [192] Nevertheless, the genetic defect, which is inherited in an autosomal recessive manner, remains unidentified to date. Southern blot analysis of native DNA from probands did not reveal a major gene mutation, suggesting altered gene expression or a possible point mutation. Therapy consists of the parenteral administration of cobalamin (OH-cobalamin, CN-cobalamin) to bypass gastric and ileal factors [193] and to achieve resolution of all clinical abnormalities. [183]

Ileal Defect Syndrome (Imerslünd-Grasbeck Syndrome)

Grasbeck and associates [194] and Imerslünd [195] independently described a syndrome consistent with an autosomal recessive selective malabsorption of vitamin B_{12}. Children present after the first year of life with hematologic abnormalities, infection, and failure to thrive, as in congenital pernicious anemia, with the exception that the Schilling test result cannot be corrected by the administration of IF. The activity of the urinary receptor for the IF-cobalamin complex is more than 600 times lower in affected patients than in controls, and this has been suggested as a diagnostic test for Imerslünd-Grasbeck syndrome. [196] Proteinuria that is not associated with progressive renal failure and does not correct with treatment is also part of the phenotype specific to this syndrome. [197] The defect occurs in the transport mechanism of the IF-cobalamin complex at the level of the ileal enterocyte. The study of various probands has shown that the defect affects either receptor binding [198] or postbinding processing in the cell. Deficient cobalamin-IFR activity has been demonstrated in the ileal biopsy specimens of patients with Imerslünd-Grasbeck syndrome. [199] However, in one report of two sisters with Imerslünd-Grasbeck syndrome, [200] the affected patients showed significantly greater receptor activity than controls, with undetectable protein on immunoblotting of total biopsy membrane preparations. The investigators hypothesized that the patients overexpressed an unstable receptor. An explanation of these seemingly contradictory results requires further investigation of individuals affected with the disorder. [201] Linkage studies have been used to assign the location of the disorder to chromosome 10. Within this locus, the human cubilin gene encodes a protein that has IF-cobalamin activity with megalin, another protein. [202], [203] However, the nature of this interaction has not been discovered. As in IF deficiency, the exact genetic defect is not known, and the parenteral administration of cobalamin leads to resolution of the symptoms.

Transcobalamin II Deficiency

Three forms of TCII deficiency have been described with the following characteristics: (1) absence of TCII from the plasma (the most common phenotype); (2) presence of immunoreactive TCII that is unable to bind cobalamin 1; and (3) immunoreactive TCII that is unable to promote the uptake of cobalamin 1 into cells. An absence or abnormality of TCII impairs the TCII-dependent tissue uptake of cobalamin. Intestinal absorption is usually normal, as are serum levels of cobalamin bound to TCI and other haptocorrins. [204] Hakami and colleagues [205] reported low intestinal absorption despite exogenous IF in two siblings with neonatal megaloblastic anemia and TCII deficiency. In contrast to patients with congenital IF deficiency, patients are normal at birth but present shortly thereafter. The genetic defect that causes TCII deficiency remains to be fully described. Patients with TCII deficiency have been shown to have various mutations within the coding region of the gene for TCII. [206] The 5' promoter for TCII contains regulatory elements that may also play a role in its expression in vivo. [207] Symptoms of TCII deficiency include vomiting, diarrhea, and hypotonia in the first few weeks or months of life associated with megaloblastic anemia and failure to thrive; subsequently, immunologic and neurological abnormalities develop. [208] The administration of large doses of parenteral vitamin B_{12} is the treatment of choice to achieve passive diffusion of the vitamin into cells.

CHAPTER 78

Ellen Li

BACTERIAL OVERGROWTH

Bacterial overgrowth of the small bowel is a syndrome in which nutrient malabsorption is associated with excessive numbers of bacteria in the small intestine. [1], [2] Other terms that have been used to describe the syndrome of bacterial overgrowth are *blind loop syndrome, contaminated small bowel, small bowel stasis,* and *stagnant loop syndrome*. Recognition dates back to 1897, when Faber [3] reported an association between pernicious anemia and strictures of the small intestine. In 1939, Barker and Hummel [4] first postulated that the association of macrocytic anemia with intestinal strictures or anastomoses is the result of bacterial overgrowth, or "putrefaction." Patients with a variety of structural or functional disorders of the gastrointestinal tract are predisposed to the development of bacterial overgrowth. [1], [2] Evidence suggests that bacterial overgrowth may develop in the absence of an anatomic lesion or a severe motility disorder in the elderly and in children. [5], [6] Bacterial overgrowth should be considered as a possible cause of diarrhea, malabsorption, or abdominal pain in these clinical settings. Because the diagnosis of bacterial overgrowth presents several difficulties and limitations, empiric treatment often is used in clinical practice.

CONDITIONS FAVORING BACTERIAL OVERGROWTH

The conditions favoring bacterial overgrowth can be classified according to the mechanisms involved in the normal control of the enteric flora (Table 78-1). Furthermore, the presence of a single condition may not result in clinically significant small intestinal overgrowth until another condition favoring bacterial overgrowth develops.

Intestinal Stasis
Anatomic
Strictures (e.g., Crohn's disease, radiation enteritis)
Diverticulosis of the small intestine
Surgical operations
End-to-side enteroenteric anastomoses
Billroth II anastomoses
Jejunoileal bypass
Koch distal ileal pouches
Small intestinal motility disorders
Scleroderma
Idiopathic intestinal pseudoobstruction
Diabetic autonomic neuropathy
Abnormal Connection between Proximal and Distal Bowel
Fistulae (secondary to peptic ulcer disease, carcinoma)
Gastrocolic
Gastrojejunocolic
Resection of the ileocecal valve
Hypochlorhydria
Chronic atrophic gastritis
Hypochlorhydric medications
Surgical therapy for peptic ulcer disease
Immunodeficiency
Primary immunodeficiency states
Acquired immunodeficiency syndrome
Malnutrition
Age

TABLE 78-1 Conditions Favoring Bacterial Overgrowth

Stasis of the Small Intestine

Small intestinal peristalsis plays a major role in preventing bacterial overgrowth. Anatomic or structural disorders that interfere with intestinal peristalsis frequently lead to small bowel bacterial overgrowth. These include chronic small intestinal obstruction secondary to intestinal strictures, such as those caused by Crohn's disease, lymphoma, or radiation injury. [7], [8] and [9] Surgical alterations of the intestinal anatomy that create blind pouches or divert long segments small bowel, such as end-to-side enteroenteric anastomosis, the Billroth II anastomosis, jejunoileal bypass, and the Koch distal ileal pouch (for continent ileostomies), have been associated with clinically significant bacterial overgrowth [10], [11] and [12] in stagnant pouches and loops.

Diverticula of the small intestine can serve as pockets of stagnation that become clinically significant, particularly in the setting of hypochlorhydria or achlorhydria. [10] Generalized impairment of small intestinal motor function (see Chapter 11) also may lead to small bowel bacterial overgrowth. Malabsorption resulting from small intestine bacterial overgrowth has been documented in patients with intestinal hypomotility in association with scleroderma, idiopathic intestinal pseudoobstruction, or diabetic autonomic neuropathy. [13], [14] and [15] The absent or disordered migrating motor complex has been associated with bacterial overgrowth [16]; in one patient, the return of phase III of the migrating motor complex preceded the resolution of bacterial overgrowth. [17]

Abnormal Connections between Proximal and Distal Portions of the Bowel

Bacterial overgrowth of the small intestine may arise secondary to abnormal connections between the proximal bowel and the colon that lead to seeding of the proximal bowel with colonic flora. Resection of the ileocecal valve may cause retrograde seeding of the small intestine with colonic flora and contribute to the development of small intestinal bacterial overgrowth. [18], [19] Evidence also indicates that resection of the ileocecal valve (as well as a portion of the terminal ileum and cecum) results in alterations of motility that may play an important role in the development of bacterial overgrowth. [20] Gastrocolic or gastrojejunocolic fistulae may arise in patients with gastric ulcers and ulcerating carcinomas of the stomach or colon. In this situation, malabsorption results from reflux of the colonic contents into the proximal bowel. [21]

Gastric acid is responsible for decreasing the bacterial inoculum reaching the proximal small intestine. The proximal gastrointestinal bacterial concentration is significantly increased in patients with achlorhydria secondary to chronic gastritis in comparison with control subjects. [22] Gastric acid secretion also is impaired as a result of medical and surgical therapy of peptic ulcer disease. Increased bacterial counts and overgrowth have been reported in association with cimetidine therapy [23]; these may become even more significant clinically when more potent hypochlorhydric medications, such as omeprazole, are used. Gastric surgery affects bacterial

proliferation by impairing gastric acid secretion and by altering intestinal motility. The results of studies of animal models and humans after surgery suggest that impaired gastric acid secretion alone is not sufficient to cause clinically significant bacterial overgrowth. [11], [24] Hypochlorhydria, however, may promote intestinal overgrowth in patients who also have intestinal disorders associated with stasis (e.g., diverticula, delayed intestinal transit).

Immunodeficiency

Chronic diarrhea, malabsorption, and weight loss have been observed in a number of immunodeficiency states (see Chapter 51). For example, 60% of patients with common variable immunodeficiency have chronic diarrhea. Frequently, malabsorption is associated with *Giardia lamblia* infestation and responds to treatment of the giardiasis. Overgrowth of bacteria is a common finding in these patients; however, the bacterial counts (particularly those of anaerobic organisms) are lower than those in cases associated with intestinal stasis. [25] Bacterial overgrowth also may be related to decreased acid secretion in these patients. [25] Chronic diarrhea is a prominent symptom in patients with the acquired immunodeficiency syndrome (AIDS), who may have multiple opportunistic infections (see Chapter 124); however, the cause of their diarrhea and malabsorption frequently cannot be identified. Bacterial colonization of the proximal bowel has been observed in patients with AIDS, but the role it plays in the pathogenesis of AIDS-related diarrhea remains speculative because the concentration of anaerobic organisms is far lower than that usually observed in bacterial overgrowth associated with stasis. [26]

Age

The prevalence of small bowel bacterial overgrowth increases with age (15%–56%), and overgrowth can occur in the absence of an anatomic defect of the small bowel. [5], [27], [28], [29] and [30] Possible explanations are reduced gastric acidity, impaired intestinal motility, or both. Because bacterial overgrowth is not associated with baseline anthropomorphic measurements or bowel habits, the clinical significance of bacterial overgrowth in the elderly is unclear, and it should not be routinely treated. However, in patients with evidence of malabsorption and bacterial overgrowth, treatment with antibiotics can be useful. [30], [31]

PATHOGENESIS

The pathogenesis of small bowel bacterial overgrowth can be discussed in terms of the consequences of misplacing the colonic flora into the small intestine. The enteric flora, which normally is located principally within the colon, plays an important role in the metabolism of intralumenal substances (Table 78-2). The amount of intralumenal substances that the bacteria normally encounter, however, is limited by small intestinal absorption. In cases of small bowel bacterial overgrowth, the bacteria have much greater access to nutrients and other intralumenal substances. In addition to intralumenal bacterial metabolism, evidence suggests that mucosal injury also results in the malabsorption of fats, carbohydrates, and proteins [32], [33]; however, bacterial invasion does not appear to be involved. [34]

Bacterial Metabolism of Intralumenal Substances
Impaired deconjugation of bile acids
Impaired vitamin B_{12} metabolism
Impaired metabolism of carbohydrates
Malabsorption of fats and vitamins A, D, and E; generation of secretagogues
Malabsorption of vitamin B_{12}
Intestinal gas (H_2, CO_2), osmotic diarrhea
Mucosal Injury
Decreased brush border enzyme activity
Lactase, enterokinase, peptidase
Impaired uptake of monosaccharides
Impaired uptake of peptides
Impaired uptake of lipids
Lactose intolerance
Hypoproteinemia
Carbohydrate intolerance
Fat malabsorption

TABLE 78-2 Pathogenesis of Bacterial Overgrowth

The surgical creation of a self-filling blind loop (Fig. 78-1) in a variety of animal models results in a marked proliferation of both aerobic and anaerobic bacteria and reproduces many of the manifestations of overgrowth observed in humans. [35], [36] Much of the experimental work defining the pathogenesis of small bowel bacterial overgrowth is based on these models.

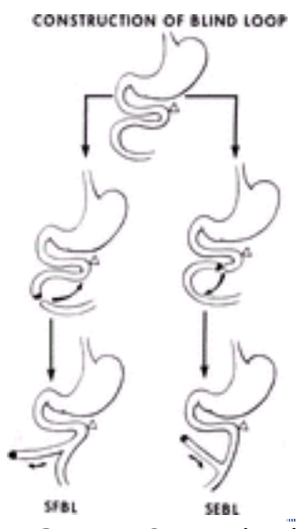

FIGURE 78-1. Animal model of small bowel bacterial overgrowth. Diversion of an isoperistaltic segment of jejunum results in the formation of a self-filling blind loop (*SFBL*). The SFBL is often used to characterize the pathophysiology of bacterial overgrowth in the small bowel because it results in the proliferation of colonic-type bacterial flora and sequelae that mimic those observed in human disease. A short, patent, antiperistaltic segment of jejunum, referred to as a self-emptying blind loop *(SEBL),* serves as an operated control because bacterial overgrowth and its sequelae do not develop postoperatively. (From ref. [45].)

Malabsorption of Fats and Fat-Soluble Vitamins

The bacterial deconjugation of bile acids is the primary mechanism for the malabsorption of fats and fat-soluble vitamins. [37], [38] Normal fat absorption requires a critical concentration of conjugated bile acids for the assembly of mixed micelles. The deconjugation of bile acids by lumenal bacteria, particularly anaerobic organisms, [39] reduces the level of conjugated bile acids below the critical micellar concentration. Steatorrhea has been relieved in patients [37] and experimental animals [38] with bacterial overgrowth by the administration of conjugated bile acids; however, the observation that complete biliary diversion in animals does not produce the steatorrhea seen in bacterial overgrowth suggests that other factors may play a role. [19] Deficiencies of vitamins D, A, and E have been reported as complications. [40], [41] The synthesis of vitamin K by lumenal bacteria, however, accounts for the absence of coagulopathy in patients with bacterial overgrowth. It has been suggested that bacterial metabolites (e.g., hydroxylated fatty acids and unconjugated bile acids) may have a toxic effect on the intestinal mucosa, resulting in the malabsorption of fats, carbohydrates, and proteins. Many of these metabolites serve as secretagogues that contribute to the development of diarrhea.

Carbohydrate Intolerance

Bacterial overgrowth results in carbohydrate intolerance secondary to a reduction of brush border disaccharidases and a decreased uptake of monosaccharide. [42], [43], [44] and [45] Lactase activity is the first to be reduced and is the last disaccharidase activity to recover after antibiotic therapy has been administered. [43], [45] Evidence

suggests that anaerobic organisms produce proteases and glycosidases that release or destroy hydrolases on the brush border. [42], [43], [46] Carbohydrate intolerance results in an increased delivery to the small intestine of osmotically active carbohydrate fragments, which contribute to the development of the diarrhea associated with bacterial overgrowth. Bacterial metabolism of carbohydrates to hydrogen and carbon dioxide may play a role in the development of abdominal pain and is the basis of various breath tests used to diagnose bacterial overgrowth.

Hypoproteinemia

Hypoproteinemia is common in bacterial overgrowth, although severe protein nutrition is rarely seen. [47] Normal protein assimilation is disrupted by multiple factors. Bacteria compete with the host for protein substrates [44]; decreased amino acid and peptide uptake has been demonstrated in experimental models, perhaps reflecting mucosal injury [47]; decreased levels of enterokinase have been noted in patients with bacterial overgrowth and may impair the activation of pancreatic proteases [48]; and finally, a protein-losing enteropathy has been described in patients and experimental animals with bacterial overgrowth. [49]

Malabsorption of Water-Soluble Vitamins

The association of macrocytic anemia with bacterial overgrowth is the result of direct competition between the intestinal flora and the host for vitamin B_{12}. The anaerobic organisms are primarily responsible because only anaerobicidal therapy reversed vitamin B_{12} deficiency in an experimental model of stasis. [19] Anaerobic organisms, in contrast to aerobic organisms, can use vitamin B_{12} either in its free form or when it is complexed with intrinsic factor. [50], [51] When bacteria take up the vitamin, not only does it become unavailable to the host, but inactive metabolites are produced that compete with normal vitamin B_{12} binding and absorption. [52] In contrast, folate levels are normal or elevated in bacterial overgrowth because bacteria synthesize folate that subsequently is absorbed by the host. Levels of thiamin [53] and nicotinamide, [54] two other water-soluble vitamins, have also been reported to be low in bacterial overgrowth.

Although iron deficiency anemia has not been clearly associated with bacterial overgrowth in humans, increased intestinal losses of iron and blood were documented in animal models. [55] Mineral and trace element deficiencies have not been reported in patients with bacterial overgrowth.

Liver Disease

Hepatobiliary injury has been observed in experimental models of bacterial overgrowth in susceptible rat strains. [56], [57] The injury can be prevented by antibiotic treatment. [58] It has been suggested that bacterial cell wall polymers or other bacterial toxins from the blind loop cause hepatic lesions in genetically susceptible hosts. [56] A high prevalence of bacterial overgrowth and elevated levels of tumor necrosis factor-a have been detected in patients with nonalcoholic steatohepatitis (NASH), and it has been proposed that bacterial overgrowth plays a role in the pathogenesis of NASH by triggering cytokine release. [59], [60]

Small bowel bacterial overgrowth occurs with increased frequency in patients with cirrhosis. [61], [62] The mechanisms are likely to be multifactorial and include gastric hypoacidity and delayed small bowel transit. The consequences of this change are not fully understood. It has been suggested that patients with cirrhosis and small bowel bacterial overgrowth are predisposed to the spontaneous development of bacterial peritonitis. [61], [62] and [63]

PATHOLOGY

Lumenal bacteria clearly influence intestinal morphology. Many of the normal morphologic characteristics of the intestinal epithelium are seen only in association with a resident bacterial flora (see Chapter 25). In the germ-free state, the villi are thinner and longer, and the crypts are shallower. The mucosal cells are cuboidal rather than columnar. The lamina propria consists of a sparse stroma infiltrated with a few lymphocytes and macrophages, plasma cells are absent, and the Peyer patches are smaller, with fewer germinal centers. On light microscopy, the histological appearance of the small intestine with bacterial overgrowth usually is not significantly different from that of the intestine with a normal enteric flora. The main purpose of obtaining a mucosal biopsy specimen in the evaluation of these patients is therefore to rule out mucosal diseases such as celiac sprue. Histological evidence of mucosal damage, however, has been found in some cases of bacterial overgrowth, including subtotal villus atrophy and increased inflammatory cells within the lamina propria. [33] Focal areas of ulceration and erosion have been observed in some instances and may be important in understanding the symptoms of “pouchitis” associated with bacterial overgrowth after the surgical creation of a continent ileostomy (Koch pouch) or ileoanal anastomosis. [64], [65] Ultrastructural studies of experimental models of bacterial overgrowth have revealed vacuolization of microvillus membranes and swelling of the mitochondria (Fig. 78-2), suggesting that bacterial overgrowth does result in damage to the enterocyte. [32]

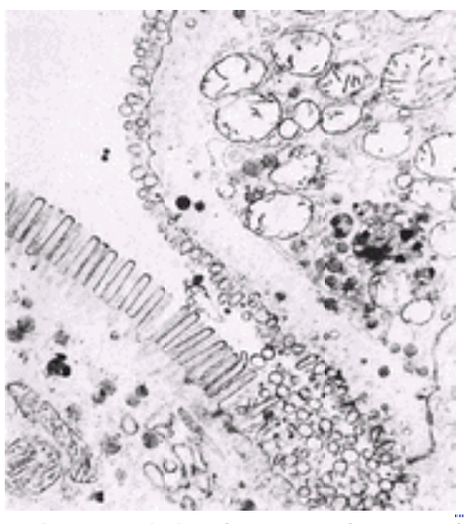

FIGURE 78-2. Electron micrograph of columnar cells in the midvillus area of a self-filling blind loop. In the cell at the lower left, the microvilli are regular, and the mitochondria and endoplasmic reticulum are unaltered. In the cell at the upper right, the microvilli are altered, and the mitochondria and endoplasmic reticulum are swollen. Alterations of the microvilli include blunting, swelling, budding, and ballooning. Original magnification ×22,000. (From ref. [32].)

CLINICAL MANIFESTATIONS

Many of the clinical features of bacterial overgrowth can be predicted based on the pathogenesis of the disorder (Table 78-3). Diarrhea and weight loss are prominent symptoms and are largely a consequence of the malabsorption and maldigestion of fats, carbohydrates, and proteins. In addition, many patients with bacterial overgrowth curtail their intake to reduce symptoms. [2] The association of macrocytic anemia with intestinal strictures is a manifestation of vitamin B_{12} deficiency. Patients also may present with the neurological changes associated with vitamin B_{12} deficiency. Recurrent abdominal pain may be reported, particularly among young children, as a presenting symptom. [6] Other presentations include night blindness, osteomalacia, tetany, peripheral neuropathy, and edema, [66], [67] reflecting malabsorption of micronutrients such as vitamins A, D, and E, as well as thiamin and nicotinamide.

Diarrhea
Steatorrhea
Malnutrition
Macrocytic anemia
Abdominal pain
Peripheral neuropathy
Tetany
Osteomalacia
Night blindness
Dermatitis, hepatic injury, nephrotoxicity, and arthritis (observed in jejunoileal bypass)

TABLE 78-3 Clinical Manifestations of Bacterial Overgrowth

Extraintestinal manifestations of bacterial overgrowth have been observed, especially in patients who have undergone jejunoileal bypass. These include dermatitis, hepatic injury, nephrotoxicity, and arthritis. [68], [69] and [70]

DIAGNOSIS

The diagnosis of bacterial overgrowth should be considered in patients with chronic diarrhea who have the predisposing conditions discussed previously in this chapter. The differential diagnostic considerations include other causes of malabsorption and maldigestion: intestinal mucosal diseases (e.g., celiac sprue), infections (particularly parasitic diseases such as giardiasis), and pancreatic insufficiency. In patients with underlying diseases that favor bacterial proliferation, such as Crohn's disease or scleroderma, it may be difficult to distinguish whether clinical deterioration is caused by the development of bacterial overgrowth or by worsening of the primary intestinal disease. It is possible that the diagnosis should also be considered in patients with symptoms of irritable bowel syndrome. A high prevalence of bacterial overgrowth has been observed in patients in whom irritable bowel syndrome has been diagnosed. Furthermore, eradication of bacterial overgrowth appears to reduce their intestinal complaints. [71]

Microbiologic culture of small bowel aspirates is considered the most direct method for diagnosing bacterial overgrowth (Table 78-4). [1], [2] In general, the diagnosis of bacterial overgrowth is considered to be confirmed if the count exceeds 10^5 colonies per milliliter after duodenal intubation. [2] A variety of techniques have been reported: the use of sterile and nonsterile tubes, [72] the capsule method, [73] direct needle aspiration of the gut contents, [74] and the string test. [75] The feasibility of collecting aspirates from the proximal small bowel under direct visualization at the time of endoscopy has been demonstrated and can facilitate the collection of samples during routine endoscopy. [76] Small intestinal aspirates are obtained by placing a sterile suction catheter inside a sterile overtube that is passed through the suction channel of the endoscope after the desired collection site is reached. The aspirates should be transferred immediately to an anaerobic transport vial and the contents plated for both aerobic and anaerobic organisms. [76] Significant bacterial overgrowth usually is associated with the detection of anaerobic organisms. Because of the technical difficulties of culturing fastidious anaerobic organisms, the presence of more than 10^5 colony-forming units per milliliter in the duodenum is considered diagnostic for bacterial overgrowth. [2] Analyses of unconjugated bile acids [77] and short-chain fatty acids [78] in the fluid also have been performed but are largely investigational tools. In addition to the technical difficulties involved in collecting the specimen properly, without contamination by mouth flora, and in transporting and culturing the fluid, an aspirate of the proximal bowel may not reflect distal bacterial overgrowth. [79]

TESTS	LIMITATIONS
Culture of small intestinal aspirate	Invasive, possible contamination with oral flora, difficulty in transport of anaerobic cultures, distal intestinal overgrowth can be missed
^{14}C-xylose breath test	Radioactivity, decreased sensitivity
H_2 breath tests	
Glucose-H_2	20% of population unable to produce H_2, decreased sensitivity
Lactulose-H_2	Distal intestinal overgrowth can be missed because of overlap between early and late peak

TABLE 78-4 Diagnostic Tests for Bacterial Overgrowth

Breath tests were devised as a less invasive alternative to intubation of the proximal bowel. These tests measure the breath excretion of carbon dioxide or hydrogen produced during the intralumenal bacterial metabolism of an administered substrate (see Chapter 42). The bile acid or ^{14}C-cholylglycine breath test was one of the first breath tests developed, but it cannot distinguish bacterial overgrowth from ileal malabsorption. [80] Because of its poor sensitivity and specificity, this test largely has been abandoned. A radioactively labeled pentose, ^{14}C-D-xylose, is a more ideal substrate for breath testing because it is minimally metabolized by the host after absorption. Xylose is absorbed in the proximal bowel, whereas bile acids are absorbed in the ileum, so the chance of obtaining a false-positive measurement as a result of colonic metabolism is reduced. [19] The sensitivity of this test in comparison with that of microbiologic culture ranges from 30% to 100%. [31], [81] The specificity of the test appears to be high (89%–100%), and it is well tolerated. [31], [81] The use of stable isotopes in combination with mass spectrometry, such as the ^{13}C-xylose breath test, may become more widespread in the future, in an effort to avoid the administration of radioactive substrates. [82]

The hydrogen breath tests also have the advantage of not involving radioactive substrates. A major problem with these tests is that 15% to 20% of the human population harbor flora that does not produce hydrogen. [83] Lactulose and glucose are two substrates often used for the purpose of diagnosing bacterial overgrowth. Patients with bacterial overgrowth who are administered lactulose exhibit an early breath hydrogen peak from small intestinal bacterial fermentation, followed by a prolonged peak from colonic bacterial metabolism. [83] In a case of distal intestinal overgrowth, it may be difficult to resolve the two peaks. In a study from Burma comparing the 10-g lactulose-hydrogen breath test with the Enterotest string test, only 2 of 15 children with more than 10^5 organisms per milliliter had a positive breath test result. [84] A comparison of the glucose-hydrogen and lactulose-hydrogen tests showed sensitivities of 62% and 68%, respectively, and specificities of 83% and 44%, respectively, in comparison with jejunal culture. [85] An elevated level of fasting breath hydrogen has been observed in some patients with bacterial overgrowth, but this is a relatively insensitive indicator of bacterial overgrowth. [86] Analysis of unconjugated bile acids in the serum has been performed in patients with bacterial overgrowth and may provide a noninvasive test for bacterial overgrowth. [87]

In summary, the available diagnostic tests all have their limitations. Many of them are used primarily as investigational tools and are not widely available in institutions. Barium studies may be useful for documenting an anatomic defect or suggesting the presence of a severe motility disorder. In certain clinical situations, such as a need to document fat malabsorption or vitamin B_{12} malabsorption in the setting of an anatomic defect or severe motility disorder, it may be reasonable to consider a course of empiric antibiotic therapy without further confirmation of the diagnosis. In the absence of a documented predisposing abnormality of the gastrointestinal tract, however, it is recommended that further diagnostic testing be performed. Routine upper gastrointestinal endoscopy with small bowel biopsy and culture of an aspirate obtained by means of a sterile overtube [69] may be the most efficient means of confirming the diagnosis and excluding other causes of malabsorption, such as celiac sprue and giardiasis.

TREATMENT

Initial management consists of fluid and nutritional support, including the correction of vitamin deficiencies (Table 78-5). After bacterial overgrowth has been diagnosed, an attempt should be made to identify an underlying cause. Surgical correction of an anatomic cause of intestinal stasis should be considered. Severe motility disorders are more difficult to manage. The administration of low doses of octreotide to patients with scleroderma for 3 weeks cleared bacterial overgrowth, as demonstrated by a reversal of abnormal breath hydrogen excretion. [88] Octreotide stimulated intestinal motor activity in these patients. At higher doses, octreotide may cause steatorrhea secondary to hypomotility and bacterial overgrowth. [89] The prokinetic agent cisapride has been shown to normalize intestinal motility in patients with motor disorders [90] and has been efficacious in the treatment of bacterial overgrowth in patients with cirrhosis. [63], [91] The efficacy of motilin receptor agonists in the treatment of dysmotility-associated bacterial overgrowth remains to be tested. [92] Often, the underlying lesion cannot be corrected, and the primary treatment is directed at suppressing the bacterial overgrowth with antibiotics. Although numerous antibiotics have been reported to be effective, very few controlled trials have examined the selection of antimicrobial agents. In a crossover randomized trial, both norfloxacin and amoxicillin-clavulanic acid given for 7 days were effective in treating bacterial overgrowth–related diarrhea and in reducing the mean volume of breath-excreted hydrogen. [93] The mean daily number of stools decreased within 1 to 3 days, but diarrhea often recurred 6 days after antibiotics had been discontinued. Pouchitis in ileal reservoirs, in patients with ulcerative colitis, is associated with

overgrowth of anaerobes and responds to metronidazole. [94]

Nutritional Supplementation
Increase calorie intake
Correct micronutrient deficiencies (e.g., vitamin B_{12})
Correction of Intestinal Stasis
Surgery (e.g., resection of strictures)
Prokinetic agents (e.g., octreotide in scleroderma)
Antibiotic Treatment

TABLE 78-5 Treatment of Bacterial Overgrowth

In a number of patients, symptoms recur after cessation of therapy. For these patients, it may be necessary to rotate antibiotic regimens. Probiotic therapy may be useful in prolonging remission after antibiotic therapy. Probiotics may also exhibit some efficacy as primary therapy in the treatment of small bowel bacterial overgrowth, but the data are less convincing. Treatment with *Saccharomyces boulardii,* a probiotic agent, for 7 days showed no efficacy in one trial. [93] Probiotic therapy with *Lactobacillus plantarum* 299V and *Lactobacillus* GG has been reported helpful in treating children who have small bacterial overgrowth associated with short bowel syndrome. [95] The administration of a high dose of a probiotic preparation (5×10^{11} viable lyophilized bacteria per gram: four strains of lactobacilli, three strains of bifidobacteria, and one strain of *Streptococcus salivarius* subspecies *thermophilus*) to patients in remission from chronic pouchitis significantly reduced the rate of relapse. [96]

Because some patients with chronic underlying gastrointestinal disease respond dramatically to a brief course of antibiotic treatment, bacterial overgrowth is an important entity to consider in their management.

CHAPTER 79

Richard N. Fedorak

SHORT BOWEL SYNDROME

The term *short bowel syndrome* covers the symptoms and pathophysiological disorders associated with a malabsorptive state resulting from the removal of a large portion of the small or large intestine. The extent of intestinal resection that will produce this syndrome varies from one person to another. In children, survival without enteral supplements or total parenteral nutrition is generally possible if more than 40 cm of the small intestine (i.e., 20% of the normal length), measured distally from the ligament of Treitz, remains. In adults, survival without enteral or parenteral nutrition is generally possible if the residual length of the small intestine, measured distally from the ligament of Treitz, is more than 150 cm (i.e., 25% of the normal length). In general, if the ileocecal valve is removed, longer lengths of residual bowel may not prevent short bowel syndrome.

Short bowel syndrome refers only to a well-organized clinical pattern that is sometimes seen in patients with intestinal resection and is not necessarily related to the length of intestine removed. The clinical consequences of removing a portion of the small intestine are extremely variable and depend on a number of factors, including the extent of resection, the site of resection, and subsequent adaptive processes. Thus, it is possible that the removal of identical lengths of small intestine may cause short bowel syndrome to develop in one person but not in another.

Significant confusion exists regarding the actual length of the small intestine. Autopsy studies report the length of the small intestine as the distance from the pylorus to the ileocecal valve. Because it is difficult to measure the length of the duodenum, however, measurements made during operations often report the length of the small intestine as the distance from the ligament of Treitz to the ileocecal valve. The mean length of the small intestine at autopsy (from pylorus to ileocecal valve) has been reported as 630 cm in men and 592 cm in women; the mean colonic length is 150 cm in both sexes. These lengths are likely to be greater than the lengths measured in vivo because tone is lost in the postmortem state. Furthermore, small intestinal lengths probably differ according to racial and genetic factors. Full-term newborns have about 250 cm of small intestine and 50 cm of colon. The small intestine develops to its adult length by about 9 years of age.

Although clear functional distinctions exist between the proximal jejunum and the distal ileum, it is difficult to determine the exact normal ratio of jejunal length to ileal length because no clear demarcation exists between the two. In general, in North American adults, the proximal two fifths (~240 cm) of the small bowel are referred to as the *jejunum,* and the distal three fifths (~360 cm) are called the *ileum.* [1], [2]

ETIOLOGY

Adults

Several conditions are associated with short bowel syndrome in adults (Table 79-1). The most common of these are intestinal resection following a vascular insult to the small intestine (thrombosis or embolism of the superior mesenteric artery, thrombosis of the superior mesenteric vein, volvulus, strangulation) and Crohn's disease, with or without multiple intestinal resections. Less common causes of short bowel syndrome are jejunoileal bypass for obesity, abdominal trauma with resultant intestinal resection, inadvertent gastrocolic fistulization at the time of operation, radiation enteropathy, and neoplasms involving the gastrointestinal tract.

Vascular Insults
Thrombosis or embolism of the superior mesenteric artery
Thrombosis of the superior mesenteric vein
Volvulus
Strangulation
Postoperative
Jejunoileal bypass for obesity
Abdominal trauma necessitating bowel resection
Inadvertent gastrocolonic/ileal anastomosis
Miscellaneous
Crohn's disease, with or without surgical resection
Radiation enteropathy
Primary or secondary neoplasms involving the gastrointestinal tract

TABLE 79-1 Causes of Short Bowel Syndrome in Adults

Infants and Children

Most of the underlying causes of short bowel syndrome in children develop during intrauterine life (Table 79-2). Prenatal vascular accidents presenting as intestinal atresia or volvulus that result from malrotation are a particularly common cause of short bowel syndrome in this age group. Less common postnatal causes include vascular insults, surgery for necrotizing enterocolitis or Crohn's disease, and trauma.

Prenatal
Vascular insults
Intestinal atresia
Volvulus
Abdominal wall defects
Postnatal
Arterial thrombosis or embolism
Venous thrombosis
Necrotizing enterocolitis
Trauma
Crohn's disease
Volvulus
Hirschsprung disease
Radiation enteropathy

TABLE 79-2 Causes of Short Bowel Syndrome in Infants and Children

FACTORS INFLUENCING SHORT BOWEL SYNDROME[3], [4], [5] and [6]

Extent of Intestine Removed

Generally, the more extensive the resection of the small intestine, the greater the loss of absorptive surface area that transports nutrients, water, and electrolytes. It is clear, however, that the length of residual intestine and its function are more important prognostically than the extent of intestine removed. Short bowel syndrome can result from either a single massive intestinal resection or repeated lesser resections. Mesenteric vascular disease is more prevalent among patients who have undergone massive resection, whereas Crohn's disease is more prevalent in patients who have undergone repeated surgical resections leading to short bowel syndrome.[7], [8] Although the 30-day mortality rate is higher in patients who have had a massive resection, those surviving longer than 30 days have similar survival rates at 5 years.[8]

The amount of small intestine remaining after resection determines the surface area available for absorption, as well as the transit time and subsequently the time during which nutrients and nonnutrient fluids and electrolytes are in contact with the absorptive surface of the intestine.

About 50% (~300 cm) of the small intestine usually can be resected without the development of the significant nutrient or electrolyte losses that lead to short bowel syndrome. The removal of more than 75% (~450 cm) of the small intestine almost invariably results in fluid or electrolyte malabsorption that requires enteral or parenteral replacement therapy.

Site of Intestine Removed

Jejunum The jejunum, in its intact state, absorbs a significant fraction of the nutrients and water required by the body, but removal of the jejunum alone generally causes only a limited defect in the absorption of macronutrients, electrolytes, and free water. This limited effect is a consequence of the fact that the ileum is the part of the intestine with the greatest capacity for adaptation, and it is able to compensate for, and take over, almost all the absorptive functions of the jejunum.[9] Thus, jejunal resections are often reasonably well tolerated. Removal of the jejunum reduces the secretion of cholecystokinin and secretin, which may lead to subsequent decreases in biliary and exocrine pancreatic secretions; in turn, these decreases compromise nutrient absorptive capacity. In addition, cholecystokinin, vasoactive intestinal peptide, gastric inhibitory peptide, and serotonin, all of which are distributed mainly in the jejunum, inhibit gastric secretion. Thus, gastric hypersecretion is more likely to occur after resection of the jejunum.[10], [11] Increased serum gastrin levels and gastric hypersecretion also are seen more frequently after jejunal resection; these increases probably are also related to the length of bowel resected.[12], [13]

Ileum In the ileum, which is relatively impermeable in comparison with the jejunum, the solvent drag of water and electrolytes is less than in the jejunum; however, the ileum remains critically important in the active transport of both nutrients and nonnutrients. If the ileum is resected, the remaining colon is often incapable of handling fluids or adapting to prevent extensive fluid losses as the jejunum continues to pour large amounts of chyme into the impermeable residual ileum and nonabsorptive colon. For this reason, patients usually poorly tolerate extensive ileal resections. The ileum is the only site of active bile acid absorption from the intestine, although small amounts of bile acids are absorbed by passive diffusion in the jejunum and colon. Therefore, a loss of more than 100 cm of ileum usually precludes the active intestinal absorption of bile acids; thereafter, the passive absorptive capacity of the rest of the small intestine is rapidly overwhelmed, and bile acids are left in the lumen and spill into the colon.[5] These bile acids are deconjugated by colonic bacteria. The deconjugated bile acids directly stimulate the colon to secrete fluid and electrolytes, causing a secretory watery diarrhea and thereby aggravating the short bowel syndrome.[9], [10] Bile acids stimulate active anion secretion in the colon through several mechanisms: increasing cytosolic calcium levels within colonocytes through a calcium ionophore effect; increasing prostaglandin synthesis in lamina propria cells; stimulating excitatory enteric neurons, which then stimulate active anion secretion and propulsive motor contractions; and increasing tight junction permeability to fluid and electrolytes. During intestinal adaptation, the body compensates for bile acid loss into the colon by maintaining the size of the bile acid pool through an up to eightfold increase in hepatic bile acid synthesis. The more extensive losses of ileum, however, result in severe bile acid malabsorption wherein loss exceeds synthesis. A reduction in the circulating pool of bile salts follows, leading to impaired intestinal micelle formation and the spillage of fat (steatorrhea) into the colon. Fat within the colon is hydroxylated by bacteria into hydroxy fatty acids. Hydroxystearic acid is the hydroxy acid most often associated with steatorrhea, and it has stimulatory effects on colonic fluid and electrolyte absorption. Hydroxy fatty acids stimulate net secretion through several mechanisms: changing net absorption to net secretion, increasing mucosal permeability, and increasing propulsive motor activity. These effects are similar to those of bile acids and may be related to the detergent properties of both hydroxy fatty acids and bile acids. The ileum is the primary site of vitamin B_{12} absorption. Malabsorption of vitamin B_{12} occurs after the resection of more than 60 cm of ileum. The intestine appears to be largely unable to recruit new vitamin B_{12} receptors into residual ileum or jejunum. Resection of the distal ileum also affects nutrient absorption in the jejunum. A 50% distal ileal resection in one rat model decreased transmucosal jejunal calcium absorption by unknown mechanisms that did not appear to involve the brush border membrane.[14] Whereas the mucosal morphologic and functional absorptive response to distal ileal resection has been well documented, little is known about the motor response. In dogs, initial motor responses to resections of the distal small intestine of various lengths were dominated by the development of abnormal motility patterns, with prominent cluster activity noted in the intestinal remnant.[15] The intact ileum markedly slows intestinal transit[16]; thus, ileal resection decreases the intestinal transit time significantly, impairing the ileal brake phenomenon thought to be controlled by peptide YY.[17]

Colon Throughout the intestine, motility is slowest and absorptive capacity is highest in the colon, and absence of the colon significantly increases the rate of transit and the liquidity of stools. The primary function of the colon is to absorb the 1 to 2 L of fluid it receives from the ileum. The liquidity of the feces and the extent of fluid and electrolyte loss in the colon depend on the total volume of fluid and its rate of arrival at the cecum, and also on the presence of unabsorbed solutes such as bile salts. The removal of both ileum and colon obviously drastically increases fluid loss, dehydration, volume depletion, hypocalcemia, and hypomagnesemia. Preservation of the colon in cases of major small intestinal resection appears to lessen the severity of short bowel syndrome because the colon not only provides an absorptive surface area but also exerts a braking effect on early gastric emptying.[17] Preservation of even 50% of the colon is associated with significantly lower morbidity and mortality rates.[18] Although retention of the colon improves fluid and electrolyte absorption, colonic conservation also can have maladaptive consequences. Colonic bacteria deconjugate and hydroxylate unabsorbed bile salts and fats, respectively, creating solutes (bile acids and fatty acids) that limit water absorption in the colon through direct stimulation of the secretion of colonic fluid and electrolytes and through osmotic effects. In addition, the combined effects of massive small bowel resection, fat malabsorption, and an intact colon lead to the formation of calcium oxalate renal stones as free fatty acids in the colonic lumen preferentially bind calcium, leaving oxalate unbound and free to be absorbed systemically through the colonic mucosa.

Presence of an Ileocecal Valve

The ileocecal valve functions to prolong the intestinal transit time, thereby increasing the duration of contact of the lumenal contents with the small intestinal mucosal surface and enhancing the absorption of nutrients, fluids, and electrolytes.[5], [6] If the ileocecal valve is removed during an intestinal resection, the likelihood of the development of short bowel syndrome, often in a severe form, is increased.[18], [19] In an outcome study of neonatal short bowel syndrome, the presence of an ileocecal valve was not significantly correlated with successful weaning from parenteral nutrition, but it did reduce the mean duration of parenteral nutritional therapy from 20 to

7 months. [20] In addition, the ileocecal valve serves as a barrier that prevents the migration of lumenal colonic microorganisms into the distal small bowel. [10], [21] Removal of the ileocecal valve may result in bacterial overgrowth within the small intestine. These bacteria deconjugate bile salts within the small intestinal lumen; impaired micelle formation follows, so that the absorption of fat and fat-soluble vitamins is reduced. Furthermore, deconjugated bile salts spill into the colon and directly stimulate the colonic secretion of fluid and electrolytes, further aggravating the short bowel syndrome. Bacterial overgrowth associated with enteritis in children with short bowel syndrome prolongs the need for parenteral nutrition. [22] Finally, the bacteria use intralumenal vitamin B_{12} for their own metabolic purposes, limiting the availability of vitamin B_{12} for absorption by the host and exacerbating vitamin B_{12} deficiencies.

Intestinal Adaptation

Jejunum and Ileum Following resection of a major portion of the small bowel in experimental animal models, adaptive changes affect all layers of the remaining intestine. Lumenal dilation with thickening and lengthening of the gastrointestinal tract develop in association with hyperplasia of the crypt-villus axis, and the mucosal surface area increases significantly. [23], [24], [25], [26], [27] and [28] These effects are more noticeable in residual ileum (i.e., after jejunal resection) than in residual jejunum (i.e., after ileal resection). The number of cells in the proliferative zone of the crypts increases, and these cells rapidly migrate up the villi, causing villus hyperplasia and a parallel increase in the production of brush border membrane enzymes. This increase in mucosal mass is confirmed by increases in mucosal wet and dry weight, protein, and RNA and DNA contents. [29] An attempt to identify the molecular mechanism behind the observation of ileal hyperplasia in the rodent model of short bowel syndrome demonstrated the expression of a variety of nutrient absorptive and heat shock proteins in the residual intestine early in the adaptive process. [30] In addition to morphologic changes, an up-regulation of specific functional absorptive activity occurs in these animal models. [31], [32] The absorption of glucose, sucrose, bile acids, vitamin B_{12}, and calcium is increased in animal models of short bowel syndrome. [33] This increase is related to an increase in the number of absorptive cells rather than to an increase in the capacity of individual cells. [28], [34] In contrast to the plethora of findings in animal models of short bowel syndrome, few data are available regarding functional absorptive adaptation following the resection of human intestine. Dowling and Booth [35] reported an increase in jejunal glucose absorption in patients with short bowel syndrome that was proportional to the amount resected; furthermore, intestinal adaptive responses in humans most often required more than 1 year to reach maximum development. [10], [12], [13], [35]

Colon The colon also undergoes adaptive dilation, lengthening, and mucosal proliferation. These forms of adaptation result in an increased capacity to absorb fluid and electrolytes. [36] Several animal studies suggest that the colon also may be able to up-regulate the absorption of glucose and amino acids, if only to a limited extent. [12], [29]

Mechanisms of Intestinal Adaptation

Direct Effect on Epithelial Cells Enteral nutrients appear to stimulate intestinal adaptation through at least three major mechanisms: direct contact with epithelial cells, stimulation of trophic gastrointestinal hormone secretion, and stimulation of pancreatic and biliary secretions trophic to the small intestine. [12] Again, most experiments on potential stimuli and mechanisms of intestinal adaptation focus on animal, rather than human, models. Evidence that intralumenal nutrients have a direct effect on intestinal adaptation comes from animal studies in which segments of ileum were transposed into the proximal jejunum. The mass of ileal mucosa in this position increased markedly, and transposed villi became larger than those in the adjacent jejunum. In these experiments, the concentration of intralumenal nutrients, rather than simple osmolality, stimulated lengthening of the relatively short ileal villi. [5], [6] Without exposure to intralumenal nutrients, intestinal adaptation did not occur; rather, hypoplasia developed. [5], [6] In addition, nonnutritive agents did not stimulate mucosal growth, implying that the absorption or metabolism of lumenal nutrients is necessary for the process of adaptation to take place. [5], [37] The extent to which enteral nutrients stimulate intestinal adaptation also depends on the type and complexity of the nutrient administered. [37], [38] Disaccharides are more potent stimulants of adaptation than monosaccharides. [38] In addition, a nutrient need not always be metabolized for it to induce adaptation: 3- *O*-methyl-D-glucose, a nonmetabolizable glucose analog transported by the sodium/glucose cotransport system, stimulates intestinal adaptation in a rat model of short bowel syndrome. [39], [40] Fats that are highly unsaturated appear to be more effective in inducing intestinal adaptation than fats that are less unsaturated. [41] In animal models of short bowel syndrome, morphologic and functional intestinal adaptation following intestinal resection generally does not occur in the absence of enteral nutrition or oral feeding; in fact, a significant degree of mucosal atrophy results if all nutrients are provided parenterally. [12], [29], [42] Whether it is appropriate to extrapolate findings in rodent models to human short bowel syndrome has been questioned (see below). [40], [43] Jejunal biopsy specimens taken from eight normal volunteers before and after 14 days of parenteral nutrition therapy demonstrated decreased villus height, a decreased villus cell count, and increased intestinal permeability during parenteral nutrition, but no changes in DNA, RNA, and protein content in comparison with controls, suggesting that the total enterocyte number did not change. [44], [45] In a study of similar design, parenteral nutrition did not affect immunoglobulin-producing lymphocytes in the lamina propria, intestinal permeability, or bacterial translocation. [46] These results suggest that, in contrast to the findings in animal models, depriving the human intestinal lumen of enteral feeding does not lead to intestinal hypoplasia or immune dysfunction. Additional human studies of longer duration and with functional absorptive measurements must be conducted before the direct effects of enteral feeding on intestinal adaptation, identified in the rodent models of short bowel syndrome, can be confirmed. [47]

Stimulation of Trophic Gastrointestinal Hormones The second mechanism by which enteral nutrients stimulate intestinal adaptation is stimulation of the secretion of trophic gastrointestinal hormones. Thiry-Vella fistula models have been used to demonstrate this mechanism of action. Thiry-Vella fistulae are segments of bowel in which the blood supply is intact; however, because of the creation of proximal and distal ostomies, they are excluded from the flow of enteric contents. Animals fed orally after the creation of such a fistula exhibit greater adaptation in both intact intestine and in the Thiry-Vella fistula than do animals fed intravenously. [48], [49] and [50] Several different hormones are under consideration as candidate trophic hormones. Gastrin appears to have a trophic effect only in the duodenum. Secretin and cholecystokinin stimulate intestinal mucosal growth; however, their effects seem to be exerted through their actions on biliary and pancreatic secretions rather than through direct trophism. Other hormones, including corticosteroids, prostaglandins, epidermal growth factor, enteroglucagon, and growth hormone–releasing factor, appear to stimulate epithelial cell proliferation in the small intestine. [28], [51], [52], [53] and [54] The role of these hormones in the intestinal adaptation that occurs following intestinal resection remains to be clarified.

Gastrin. Gastrin produces mucosal hyperplasia in the rat stomach and duodenum. When the major source of endogenous gastrin is removed by antrectomy, the resulting gastric and duodenal hypoplasia can be prevented through pentagastrin treatment. Gastrin does not promote adaptive changes in the jejunum or ileum. Furthermore, the relationship between gastrin levels and gastroduodenal adaptation is variable. [55]

Cholecystokinin. Cholecystokinin exerts a consistent trophic action on the small intestine. When infused into dogs or rats maintained on total parenteral nutrition, cholecystokinin completely prevented villus hypoplasia in one study, [56] but other investigators have been unable to substantiate this effect. Cholecystokinin probably exerts no direct trophic effect on the intestinal mucosa; instead, it likely influences the adaptive process by stimulating pancreatic or biliary secretions. [56]

Enteroglucagon and polyamines. Enteroglucagon-producing cells are found primarily in the terminal ileum. Polyamines (putrescine, spermidine, spermine) are found in all tissues of the body and directly stimulate tissue growth. Both hormones increase RNA and DNA synthesis, which results in epithelial hyperplasia. [50], [57], [58] Blocking polyamine synthesis negatively affects the adaptation process, whereas blocking polyamine degradation increases intestinal adaptation. [58], [59] Enteroglucagon-producing cells are stimulated by carbohydrates and long-chain triglycerides to release preformed enteroglucagon, which stimulates ornithine decarboxylase, increasing polyamine production and, thus, cellular hyperplasia and intestinal adaptation. Changes in enteroglucagon levels correspond closely to changes in the crypt cell production rate, and this peptide remains a favorite candidate for identification as the humorally mediated trophic influence on the small bowel. [55], [60] Evidence suggests that precursors of enteroglucagon, such as proglucagon-derived peptides, may be responsible for some of the activities previously attributed to enteroglucagon. Ileal proglucagon messenger RNA levels increase rapidly after intestinal resection. [61] Glucagon-like peptide 2, a product of proglucagon, is capable of inducing marked villus hyperplasia within 4 days after administration, and this change provides compelling evidence that proglucagon plays a significant role in the growth and adaptation of intestinal epithelium. [62], [63] and [64] The mechanisms responsible for the up-regulation of proglucagon in short bowel syndrome are not yet known; however, the fact that dietary fiber fermentation modulates intestinal proglucagon expression may explain why intestinal adaptation requires oral intake. [65] One clinical study demonstrated elevated fasting and meal-stimulated plasma levels of glucagon-like peptides 1 and 2 in patients with a resected ileum and a preserved colon who had short bowel syndrome. [66] In a separate study, the meal-stimulated increase in plasma glucagon-like peptide 2 in patients with short bowel syndrome was smaller than that in control patients. [67] Although these findings in patients may simply represent an epiphenomenon of glucagon-like peptides, the results of previous animal studies suggest that these peptides do indeed play a significant role in the intestinal adaptation of short bowel syndrome (see section “Medical Management: Glucagon-like Peptide 2 Therapy,” Page 1636).

Somatostatin. Somatostatin reduces the crypt cell production rate and hyperplasia in the small intestine after resection; it also inhibits the rise in enteroglucagon levels that normally follows jejunal resection. [68] Therefore, somatostatin may modulate mucosal cell turnover by influencing glucagon release. Somatostatin causes a number of competing effects on the intestine. It increases intestinal transit time and inhibits gastric secretions, both of which would benefit the patient with short bowel syndrome; in contrast, somatostatin-induced reductions in pancreatic and biliary secretions can lead to frank fat malabsorption and steatorrhea.

Neurotensin. In rats with 80% of their intestine resected, the administration of exogenous neurotensin increased villus length in both jejunum and ileum. Increases in circulating enteroglucagon found after the administration of neurotensin suggest that the trophic effect of neurotensin may be mediated, at least in part, by enteroglucagon. [69]

Growth factors. Epidermal growth factor (EGF), a potent stimulant of gastrointestinal epithelial proliferation, stimulates DNA synthesis and polyamine synthesis in the small intestine of experimental animals. [70], [71] In animals with 70% to 80% of their intestine resected, EGF receptor activity was increased, and EGF augmented not only intestinal size but also expression of the sodium/glucose cotransport carrier. [71], [72], [73], [74] and [75] Insulin-like growth factors also stimulated intestinal adaptation after small intestinal resection in the rat. [76], [77] Insulin-like growth factor type I transgenic mouse models have been used to demonstrate that insulin-like growth factor regulates intestinal mass and augments colonic fluid and electrolyte absorption. [64], [78], [79] Nevertheless, no evidence is available to support any beneficial effects of the administration of EGF at the time of resection, or to support the use of EGF in well-adapted short bowel syndrome, [73] which suggests the existence of an optimal window for growth factor augmentation of adaptation.

Prostaglandins. Prostaglandins of the E_2 class stimulate mucosal hyperplasia in the proximal small bowel of rats. [74], [80] Hollworth and colleagues, [75] however, found that prostaglandins have a strong trophic effect not only in the small bowel but also in the cecum and colon.

Glutamine. Glutamine is an important fuel for enterocytes, colonocytes, and other rapidly dividing cells. [81] In humans who have undergone intestinal resection, however, the turnover of glutamine is markedly diminished. [82] Glutamine appears to play an important role in maintaining the structural integrity of the small intestine. In animal studies, glutamine-enriched parenteral nutrition prevented the deterioration of gut permeability and preserved mucosal structure. [83], [84] In contrast, rat enteral diets supplemented with 2% glutamine had no beneficial effect on intestinal adaptation following massive small bowel resection. [85] In three human subjects with short bowel syndrome, intestinal use of glutamine was increased during adaptive hyperplasia following intestinal resection. [86], [87] Glutamine is unstable, however, and it is not generally available in parenteral form except as alanylglutamine. Furthermore, to be effective, glutamine must be administered in pharmacological doses of at least 0.5 g/kg daily. The requirements for large doses of glutamine and the variable results have raised the question of whether the role of glutamine alone, as a fuel for the enterocyte, has been exaggerated. In initial studies, the intestinal metabolism and oxidation of lumenal glutamate and glutamine were identical, with 60% of the carbon atoms of both precursors oxidized to carbon dioxide, which led to the hypothesis that perhaps both glutamate and glutamine are important amino acids in intestinal adaptation. [88] In an infant swine model in vivo, glutamate rather than glutamine appeared to be the preferred source for mucosal glutathione synthesis [89], [90] and a preferred substrate for intestinal proline synthesis. [91] Taken together, these results highlight the relative importance of enteral and systemic glutamate and glutamine as key precursors for the intestinal synthesis of amino acids, which in turn may become essential during conditions of short bowel syndrome. However, no controlled human clinical trials have thus far demonstrated that glutamate or glutamine supplementation directly enhances morphologic or functional improvement in the small intestine of patients with short bowel syndrome. [92]

Arginine. The intestine is an important site for the synthesis of citrulline, which then enters the circulation to act as the primary precursor for renal arginine synthesis. Dietary arginine thus becomes nutritionally indispensable in rats with massive small intestinal resection. [93] The results of studies in pigs suggest that intestinal enterocytes are capable of turning on the synthesis of arginine, which in turn induces intestinal polyamine synthesis for maintenance and growth of the intestinal mucosa. [94], [95], [96], [97] and [98] Thus, dietary and synthesized amino acids may play an important role in intestinal adaptation following intestinal resection.

Short-chain fatty acids. Acetate, propionate, and butyrate are the principal short-chain fatty acids produced by bacterial fermentation of the carbohydrates and fibrous polysaccharides that spill into the colon. [99] These short-chain fatty acids are absorbed by the colon and metabolized in the colonic epithelial cells as a source of fuel; carbon atoms are salvaged that would otherwise be lost. It has been estimated that up to 3 kJ of energy can be absorbed each day by the human colon in the form of short-chain fatty acids. [100] Supplementation of an elemental diet with pectin, a fiber completely fermented to short-chain fatty acids in the colon, improved adaptation of the ileum, jejunum, and colon after massive small bowel resection. [101] Subsequent studies on the supplementation of parenteral nutrition with short-chain fatty acids [102] and the intracecal infusion of short-chain fatty acids [103] confirmed that supplementation reduces the mucosal atrophy and intestinal immune dysfunction [104] associated with total parenteral nutrition following massive small bowel resection in animal models. [105] In addition to their local effects, systemic short-chain fatty acids can affect the motility of both the stomach [106] and the ileum [107] through neuroendocrine mechanisms, likely through the expression of proglucagon and peptide YY. [108], [109] and [110] Furthermore, both systemic and enteral short-chain fatty acids exert a trophic effect on the jejunum [111] by increasing mucosal mass, DNA, and villus height. These morphometric effects were associated with an increase in amino acid absorption in a pig model of small bowel resection. [105] The effects are yet to be confirmed in human short bowel syndrome. It is important to remember that excess amounts of intralumenal short-chain fatty acids, amounts higher than the concentrations that can be absorbed by the colon, aggravate diarrhea by directly stimulating fluid and electrolyte secretion and by exerting an osmotic effect that limits water absorption from the colon.

Stimulation of Pancreatic and Biliary Secretions The third mechanism by which lumenal nutrients stimulate intestinal adaptation is the production and stimulation of pancreatic and biliary secretions. Nutrients that stimulate biliary and exocrine pancreatic secretions produce mucosal hyperplasia, especially when such nutrients are present in concentrations higher than usual in the residual ileum. Ileal mucosal growth is markedly enhanced when biliary and pancreatic ducts are transplanted to the residual ileum of otherwise normal rats. [28] The presence of food is likely essential for these gastrointestinal secretions to exert their trophic effect. [12]

CLINICAL MANIFESTATIONS

As a result of gradual intestinal adaptation, the clinical course of a patient with short bowel syndrome passes through a number stages. [112], [113] and [114]

The first stage usually lasts 1 to 2 weeks and is characterized by a period of substantial fluid and electrolyte loss resulting from overwhelming diarrhea. During this stage, fluid, electrolytes, and nutrition are usually supplied by the parenteral route. The intensity of the watery diarrhea generally decreases during the next several months. Oral intake and the subsequent gastric hypersecretion can aggravate fluid and electrolyte loss. Parietal cell hyperplasia, hypergastrinemia, and hypersecretion of gastric acid also can alter the duodenal pH and inactivate pancreatic lipase, contributing to steatorrhea.

The second stage is the period of intestinal adaptation, during which oral intake is initiated and gradually increased. Full or partial enteral or parenteral supplementation often is required to maintain optimal nutritive and fluid and electrolyte status. This stage may last from several months to longer than a year.

During the third stage, maximum intestinal adaptation is achieved, and a relatively normal oral intake is usually possible. Whereas some patients never reach the stage of full oral nutrition, life at home can continue with the patient supported by a combination of enteral or parenteral nutrients and electrolytes.

Diarrhea

Diarrhea is inevitable in patients who have undergone extensive small intestinal resection as a consequence of multiple factors: reduction of the absorptive surface area; decreases in intestinal transit time; humorally mediated gastric, small intestinal, and colonic hypersecretion; increases in the osmolality of colonic contents, followed by osmotic diarrhea secondary to malabsorption of fat and carbohydrates; bacterial overgrowth in the small intestine and associated structural damage to enterocytes (increased permeability, decreased brush border membrane function); and colonic hypersecretion, which results from increased levels of dehydroxylated bile acids and hydroxylated fatty acids associated with the spillage of bile acids and fat, respectively, into the colon, where bacteria metabolize them into their secretory solutes. Because the diarrhea in short bowel syndrome is complex, it is critical to evaluate its possible causes so that management is approached correctly.

Gastric Hypersecretion

Gastric hypersecretion secondary to hypergastrinemia occurs within 24 hours after intestinal resection and can result in excessive fluid and electrolyte loss, peptic ulcer disease, and compromised intestinal absorption. [115], [116] and [117] Absorptive compromise occurs as a consequence of reduced lipase activity (as a result of spillage of gastric acid into the duodenum and subsequent lowering of the duodenal pH), which leads to impaired micelle formation and reduced intralumenal lipid absorption. Gastric hypersecretion responds well to histamine receptor antagonists or proton pump inhibitors; furthermore, it almost always abates with time. The cause of gastric hypersecretion remains unclear because serum gastrin levels have been found to be both elevated [115] and unchanged [118] in patients with gastric hypersecretion following intestinal resection. Normal acid secretion also has been noted in patients with hypergastrinemia, and in some patients, hypochloriduria develops after intestinal resection.

Steatorrhea

Several mechanisms are responsible for the steatorrhea of short bowel syndrome. Following surgical resection, gastric hypersecretion can alter the pH in the duodenum and inhibit the action of pancreatic enzymes, particularly lipase (see section “ Gastric Hypersecretion”). In the case of ileal resection and loss of the bile salt–reabsorbing region of the intestine, depletion of the bile salt pool can lead to insufficient micelle formation and steatorrhea (see section “ Site of Intestine Removed”).

Carbohydrate Malabsorption

After extensive resection, carbohydrates pass from the small intestine into the colon, where they are metabolized by bacteria into short-chain fatty acids. These short-chain fatty acids (butyric acid, propionic acid, acidic acid) cause diarrhea through two mechanisms (see section “ Mechanisms of Intestinal Adaptation”). First they cause an osmotic diarrhea, and then they directly stimulate the colon to secrete fluid and electrolytes. Changes in the osmotic load and malabsorption of carbohydrates are probably the most important causes of diarrhea in short bowel syndrome. Increases in intestinal permeability and further carbohydrate and fluid malabsorption have been demonstrated in patients with short bowel syndrome who have episodes of sepsis [119] and may help explain the intermittent and rapid deterioration that sometimes occurs in patients with short bowel syndrome with seemingly minor infections.

In children with short bowel syndrome, the development of clinically significant D-lactic acidemia and D-lactic aciduria is well described and leads to increased serum levels of lactate, acidosis, and compensatory hyperventilation. [120] The D-lactic acid is derived predominantly from malabsorbed fermentable carbohydrates that are delivered to the colon, where lactobacilli abundantly metabolize them to D-lactic acid.

Protein Malabsorption

Protein is usually well tolerated as a caloric source in short bowel syndrome and contributes relatively little to the osmotic load. However, protein is metabolized by colonic bacteria in the same way as malabsorbed carbohydrates and can produce a similar osmotic type of diarrhea, although it is consumed in much smaller quantities than carbohydrates and so usually causes much less severe diarrhea.

Fluid and Electrolyte Malabsorption

Fluid and electrolyte losses can be enormous and are common during the first few weeks after intestinal resection. Daily fecal effluents larger than 5 L can be seen. It is during this time that prompt replacement therapy is important to prevent severe hypovolemia, hyponatremia, and hypocalcemia.

Vitamin and Micronutrient Deficiencies

Vitamin B_{12} deficiency is likely after ileal resection because the recruitment of vitamin B_{12}–intrinsic factor receptors into the jejunum is extremely limited. In addition, colonic or small intestinal bacteria can metabolize vitamin B_{12}, further aggravating vitamin B_{12} deficiency. Vitamin B_{12} deficiency (as well as folate deficiency) leads to hyperhomocysteinemia and has been associated with venous thrombosis in patients with short bowel syndrome. [121] Other water-soluble vitamins are well absorbed throughout the entire small intestinal tract and are generally well preserved except in the shortest intestines. [122], [123]

Mineral deficiencies, including those of calcium and magnesium, are common. They occur secondary to the malabsorption of fatty acids, which form soap complexes with these divalent cations. [122] The administration of vitamin D and calcium supplements is usually helpful in correcting calcium deficiency, but magnesium deficiency may be more difficult to manage because the enteral administration of most magnesium salts results in osmotic diarrhea. Magnesium gluconate is less likely to cause diarrhea than is magnesium oxide or magnesium sulfate. Calcium depletion can be exacerbated by malabsorption of vitamin D. Although calcium deficiency normally results in an increased secretion of parathyroid hormone, in patients with concomitant calcium and magnesium depletion, the release of this hormone is decreased because of the magnesium deficiency. [122]

Steatorrhea also is associated with the decreased absorption of fat-soluble vitamins, particularly vitamin D, but also vitamins A, K, and (rarely) E.

The absorption of trace elements, like that of water-soluble vitamins, is usually sufficient after intestinal resection. [122], [123] Clinical zinc deficiency resulting from diarrhea can develop fairly rapidly, however, and has been described to impair intestinal epithelialization and adaptation.

Systemic Manifestations

Renal dysfunction, both permanent and intermittent, can occur as a consequence of hypovolemia. This complication often develops soon after intestinal resection, but the fluid balance of some patients with short bowel syndrome is sufficiently precarious that short episodes of viral gastroenteritis can “tip” them into renal failure.

An increased incidence of renal calculi in association with ileal resection or ileal disease is well documented. [124], [125], [126] and [127] Hyperoxaluria is frequent in these patients, and the calculi are predominantly formed from calcium oxalate. [127] The hyperoxaluria appears to be secondary to an increased absorption of dietary oxalate, particularly in the colon. The increase involves two mechanisms. First, steatorrhea contributes to the increased absorption of oxalate through an increase in lumenal fatty acids, which preferentially bind to calcium, leaving free oxalate in the lumen that can readily be absorbed. Second, bile salts that enter the colon of these patients appear to increase the colonic mucosal permeability, thereby allowing increased oxalate absorption in the colon. [126], [127] In addition to hyperoxaluria, other mechanisms may be responsible for increases in renal calcium oxalate and calculi. [128] These include a decreased urinary concentration of calcium-binding anions, such as phosphate and citrate, and diminished urine flow.

Patients with short bowel syndrome are at significant risk for cholelithiasis if the length of the intestinal remnant is less than 120 cm, if total parenteral nutrition is required, or if the terminal ileum is resected. The incidence of gallstones increases threefold after ileal resection. [129], [130] Interruption of the enterohepatic circulation of bile and the subsequent bile salt malabsorption lead to an increase in the hepatic synthesis of cholesterol; bile becomes supersaturated with cholesterol, and gallstones develop. A significant number of patients with ileostomies have calcium-containing radiopaque gallstones rather than radiolucent cholesterol gallstones. [129] Some other mechanism, therefore, must be involved. It also appears that interruption of the intrahepatic circulation predisposes humans to an increase in pigment stones. [131], [132] and [133] With this understanding of the pathophysiology of gallstone formation, prophylactic cholecystectomy should be considered in all patients who have undergone extensive intestinal resection. [134]

In addition to the increased risk for cholelithiasis, the incidence of intrahepatic cholestasis and hepatic dysfunction is increased (65%) in patients with short bowel syndrome; these conditions are usually associated with parenteral nutrition therapy and sepsis. [135] Hepatic dysfunction, particularly in children with short bowel syndrome, results in liver failure, cirrhosis, and the need for liver transplantation.

An increased risk for infectious complications, mainly caused by the egress of lumenal intestinal bacteria to distant organs, a process termed *bacterial translocation,* has been described in pediatric, but not adult, patients with short bowel syndrome. [40], [136] In animal models of short bowel syndrome, rates of bacterial translocation were increased as a consequence of intestinal bacterial overgrowth in the residual bowel, and bacterial translocation was positively correlated with removal of the ileocecal valve. [137]

MEDICAL MANAGEMENT

Nutritional Management

The nutritional management of short bowel syndrome is a dynamic process that follows the evolution of the clinical and adapted state of the bowel. Depending on the length of resection and the postsurgical adaptation, the process will result in one of four nutritional outcomes: maintenance of a balanced nutritional status on a normal or modified oral diet, maintenance through the use of defined enteral formula diets, maintenance through enteral intake with parenteral electrolyte and fluid supplementation, or maintenance through total or partial parenteral nutritional intake supplemented by variable amounts of enteral intake. Whatever the source of nutrition, the caloric intake should be increased slowly and progressively until a target is reached of about 32 kcal/kg of ideal body weight per day. This targeted caloric intake, in general, will compensate for the increased losses that result from inefficient and inadequate absorption.

Parenteral Therapy In the immediate postoperative period, all patients who have undergone extensive small intestinal resection require total parenteral nutrition. Sodium losses in early secretions are often high (80–120 mmol/L), and electrolyte losses must be monitored carefully. As the amount of enteral nutrition is gradually increased, the duration and intensity of parenteral nutrition infusion can be reduced. Initially, parenteral nutrition can be stopped for one or two nights each week.

Eventually, administration every other night or every third night is possible. If more than 25% of the patient's intestine remains, it should be possible to stop total parenteral nutrition completely. Some patients, however, require parenteral therapy, particularly fluids and electrolytes, for extended periods. In a study of 135 patients with short bowel syndrome, small intestinal length (>35 cm with an ileojejunal anastomosis), preservation of the colon, and an ileocolonic anastomosis were the features most predictive of the ability to wean from parenteral nutrition. [138]

Oral Therapy A balanced solution containing carbohydrates and electrolytes can be given orally once stool output is less than 2 L daily. As previously noted, early oral feeding is important to intestinal adaptation. Clear fluid diets are not useful because their nutritional value is inadequate; they are also severely hyperosmolar and likely to provoke osmotic diarrhea (Table 79-3). Full fluid diets are also poorly tolerated because they contain lactose; most patients with short bowel syndrome cannot tolerate lactose. Because the tight junctions of the jejunum are extremely permeable, supplements high in glucose and low in sodium often promote sodium and water losses and aggravate short bowel syndrome. To optimize oral fluid and electrolyte absorption, a balanced oral replacement solution is necessary. A solution that contains an isosmotic sodium and glucose mixture takes advantage of the small intestinal sodium/glucose cotransport carrier to enhance salt and water absorption. These solutions can be purchased ready-made (Table 79-4) or mixed at home (Table 79-5). The patient should sip the solution at frequent intervals throughout the day to prevent nausea and to avoid passing a large bolus of fluid rapidly through the short intestine. [139] The oral replacement solution also can be used instead of parenteral electrolytes at a later stage to reduce parenteral requirements. Patients with short bowel syndrome, in general, require an oral intake with a higher sodium concentration. Those with less than 100 cm of residual jejunum are usually net sodium secretors [140] and can achieve an optimal sodium balance with an intake of 120 to 160 mmol/L per day, [139] whereas oral replacement solutions with lower sodium concentrations of 90 mmol/L do not maximize sodium balance. [141] Sports drinks like Gatorade are too low in sodium to be of use as oral replacement solutions in patients with short bowel syndrome. They are designed to replace fluid losses and prevent dehydration from perspiration, not intestinal efflux.

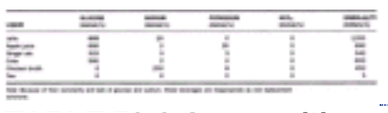

TABLE 79-3 Composition of Some Common Household Beverages

TABLE 79-4 Commercially Available Oral Replacement Solutions

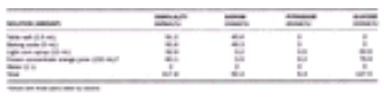

TABLE 79-5 An Isosmotic Oral Replacement Solution That Can Be Mixed at Home

For patients with more than 60 to 80 cm of small bowel, oral feeding should be reintroduced slowly until a normal or modified oral diet is reached. Because gastric emptying is slower for solids, they should consume dry solids at meals and take only isotonic fluids 1 hour later; this regimen improves the absorption of nutrients. Diarrhea that occurs as a consequence of oral feeding usually can be managed with an antidiarrheal agent, which should be taken on a regular basis 1 hour before meals and snacks. Waiting to take an antidiarrheal agent until after a meal has been started and diarrhea has occurred is not effective (see section " Management of Diarrhea"). Care must be taken to limit the amount of lactose in the diet because the initial disease, gastric hypersecretion, or surgical therapy can cause lactose intolerance. It may be useful to test the lactose tolerance of patients to provide them with specific guidelines about lactose intake. The lactose tolerance of patients with short bowel syndrome and a jejunocolonic anastomosis is greater than that of patients with a terminal jejunostomy; the lactose provided in yogurt is generally better tolerated than the lactose in milk. [142] Patients with significant ileal resection and an intact colon in whom steatorrhea is expected to develop may require monitoring of their oxalate secretions (see section " Systemic Manifestations"). A low-oxalate diet is difficult to follow, but guidance can be provided regarding which foods are high in oxalate. Oral calcium decreases oxalate absorption because insoluble salts form. A 4-g dose of cholestyramine given three times daily reduces bile salt–induced diarrhea and also binds intralumenal oxalate, further decreasing oxalate absorption. Attention to vitamin and mineral supplementation is critical. In general, a multiple-vitamin preparation with minerals will suffice (see section " Vitamin and Mineral Supplementation"). For patients with ileal resection, vitamin B_{12} should be administered once monthly. Traditionally, low-fat diets (often with medium-chain triglycerides) and high-carbohydrate diets have been sed to treat patients with short bowel syndrome. This practice was based on an understanding that steatorrhea has many adverse effects on fluid absorption, that dietary fat induces the secretion of gastrointestinal hormones, and that carbohydrates malabsorbed in the small bowel undergo fermentation in the colon to short-chain fatty acids. These short-chain fatty acids are easily absorbed across the colonic mucosa, so that carbohydrate energy is salvaged that would have otherwise been lost in the feces. In one study, a high-fat diet had the same effect on ileostomy volume output as a low-fat diet. [143] In this study, although steatorrhea from the ostomy increased with the high-fat diet, the proportion of fat absorbed was equivalent to that absorbed from a low-fat diet, suggesting that net absorption is more important than whether the regimen is high in fat. [144], [145], [146] and [147] In contrast, in patients without an ileostomy and with an intact colon, oral fat intake often is limited by the amount of fat that reaches the colon and is subsequently metabolized to hydroxy fatty acids, which in turn lead to secretory and osmotic diarrhea. Divalent cations, including calcium, magnesium, zinc, and copper, may bind to fatty acids in the stool, and excessive fecal losses of these minerals have been documented in patients with steatorrhea. [143], [146] Steatorrhea also exacerbates malabsorption of the fat-soluble vitamins A, D, E, and K. Increased fecal losses of fat enhance dietary oxalate absorption, oxaluria, and renal stone formation. Recommendations regarding dietary fat intake therefore must be based on the individual patient's symptoms following bowel resection. In addition, it is important to balance the beneficial effects of fat restriction against the reduced food palatability and caloric intake associated with low-fat diets. A low-fat and low-oxalate diet, for instance, is likely to be completely unpalatable. Medium-chain triglycerides can be used as caloric supplements for patients with short bowel syndrome. Medium-chain triglycerides are hydrolyzed in the intestinal lumen to water-soluble components, which are absorbed in the absence of bile salts. [148] These medium-chain fatty acids do not require resynthesis in the enterocyte and can be absorbed directly into the portal circulation. Thus, medium-chain triglycerides may serve as a nutritional source for patients with significant long-chain triglyceride malabsorption. However, medium-chain triglycerides have an unpleasant taste, their osmotic load in the proximal small intestine sometimes causes diarrhea (in doses of more than 35 g/d), and they do not provide essential fatty acids. Furthermore, they have a slightly lower caloric density than long-chain fatty acids (8.3 kcal/g compared with 9.0 kcal/g). Low-fiber diets remain controversial. Their use is based on observations that some types of dietary fiber, such as wheat bran, increase intestinal transit times and fecal weight. [149] It is now clear, however, that dietary fiber has variable effects on the intestine. [150] Soluble fibers such as pectin do delay gastric emptying and increase intestinal transit time. [151], [152] and [153] They also bind bile salts and have a significant water-retaining capacity. In addition, bacterial fermentation of fiber in the colon can produce short-chain fatty acids. In high concentrations, the short-chain fatty acids cause moderate diarrhea and colonic secretion, but in low concentrations, they actually may provide fuel for colonocytes and help to heal and prevent inflammation.

Enteral Therapy Patients who cannot tolerate a normal oral diet and those with a short bowel (<60–80 cm) often benefit from an enteral formula. If a chemically defined formula is used, it is important to control the rate of infusion to match osmotic inflow with osmolar absorption. Rates of full-strength infusion usually begin at 25 mL/h and gradually increase to 125 mL/h. The rate is modulated according to the tolerance displayed by the small intestine. If a polymeric formula is used, it should be lactose free because most patients with a massive small intestinal resection do not have an adequate reserve of lactase. Elemental or semi-elemental diets require a minimal absorptive surface. [112], [154] These diets may be useful for persons with a short gut during the early adaptive stage [155]; they also decrease the secretion of digestive juices [156] and gastric hypersecretion. Nevertheless, significant evidence suggests that elemental diets are not absorbed more readily than polymeric diets. [144], [157], [158] Elemental or semi-elemental formulas contain amino acids in a free form as well as dipeptides and tripeptides. Because separate carrier mechanisms exist for free amino acids and dipeptides, a mixture of amino acids and dipeptides results in increased protein absorption. [159], [160] and [161] Many enteral feeding formulations have a high content of carbohydrates in the form of sucrose or glucose polymers. These high levels lead to carbohydrate malabsorption and spillage of carbohydrates into the colon, with resultant osmotic diarrhea. Elemental formulas are low in fat, often providing the minimal amounts to meet essential fatty acid requirements. The formulas are effectively absorbed within the first 100 cm of jejunum [162] and stimulate adaptation of the proximal small intestine. [163] The unpleasant taste of elemental or semi-elemental formulas, however, often limits oral intake, and because they are hyperosmolar, they may considerably worsen diarrhea. The formulas therefore should be provided by slow, constant infusion. Polymeric diet supplements generally provide about 30% of calories as fat and contain intact protein sources. They are more palatable than elemental diets; they are also less hyperosmolar and considerably less expensive. Patients with short bowel syndrome absorb less than 100% of oral calories and protein. Many of them therefore need to consume calories and protein in excess of the normal estimated requirement. [164] Nevertheless, overfeeding

must be avoided carefully because it can induce a loss of endogenous fluid and electrolytes into the gut. Excess consumption of fats, fiber, concentrated sweets and sugar, milk and milk products, caffeine, and alcohol may increase normal outputs. [165], [166], [167] and [168] High enteral loads of carbohydrate should be avoided. Alterations of the bacterial flora in the colon, particularly overgrowth of *Lactobacillus acidophilus,* may result in the excessive production of D-lactate from unabsorbed carbohydrates, and severe metabolic acidosis and encephalopathy have been described. [169], [170] and [171]

Vitamin and Mineral Supplementation

In general, vitamin and mineral supplements are included in enteral and parenteral solutions. As patients are weaned from these solutions, and once they have stopped them completely, vitamin and mineral deficiencies may slowly develop because of inadequate intake (as patients try to prevent diarrhea), excess nutrient losses (from the short bowel), or a combination of both. Table 79-6 presents an example of a liquid vitamin and mineral oral supplementation regimen that could be considered for some patients as they are weaned from parenterally supplied vitamins and minerals. Liquid supplements are preferable to solid pills because hard outside matrices often do not dissolve during rapid transit through a short bowel.

ADEKs multiple vitamin Four tablets per day, chewed or crushed throughly; each tablet contains 4000 IU of vitamin A, 3 mg of β-carotene, 400 IU of vitamin D, 150 IU of vitamin E, 0.15 mg of vitamin K, 60 mg of vitamin C, 0.2 mg of folic acid, 1.2 mg of thiamin, 1.3 mg of riboflavin, 10 mg of niacin, 1.5 mg of vitamin B_6, 12 μg of vitamin B_{12}, 50 μg of biotin, 10 mg of pantothenic acid, and 7.5 mg of zinc.
Calcium gluconate liquid 400 mg PO twice daily = 448 mg of elemental calcium twice daily
Ferrous sulfate liquid 300 mg PO twice daily = 60 mg of elemental iron twice daily
Vitamin D_2 capsule 50,000 IU once per week
Phosphate-Novartis (tablet dissolved) 500 mg PO twice daily = 500 mg of elemental phosphorus twice daily
Potassium liquid 60 mL PO twice daily = 40 mEq of potassium chloride twice daily
Magnesium glucoheptonate liquid 30 mL PO twice daily = 150 mg of magnesium twice daily
Follow-up blood work (every 4 to 6 months): vitamins A, B_{12}, D, and E; prothrombin time and International Normalized Ratio; zinc, magnesium, phosphorus, calcium, albumin, red blood cell folate, iron, total iron-binding capacity, ferritin; complete blood cell count; electrolytes.

Note: Exact doses will vary depending on the requirements of individual patients.

TABLE 79-6 An Oral Vitamin and Mineral Supplement for Use in Selected Patients with Short Bowel Syndrome

Bile Supplementation

Bile acid replacement with oral conjugated bile acids (2 g per meal in the form of ox bile or synthetic cholylsarcosine supplementation) did not worsen diarrhea in a patient with an ileostomy, and it did cause fat absorption to increase by 40 g/d and eventually led to a significant weight gain. [172] This carefully conducted balance study suggests that conjugated bile acid replacement therapy can be considered for some patients with short bowel syndrome.

Management of Diarrhea

In general, the cause of the diarrhea must be identified before appropriate treatment can begin (e.g., bile acid–induced diarrhea, steatorrhea, osmotic diarrhea, bacterial overgrowth; see Chapter 42 and Chapter 78). Nevertheless, in the absence of sufficient intestinal adaptation, debilitating diarrhea develops simply because the intestinal surface area is inadequate for absorption to take place, and antidiarrheal therapy becomes an integral part of the management of short bowel syndrome.

Opiates are the most widely used products in the treatment of diarrhea associated with short bowel syndrome. Clinically available opiates include natural substances, such as paregoric and opium alkaloids, and synthetic preparations, such as codeine, diphenoxylate (Lomotil), and loperamide (Imodium). These agents relieve diarrhea by reducing intestinal secretion or by promoting intestinal absorption and reducing intestinal motility. For the diarrhea of short bowel syndrome, these agents should be taken on a regular basis 1 hour before meals, as the liquid formulation when available: 30 to 150 mg of codeine daily, 7.5 to 20 mg of diphenoxylate daily, or 6 to 20 mg of loperamide daily. As-needed dosing, rather than regular dosing, often results in unnecessary diarrhea and loss of the nutrient value of a meal before the opiate has had time to exert a therapeutic effect.

a $_2$-Adrenergic agonists are potent stimulators of intestinal absorption. These agents stimulate sodium and chloride absorption and inhibit bicarbonate and chloride secretion in the colon and small intestine. In addition, a $_2$-adrenergic agonists reduce intestinal motility. A 0.1- to 0.2-mg dose of clonidine, taken with each meal, can act as an adjunct to opiates, helping to prevent the difficult-to-control diarrhea of short bowel syndrome. [173], [174] Despite the fact that clonidine has profound antidiarrheal effects in experimental conditions, its centrally mediated hypotensive and sedative effects limit its use as an antidiarrheal agent.

Octreotide, a long-acting somatostatin analog, has been used to treat diarrhea of both neuroendocrine and nonneuroendocrine origin. The response in cases of short bowel syndrome–associated diarrhea has been variable, and although the diarrhea may respond initially, tachyphylaxis has been known to occur. [167] A therapeutic trial of octreotide when diarrhea cannot be controlled with conservative measures is warranted. In animal models of massive intestinal resection, physiological and pharmacological doses of octreotide reduced intestinal secretion and, importantly, did not alter the development of intestinal adaptation. [168] The standard initial therapy is 50 to 100 μg given subcutaneously over an 8- to 12-hour period; titration is based on the clinical and biochemical effects, with the dose escalated by 50 μg per week up to a maximal dose of 200 μg. The dose can be increased in 100-μg increments from 200 to 500 μg every 8 hours. Once the effectiveness of octreotide has been demonstrated in an individual patient, the patient can be switched to a comparable dose of the long-acting release depot octreotide preparation, which has similar beneficial effects of decreasing fecal output. [175]

The adverse effects of octreotide are usually mild and depend on the duration of therapy. Short-term side effects include pain at the injection site and transient nausea and bloating. Lanreotide, a new somatostatin analog, significantly reduces duodenal-to-cecal transit time in healthy male patients; however, it concomitantly decreases carbohydrate and fat absorption and thus may worsen diarrhea. It is quite possible therefore that somatostatin analogs have mixed effects in the management of diarrhea associated with short bowel syndrome. [176]

Recombinant Growth Hormone Therapy

The effects of low-dose recombinant human growth hormone (0.024 mg/kg daily) on body composition and absorptive capacity in patients with short bowel syndrome resulting from Crohn's disease were examined in a placebo-controlled crossover clinical trial. [177] Body weight and lean body mass increased, but no effect on nutrient absorption was noted. In an uncontrolled study, 8 weeks of recombinant human growth hormone treatment led to increases in body weight and in lean and fat-free body mass; the changes correlated positively with increases in serum levels of insulin-like growth factor-I. The combination of growth hormones and oral glutamine supplementation with a high-carbohydrate, low-fat diet appeared superior to either agent alone. [178] In this uncontrolled study of 47 patients, protein absorption increased by 40% and stool output decreased by 30%; of the patients, 40% were weaned from total parenteral nutrition within 1 year and another 40% were able to decrease their total parenteral nutrition requirements when they followed the diet. [178] In contrast, in a randomized, double-blinded, controlled trial, no benefit of growth hormone and glutamine on intestinal morphology, stool losses, or macronutrient absorption could be demonstrated in patients with short bowel syndrome. [179] Similarly, in a randomized, double-blinded, placebo-controlled crossover study, a combination of growth hormone (0.12 mg/kg per day) with oral (28 g/d) and parenteral (5.2 g/d) glutamine for 28 days did not improve intestinal absorption in patients with short bowel syndrome on their usual diet, [180] nor did it affect body weight or composition. [181] An analysis of published clinical studies of the use of recombinant growth hormone, glutamine, and low-fat, high-carbohydrate diets did not demonstrate benefit. [182]

The importance of a multidisciplinary approach involving a dedicated nutritional support team to optimize diet is demonstrated in the review by Wilmore [183] encompassing more than 300 patients with short bowel syndrome who received glutamine, growth hormone, and a dietary regimen optimized to enhance absorption.

After 2 years of long-term follow-up, 40% of the group could be weaned completely from parenteral nutrition, and 40% were able to reduce their parenteral nutrition requirements.

Whether growth hormone treatment will yield better outcomes in pediatric than in adult patients remains to be determined. Indeed, case reports have been published describing particularly impressive results in children with a combination of surgical lengthening and growth hormone administration. [184] These findings may imply different intestinal responses in children and adults to trophic growth hormones. Further studies are required to evaluate this promising therapy more fully.

Glucagon-like Peptide 2 Therapy

In a human clinical trial, 400 µg of glucagon-like peptide 2 was administered subcutaneously twice a day for 35 days to eight patients with short bowel syndrome. Treatment with glucagon-like peptide 2 improved the intestinal absorption of energy and nitrogen, increased body weight, and slowed the gastric, but not the small intestinal, emptying time. [185] Although the clinical effects of glucagon-like peptide 2 in this pilot study were modest, they are encouraging and will provide a basis for additional studies to determine the optimal dose and duration of therapy.

SURGICAL MANAGEMENT

Many of the surgical approaches require technical perfection and careful patient selection, and they are yet to be tested in clinical trials; however, along with intestinal transplantation, they will likely provide a foundation of therapy into the twenty-first century.

Techniques Designed to Slow the Transit Time

Antiperistaltic segments act like physiological valves by slowing intestinal transit and altering myoelectric activity. [186], [187] These reversed segments increase the absorption of water, nitrogen, and fat. [188], [189] and [190] The treatment of more than 30 patients with short bowel syndrome by this method has been reported thus far, with good results in about 70% of them. The ideal length for a reversal segment is 10 to 15 cm of distal small bowel in an adult and about 3 cm in an infant. [191], [192], [193], [194], [195], [196] and [197] Reversal may provide temporary relief while intestinal adaptation is taking place. [198] Patients with an extremely short intestine may not have the 10 cm of intestine required to fashion the reversal segment. Furthermore, small bowel obstruction at the antiperistaltic site is always a risk and may necessitate additional intestinal resection.

Peristaltic activity in the colon differs from that in the small intestine; it is slower and segmental and progresses by means of infrequent peristaltic rushes. [199] In dogs and rats, isoperistaltic interposition of a segment of colon between jejunal or ileal segments prolongs the intestinal transit time without causing obstruction. [199], [200] The isoperistaltic colon is placed proximally and functions by allowing the slow delivery of chyme to the distal intestine. Despite slowed transit, however, the interposed colonic segment does not show evidence of small bowel intestinalization [201] and appears to have no significant effect on the absorption of nutrients. [202] So far, about 30 cases of colonic interposition in short bowel syndrome have been reported. In these case reports, the length of the interposed colon, which does not appear to be critical, varied from 8 to 24 cm.

The colon also can be interposed in an antiperistaltic fashion. The antiperistaltic colon is placed distally. In one study, this procedure significantly improved the absorption of fat and xylose in monkeys. [203] Other authors, however, did not identify significant benefits to intestinal absorptive function. [204], [205] and [206]

Various techniques are used in the construction of valves to replace lost ileocecal valves. Nipple valves can be inserted at an ileostomy site. [207] In general, excision of the outer longitudinal muscle layer allows the inner circular muscular layer to contract without opposition, so that submucosal tunneling and the development of a nipple-like valve are possible. [208], [209] Distal bowel also can be everted and telescoped into the proximal bowel. [210] These techniques of constructing an artificial valve do not modify the intestinal motor response to intestinal resection but simply create a low-grade mechanical obstruction. [211] In both experimental animal models and in humans with short bowel syndrome, such valves have reduced the number of evacuations. [212], [213] However, despite a significantly prolonged transit time, the operation has not been shown to result in increases in absorptive surface area, functional absorptive capacity, or body weight. [214]

In principle, recirculating loops should prolong the transit time by promoting repeated exposure of the intestinal mucosal surface area to lumenal contents. This procedure is associated with high morbidity and mortality rates in experimental animals, however, [215] which appear to be related to bacterial overgrowth and the absorption of toxic metabolites.

Retrograde electrical pacing is designed to slow and reverse the flow of intestinal contents, so that chyme pools and absorption is increased through prolonged mucosal contact. In dog jejunum, retrograde electrical pacing increased water, sucrose, and sodium absorption. [216] The technique has not been applied successfully in humans.

In animal studies, intrinsic myenteric denervation of the ileum, in an attempt to slow the forward flow of intestinal contents, led to dilation of the residual small and large intestine in rats that had been subjected to massive intestinal resection and resulted in an increase in absorptive surface area and postoperative weight gain. [217]

Tapering and Bowel-Lengthening Procedures

Adaptive dilation of the proximal small bowel causes stasis and ineffective peristalsis. The simplest way to deal with this problem is excision of the dilated segment, provided the length of small intestine is sufficient. In cases in which bowel length is insufficient, the diameter of the dilated bowel can be reduced through intestinal plication or tapering enteroplasty. These simple and safe techniques allow all the mucosal surface to be preserved. [218] Recently, Ramanujam, [219] using mongrel puppies, demonstrated that plication is a remodeling technique that is superior to tapering enteroplasty.

Bianchi [220] described a technique for lengthening the bowel of pigs by using the dilated segment. The gut is tapered, and the redundant small bowel is used for lengthening purposes. Since the first clinical application, this has been the surgical technique most frequently used in attempts to reverse short bowel syndrome in children. [221], [222] Although the bowel length is increased, mucosal function may be compromised. In one study, sucrose transport was found to be decreased across the segment involved in the bowel lengthening. [31] In dogs with a 75% distal ileal resection, tapering and lengthening impaired nutritional status and intestinal absorption and adaptation. The changes in absorption and transit appeared to be related to altered intestinal transit rates, and the impaired adaptation was related to decreased enteroglucagon levels and increased somatostatin levels. [223] These findings are not surprising because intestinal lengthening does not provide new mucosa. Any benefit is likely to be attributable to the mechanical effect of slowed intestinal transit.

In a series involving five human subjects, isoperistaltic tapering and lengthening (Bianchi procedure) resulted in improvement of intestinal function. At 1 and 6 months postoperatively, stool output was decreased, D-xylose absorption was increased, and fecal fat was decreased in comparison with preoperative measurements. [224] Isoperistaltic tapering and lengthening resulted in survival off parenteral nutrition in 45% of 20 pediatric patients. Successful weaning from parenteral nutrition was related to an initial bowel length of more than 40 cm. [225] Similar results have been reported by a German pediatric surgical group in 18 children. [226]

Georgeson and associates [227] combined several different techniques. If the bowel was not sufficiently dilated, a nipple valve was constructed distally to provide partial small bowel obstruction and so induce dilation. Following this, the Bianchi technique was used to lengthen the bowel. In a small series of case reports, length was increased on average by a factor of 2.5 during 1 year; enteral intake averaged 66% of the total requirement, in comparison with less than 10% before the operation.

Intestinal regeneration takes place in full-thickness intestinal defects patched with a variety of substances, including colonic serosa and prosthetic materials. [228], [229] The new intestinal tissue, which develops by lateral growth, is functionally similar to normal intestinal mucosa. [230] In dogs, however, intestinal interposition of a patch of colon denuded of its mucosa resulted in the regeneration of colonic, rather than small intestinal, mucosa. Growth of neomucosa has never been attempted clinically.

INTESTINAL TRANSPLANTATION

Indications

Intestinal transplantation has become a life-saving treatment that can be considered for patients with irreversible intestinal failure who cannot be maintained on parenteral nutrition. Life-threatening complications of parenteral nutrition that warrant a consideration of intestinal transplantation include parenteral nutrition–associated liver disease, recurrent sepsis, and threatened loss of central venous access. The indications are similar for children and adults. Contraindications to transplantation include profound neurological difficulties, life-threatening illness, multiple-system immune diseases, and lack of venous access. The fact that intestinal failure itself can lead to the development of profound neuropathological abnormalities in the brain may be a reason to consider earlier transplantation. [231]

Because the shortage of donor organs is critical, waiting times for intestinal transplantation are prolonged. Therefore, it is important that patients with life-threatening complications of intestinal failure and parenteral nutrition therapy be identified and referred for transplantation early. [232], [233] Because the survival rate of isolated intestinal transplants is higher than that of combined intestinal-liver transplants, patients should be considered for transplantation before bridging fibrosis and cirrhosis develop. Finally, an appreciation of the unique and specific nutritional needs of the recipient and the donor is important in maximizing survival. [234]

Natural History of Short Bowel Syndrome Treated with Parenteral Nutrition

The long-term rates of survival and dependence on parenteral nutrition of adult patients with short bowel syndrome have been reviewed. [235] Rates of 5-year survival and dependence on parenteral nutrition are 55% and 45%, respectively. Survival is negatively related to end-enterostomy, a small bowel length of less than 50 cm, advanced age, and arterial infarction as a cause of the short bowel syndrome. [235], [236] Dependence on parenteral nutrition is negatively related to a small bowel length of less than 100 cm and to the absence of a terminal ileum or colon. After 2 years of parenteral nutrition, the probability of a permanent need for parenteral nutrition is 95%. Similar survival rates have been reported for children with short bowel syndrome treated with parenteral nutrition. [237] Long-term home parenteral nutrition, although it can maintain normal nutritional parameters in 80% of patients, results in frequent hospitalizations, predominantly for catheter-related problems, a 30% rate of regular opiate use, and an inability to achieve complete rehabilitation. [238]

Results

Intestinal transplantation is an evolving procedure with survival rates now comparable, at some larger centers, to those of parenteral nutrition. [239] The intestinal transplant data registry (Web site, http://www.intestinaltransplant.org/) provides updated figures for graft and patient survival from intestinal transplant centers across the world. Two thirds of the recipients are children or adolescents. Short bowel syndrome with a failure of maintenance on parenteral nutrition is the most common indication for transplantation. [240] Types of transplantation include small bowel with or without colon (40%), intestine and liver (45%), and multiple-visceral grafts (15%). As of the last major review from the transplant registry in 2001 (updated reviews are periodically posted on the Web site), the 1-year graft/patient survival rates at major centers doing more than 10 transplants since 1999 are 60%/75% for intestinal grafts, 60%/66% for intestinal and liver grafts, and 65%/70% for multiple-visceral grafts. [241] In a retrospective review from a single center performing a large number of intestinal transplants, the 1-year graft/patient survival was reported as 93%/71%. [242]

The single most important factor in both graft and patient survival is the number of transplants a center completes each year. Donor type, previous treatment of the donor, diagnosis, recipient age, and organs transplanted do not affect survival. Approximately 80% of survivors of transplantation have been able to discontinue parenteral nutrition and resume oral nutrition, 10% have a partial or nonfunctioning transplant in place, and 10% have had their transplant removed. Survival results during the last several years have improved as consequence of refinements in operative techniques, a reduced requirement for immunomodulation, and improvements in postoperative care. Rejection remains the single most important factor (60%) leading to graft failure and removal. Advances in immunosuppression have significantly reduced rejection rates. Part of the challenge in managing these patients is maintaining the delicate balance between immunosuppression, which is necessary to prevent graft versus host disease, and rejection. At the same time, the required degree of immunosuppression is associated with a high risk for lymphoproliferative disorders and intestine-derived sepsis. The incidence of lymphoproliferative disease after intestinal transplantation is 15%; it appears to be linked to Epstein-Barr virus infection, OKT3, and corticosteroids. [243] Additional reasons for graft failure are thrombosis, ischemia, and bleeding (25%), multiple-organ failure (10%), sepsis (6%), and lymphoma (1%).

Sepsis (60%) is the most frequent cause of death in this transplant population. [243] Reduced rates of sepsis and improved survival rates have been described following living-related transplantation. [244], [245] and [246] Investigations of bacterial translocation following intestinal transplantation have suggested that cold ischemia time, not rejection or the associated transplantation of the colon, influences bacterial translocation. [247] Additional causes of death are nontransplant organ failure (14%), lymphoma (14%), thrombosis, ischemia, and bleeding (13%), and graft rejection (12%).

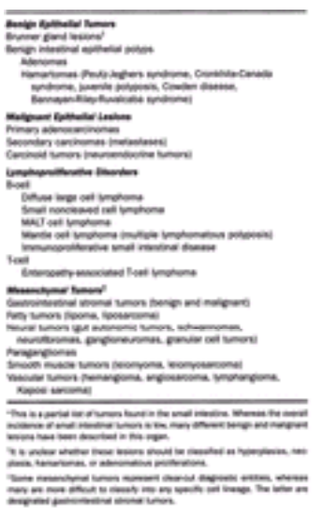
CHAPTER 80

Robert S. Bresalier and Tamir Ben-Menachem

TUMORS OF THE SMALL INTESTINE

Small intestinal tumors (tumors of the duodenum, jejunum, and ileum) are uncommon by comparison with those occurring elsewhere in the gastrointestinal tract, and fewer than 2% of malignant gastrointestinal tumors are derived from this organ. [1], [2], [3], [4], [5] and [6] Primary small intestinal tumors are derived from both epithelial and mesenchymal components of the small bowel (Table 80-1). Primary malignant tumors include adenocarcinomas, carcinoids, lymphomas, and sarcomas (now classified as gastrointestinal stromal tumors). Approximately 5300 new cases of primary small intestinal cancer occurred in the United States in 2002 (equally distributed between men and women), with 1100 estimated cancer deaths. [1] The diverse nature of small intestinal tumors makes it difficult to make generalizations about the group as a whole. Some tumors represent distinct entities, whereas others share overlapping features.



Benign Epithelial Tumors
Brunner gland lesions[†]
Benign intestinal epithelial polyps
Adenomas
Hamartomas (Peutz-Jeghers syndrome, Cronkhite-Canada syndrome, juvenile polyposis, Cowden disease, Bannayan-Riley-Ruvalcaba syndrome)

Malignant Epithelial Lesions
Primary adenocarcinomas
Secondary carcinomas (metastases)
Carcinoid tumors (neuroendocrine tumors)

Lymphoproliferative Disorders
B-cell
Diffuse large cell lymphoma
Small noncleaved cell lymphoma
MALT cell lymphoma
Mantle cell lymphoma (multiple lymphomatous polyposis)
Immunoproliferative small intestinal disease
T-cell
Enteropathy-associated T-cell lymphoma

Mesenchymal Tumors[‡]
Gastrointestinal stromal tumors (benign and malignant)
Fatty tumors (lipoma, liposarcoma)
Neural tumors (gut autonomic tumors, schwannomas, neurofibromas, ganglioneuromas, granular cell tumors)
Paragangliomas
Smooth muscle tumors (leiomyoma, leiomyosarcoma)
Vascular tumors (hemangioma, angiosarcoma, lymphangioma, Kaposi sarcoma)

*This is a partial list of tumors found in the small intestine. Whereas the overall incidence of small intestinal tumors is low, many different benign and malignant lesions have been described in this organ.
†It is unclear whether these lesions should be classified as hyperplasias, neoplasia, hamartomas, or adenomatous proliferations.
‡Some mesenchymal tumors represent clear-cut diagnostic entities, whereas many are more difficult to classify into any specific cell lineage. The latter are designated gastrointestinal stromal tumors.

TABLE 80-1 Classification of Small Intestinal Tumors*

DESCRIPTIVE EPIDEMIOLOGY

The frequency of small bowel tumors varies among different populations. [7] Reviews of the incidence and natural history of small bowel tumors are composed of small series of patients, and some may include both primary or secondary (e.g., lymphomas) tumors. Some series include periampullary tumors and tumors of the ampulla of Vater, whereas others do not. [2] The relative frequency of primary tumors ranges in the literature, with adenocarcinoma (24% to 52%), malignant carcinoid (17% to 41%), lymphoma (12% to 29%), and sarcomas (11% to 20%) the most frequent. [2], [3], [4], [5] and [6], [8], [9], [10], [11], [12], [13] and [14] The pattern of distribution of tumors in the small intestine is dependent on histological type. In Western countries, adenocarcinomas are most commonly found in the duodenum. In the setting of Crohn's disease, adenocarcinomas may occur distally in the ileum. Carcinoids and primary lymphomas occur predominantly in the ileum and jejunum. Sarcomas are found more evenly distributed. Metastases to the small bowel from adenocarcinomas and sarcomas account for approximately 50% of all small bowel tumors.

An overall age-adjusted incidence of primary small bowel cancers of 1.4 per 100,000 was reported in a United States population-based study. [5] Small but significant increases in the incidence of adenocarcinomas and carcinoids have been noted since the 1970s, [15] with a slight male predominance. The incidence of small bowel cancers rises with age, beginning at 30 years, with a mean age of diagnosis of approximately 60 years. [17] Incidence rates for adenocarcinomas and malignant

carcinoids are higher in African Americans than in whites (6.4% and 1.4% increase per year, respectively). [15]

ETIOLOGY AND PATHOGENESIS

Why Are Small Bowel Tumors Rare?

Several hypotheses have been proposed to explain this phenomenon, but objective data are mostly lacking. [17]

1. Rapid transit time and liquid lumenal contents reduce mucosal contact with putative carcinogens as well as physical damage, whereas mucosal enzymes such as benzpyrene hydroxylase detoxify them.
2. Bacterial enzymes have been postulated to play a role in colonic carcinogenesis. When bacterial flora is altered, as in bacterial overgrowth syndromes, small intestinal carcinomas develop with a higher frequency than expected. The small intestine, conversely, has low bacterial counts, with an absence of anaerobes under normal conditions.
3. Stem cells located at the crypt base lie deeper in the small intestine than the colon, perhaps reducing contact with lumenal carcinogens. The rapid differentiation of stem cells into mature, nonproliferating enterocytes and goblet cells may also protect against factors that deregulate cell growth and promote cancer development.
4. Based on preclinical data from murine models, [18] apoptosis involving damaged cells and potentially tumorigenic clones differs between the small and large intestine.
5. Lymphoid tissue in the lamina propria and Peyer patches of the ileum may provide immune surveillance against neoplastic cells through IgA-rich secretions.

Diet

The limited descriptive epidemiology of small intestinal tumors has not provided strong evidence for environmental influences on tumor formation similar to that of the large intestine. Weekly or more frequent consumption of red meat or salt-cured foods has been associated with a two- to threefold increase in risk of small intestinal cancer. [19] Another study [20] reported odds ratios (OR) for cigarette smoking of 4.6 for adenocarcinomas and 4.2 for carcinoids and an OR for alcohol consumption of 4.0 for adenocarcinomas and 3.1 for carcinoids. A population-based case control study [21] observed a significant threefold increased risk of adenocarcinoma of the small bowel in heavy drinkers (=80 g/d of ethanol) relative to moderate drinkers or nondrinkers. Frequent intake of foods rich in heterocyclic amines (fried bacon, ham, barbecued or smoked meat and fish) was associated with a significant four- to fivefold increased risk of adenocarcinoma in men, but not in women. There was also a consistent and significant trend in risk with increasing sugar intake, with an OR of 3.8 in the highest intake category. In a hospital-based case control study, [22] alcohol and tobacco did not increase the risk of adenocarcinoma of the small intestine. Risk was positively related to intake of bread, pasta, or rice (OR = 3.8), sugar (OR = 2.9), and red meat (OR = 4.6), and it was inversely related to coffee (OR = 0.4), fish (OR = 0.3), vegetables (OR = 0.3), and fruit (OR = 0.6).

Molecular Biology and Biochemical Changes

In comparison with colorectal cancer, relatively little is known about the molecular genetic events associated with the evolution of small bowel tumors. Genetic changes that lead to development of gastrointestinal cancer can generally be categorized into alterations in protooncogenes, loss of tumor suppressor gene activity, and abnormalities in genes involved in DNA mismatch repair.

Cellular protooncogenes are evolutionarily conserved human genes that play a role in signal transduction and normal regulation of cell growth. Human *ras* genes encode guanine nucleotide binding proteins that regulate intracellular signaling pathways. Point mutations in K-*ras,* especially at codon 12, have been reported in 14% to 53% of primary small intestinal adenocarcinomas, [23], [24] but not in carcinoids. K-*ras* mutations were common in sporadic and Crohn's disease–associated adenocarcinomas of the small intestine. [25] K-*ras* mutations were present in all four sporadic carcinomas with contiguous adenomas, in 2 of 11 (18%) without adenomas, and in 4 of 7 (43%) of Crohn's disease–associated carcinomas.

Allelic losses, particularly involving tumor suppressor genes at chromosome locations 5q, 17p, and 18q, play major roles in the genesis of large bowel tumors. The *APC* gene on the long arm of chromosome 5 (5q21) is mutated in the germ line of patients with familial adenomatous polyposis (FAP), and somatic mutations of *APC* occur in 60% to 80% of sporadic colorectal carcinomas and adenomas (see Chapter 89, Chapter 90, and Chapter 91). Mutation of the mouse homolog of *APC* (*Apc*) by chemical carcinogenesis or by genetic manipulation [26] results in development of large and small intestinal polyps. Small intestinal and periampullary adenomas and carcinomas are common in patients with FAP. *APC* mutations have also been reported in sporadic small intestinal adenocarcinoma, [24] but they appear to occur at a much lower frequency than in sporadic colorectal cancer.

Deletions of chromosome 17p involve the *p53* tumor suppressor gene whose product normally prevents cells with damaged DNA from progressing from the G_1 phase to the S phase in the cell cycle and regulates apoptosis. Deletions within chromosome 17p are present in approximately 75% of colorectal cancers. Mutations in *p53* were found in 27% of small bowel adenocarcinomas in one series, [24] whereas alterations in the p53 gene product and allelic loss of chromosome 17p were present in 47% of sporadic small bowel adenocarcinomas, 33% of contiguous adenomas, and 71% of Crohn's disease–associated carcinomas in a second series. [25]

Candidate tumor suppressor genes on chromosome 18q include the *DCC* or deleted in colon cancer gene and *DPC4* (*SMAD4*). *DPC4* belongs to the SMAD gene family involved in signal transduction pathways activated through the transforming growth factor ß family receptors. Loss of 18q has been reported in intestinal tumors from the Apc 1638N mouse model, [26] but rarely in human small intestinal adenocarcinomas. [25] Chromosome 18 deletions appear to be common events, however, in classical midgut carcinoids of the small intestine. [27], [28]

Alterations in genes that help to maintain DNA fidelity during replication (mismatch repair genes) are characteristic of patients with hereditary nonpolyposis colorectal cancer (HNPCC), but they may be found in approximately 15% of sporadic colorectal cancers. Mismatch repair gene mutations in *hMLH1* and *hMSH2* were present in 15 of 42 (36%) of HNPCC-associated small bowel carcinomas in one large series. [29] DNA replication errors characterized by microsatellite instability were also reported in 13% of sporadic small bowel carcinomas. [25]

RISK FACTORS AND ASSOCIATED CONDITIONS

Numerous risk factors and associated conditions have been described with relation to tumors of the small intestine (Table 80-2).

Adenocarcinoma
Familial adenomatous polyposis
Hereditary nonpolyposis colorectal cancer
Peutz-Jeghers syndrome
Juvenile polyposis syndrome
Crohn's disease
Previous history of cholecystectomy
Long-standing ileostomy (especially with Crohn's disease)
Ileal loop conduits, ileal pouches, ileal cystoplasty
Duplication cysts and Meckel diverticula
Gluten-sensitive enteropathy
Non-Hodgkin B-Cell Lymphoma
Immunoproliferative small intestinal disease
Gluten-sensitive enteropathy
Nodular lymphoid hyperplasia
Acquired immunodeficiency syndrome
Crohn's disease

TABLE 80-2 Conditions Associated with an Increased Risk of Primary Small Intestinal Neoplasia

Familial Adenomatous Polyposis

Periampullary duodenal carcinoma is the most common extracolonic malignant tumor in patients with FAP. There were 11 cases of duodenal and ampullary

adenocarcinoma reported among 1391 patients with FAP, [30] a relative risk (RR) of duodenal adenocarcinoma of 331, and an RR of 124 for ampullary carcinoma compared with the general population. Mean ages of diagnosis were 53 years for duodenal carcinoma and 49 years for ampullary carcinoma. Duodenal adenomas are common in patients with FAP, and they have been reported in up to 90% of such patients.

Hereditary Nonpolyposis Colorectal Cancer

HNPCC is an inherited disease in which colon cancers arise in discrete adenomas, but polyposis (i.e., hundreds of polyps) does not occur (see Chapter 90). Forty-two members of 40 families with HNPCC developed 42 primary and 7 metachronous small bowel tumors. [29] There were 46 adenocarcinomas and 3 carcinoid tumors. The median age at diagnosis of the index small bowel tumor was 49 years. The small bowel was the first site of carcinoma in 24 (57%) patients.

Hamartomatous Polyposis Syndromes

Hamartomatous polyposis syndromes are a group of disorders marked by the finding of multiple hamartomatous polyps in the gastrointestinal tract (see Chapter 90). The *Peutz-Jeghers syndrome* is an autosomal dominant disease, which in most families has been mapped to chromosome 19p13.3 and the *STK11* (serine threonine kinase 11) gene. Adenomatous changes have been reported in 3% to 6% of hamartomas. Extracolonic cancers are common, occurring in 50% to 90% of patients (small intestine, stomach, pancreas, esophagus, ovary, lung, uterus, breast). The RR for all cancers is 15.2 compared with the general population. [31] The small intestine represents the most frequent site of cancer development, with an RR of development of adenocarcinoma of 520 compared with the general population. Patients with Peutz-Jeghers syndrome have characteristic mucocutaneous pigment spots, which are frequent in the perioral region and across the vermillion border. Polyps are distinctive, with an arborizing pattern of growth of the muscularis mucosa extending into the branching fronds of the polyp. Patients often present with obstructive symptoms and may develop intussusception of the small bowel.

Juvenile polyposis syndrome is an autosomal dominant disease in which hamartomatous polyps may be limited to the colon, limited to the stomach, or occur throughout the gastrointestinal tract. Mixed juvenile and adenomatous polyps have been reported. The RR for small intestinal cancer is unclear, but cancers of the duodenum have been reported. Patients may present with bleeding, intussusception, and obstruction. A life-threatening protein-losing enteropathy has been reported in some patients. Germ-line mutations in the *SMAD4* (chromosome 18q21.1) and *PTEN* (chromosome 10q23) genes have been reported in separate kindreds with juvenile polyposis syndrome. [32]

Crohn's Disease

An increased incidence of both small intestinal adenocarcinoma and lymphoma has been reported to occur in *Crohn's disease,* but the magnitude of the risk is unclear. The RR of small bowel carcinoma in Crohn's disease (mostly ileal) has been estimated to be as much as 100 times that of the general population. [33] A retrospective cohort analysis of 373 patients with Crohn's disease reported 2 cases of ileal adenocarcinoma compared with an expected 0.04 cases of expected small bowel cancer (RR = 50). [34] A dysplasia-carcinoma sequence occurs in the small intestine in Crohn's disease similar to that of the colon and rectum. [25], [35] Crohn's disease–associated small bowel carcinomas and dysplasias are accompanied by frequent genetic alterations in K-*ras* and *p53*.

Diversion of Bile (Previous Cholecystectomy)

Diversion of bile to the lower small intestine either surgically or by feeding cholestyramine increases the yield of intestinal carcinomas in carcinogen-treated animals. Thus, cholecystectomy, which increases delivery of bile to the proximal bowel, could theoretically lead to an increased risk of small and large bowel cancer. Indeed, patients who underwent cholecystectomy had an increased risk of proximal intestinal adenocarcinoma that declined with increasing distance from the common bile duct. [36] The risk was significantly increased for adenocarcinoma of the small bowel (RR, 1.71) and the right-sided colon.

Gluten-Sensitive Enteropathy

An increased risk of both small intestinal adenocarcinoma and non-Hodgkin lymphoma has been reported to be associated with *celiac sprue* (gluten-sensitive enteropathy). [37], [38] (see Chapter 76). The overall incidence of malignant disease in this condition has been reported to be 11% to 13%, with an incidence of small bowel lymphomas of 4% to 7%. In some reported cases, it is not clear whether the primary diagnosis is actually celiac sprue or whether the histological changes are secondary to lymphoma per se. Lymphomas in the setting of celiac disease are usually of T-cell origin (enteropathy-associated T-cell lymphomas or EATLs). Adenocarcinomas may arise in focal areas of dysplasia. [39]

Other conditions may carry an increased RR for small bowel neoplasia (see Table 80-2), but they are relatively rare. Patients with urinary diversion to the small bowel (ileal loop conduits) appear to have an increased risk of carcinoma. Adenocarcinomas arise in the mucosa of ileostomies and ileal pouches in patients with inflammatory bowel diseases and FAP, [40] although this event is probably rare. [41]

CLINICAL PICTURE

The clinical signs and symptoms of small bowel neoplasms may have some common features, but for the most part they depend on the individual tumor type (Table 80-3). Abdominal pain may result from partial or complete small bowel obstruction, intussusception, or ischemia. Obstruction may be the result of the physical bulk of the tumor, infiltration, or annular constriction. An intense dermoplastic reaction by carcinoids causes intestinal buckling or kinking. Intussusception may occur with benign polypoid lesions, accounting for half of adult intussusception, and is common in patients with gastrointestinal stromal cell tumors (GISTs). Occult gastrointestinal blood loss is another common feature of benign and malignant small bowel tumors. Bleeding may be acute and brisk, however, in the case of ulcerated GISTs. Weight loss is especially common and pronounced in patients with small bowel lymphoma.

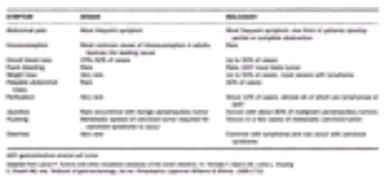


TABLE 80-3 Clinical Features of Small Bowel Tumors

ADENOCARCINOMA

Epidemiology and Risk Factors

Adenocarcinoma represents the most common primary malignant disease of the small intestine. The incidence of primary small bowel adenocarcinoma ranges between 3.0 and 6.5 per million, representing approximately 40% of primary small bowel tumors in most population-based studies (range, 24% to 42%). [17] Small bowel adenocarcinoma accounts for approximately 2% of gastrointestinal tumors and 1% of gastrointestinal cancer deaths. Fifty-five percent of these tumors occur in the duodenum, 18% in the jejunum, 13% in the ileum, and 14% in nonspecified sites. [2] The overall 5-year survival is 30.5%, with a median survival of 19.7 months. A slight male predominance is usual. The incidence of small bowel adenocarcinoma is slightly higher in blacks compared with whites. [15]

Adenocarcinomas arise from adenomas or dysplastic changes of the small intestine (see section " Pathology, Natural History, and Staging "). Adenomas and adenocarcinomas of the small intestine, and especially of the duodenum and ampulla of Vater, are most frequently encountered in the setting of FAP. Untreated duodenal and ampullary adenomas in patients with FAP were followed in the context of an endoscopic surveillance program. [42] Duodenal polyps progressed in size in 26% (25 of 95), in number in 32% (34 of 106), and in histology in 11% (5 of 45). Morphology and histology of ampullary adenomas progressed in 14% (15 of 110) and

11% (12 of 105) of patients, respectively. One patient developed a periampullary carcinoma.

Pathology, Natural History, and Staging

Adenocarcinomas of the small intestine arise in discrete adenomatous polyps, in adenomatous changes involving the ampulla of Vater, or in dysplasia associated with inflammatory bowel disease. In hamartomatous polyposis syndromes, carcinomas may arise from discrete adenomas or mixed polyps containing adenomatous components. [32] Dysplasia is associated with familial juvenile polyps, but not with solitary, sporadic juvenile polyps. Dysplastic polyps contain markers suggesting a loss of proliferative control within the epithelium and mutations in *APC*. [43]

Adenomas in the small intestine display the same gross and microscopic features as those in the large intestine. They may be pedunculated or sessile. Tubular adenomas tend to be small, whereas those with villous architecture tend to be larger. The presence of multiple duodenal adenomas or adenomatous changes in the ampulla of Vater suggests the diagnosis of FAP. Tubular adenomas contain tall, columnar, pseudostratified epithelial cells. Villous adenomas contain fingerlike villous or papillary processes similar to those in the colon. Small intestinal adenomas exhibit a spectrum of dysplasia ranging from mild dysplasia to intramucosal carcinoma and invasive cancer. Glandular crowding ("back to back" glands), loss of epithelial polarity, an increased nuclear-cytoplasmic ratio, and increased mitoses characterize high-grade dysplasia. These changes, accompanied by invasion into the lamina propria, define *intramucosal carcinoma.*

Invasive carcinoma may be found in one fourth to one half of resected villous adenomas in the setting of FAP, [43] but most duodenal adenomas appear to progress slowly to carcinoma, [42], [44] and the actual risk of malignant degeneration is probably considerably lower. Adenomatous polyps of the small intestine do occur outside the setting of FAP, but even less is known about their natural history.

Small intestinal adenocarcinomas may appear grossly as flat, stenosing, ulcerative, infiltrating, or polypoid lesions. Most are moderately differentiated tumors with gland formation and variable degrees of mucin secretion. Poorly differentiated tumors occur in approximately 20% of cases. The presence of *signet cells,* in which a large vacuole of mucin displaces the nucleus to one side, is a feature of some of these tumors. Rare adenosquamous carcinomas of the duodenum have been reported.

Adenocarcinomas are staged depending on the extent of bowel wall invasion, the presence or absence of invasion into adjacent structures, and the presence or absence of lymph node or distant metastases (Table 80-4). [45] The prognosis of patients with adenocarcinomas of the small bowel is poor. In one report, the overall 5-year disease specific survival in the United States was 30.5%, with a median survival of 19.7 months. [2] Factors significantly correlated with survival included age (poorer prognosis for patients >75 years), tumor site (duodenum worse than jejunum or ileum), disease stage, and whether cancer-directed surgery was performed. Five-year survival rates were 65% for stage I, 48% for stage II, 35% for stage III, and 4% for stage IV tumors. Similar trends have been reported from Europe. [6], [46], [47] and [48] Adenocarcinomas arising in the setting of HNPCC have a better prognosis than those occurring in FAP or in the general population. [29] Patients with tumors arising at or near the ampulla of Vater may do better than those with more distal tumors, perhaps because they become symptomatic earlier. Five-year survival rates approaching 50% have been reported for patients with node-negative cancers of the ampulla after radical resection.

Stage 0
Carcinoma in situ: TIS N0 M0
Stage I
Tumor invades lamina propria or submucosa: T1 M0 N0
Tumor invades muscularis propria: T2 N0 M0
Stage II
Tumor invades muscularis propria into the subserosa or into the nonperitonealized perimuscular tissue (mesentery or retroperitoneum*) with extension 2 cm: T3 N0 M0
Tumor perforates the visceral peritoneum or directly invades other organs or structures includes other loops of small intestine, mesentery or retroperitoneum 2 cm, and the abdominal wall by way of the serosa; for the duodenum only includes invasion of the pancreas: T4 N0 M0
Stage III
Any degree of bowel wall perforation with regional lymph node metastasis; any T N1 M0
Stage IV
Any degree of bowel wall perforation with or without regional lymph node metastasis, with distant metastasis

*The non-peritonealized perimuscular tissue is, for the jejunum and ileum, part of the mesentery, and for the duodenum, in areas where serosa is lacking, it is part of the retroperitoneum.

Adapted from ref. 45.

TABLE 80-4 Staging of Small Intestinal Adenocarcinoma: American Joint Committee on Cancer (TNM Classification)

Clinical Picture

The mean age of presentation for adenocarcinomas is approximately 65 years, with a wide range of age at presentation. [2] Fewer than 1% of tumors occur before age 30 years, and approximately 85% occur after age 50 years. Symptoms relate to tumor size, location, and blood supply. Small tumors are asymptomatic or may present with anemia secondary to chronic blood loss, but for the most part they are indolent and difficult to diagnose. Abdominal pain and other obstructive symptoms such as nausea and vomiting are common late symptoms as tumors obstruct from infiltration with lumenal narrowing or mass effect. Anorexia and weight loss are also common symptoms. Ileal tumors may present uncommonly with intussusception. Tumors located in the periampullary duodenum or ampulla of Vater may cause obstruction of the common bile duct, presenting with jaundice and other signs of biliary obstruction.

Diagnosis

Endoscopy (with forward and side viewing) may be used to examine the duodenum where a lesion is suspected or in families with FAP. Screening for duodenal adenomas and lesions of the ampulla of Vater, and surveillance after adenomas are removed endoscopically, should be performed in persons exhibiting the phenotype of FAP or in family members in whom genetic testing is positive for mutations in the *APC* gene. Individual polyps may be examined by biopsy or, if possible, removed by snare cautery and the ampulla examined by biopsy as necessary. There is a high incidence of adenomatous change in the papilla, even if the appearance is normal. It has been suggested that the slow evolution of duodenal and papillary lesions may justify an endoscopic surveillance interval of 3 years for most untreated patients with FAP. [40] Upper endoscopic surveillance should begin at age 20 years, and biopsies should be taken of any suspicious lesions and of the papilla, even if normal appearing. Push enteroscopy is of use in identifying and biopsying small bowel lesions seen on small bowel barium studies or computed tomography (CT), in evaluating occult gastrointestinal bleeding, and in surveillance of patients with Peutz-Jeghers syndrome, in whom polyps occur throughout the gastrointestinal tract. [49] Colonoscopy with intubation of the terminal ileum may be helpful in examining the terminal ileum in patients with Crohn's disease or in biopsy of suspicious lesions suggested by radiographic procedures.

Small bowel follow-through is 70% to 80% accurate for detection of duodenal lesions. [50] This can be improved by the use of hypotonic duodenography. Barium studies, however, are not as accurate in detecting more distal tumors. The tumor detection rate of enteroclysis (95%) is greater than that for small bowel follow-through (61%). [51] The radiologic appearances of small bowel adenocarcinomas are similar to those of the colon, including annular narrowing or stricture formation (Fig. 80-1) and filling defects comprising polypoid or ulcerated masses. Seventy percent of tumors in the duodenum are polypoid. Large duodenal lesions are ulcerative in 20% of cases. Adenocarcinomas of the jejunum are primary annular-constricting lesions (75%) and may be partially ulcerated or fungating. Differentiation of the infiltrating form of adenocarcinoma from stenosing Crohn's disease may be difficult.

FIGURE 80-1. Annular constricting adenocarcinoma of the jejunum. This upper gastrointestinal barium study demonstrates an “apple-core” lesion (*arrow*).

CT is increasingly used in demonstrating small bowel tumors and their complications and is often preferable to small bowel follow-through. [52] Occasionally, intussusception and obstruction may be associated with polypoid adenocarcinomas that may be detected on CT examination (Fig. 80-2). CT can be helpful in guiding the surgeon to the source of obstruction. Endoscopic ultrasonography can also be used for diagnosing and staging small bowel tumors.

FIGURE 80-2. Computed tomography scan demonstrating intussusception in the terminal ileum resulting from a small intestinal cancer (*asterisk*). Intussusception gives the impression of a soft tissue “mass” or “bowel within bowel” surrounded by contrast. Layers of serosal fat are seen in the periphery and centrally.

Therapy

Pedunculated adenomas of the duodenum may be removed by endoscopic snare polypectomy. It is often difficult to remove villous adenomas of the small intestine in this manner. These lesions are often sessile and contain foci of invasive carcinoma. Local mucosal resection can be performed surgically for some lesions, but wide excision is indicated for villous adenomas containing invasive cancer.

Surgical resection is the treatment of choice for adenocarcinoma of the small intestine. Resection of the tumor with adjacent mesentery and lymph nodes with a wide margin (=10 cm) of normal bowel on either side of it is practical for adenocarcinomas of the jejunum. Malignant tumors of the terminal ileum are treated as cecal tumors with terminal ileal resection and right hemicolectomy. Villous adenomas of the duodenum containing invasive carcinoma and carcinomas of the ampulla of Vater usually require pancreatoduodenectomy (Whipple procedure) with curative intent. In some cases, local resection of pedunculated polyps may be adequate, but a clear margin of resection is mandatory in this situation. Disease-specific survival for primary small bowel adenocarcinomas confined to the small intestine (local disease) was 47.6, for regional disease it was 33%, and in distant disease it was 3.9%. [2]

The role of postoperative chemotherapy, either in the adjuvant setting or for unresectable lesions, has not been defined in patients with adenocarcinoma of the small intestine. Small series have claimed some benefit for 5-fluorouracil [53] and the nitrosoureas, but objective evidence of an impact on survival is lacking. Palliative radiation may have some role in controlling chronic blood loss associated with duodenal tumors, but it is difficult in more distal small bowel tumors because of a mobile mesentery and difficulty in localizing the target field. Chemoprevention with aspirin and other nonsteroidal antiinflammatory drugs and selective cyclooxygenase-2 inhibitors may be useful in the care of patients with FAP. Whereas several short-term studies demonstrated the ability of these agents to reduce the size and number of colonic polyps in FAP, data concerning small intestinal tumors are scant. These agents may reduce the size and number of small intestinal polyps in murine models of FAP. [26] Sulindac therapy was associated with a decrease in mucosal proliferation, but a trend toward duodenal polyp regression was not significant in one 6-month human trial. [54]

CARCINOID TUMORS

Epidemiology

Carcinoid tumors—or argentaffinomas—belong to a family of rare neuroendocrine neoplasms known also as amine precursor uptake and decarboxylation tumors. This entire family of neoplasms has in common the ability to secrete amines and polypeptides, which produce the characteristic clinical syndromes with which they sometimes present. Seventy-four percent of carcinoid tumors occur in the gastrointestinal tract. [55] Most appear in the appendix, followed in frequency by the small bowel and rectum. Most of the clinically significant carcinoid tumors are located in the small bowel. Most (87%) small bowel tumors are in the ileum, especially within 2 feet of the ileocecal valve. The incidence rate of small bowel carcinoids is estimated to be 1.2 to 6.5 cases per million persons. [5], [16], [17], [55], [56], [57], [58], [59] and [60] Autopsy studies cite a tenfold higher rate of carcinoids that were not evident clinically. [61] The median age at diagnosis is 60 years, but carcinoids have been detected in a wide range of ages (22 to 84 years). In the United States, the incidence of small bowel carcinoids is somewhat higher in men and in African Americans. [55]

No specific risk factors for carcinoids have been proven. However, cigarette smoking and alcohol consumption have been associated with an increased risk of developing small bowel carcinoids. [20] The incidence rates of carcinoids in first-degree relatives of patients with carcinoid tumors was higher than the expected population incidence rates. [62] The calculated cumulative probability that a first-degree relative will develop a carcinoid tumor by age 80 years was 1.5%. Persons with carcinoid tumors, particularly tumors of the small bowel, may have an increased incidence of coexisting noncarcinoid malignant diseases, [55], [61], [63] although a lack of association [60], [62] has also been reported. The noncarcinoid neoplasms are mostly adenocarcinomas of the gastrointestinal tract (50%), followed in frequency by lung, cervix, and prostate carcinomas. [61]

Pathology, Natural History, and Staging

Carcinoid tumors are malignant, despite their sometimes indolent course. Small bowel carcinoids, in particular, are associated with locoregional spread or metastases at the time of diagnosis. The tumors are usually intramucosal, and they rarely ulcerate to the lumen of the bowel. Small bowel carcinoids spread locally. When serosal breach has occurred, an intense local fibroblastic reaction is commonly seen. [64], [65] The desmoplastic reaction is responsible for many of the clinical findings in patients with small bowel carcinoid. Another characteristic feature of small bowel carcinoids is multicentricity. At the time of diagnosis, 35% of patients will have more than one tumor in the small intestine. [61], [66] Tumor size varies in several series, but most are 2 cm or less in diameter. Only 6% of small bowel carcinoids smaller than 1 cm have been associated with metastases, whereas 80% of patients with tumors larger than 2 cm will present with metastases. [67], [68] and [69] Microscopically, sheets of uniform cells with hyperchromatic nuclei are arranged in characteristic clumps (Fig. 80-3). Light microscopy of metastases to the liver cannot differentiate a carcinoid from an islet cell tumor.

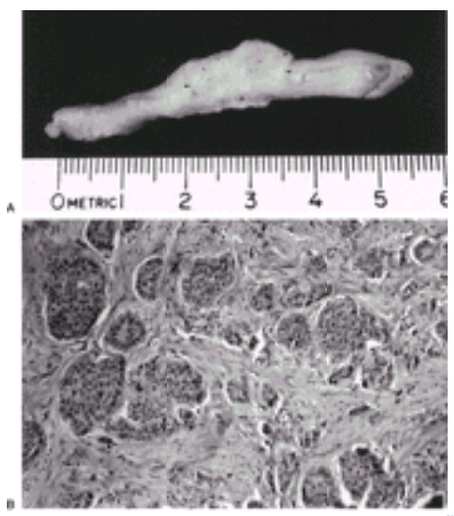

FIGURE 80-3. Carcinoid tumors of the small intestine. (**A**) A gross specimen of a nodular small intestinal carcinoid is demarcated by *arrows.* Carcinoid tumors develop deep in the mucosa and grow slowly, extending into the underlying submucosa and the overlying mucosa. (**B**) Histological section shows a small intestinal carcinoid tumor characterized by closely packed, round, regular and monomorphous cell masses, buds, and islands. Lumina and rosette-like structures are also present. Desmoplastic reaction is responsible for many of the clinical findings of small intestinal carcinoid tumors.

Carcinoid tumors can be classified in terms of the substances they secrete. [70] "Typical" small bowel (midgut) carcinoids secrete serotonin (5-HT), and they contain the enzyme dopa decarboxylase, which converts 5-hydroxytryptophan (5-HPT) to 5-HT. 5-HT is further metabolized and is excreted in the urine as the metabolite 5-hydroxyindoleacetic acid (5-HIAA). "Atypical" carcinoids (mostly foregut and hindgut) lack dopa decarboxylase and do not secrete 5-HT. [71] 5-HPT is released into the blood and can be measured in platelets and urine. Some 5-HPT is decarboxylated in the kidney before excretion, and 5-HT can thus be detected in the urine, but not 5-HIAA. [72]

Carcinoid tumors do not have a specific staging system. Most authors describe small bowel carcinoids in terms of size, degree of bowel wall invasion, presence or absence of lymph node involvement, and presence or absence of distant metastases.

The natural history of small bowel carcinoids is more favorable than that of adenocarcinomas of comparable stage. Five-year survival rates are 65% for local disease, 64% for regional disease, 36% for metastatic disease, and 55% overall for all patients with small bowel carcinoids. [55] However, the 25-year survival of patients with regional spread is reported to be less than 20%. [61] Patients with liver metastases and the carcinoid syndrome have a prognosis similar to that of patients with metastases who do not have the syndrome, but survival is lower for patients with carcinoid heart disease who develop valvular dysfunction. [61], [72]

Clinical Picture

Patients with small bowel carcinoids can present with nonspecific gastrointestinal symptoms, small bowel obstruction, intestinal ischemia, intussusception, gastrointestinal hemorrhage, hepatomegaly, or symptoms of the carcinoid syndrome. [73] Many of the signs and symptoms of small bowel carcinoids result from the intense desmoplastic reaction of the mesentery in proximity to the tumor, leading to partial small bowel obstructions and nonspecific gastrointestinal symptoms. [74] Complete bowel obstruction was the presenting symptom in 13% of patients in one series. [75] Nodal involvement causes compression of the main mesenteric arteries, leading to small bowel infarction. [76] Regional vascular thickening of medium-size arteries has been described with carcinoid, and this may act synergistically toward bowel ischemia formation. [77], [78] Gastrointestinal hemorrhage and intussusception are uncommon presentations of small bowel carcinoids. [79] Asymptomatic hepatomegaly from metastases is more common with carcinoids and islet cell tumors than with neoplasms of epithelial origin, so transaminases may not be abnormally elevated despite hepatomegaly and a large tumor burden. [80]

The most common clinical situation is a prolonged history of nonspecific abdominal pain that did not much alter the patient's lifestyle. The median time from onset of symptoms to diagnosis is reported to be 2 years, and it may be as long as 20 years. [61], [81] Investigation is not always sought by the patient, or has a low yield, thus prolonging the interval to diagnosis and treatment.

Patients with liver metastases from carcinoids may exhibit symptoms and signs of the *carcinoid syndrome,* caused by a variety of mediators. Overall, 10% to 18% of patients with small bowel carcinoid tumors will present initially with the carcinoid syndrome. [82], [83] and [84] Flushing of the face and neck occurs in most patients, and it may be episodic or permanent. Flushing is most commonly transient and simulates a mild sunburn involving the face, neck, and upper trunk (the *midgut flush* associated with ileal carcinoids). The so-called *foregut flush* is more intense, frequently associated with conjunctival injection and edema, and has a greater tendency to involve the body more diffusely. [61] Diarrhea is seen in 75% of patients and manifests as intermittent episodes of explosive, watery diarrhea resulting from intestinal hypermotility. Steatorrhea is rare. Abdominal cramping may accompany the diarrhea episodes about 50% of the time. Dyspnea can result from advanced carcinoid heart disease or, less frequently, from bronchoconstriction and asthma. Two thirds of patients with carcinoid syndrome will present with a large liver or an abdominal mass; 40% will have heart valve abnormalities that can be auscultated at presentation. Other less common signs include cyanosis (25%), peripheral edema, arthritis, and pellagra (2% to 7%). [82], [84]

Diagnosis

Carcinoid tumors of the small intestine frequently do not manifest clinically until regional spread has occurred or metastatic disease is present. Small, localized tumors are most often diagnosed incidentally during endoscopic or radiologic examinations performed for unrelated reasons.

Biochemical Markers Urinary 5-HIAA is the most common test used to screen for carcinoid tumors. Most small bowel carcinoids secrete 5-HT, and urinary 5-HIAA is subsequently high. [85] Unfortunately, it is not highly specific or sensitive for localized tumors because other neuroendocrine tumors can secrete 5-HT, and small carcinoids may secrete very small amounts of 5-HT. In contrast to localized tumors, urinary 5-HIAA is very sensitive and specific for the carcinoid syndrome because of the large tumor burden necessary to produce the features of the syndrome. [86] Elevated levels of more than 30 mg of 5-HIAA in 24 hours with provocative testing are diagnostic of the syndrome. False-positive 5-HIAA measurements can occur in diseases such as celiac disease, Whipple disease, and tropical sprue and when 5-HT–rich foods such as walnuts, bananas, and avocado are ingested, [87] but these levels are lower than those associated with carcinoid tumors. False-negative 5-HIAA determinations have been reported with the use of aspirin, levodopa, and phenothiazines. 5-HT overproduction can also be assessed by measuring platelet and urinary 5-HT levels, which are not affected by food or medications. [26] Urinary 5-HIAA, platelet 5-HT, and urinary 5-HT levels are elevated in all patients with small bowel carcinoids. [71] Chromogranin A is another useful biochemical marker of carcinoid tumors found in the serum. Chromogranin A is produced by most neuroendocrine tumors, and it has a very high sensitivity for all types of neuroendocrine tumors. The sensitivity of this substance for carcinoid tumors approaches 80%. [88] It can be used to monitor treatment response and recurrence or for diagnostic purposes in patients who do not have elevated 5-HIAA urine measurements. Neuron-specific enolase is less specific than chromogranin A, and this value is elevated in only 40% of patients with carcinoid tumors. [89]

Radiologic Imaging

Conventional barium studies of the small intestine may identify the primary lesion as a smooth, semilunar filling defect in the lumen or, more often, as wall thickening, lumen angulation, and nonspecific mass effect. Enteroclysis is generally more successful than conventional small bowel barium studies. [52], [90] CT scans of the abdomen are more sensitive for detecting regional and distal spread, rather than a localized primary tumor. Seventy percent of patients with regional spread will have some degree of mesenteric calcification. [91] One third of patients with small bowel carcinoid may have a characteristic bulky, conglomerate calcification of a mesenteric mass. [92] The mass may also be associated with linear soft tissue strands radiating into the surrounding mesentery in a stellate pattern and displacing adjacent loops

of bowel. CT scans are also useful to detect hepatic metastases and are somewhat less sensitive than magnetic resonance imaging examinations. [93]

Scintigraphy has long been used for detecting neuroendocrine tumors. Radioiodine (^{131}I or ^{123}I)-labeled metaiodobenzylguanidine (I-MIBG) has a sensitivity of 50% to 60% for diagnosing carcinoid tumors and their metastases. [94], [95] Somatostatin receptors are expressed by 87% of carcinoid tumors and are therefore ideal for detection using radiolabeled somatostatin analogs. Indium-labeled [^{111}In]pentetreotide has a sensitivity of 67% to 80% for detection of carcinoid tumors and their metastases. [96], [97] and [98] [^{111}In]pentetreotide is more sensitive than [^{123}I]MIBG and conventional CT scanning. [99] Octreotide-labeled scintigraphy is useful for diagnosis, to predict who will respond to octreotide therapy and to locate tumors before surgical debulking. [98], [99] Positron emission tomography with octreotide labeled with copper tetraazacyclotetradecane is as sensitive as indium-labeled pentetreotide scintigraphy for detecting metastatic carcinoids. [100]

Endoscopy Small bowel carcinoids have been detected endoscopically in the duodenum, proximal jejunum, and terminal ileum. The tumors generally appear as nodular, submucosal protuberances that are yellowish and shiny. Ulcerated lesions and pedunculated lesions have been reported as well. [101] Endoscopic biopsies of lesions are often unrevealing, because the tumors are frequently subepithelial. Snare polypectomy or endoscopic mucosal resection of the lesion is much more successful for obtaining a histological diagnosis. [102] Duodenal carcinoids can also be diagnosed by endoscopic ultrasound. Small, noninvasive lesions usually arise from the deep mucosa or submucosa, and at endosonography they appear as moderately hypoechoic masses in the second or third echo layers. [103], [104], [105] and [106] Determination of invasion with endoscopic ultrasound can be useful for staging purposes, [103] as well as to gauge the appropriateness of endoscopic resection as a therapeutic measure. [105], [107], [108]

Treatment

Localized Tumors Localized small bowel tumors should be resected and removed completely. [67], [70], [80], [109] Duodenal carcinoids are less likely to metastasize, and they can often be removed endoscopically, preferably after endosonographic verification that there is no deep tumor invasion. Pedunculated carcinoids can be removed by snare polypectomy, but subepithelial, sessile growths will require endoscopic mucosal resection after submucosal injection of saline. [102], [107], [108], [110], [111] and [112] Duodenal carcinoids that show spread beyond the submucosa and carcinoids of the jejunum or ileum should undergo surgical resection. The 5-year survival of patients with local disease who undergo wide excision and removal of regional lymph nodes approaches 75%. [113]

Tumors with Regional Spread Small bowel carcinoids with regional spread should also undergo wide surgical resection. [67], [70], [80], [109] In some case series, the 5-year survival of patients for whom careful excision of all peritoneal and nodal metastases was possible was 65% to 71%, [114], [115] compared with a 5-year survival of 38% for patients in whom regional tumor spread could not be completely excised. [115]

Distant Metastases The approach to patients with metastatic small bowel carcinoids is multimodal. [116] The goals of therapy are to suppress the symptoms of carcinoid syndrome, to improve quality of life, and, if possible, to prolong survival. Patients with symptomatic bowel obstruction can undergo segmental bowel resection or enteroenteric bypass and, if possible, surgical debulking of tumor deposits to decrease symptoms related to tumor burden. [61], [72] Targeted scintigraphic therapies may be more successful when the tumor burden is small. [117], [118] and [119] Wedge resection of solitary liver metastases and hepatic lobectomy have both been performed successfully in patients with metastatic carcinoid tumors. [120] Hepatic artery embolization results in ischemia of liver metastases, [121] decreases urinary 5-HIAA levels by 40%, and provides partial improvement of the symptoms of carcinoid syndrome in up to 80% of patients, [116], [122] with a survival benefit of a median increase of 2 years. [119], [123] Combination intraarterial chemotherapy followed by hepatic artery embolization may be more effective than embolization alone. Complete resolution of carcinoid syndrome symptoms was reported in 70% of patients for an average of 29 months using doxorubicin (Adriamycin) and iodized oil. [124] Similar success has also been reported with a combination of 5-fluorouracil, doxorubicin, cisplatin, mitomycin C, and polyvinyl alcohol, although with a higher rate of complications. [125] The mortality from hepatic artery embolization or chemoembolization is 0% to 2%. Common complications include fever, abdominal pain, nausea and vomiting, and transient transaminase elevations. Less commonly, myelosuppression, arterial thrombosis, liver abscess, and cardiac dysrhythmias may occur. [121], [126], [127] Receptor-targeted therapy with [^{131}I]MIBG and [^{111}In] pentetreotide is variably successful for controlling the symptoms of metastatic carcinoid syndrome. [70], [128], [129] and [130] One series reported complete response in 50% of 20 patients treated with [^{131}I]MIBG, [131] but a review of 229 patients reported a mean symptomatic response of only 23%. [132] [^{131}I]MIBG therapy has relatively few side effects, and it decreases the octreotide requirements for patients with metastatic carcinoid syndrome. [131] [^{111}In]pentetreotide and yttrium-labeled octreotide show promise for symptom control and reducing tumor burden. [128], [133] Symptom control is best achieved with octreotide, a somatostatin analog that inhibits 5-HT release. Therapy with octreotide reduces flushing in more than 70% of patients and diarrhea in more than 60%, [134], [135] and [136] it decreases urinary 5-HIAA levels in about 70% of patients, and it may prevent further tumor growth in patients who respond symptomatically to octreotide. [137] The newer long-acting somatostatin analog, lanreotide, can be injected once every 2 to 4 weeks, with comparable efficacy to that of daily administered octreotide. [137], [138] Complications of prolonged high-dose octreotide therapy include steatorrhea, gallstone formation, and development of resistance to the medication. The role of systemic cytotoxic chemotherapy in the management of metastatic carcinoid is debated. Response rates range between 10% and 40%, and toxicity is significant. [139], [140], [141], [142], [143], [144], [145], [146] and [147] At present, chemotherapy is reserved for patients who do not respond to the other treatment modalities described earlier. Patients treated with interferon had a median survival of 80 months, compared with a median survival of 8 months in patients treated with streptozocin and 5-fluorouracil. [148] The addition of interferon to octreotide monotherapy may improve symptom control, [149] or it may lead to stabilization of tumor progression. [150] Interferon in combination with 5-fluorouracil decreased 5-HIAA levels in 50% of patients, but tumor regression was seen in only 10% to 20%. [151] Combination interferon therapy and hepatic chemoembolization has been shown to improve the median survival of patients treated with interferon alone. [152]

MESENCHYMAL TUMORS

Of the *mesenchymal small intestinal tumors,* the most common variant is the *mesenchymal spindle cell tumor* (see Table 80-1). Some mesenchymal tumors represent clear-cut diagnostic entities (e.g., lipoma, ganglioneuroma), whereas most are more difficult to classify into any specific cell lineage. Tumors may share overlapping features of several diagnostic entities, or they may be histologically heterogeneous. Thus, the general term *gastrointestinal stromal cell tumors* (GISTs) was coined to describe the group. Most GISTs have a spindle cell appearance, but electron microscopy and immunostains indicate that most GISTs are not true smooth muscle tumors. [153], [154] It has been suggested that up to 94% of "smooth muscle" tumors in the older literature are actually not of muscle origin and would be classified today as GISTs. [153], [155]

Epidemiology

Approximately 60% of GISTs are found in the stomach, 20% to 30% occur in the small bowel, and the remaining tumors are scattered in the esophagus, colon, and mesentery. [154] Benign GISTs are three to four times more common than malignant GISTs. [153], [156], [157] Malignant GISTs are gut-specific sarcomas and represent 11% to 12.7% of all small bowel malignant tumors, with an incidence of 1.2 to 1.5 cases per million persons. [5], [16], [59], [158] Malignant GISTs are somewhat more common in male than in female patients, and they can be found in all ages, but the most common age range at the time of diagnosis is 50 to 59 years. [17], [159]

Kaposi sarcoma is thought to result from a herpes-type virus. [160], [161] Small bowel schwannomas can be seen in patients with neurofibromatosis. [162] Small bowel ganglioneuromas have been reported in association with the multiple endocrine neoplasia type 2 syndrome. [163]

Pathology

GISTs of the small bowel occur most frequently in the jejunum, followed by the ileum, and then the duodenum. Benign GISTs are generally smaller than 5 cm in diameter, but tumors larger than 20 cm have been reported. Malignant GISTs are greater than 5 cm at time of diagnosis in 80% of patients. [159], [164], [165] GISTs mostly arise from the muscularis propria and generally grow extramurally, but benign GISTs of the duodenum are more likely to grow intralumenally or intramurally. [159]

GISTs have a slightly different histological appearance than true leiomyomas, leiomyosarcomas, and schwannomas, with more cellularity and less cytoplasmic eosinophilia. Small bowel GISTs generally have a spindle cell–like appearance, but infrequently they can appear epithelioid. [153] GISTs can be classified by ultrastructural characteristics as myoid, neural, or ganglionic phenotypes, but the frequent presence of several different ultrastructural phenotypes suggests a common origin to all subtypes. [155]

Ninety-four percent of GISTs express CD117, the c-kit protooncogene protein that is a transmembrane receptor for the stem cell growth factor, [166], [167] and 70% to 80%

of GISTs express CD34, the human progenitor cell antigen. [168], [169] and [170] Less frequently, GISTs stain positive for actin and desmin (implying myogenic differentiation), but seldom are they S100 positive (a protein found in neuron-differentiated cells). [153] True leiomyomas and leiomyosarcomas are positive for actin and desmin, but do not express CD117 or CD34; and schwannomas express S100, but not CD117 or CD34. When spindle cell tumors are excised, immunohistochemical markers should be used to determine whether the neoplasm is a GIST or not. [154]

Observations that normal intestinal Cajal cells also express CD117 and CD34 pose the possibility that GISTs are of the same embryonic origin as Cajal cells. This would explain the similar morphology and intramural location of GISTs and true smooth muscle tumors. [153] The c- *kit* gene on chromosome 4 shows mutations of exon 11, especially in malignant tumors. [171] Some malignant GISTs also display loss of 14q and chromosome 22 on comparative genomic hybridization. [172] These genetic changes are not found on true smooth-muscle tumors.

Natural History and Prognosis

GISTs of the small bowel tend to invade locally, and they frequently present with peritoneal seeding or direct invasion to adjacent organs. [159], [165] Lymph node metastases are uncommon, but 31% to 41% of patients with small bowel GISTs will present with liver metastases.

Overall, 5-year survival rates are variable, ranging between 7% and 56%. [159], [165], [173], [174] and [175] In general, survival is favorable for patients without extralumenal tumor invasion or metastases and for tumors smaller than 2 to 5 cm.

Many factors have been suggested as prognostic indicators for GISTs (Table 80-5). [165], [173], [174], [176], [177] Unfortunately, except for tumor size and the number of mitotic figures, most of these factors are not found consistently. The most useful indicators of survival and the risk of metastases are the size of the tumor at presentation, the mitotic index (the number of mitotic figures per 50 high-power fields), and histological evidence of tumor invasion into the lamina propria. [154] None of the other factors in Table 80-5 have consistently been shown to predict prognosis accurately. GISTs should not be classified as “benign” or “malignant,” but rather by the risk for malignant behavior.

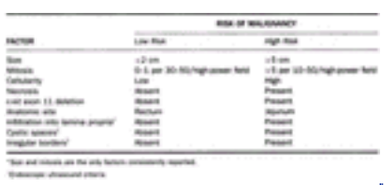

TABLE 80-5 Gastrointestinal Stromal Cell Tumors: Prognostic Factors*

Clinical Picture and Diagnosis

Most GISTs less than 5 cm in diameter are discovered incidentally at endoscopy, by barium x-ray studies, or in gastrointestinal specimens resected for other reasons. The small tumors are generally asymptomatic. In contrast, at least 80% of patients with larger tumors will have symptoms related to the GIST. [159], [165], [173], [174] and [175], [177] More than 50% of patients with tumors greater than 5 cm will have either a palpable abdominal mass or gastrointestinal hemorrhage. Bleeding from ulcerated small bowel GISTs is usually acute, and it may be brisk. [178] Thirty to 40% of patients with small bowel GISTs will present with abdominal pain, nausea and vomiting, or weight loss, and 40% of patients with ileal tumors may present with intussusception. [159]

Small bowel barium studies can detect GISTs 53% to 72% of the time. [179] CT has been reported to detect 89% to 98% of large GISTs. [180] Angiography may also be useful because of the characteristic “tumor blush” noted in more than 85% of tumors.

Endoscopic diagnosis of small bowel GISTs is difficult because most tumors are submucosal. If ulceration is present, biopsies can identify the tumor as a GIST. GISTs appear by endoscopic ultrasound as hypoechoic masses arising from the fourth echo layer (muscularis propria). Putative endosonographic criteria to differentiate benign from malignant GISTs include tumor size greater than 4 cm, irregular extralumenal margins, and cystic spaces. [181], [182] and [183] The positive predictive value for malignancy approaches 100% when any two of these findings are present.

Immunohistochemical staining should be performed on resected spindle cell tumors and biopsies of tumors suspected to be GISTs. CD117 positivity confirms that the tumor is a GIST.

Treatment

Segmental bowel resection, and not simple enucleation, is the treatment of choice for GISTs. [155], [156], [157], [158] and [159] Given the biology of these tumors, wide margins and extensive lymph node dissection are not necessary. Aggressive resection of organ segments that have been invaded with tumor and of hepatic metastases also appears to confer some improvement in survival. [175], [177], [184], [185], [186] and [187] Nonetheless, despite complete resection with negative margins, 44% to 80% of patients will suffer local or peritoneal recurrence. Most recurrences will occur within 2 years, but lag times of 10 years have also been reported. [188], [189]

Chemotherapy and radiation therapy have not been beneficial for patients with unresectable metastases and for patients with tumor recurrence. [190], [191] The tyrosine kinase inhibitor STI571, specific for the unregulated mutant c- *kit* (CD117) tyrosine kinase, was given to a patient with metastatic GIST for 11 months. The volume of metastases decreased fivefold, and no new lesions were detected. [192] Clinical trials with STI571 are eagerly awaited.

Although the accepted treatment of small bowel GIST larger than 4 or 5 cm is surgical resection, it is unclear what to do with smaller tumors. This gap in our knowledge is important because as endosonography use becomes more prevalent, more small GISTs will likely be diagnosed.

LYMPHOMAS

A *primary small bowel lymphoma* (PSBL) is characterized by the following:

1. The absence of palpable peripheral lymphadenopathy
2. A normal peripheral leukocyte count and differential
3. No mediastinal lymphadenopathy on a chest radiograph
4. Involvement of only the organs of the gastrointestinal tract and proximal regional lymph nodes
5. No involvement of the liver or spleen, unless by direct extension from the primary gastrointestinal tumor. [193], [194] and [195]

Extranodal lymphomas of the intestine can be classified according to the cell lineage (see Table 80-1) or according to their clinical characteristics. The latter method categorizes small bowel lymphomas into either PSBLs, which tend to be focal, or immunoproliferative small intestinal disease (IPSID), which is diffuse.

Epidemiology

Small bowel lymphomas represent 1% to 10% of all extranodal lymphomas [193] and 7% to 25% of all small bowel tumors. [5], [16], [59] Rates of small bowel lymphomas ranges from 0.9 to 3.6 cases per million. [5], [16], [58], [59], [193], [196], [197] The median age at diagnosis of PSBL is 67 years, whereas IPSID is generally diagnosed in the second or third decade of life. PSBL is more common in men than in women, at a ratio of 1.5:1. In the United States, small bowel lymphomas are more common in

whites than in African Americans. Population registries from the Middle East suggest a higher incidence than in Europe or the United States, [193] perhaps because of the high preponderance of IPSID. Studies from the United Kingdom, [196] Germany, [58] Denmark, [197] Ireland, [198] and the United States [17] show an increase of 30% to 50% since the early 1970s.

Risk Factors

Several diseases and immuno deficiency states are associated with an increased risk of developing PSBL. Patients with long-standing celiac disease have a 4% to 7% incidence of small bowel lymphomas. [199], [200] These are usually T-cell lymphomas and are frequently termed EATLs. Nodular lymphoid hyperplasia is usually an incidental finding in the terminal ileum. Diffuse nodular lymphoid hyperplasia is seen in primary immunodeficiencies, and it is associated with intestinal lymphomas. [201] Rarely, diffuse nodular hyperplasia and intestinal lymphoma can occur in the absence of immunodeficiency. [202] Some authors report an increased incidence in patients with inflammatory bowel disease using immunosuppressive medications, [203] some report an increased risk only in male patients with Crohn's disease, [204] and others report no increased risk at all. [205], [206] Small bowel lymphoma has been associated with congenital and acquired immunodeficiency states. [207] Patients with acquired immunodeficiency syndrome have a 30% risk of developing lymphomas, of which 10% to 25% will be PSBLs. [208] Immunosuppression after solid organ transplantation has been associated with an increased risk of lymphoma. Most extranodal lymphomas are PSBLs. There appears to be a correlation with the nature and dose of immunosuppression. For example, 30% of small bowel, heart, or lung recipients will develop lymphoma, whereas only 5% of kidney recipients will acquire the disease. [209]

IPSID occurs almost exclusively in the Middle East, Africa, Southeast Asia, and South America, regions in which poor hygiene and malnutrition are endemic. Malnutrition can impair the bowel's normally vigorous defenses in a variety of ways. [210] In response to the abnormal antigenic presentation, specific clonal lines of IgA-secreting B cells proliferate in the lamina propria. [156] The a-heavy chains can be detected in the blood of up to 69% of patients with early-stage IPSID. [211] IPSID is reversible when treated with antibiotics in the early, prelymphomatous phase. [212], [213]

Pathology

PSBLs occur most often in the ileum, followed by the jejunum, and then the duodenum. [5], [16], [58], [59] They are generally localized to one segment of the bowel, except in the case of *mantle cell lymphoma,* otherwise known as *multiple lymphoid polyposis* (MLP). The tumors have many different appearances. They may be large exophytic masses (Fig. 80-4 *A*), polyplike (Fig. 80-4 *B*), ulcerlike, or nodular. [214] Tumor growth and extension are frequently intramural for a prolonged period. Involvement of regional lymph nodes is present in approximately 50% of patients with most types of PSBL, except low-grade *mucosa-associated lymphoid tissue (MALT) lymphomas,* in which lymph nodes are involved in only 30% of patients. [214], [215], [216] and [217] IPSID tends to be a diffuse jejunal disease. Gross findings can range from thickened folds to discrete masses, [212], [218], [219] affecting a significant portion of the intestine in a contiguous fashion. [220] This feature probably explains the different clinical presentation of IPSID from PSBL, which usually has normal mural architecture in bowel segments not affected.

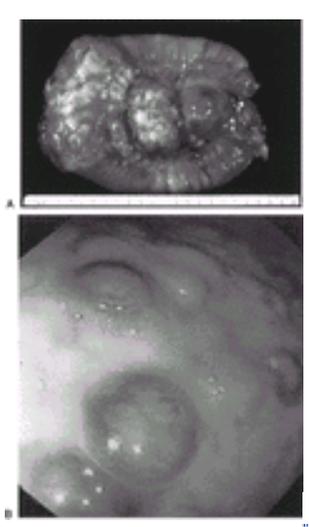

FIGURE 80-4. Primary small intestinal lymphomas. (**A**) A gross specimen of a primary lymphoma extensively involving the small intestine. (**B**) Mantle cell lymphomatous polyposis of the intestine seen endoscopically. The mucosa is studded with elevated polypoid nodules.

Most small bowel lymphomas are B-cell derived. The different histological patterns of small bowel lymphomas are summarized in Table 80-6. The diffuse large cell type—the most common intestinal lymphoma—and the small noncleaved cell type are similar histologically to their nongut counterparts. [199]

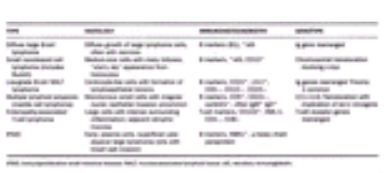

TABLE 80-6 Features of the Major Gastrointestinal Lymphomas

MALT lymphomas occur in nongut sites, but they are most common in the gastrointestinal tract. The characteristic cells are centrocyte-like cells that resemble the small cleaved centrocyte cells of nodal follicular cell lymphomas. [221] Mantle cell lymphomas (MLP) show monotonous small cells with irregular nuclei arranged in a pattern similar to the mantle zone of lymph node follicles. The mucosa and submucosa are most often involved. Despite the lack of deep invasion, MLP is a very aggressive lymphoma that presents frequently with distant lymph node and bone marrow involvement. [217], [222] EATL is a high-grade lymphoma composed of large cells resembling histiocytes. The adjacent mucosa displays the characteristic findings of celiac disease: villous atrophy, crypt hyperplasia, and abundant intraepithelial lymphocytes. Epithelial invasion is common, and the subsequent mucosal ulceration displays an intense inflammatory infiltrate. [223]

IPSID has a distinctive histological appearance that is characterized by a dense mucosal and submucosal cellular infiltrate throughout the length of the affected intestine. In the early (possibly benign) phase, plasma cells and small lymphoid cells predominate. In the late phase, dysplastic changes in the small cells are noted, with an increase in the proportion of large cells evolving into a diffuse large cell lymphoma. [212], [218], [219]

Staging and Prognosis

MLP, EATL, and IPSID tend to have the worst prognosis. [224], [225], [226], [227] and [228] The staging system for PSBL has evolved from the Ann Arbor classification originally devised for Hodgkin lymphoma (Table 80-7). Patients presenting with stage I PSBLs or low-grade MALT PSBLs have median 5-year survivals of 50% to 60% and 44% to 65%, respectively, and they have the best chance of cure. [229] The median survival of patients with stage II disease is only 20%. [224], [225], [226], [227] and [228]

Stage I Tumor confined to the gastrointestinal Single primary lesion or multiple noncontiguous lesions
Stage II Tumor extending in the abdomen from a primary gastrointestinal site Nodal involvement II1 local (paragastric or paraintestinal) II2 distant (mesenteric, paraaortic, paracaval, pelvic, inguinal)
Stage IIIE Penetration of serosa to involve adjacent organs or tissues
Stage IV Disseminated extranodal involvement or a gastrointestinal tract lesion with supradiaphragmatic nodal involvement

TABLE 80-7 Staging System of Primary Gastrointestinal Lymphoma

Two different staging systems have been devised for IPSID. One stages IPSID by the histological findings of prelymphomatous and lymphomatous stages, [219] and the other stages the disease by the bulk of tumor and extent of distant nodal and organ involvement. [220] Neither system has been validated in large survival cohorts.

In addition to the stage at presentation and the cell type, many criteria have been reported as being adverse prognostic factors for PSBL. These include a tumor larger than 7 cm, age greater than 70 years, the presence of B symptoms (fever, night sweats, and weight loss), mural invasion beyond the muscularis propria, distant lymph node involvement, unresectability of the tumor, elevated serum lactate dehydrogenase, elevated serum ß $_2$-microgobulin, and the presence of *BCL-2* genomic alterations. [224], [225], [226], [227] and [228], [230], [231], [232], [233], [234] and [235]

Clinical Picture and Diagnosis

The symptoms of PSBL are usually nonspecific and may continue for 4 to 18 months before a diagnosis is rendered. [224], [226] Abdominal pain, often described as crampy, is reported in 65% to 87% of patients with PSBL. Weight loss is seen in approximately 50% of patients with PSBL. The remaining symptoms are present in fewer than 30% of patients and include gastrointestinal hemorrhage, malaise, night sweats and fatigue, or acute abdomen resulting from bleeding or perforation. [220], [224], [225], [227], [228], [232] Small bowel obstruction is the presenting symptom in 5% to 12% of patients. Diarrhea and malabsorption are common in EATL. In fact, patients with celiac disease who become unresponsive to a gluten-free diet should be investigated aggressively for small bowel lymphoma. [223] The most common physical finding is a palpable abdominal mass, present in 30% to 50% of patients.

The symptoms of IPSID differ from those of PSBL. Nearly all patients with IPSID have diarrhea, weight loss, anorexia, and abdominal pain. Emesis and fever occur in 50% of patients. The physical examination in IPSID reveals clubbing of the fingers and ankle edema in 50% to 75% of patients. Later in the disease, ascites, hepatomegaly, and a palpable mass may be present. [212], [218], [219] and [220] Up to 70% of patients will have the a-heavy chain paraprotein in the serum.

Small intestine barium studies, especially enteroclysis, are quite accurate for detecting small bowel neoplasms. [179] CT is less sensitive for small lesions, but it detects most lesions larger than 5 cm. Small bowel lymphomas are categorized by CT as follows: primary, divided into circumferential and cavitary; diffuse, usually EATL; and mesenteric. [180] Because of their location, most small bowel lymphomas require laparotomy for tissue diagnosis. Those located within the proximal 60 cm of the jejunum can usually be identified and sampled for biopsy at enteroscopy. [101] The accuracy of endoscopic biopsy for diagnosing lymphomas is 82% on the first attempt, with an additional 10% on the second attempt. [162] Tissue should be sent both in formalin for standard studies and in saline for flow cytometry analysis. Characteristic findings at endosonography of an irregular hypoechoic mass disrupting the normal echo architecture may suggest the presence of a PSBL despite normal mucosal biopsies. [104] Unlike primary gastric lymphomas (especially MALT lymphoma), the role of endoscopic ultrasound in staging of duodenal lymphomas is not clear. Laparotomy for a diagnosis of lymphoma should be performed if the suspicion for IPSID is high despite normal endoscopic biopsies.

Patients with a confirmed diagnosis of small bowel lymphoma should undergo several studies for staging purposes, including a physical examination, indirect laryngoscopy to exclude involvement of Waldeyer ring, CT scan of the abdomen and chest to assess distant lymph node sites, bone marrow aspiration and biopsy, and lactate dehydrogenase and ß $_2$-microgobulin determinations. [209]

Treatment

The mainstay of treatment for PSBL is surgical resection. Complete resection with lymph node sampling is recommended to avoid a further operation. [209] The ability to achieve complete resection is associated with an improved survival compared with retained tumor after the surgical procedure [236], [238] and may improve response to chemotherapy and radiotherapy. [237], [238] and [239]

PSBL that cannot be completely resected is usually treated by chemotherapy and sometimes with the addition of radiotherapy. The chemotherapeutic regimen usually includes anthracycline, but there is no consensus on the best combination of drugs. [240], [241], [242] and [243] Aggressive chemotherapy causes perforation of the small bowel in 5% to 15% of patients. For some patients with diffuse MLP and EATL, chemotherapy is the only option, but response to chemotherapy is usually poor. The 5-year survival for patients with stage I and II MLP and EATL is approximately 20% to 25%. [214], [226], [227], [244]

IPSID is less amenable to surgical resection than PSBL because of the diffuse nature of the tumor and the low performance status of patients at the time of presentation. Nutritional support with total parenteral nutrition is essential, because malnutrition is severe and likely will not improve unless significant tumor regression is possible. Patients with IPSID in the prelymphomatous stage can be offered a trial of tetracycline or metronidazole for 6 to 12 months. [213], [218] Patients who do not respond to antibiotics or patients already in the lymphomatous stage may benefit from anthracycline-based chemotherapy. [245] A few patients with resectable stage I and II disease have a 5-year survival of 40% to 47%, whereas most other patients whose tumors are unresectable have a 5-year survival of only 0% to 25%. [246] A complete response rate of 62% to 69% and a 3.5-year survival rate of 58% to 70% have been reported in small groups of patients receiving anthracycline-based combination chemotherapy with or without tetracycline. [247], [248] and [249]

SECONDARY TUMORS

Metastatic tumors represent the most common tumors involving the small intestine in many series. Grossly, secondary tumors often present as submucosal nodules or plaques, and they may grow to form intramural masses that cause obstruction, intussusception, or perforation. Often, tumors present as stenotic lesions or infiltrative lesions simulating Crohn's disease. Metastases from melanoma and from carcinomas of the lung, testes, adrenal, ovary, stomach, large intestine, uterus, cervix, liver, and kidney to the small intestine have all been reported. Metastatic melanoma accounts for one third of small bowel metastases. [250] Lesions are typically multiple and present as polypoid lesions that may cause obstruction or intussusception. Tumors of the pancreas, stomach, colon, or mesentery may also involve the small bowel by contiguous spread.

CHAPTER 81

Marc S. Levin

MISCELLANEOUS DISEASES OF THE SMALL INTESTINE

The diseases discussed in this chapter should be considered in patients presenting with gastrointestinal hemorrhage, abdominal pain, diarrhea, intestinal obstruction, or perforation that eludes diagnosis by routine gastroduodenal endoscopy and radiographic studies. Topics include ulceration of the small intestine, small intestine complications of drug therapy, necrotizing enterocolitis (NEC), and protein-losing gastroenteropathy (PLGE). Although most of these entities are infrequently encountered in clinical practice, differentiating them from diseases that are more common can yield important therapeutic benefits.

ULCERS OF THE SMALL INTESTINE

Many causes of *small intestine ulcerations* distal to the duodenum have been identified (Table 81-1). Most of these produce solitary ulcers with sharp borders and normal surrounding mucosa. With surgical resection or removal of offending agents, these ulcers seldom recur and are associated with a benign clinical course. The mortality from multiple ulcers occurring in an abnormal mucosa, as is occasionally seen with gluten-sensitive enteropathy (GSE) or unclassified sprue, chronic ulcerative (nongranulomatous) jejunoileitis (CUJ), or lymphoma, can be as high as 75%. [1] It is essential to attempt to define the underlying cause of small intestine ulcers if possible.

Infectious: tuberculosis, typhoid, cytomegalovirus, syphilis, parasites, strongyloidosis hyperinfection, *Campylobacter*, yersiniosis
Toxic: acute jejunitis (*jt*-toxin-producing *Clostridium perfringens*), arsenic
Inflammatory: Crohn's disease, systemic lupus erythematosus with high serum antiphospholipid levels, diverticulitis
Mucosal: gluten-sensitive enteropathy (jejunoileitis)
Neoplastic: malignant histiocytosis, lymphoma (primary), adenocarcinoma, melanoma, Kaposi sarcoma (secondary)
Vascular: mesenteric insufficiency, giant cell arteritis, vasculitis, vascular abnormality, amyloidosis (ischemic lesion)
Hyperacidic: Zollinger-Ellison syndrome, Meckel diverticulum, stomal ulceration
Metabolic: uremia
Drug-related: potassium chloride, nonsteroidal antiinflammatory drugs, antimetabolites
Radiation-induced: therapeutic, accidental
Idiopathic: primary ulcer, Behçet syndrome

TABLE 81-1 Causes of Small Intestine Ulceration

Primary (Idiopathic) Small Bowel Ulcers

Epidemiology and Etiology The diagnosis of primary small bowel ulcers is made after identifiable causes of small bowel ulcers have been eliminated and thus is unlikely to represent a distinct etiologic entity. With increasing recognition of secondary causes of small intestine ulceration, fewer patients fall into this diagnostic category. The incidence of idiopathic small bowel ulceration is unknown. A review based on 59 patients (6 were taking enteric potassium preparations) found an incidence of 4 small bowel ulcers per 100,000 new patients. [2] Men and women were affected equally, and all age groups were affected (Table 81-2). [2], [3], [4], [5], [6] and [7] These data suggest that primary small bowel ulceration is an uncommon disorder. However, because asymptomatic and uncomplicated intestinal ulcers are rarely detected, the true incidence of this entity is certainly higher than estimates, based on clinical experience.

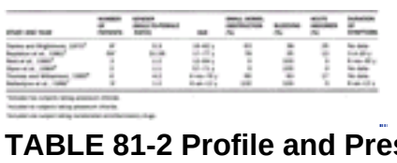

TABLE 81-2 Profile and Presenting Symptoms of Primary Small Bowel Ulcers

Clinical Features Symptomatic complications of small bowel ulcers include bleeding, perforation, and obstruction. The incidence of these complications is not known. Intestinal obstruction appears to occur more frequently than with duodenal ulcers. Intermittent crampy abdominal pain resulting from partial small bowel obstruction is the most frequent presenting complaint (63% to 100% of patients; see Table 81-2). Symptoms related to intermittent partial small bowel obstruction have been reported for 3 days to 20 years preceding presentation. [2] Patients with small intestine obstruction or perforation also can present with an acute abdomen. Although ulcers are more commonly seen in the ileum, perforated ulcers are more common in the jejunum (78% versus 11%). [2] Because ileal ulcers, which are less likely to perforate, are more prevalent, the overall incidence of perforation is only 22%. Gastrointestinal bleeding is also common, especially in younger patients, who present with intestinal hemorrhage or with occult blood loss. Patients presenting with gastrointestinal bleeding often have symptoms consistent with a history of intermittent intestinal obstruction as well. The diagnosis of small intestine ulceration should be considered if intestinal bleeding and evidence of small intestine obstruction coexist.

Pathology Most primary small intestine ulcers (75%) are located in the middle to distal ileum. [1] In one report, a solitary ulcer was found in 70%, two or three ulcers in 20%, and more than three in 10% of patients. [2] Ulcers typically have sharply demarcated borders and vary in diameter from 0.3 to 5 cm. [2] The pathological features are nonspecific and are identical to those of peptic ulcerations. [8] A marked eosinophilic infiltrate is sometimes present. [9] The surrounding mucosa is usually normal. Granulomata, sinus tracts, and pathological vascular changes are not seen. Granulation tissue and fibrosis that extend deep into the bowel wall may produce intestinal stenosis. The absence of granulomata and the normal surrounding mucosa are features that help to distinguish idiopathic ulcers from those seen in Crohn's disease and in CUJ.

Diagnosis Both detection of intestinal ulceration and exclusion of known etiologic agents are required to support a diagnosis of primary small bowel ulcers. A careful history is necessary to identify exposure to potentially ulcerogenic substances such as nonsteroidal antiinflammatory drugs (NSAIDs) and enteric-coated potassium preparations. Prior abdominal surgery and other risk factors that predispose to intestinal ischemia should be identified. Assessment of immune status also may be

useful. It is important to exclude cytomegalovirus infection in immunocompromised patients because of the propensity for cytomegalovirus ulcers to bleed or perforate. Other infectious causes, including *Salmonella typhi,* need to be excluded. [10], [11] There are no pathognomonic biochemical abnormalities, and the only laboratory tests that are useful for diagnostic purposes are those that help to establish an alternative diagnosis. Small intestine ulcers can be detected radiographically, endoscopically, or at laparotomy. Although small intestine ulcers cannot be detected by plain abdominal radiographs, small bowel dilation suggestive of obstruction and pneumoperitoneum indicative of perforation may be detected. Conventional contrast radiography of the small intestine rarely identifies primary ulcers of the small intestine. [2] Enteroclysis is a superior technique for demonstrating small intestine mucosal lesions (see Chapter 152). It should be considered the radiographic procedure of choice in the evaluation of suspected ulcers of the small intestine. Although intestinal strictures may be readily detected, small intestine ulcers are seldom demonstrated radiographically. Ileal ulcers can, on rare occasions, be detected if contrast material is refluxed into the terminal ileum; however, the yield from barium enemas does not justify their use for detecting small bowel ulcers. Other radiographic techniques, such as technetium 99m (^{99m}Tc)–labeled red cell scanning and mesenteric angiography used for the evaluation of gastrointestinal bleeding, or ^{99m}Tc pertechnetate for the diagnosis of a Meckel diverticulum, may lead indirectly to the detection of small intestine ulcerations. Small intestine enteroscopy is a useful adjunct for the diagnosis of small intestine lesions because of improvements in equipment and technique. [12], [13], [14], [15] and [16] In the setting of obscure gastrointestinal bleeding, for example, a diagnosis was made in 50% of 258 patients, all of whom had negative results of enteroclysis. [17] These data suggest that enteroscopy is useful in the evaluation of small bowel ulcers, although it has not been specifically evaluated for this purpose. Intraoperative enteroscopy with laparotomy or laparoscopy also can be a valuable adjunct in difficult cases. [18], [19] and [20] Based on animal studies and clinical experience in detecting small bowel angiodysplasias, wireless capsule endoscopy may prove superior to push enteroscopy for the detection of small intestinal ulcers. [21], [22] and [23] Despite the refinement of enteroclysis and enteroscopy, many symptomatic idiopathic small intestine ulcers are not detected without surgical intervention. In the patient with persistent gastrointestinal blood loss or abdominal pain with evidence of small bowel obstruction, surgical exploration with or without intraoperative enteroscopy should be given serious consideration (see Chapter 161).

Therapy The therapy for primary small intestine ulcers is dictated by the severity of complications. Emergency surgical intervention is required if an acute abdomen or pneumoperitoneum indicative of intestinal perforation is present. Life-threatening intestinal bleeding is an indication for diagnostic and therapeutic mesenteric angiography or surgical exploration (see Chapter 33). The best therapy for ulcers that present with less serious complications is also surgical resection. Detection of small bowel ulcers is usually readily accomplished at laparotomy. Intraoperative enteroscopy may be a useful adjunct. Most ulcers can be managed by surgical resection with end-to-end anastomosis, providing adequate material for pathological analysis with a low incidence of complications and ulcer recurrences. Simple oversewing of primary small bowel ulcers is not recommended. With such an approach, the amount of material available for pathological analysis is limited, and the risk of ulcer recurrence is high. Medical management with antiinflammatory or immunosuppressive agents is not effective therapy for intestinal ulcers or strictures. Furthermore, unsuspected perforation is often found at surgery. [2]

Drug-Induced Small Bowel Ulcers

The entrapment of a pill or capsule before dissolution or the release of large concentrations of a drug in a segment of intestine can result in localized ulceration because of physical pressure or specific cytotoxic effect. NSAIDs remain the most common cause of drug-induced small intestine ulcers. In the 1960s, enteric-coated potassium chloride (KCl) was introduced and was soon recognized to be an intestinal ulcerogen. Ferrous salts, digoxin, corticosteroids, zirconium, and clofazimine have all been implicated as ulcerogens as well. [24]

Nonsteroidal Antiinflammatory Drugs These drugs are a heterogeneous group of organic acids that inhibit prostaglandin synthesis and have analgesic antiinflammatory and antipyretic properties. [25] Although they have been used for decades in the treatment of inflammatory arthropathies, their use now includes many nonrheumatologic problems. [25] Many generic NSAIDs are available without prescriptions. As a result, NSAIDs are among the most commonly used drugs worldwide. Numerous publications have addressed the magnitude and cost of NSAID-associated gastrointestinal complications, which have been described as an emerging epidemic. [26], [27], [28], [29], [30], [31], [32], [33], [34], [35] and [36] Because of the increased use of NSAIDs, the introduction of more potent NSAIDs, and improvements in small intestine diagnostic methods, small bowel enteropathy is a more frequently diagnosed complication of NSAID use. Multiple ulcerations, mucosal diaphragms, ileal strictures, and perforations have all been associated with NSAID use. [30], [37], [38], [39], [40] and [41] Although the rate of small bowel ulcers with cyclooxygenase-2–selective inhibitors is unknown, the risk is likely to be less than for generic NSAIDs. The epidemiology of NSAID-induced enteropathy is not well characterized. Up to 70% of patients who take NSAIDs have evidence of increased intestinal permeability or inflammation, [30], [42], [43], [44], [45] and [46] but most are asymptomatic. An autopsy study showed the presence of nonspecific small intestine ulcers in 8.4% of 249 patients who had NSAIDs prescribed during the 6 months before death, compared with an incidence of 0.6% in 464 patients who had not used NSAIDs. [47] Three of the long-term users of NSAIDs were found to have died of perforated nonspecific small intestine ulcers. Small intestine erosions or ulcerations were detected by small bowel enteroscopy in 7 of 15 iron-deficient patients receiving long-term NSAID therapy for rheumatoid arthritis. [48] All the patients had negative results of upper and lower endoscopy. These studies indicate a high prevalence of unsuspected gastrointestinal lesions in patients taking NSAIDs. A metaanalysis of studies examining the association between NSAIDs and serious adverse gastrointestinal events indicated that NSAID users are at three times greater risk than are nonusers. [47], [49] Independent risk factors seem to be age exceeding 60 years, previous NSAID complications, and concomitant steroid use. This study did not analyze small bowel effects independently, so it is not certain whether this risk profile is applicable to NSAID-induced small intestine enteropathy.

Pathophysiology. Increased intestinal permeability, which enhances susceptibility to lumenal macromolecules and toxins, has been implicated in the pathogenesis of NSAID-induced enteropathy. [50] This defect in permeability is evident within hours after NSAID administration, [30], [51] and in rats it may be ameliorated by pretreatment or simultaneous treatment with glucocorticoids, sulfasalazine, or tetracycline. [52] The mechanisms by which NSAIDs injure the small intestine mucosa are unknown but are thought to include a role for enteric bacteria, the enterohepatic circulation, neutrophil infiltration, and suppression of prostaglandin synthesis. [53], [54] Because cyclooxygenase-1–mediated synthesis of prostaglandins appears to be less important as a cytoprotective mechanism in the small intestine, NSAID-mediated cyclooxygenase inhibition is not thought to be the major pathogenic mechanism in NSAID-induced enteropathy. [55], [56] Furthermore, cyclooxygenase-1 knock-out mice had no apparent intestinal disorders. [57] Although nitric oxide derivatives of NSAIDs are equally potent suppressers of prostaglandin synthesis as their parent compounds, the magnitude of small intestinal injury is markedly attenuated with these agents. [58], [59], [60] and [61] In rats, diclofenac, but not nitrofenac (a nitric oxide derivative that does not undergo extensive enterohepatic circulation), caused increases in epithelial permeability, gram-negative bacterial colonization, and intestinal ulceration. [62] /SUP>In these rats, the increased bacterial load, which occurred after the changes in intestinal permeability, may have exacerbated the NSAID injury. [53] These studies suggest that NSAIDs primarily alter intestinal permeability through local rather than systemic effects and suggest a pathogenic role for enteric bacteria. Additional studies indicate that NSAID-induced microvascular leakage also contributes to NSAID-induced enteropathy. [63] In rats, NSAID-induced plasma leakage requires induction of calcium-independent nitric oxide synthase and occurs only in the presence of gut bacteria. [64] The relative importance of local and systemic effects in the pathogenesis of NSAID-induced enteropathy was also addressed in human volunteers who received either indomethacin or the prodrug nabumetone. Because only indomethacin increased intestinal permeability, local effects of NSAIDs appear to be more important. [65] Another prodrug, sulindac, was compared with indomethacin, with similar results. [66] To date, clinical trials comparing cyclooxygenase-2–selective inhibitors with nonselective cyclooxygenase inhibitors have not had the power to address the comparative magnitudes of small intestinal enteropathy. A proposed cyclooxygenase-independent direct mechanism for NSAID damage is inhibition of glycolysis and the tricarboxylic acid cycle, leading to reduced cellular adenosine triphosphate production and uncoupling of oxidative phosphorylation. [55], [67], [68] Coadministration of glucose and citrate with indomethacin to humans was shown to prevent the increased permeability seen with indomethacin alone, [67] a finding compatible with this hypothesized mechanism. NSAID-associated intestinal injury primarily affects the distal small intestine. Intestinal ulcers induced by NSAIDs are pathologically identical to primary ulcers and to other drug-induced ulcers. Strictures are seen in up to 5% of patients receiving long-term NSAID therapy for arthritis. [30] In addition to strictures that are indistinguishable from those seen in Crohn's disease and other disorders, apparently unique, diaphragmlike strictures have been described (Fig. 81-1). [37], [39], [69], [70] and [71] These strictures encroach on and narrow the lumen to an opening as small as 1 mm in diameter. [69] They usually occur as multiple strictures separated by only a few centimeters of normal bowel. [69] Submucosal fibrosis replacing or merging with the muscularis mucosae is characteristic. [37], [69] Mild inflammation of the overlying mucosa is invariably present, with or without shallow ulceration. [37] The adjacent mucosa is usually completely normal. Patients with this "diaphragm disease" present with weight loss, hypoalbuminemia, anemia, and intermittent vague abdominal pain. [69] The diaphragm-like strictures are difficult to detect radiologically and can be missed at laparotomy unless an enterotomy is performed. [69], [70] and [71] Small bowel enteroscopy, which is useful for detecting intestinal ulcers, [48] may also be useful for detecting NSAID-related intestinal abnormalities. [72]

FIGURE 81-1. Nonsteroidal antiinflammatory drug–induced small intestine strictures. (**A**) Diaphragm strictures of the small intestine are apparent in resected intestine. (**B**) Enteroclysis study in a

patient taking nonsteroidal antiinflammatory drugs. Diaphragm strictures (*arrows*), which were found at surgery, are difficult to appreciate and resemble exaggerated plica circularis. (From ref. [55].)

Morphologically, the presentation of NSAID-related enteropathy is often similar to that of Crohn's disease, with transmural injury that can cause stricture formation. [55, 68] In addition, although most patients with NSAID-associated small intestine enteropathy are asymptomatic, some patients receiving long-term treatment present with clinical features of Crohn's disease. [25] In a prospective study, 10% of patients with colitis not secondary to Crohn's disease were thought to have NSAID-induced colitis, [73] but NSAIDs may exacerbate Crohn's disease and ulcerative colitis. [28, 74, 75 and 76] These reports emphasize the importance of obtaining an accurate drug history for all patients presenting with an illness resembling Crohn's disease. NSAIDs have been reported to be associated with a variety of other intestinal disorders, including collagenous colitis, [77] nonceliac flattening of small intestinal mucosa, [78, 79 and 80] celiac sprue, intestinal malignant diseases, [80] and perhaps diverticulitis. [55] Nevertheless, the available data are not sufficient to establish a true association between NSAID use and any of these conditions. [68]

Therapeutic Considerations. There are no practical means to diagnose NSAID-associated enteropathy routinely. Noninvasive techniques to assess NSAID effects on the small intestine are being studied as alternatives to endoscopy or surgery. [81] Most patients who take NSAIDs appear to have intestinal inflammation by indium 111 leukocyte scans and fecal excretion, [43] and increased intestinal permeability by chromium 51 (^{51}Cr)-EDTA absorption. These abnormalities usually resolve after the medications are discontinued, but inflammation may persist for up to 16 months. [30] Discontinuation of NSAIDs should be sufficient for treatment of uncomplicated ulcers. Surgical intervention is required for therapy of intestinal perforation or symptomatic strictures. The optimal regimen for patients for whom there is no good alternative to continued NSAID use has not been established. Based on the observation that nabumetone and sulindac did not increase intestinal permeation to ^{51}Cr-EDTA, switching to these or other prodrugs may be beneficial. Observations in rats indicate that switching to NSAIDs that are less potent inhibitors of cyclooxygenase also may be helpful. [82, 83] The hypothesis that cyclooxygenase-2–selective NSAIDs, by preserving the cytoprotective effects of prostaglandins synthesized by cyclooxygenase-1, may be less enteropathic than nonselective NSAIDs has not been directly addressed by the clinical trials completed to date. A double blind crossover study demonstrated that unlike indomethacin, cyclooxygenase-2 inhibition with rofecoxib did not increase intestinal permeability in healthy subjects. [84] In another double-blind, crossover study, nimesulide, another cyclooxygenase inhibitor, did not increase intestinal permeability or excretion of calprotectin, a marker of intestinal inflammation. [85] Delivery of NSAIDs encapsulated in liposomes was protective in a rat study. [86] The degree of ulceration in rats was related to the amount of active drug excreted in bile. [82, 83, 87] Human studies have not established that the incidence of small intestine enteropathy or upper gastrointestinal bleeding can be reduced by using prodrugs or NSAIDs with decreased biliary excretion of active drug or enteric-coated or slow-release formulations. [81] Germ-free rats are resistant to indomethacin-induced intestinal lesions, [88] and antibiotics can reduce the incidence of indomethacin-induced small intestine ulcers in rats. [89] In humans, metronidazole [66] and sulfasalazine [90] reduce intestinal inflammation, a response not yet proven to correspond to prevention of or recovery from NSAID-induced complications. In studies using rats, pretreatment or concurrent treatment with glucocorticoids, sulfasalazine, tetracycline, sucralfate, [91] pentagastrin, [92] naloxone (tested because morphine potentiates the ulcerogenic effect of indomethacin), [93] clonidine, [94] or thromboxane synthetase inhibitors [52] reduced indomethacin-induced permeability and inflammatory changes in rats. Drugs that exacerbated the intestinal toxicity of indomethacin in rats include cyclosporine [95] and morphine. Although prostaglandin E analogs such as misoprostol and enprostil prevent NSAID-associated injury of the stomach and duodenum, [96, 97, 98, 99 and 100] their effects in the remaining small intestine are not known. Protection was demonstrated in animal models. [101, 102 and 103] In human subjects, high-dose misoprostol prevented NSAID-induced permeability changes in one study, [104] but therapeutic doses did not. [65]

Potassium Chloride The introduction of enteric-coated KCl tablets in the 1960s was associated with an unacceptably high incidence of small intestine ulceration, attributed to high lumenal concentrations of KCl resulting from the rapid dissolution of the tablets in the small intestine. Slow-release formulations using a wax-polymer matrix (dissolution in approximately 4 hours) or microencapsulation (dissolution in 8 to 10 hours) were developed in an attempt to eliminate this adverse effect; the incidence of gastrointestinal ulceration was reduced but not eliminated. Two cases of small intestinal ulceration occurred from 1970 through 1983 (3 in 100,000 patient-years of slow-release wax matrix tablet use), compared with 56 cases from 1960 through 1965 (65 in 100,000 patient-years of enteric preparations). [105] Regardless of the preparation used, the risk of ulceration is increased if intestinal transit is delayed by concurrent medications, general debility, or advanced age. [106] The clinical presentation, diagnosis, and treatment of patients with KCl-induced small intestine ulcers or strictures are the same as those for patients with primary or NSAID-induced ulcers. Although the ulcers can occur anywhere along the gastrointestinal tract, they are most common in the distal ileum. [107]

Other Drugs Parenteral gold therapy also has been associated with enterocolitis, with edema and ulceration limited to the ileum. [108, 109 and 110] This rare complication is most common in middle-aged women and can occur shortly after the initiation of therapy. This disorder has a high mortality rate; thus, prompt cessation of gold therapy is essential. Therapy includes bowel decompression and antibiotics. Steroids are frequently used, although efficacy has not been proven. Octreotide was used successfully in one case. [111] Other drugs for which there are reports of small intestine ulcers or perforation include corticosteroids, [112] cytarabine [113] and other chemotherapeutic agents, digoxin, [114] and ferrous sulfate preparations. [14]

Small Bowel Ulcers Associated with Systemic Disorders (See Chapter 128)

Behçet Syndrome *Behçet syndrome* is a systemic disease that affects the skin, joints, vascular system, central nervous system, and intestinal tract. Oral and genital ulcers are a common feature of the syndrome; intestinal ulceration has been described in fewer than 1% of all patients with Behçet syndrome. [115] The ileocecal region is most frequently involved. [116] Multiple deep ulcers in a background of minimally inflamed mucosa are characteristic. The lesions predominate at sites coinciding with intramucosal lymphoid tissue. [117] The ulcers bleed easily and are often penetrating. The abnormalities are readily differentiated from those of Crohn's disease or ulcerative colitis. [116, 118] The optimal treatment of Behçet syndrome has yet to be established. No medical treatment significantly alters the natural course of this syndrome. Immunomodulation with corticosteroids, methotrexate, colchicine, thalidomide, [119, 120 and 121] cytotoxic agents, cyclosporine, and tacrolimus (FK506) have been used for treatment of multisystem Behçet syndrome. [122] Recombinant interferon-a may benefit patients with systemic involvement including intestinal ulcers. [123, 124, 125 and 126] Surgery with wide resection margins should not be delayed in patients with complicated intestinal cases, although ulcer recurrence is common postoperatively. [116, 127, 128] Most recurrences occur within 2 years of surgery and consisted of one or two deep ulcers at or near the anastomotic site. [119]

Collagen Vascular Diseases Patients with *systemic lupus erythematosus* (SLE) can have intestinal ulcerations. [129] Microthrombosis and vasculitis with intestinal ischemia are the likely mechanisms for this uncommon complication of SLE. Mesenteric vasculitis often presents with vomiting, fever, and hematochezia. It can progress to bowel infarction, which is associated with high mortality. Mesenteric vasculitis presenting with small bowel ischemia and stricture has also been reported in patients with other inflammatory disorders, [130] including rheumatoid arthritis, scleroderma, polyarteritis nodosa, Henoch-Schönlein purpura, Wegener granulomatosis, giant cell arteritis, Churg-Strauss syndrome, and Sézary syndrome. [131] Spondylarthropathies have also been associated with an increased incidence of ileal ulceration, although this is most often caused by concurrent inflammatory bowel disease. [132] Patients with acquired antiphospholipid antibodies and SLE or related autoimmune diseases are at increased risk of developing intestinal ischemia and hemorrhage related to mesenteric arterial thrombosis. [133, 134] *Cryptogenic multifocal ulcerous stenosing enteritis* is an idiopathic syndrome characterized by intermittent bouts of intestinal obstruction and ulcerative stenosis and steroid responsiveness. [135] Patients present with multiple jejunal and proximal ileal stenoses associated with superficial ulcers but share no other characteristics of Crohn's disease. The presence of systemic symptoms (weight loss, fever, malaise) in most patients, the responsiveness to steroids, and the demonstration of C2 deficiency in one reported case suggest that this syndrome is a variant of polyarteritis nodosa or an unclassified independent vasculitis. [135]

Diffuse Small Bowel Ulceration and Concurrent Malabsorption

A rare clinical syndrome consisting of malabsorption, abdominal pain, and multiple nonmalignant ulcers of the small intestine has been described. [136] Typically, these patients are in the sixth or seventh decade of life and have long-standing GSE. In such patients, the disorder is characterized by extensive villus atrophy and small bowel ulcerations that fail to improve on gluten withdrawal. There is also a distinct subgroup of patients who do not have GSE. The term *chronic ulcerative (nongranulomatous) jejunitis* (CUJ) and synonyms such as idiopathic mucosal enteropathy, idiopathic chronic ulcerative enteritis, unclassified sprue, malignant histiocytosis, and enteropathy-associated T-cell lymphoma (EATL) have been applied to this latter group of patients. The nomenclature reflects the poor understanding of the etiology and pathophysiology of CUJ. [136, 137] For the purposes of this chapter, *CUJ* is used to describe this disease in patients with and without evidence of GSE.

The typical histological features of CUJ are partial or total villus atrophy, mucosal ulceration, crypt hyperplasia, and an inflammatory cell infiltrate. [138, 139] The loss of intestinal villi results in a marked decrease in the absorptive area of the intestine, and the aborted maturation of the enterocytes results in lower levels of digestive enzymes on the intestinal brush border. The effects of these disturbances are malabsorption of all dietary components and a variable degree of PLGE. Although the mechanism is poorly understood, villus atrophy appears to be related to infiltration by activated T cells. [140]

Etiology CUJ that occurs without a prior history of GSE is usually more extensive in distribution and fails to respond to gluten withdrawal. CUJ and GSE are both associated with splenic atrophy of unknown origin, and most cases of CUJ are preceded by a variable period of suspected or proven GSE. [1, 141, 142 and 143] Nevertheless, it seems clear that CUJ can develop without GSE. [144, 145] Although small bowel lymphoma can resemble GSE clinically, [146] there is strong evidence that lymphomas arise in chronic GSE. [147, 148, 149, 150 and 151] The incidence of malignant degeneration may be decreased by a strict gluten-free diet. [152] In contrast to primary small intestine lymphomas, the typical lymphoma associated with GSE is derived from T cells. [153, 154 and 155] These lymphomas, which are referred to as *enteropathy-associated T-cell lymphomas* (EATLs), are difficult to differentiate from those of CUJ. Histologically, both EATLs and CUJ exhibit villus atrophy, ulceration, and mucosal infiltration by activated T cells. Both disorders usually present with splenic atrophy. The major diagnostic difficulty results from the observations that EATL may be indolent in its early stages,

and patients with CUJ can develop lymphoma several years after diagnosis. In some cases, retrospective examination of biopsy samples obtained at the time of diagnosis of CUJ have revealed typical malignant cells. [138] , [141] , [156] Using the polymerase chain reaction, clonal rearrangements of the T-cell receptor were found in tumor specimens and in enteropathic bowel without evidence of tumor involvement from the same patients. [157] , [158] Analysis of intestinal biopsies from patients with CUJ and refractory GSE revealed that the monoclonal cytologically normal, noninvasive intraepithelial T lymphocytes share an aberrant immunophenotype with EATL. [159] In one series, all the patients with CUJ had metastatic disease at the time of diagnosis, [138] but in a different retrospective study, no evidence of preexisting lymphoma was detected. [142] These data indicate that CUJ is a significant risk factor for the development of lymphoma and suggest that this development may be invariable. Non–T-cell lymphomas, such as immunoproliferative small intestinal disease and Mediterranean (B-cell) lymphoma, can also be accompanied by mucosal atrophy and ulceration and may have all the features of CUJ (see Chapter 80). This group may have a dramatic response to antibiotics or cytotoxic agents. [160] , [161] , [162] and [163] These lymphomas cannot be differentiated solely based on morphology; thus, it is important to determine cell surface markers for proper diagnosis.

Clinical Features The age at diagnosis of CUJ tends to be older than it is for typical GSE. Childhood cases have not been reported. The onset of CUJ is indolent. Patients with CUJ with and without known GSE were symptomatic for a mean of 13 and 4.5 years, respectively. Most patients present with chronic symptoms that are typical of malabsorption syndromes. Midepigastric pain and weight loss associated with steatorrhea and diarrhea are common. [142] Shortly after presentation, 20% to 30% of patients have ulcer complications such as small bowel obstruction (30%), melena (25%), and perforation (22%). Along with symptoms caused by these complications, patients with CUJ may have low-grade fever and signs of malnutrition.

Pathology Multiple superficial or deep ulcers are invariably present in the stomach, small bowel, and colon. [142] , [164] Splenic atrophy is often present. Lymphomatous infiltration of lymph nodes, liver, spleen, and bone marrow is common with concurrent lymphoma. [138] According to Isaacson, [139] there are “variable degrees (usually severe) of villus atrophy, crypt hyperplasia, intraepithelial lymphocytic infiltration, irregularity of surface enterocytes, and a dense lamina propria infiltrate consisting almost solely of plasma cells with a variable number of eosinophils and occasional neutrophils.” Invasion of the epithelial layer may cause ulceration (Fig. 81-2). Subepithelial collagen deposition, which is also seen in GSE, and marked fibrosis of the ulcer base also may be present. Crypt hyperplasia and villus atrophy are seen in the adjacent mucosa, and the remaining mucosa is usually normal. It is imperative that multiple sections be exhaustively examined for malignant cells to avoid missing the diagnosis of lymphoma. Neoplastic cells are derived from T cells. [153] , [154] and [155] , [165] They resemble histiocytes, with minimal or no atypia, and the presence of intracellular erythrocytes, platelets, and cell debris is a common feature (Fig. 81-3). [138] Confusion with Hodgkin disease may occur because of similarities with Reed-Sternberg cells. [146] , [147] , [166]

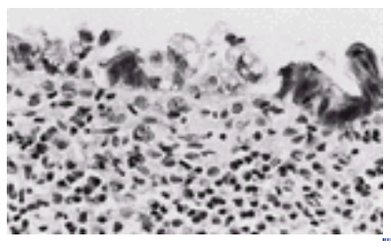

FIGURE 81-2. The malignant chronic ulcerative nongranulomatous jejunoileitis cells have invaded the surface epithelium and produced an ulcer. An exuberant plasma cell infiltrate is seen in the subepithelial tissue (original magnification ×400). (From ref. [139] .)

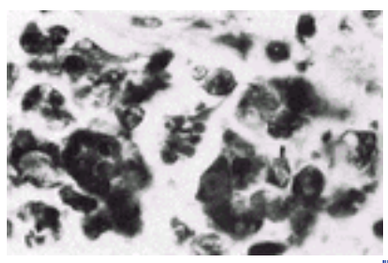

FIGURE 81-3. Chronic ulcerative nongranulomatous jejunoileitis tumor cells show typical erythrophagocytosis (original magnification ×1000). (From ref. [138] .)

Diagnosis The diagnosis of CUJ should be considered in patients with established or apparent GSE who present with worsening malabsorption despite continued compliance with gluten-free diets. CUJ is essentially a diagnosis of exclusion, whether or not a history of celiac disease is present, unless lymphoma is detected. Disorders presenting with malabsorption and intestinal ulceration that must be excluded include Crohn’s disease, ischemic enteritis, radiation enteritis, lymphoma, drug-induced ulceration, vasculitis, Zollinger-Ellison syndrome, and Whipple disease. The patient with suspected CUJ should be assessed for malnutrition, and a careful evaluation of the extent of disease should be undertaken. Malabsorption and PLGE account for hypoalbuminemia, and hypoglobulinemia and deficiencies of divalent cations, iron, and folate are common. Hyposplenism is often present. [143] Intestinal perforation should be ruled out if leukocytosis, with or without fever and peritoneal signs, is present. The diagnosis of CUJ is rarely made radiographically. Evidence of bowel thickening and of complications such as small bowel perforation or obstruction may be present on plain films. Demonstration of small bowel strictures by contrast studies (Fig. 81-4) or by computed tomography helps to distinguish CUJ from uncomplicated GSE: small bowel dilation is typical of the latter. [167] , [168] and [169] Bowel thickening, mesenteric lymphadenopathy, and splenic atrophy are consistent with CUJ. However, lymphadenopathy in patients with GSE is not diagnostic of lymphoma.

FIGURE 81-4. Chronic ulcerative nongranulomatous jejunoileitis (CUJ). Thirty-minute small bowel follow-through shows prominent intestinal folds, thickening of the bowel wall, diffuse lumenal narrowing, and mucosal ulceration (*arrows*). Dilation, which is typical of gluten-sensitive enteropathy, is not a feature of CUJ. (From ref. [169] .)

Small bowel biopsies are essential for establishing the presence of CUJ. Although the yield from blind biopsies is poor, improvements in the ability to obtain endoscopic biopsy samples should markedly reduce the need for surgery to establish the diagnosis. [169] Biopsy samples obtained from ulcerated regions are the most desirable. As discussed earlier, it is essential that adequate tissue is obtained, sectioned extensively, and examined by an experienced pathologist before excluding the diagnosis of EATL. [139] A careful search for disseminated lymphoma at the time of presentation is essential. [138] It is also important to assess for the presence of B-cell surface markers because B-cell lymphomas and immunoproliferative small intestinal disease may be associated with villus atrophy. Polymerase chain reaction has been used to detect diagnostic T-cell receptor gene rearrangements in biopsies. [160]

Therapy No specific therapy has been shown to modulate the course of CUJ. Most patients have unresponsive malabsorption, and life expectancy at diagnosis is less than 2 years. Surgical resection of severely affected bowel has been of benefit in some cases. [142] , [156] Although patients with CUJ are at increased risk of intestinal perforation, prednisone therapy should be considered in all symptomatic patients with no evidence of lymphoma. The dose should be reduced to the minimum necessary to maintain a symptomatic response with tolerable side effects. Although CUJ does not respond to removal of dietary gluten, it is possible that this measure may impede the development of lymphoma. [152] If a localized lymphomatous infiltrate is found, local excision is mandatory. Although some patients have been cured by resection alone, [170] most remain symptomatic after the surgical procedure. Mortality in these patients is very high, presumably because of progression of the lymphoma. The impact of adjuvant radiation and of chemotherapy has not been evaluated. Disseminated T-cell lymphoma should be treated with aggressive chemotherapy. No trials have been conducted, but the principles are probably similar to those used in the treatment of other lymphomas, using combinations such as cyclophosphamide, hydroxydoxorubicin, vincristine, and prednisone. [171]

DRUG-INDUCED SMALL BOWEL DISEASE

Many of the drugs used today mediate various mechanisms of injury, including the following: erosive damage by NSAIDs and KCl; ischemic damage by cardiac drugs, cocaine, ergotamine alkaloids, and oral contraceptives; hematomas from anticoagulants; motility disorders from opiates; malabsorption; and inhibition of epithelial cell turnover by chemotherapeutic agents. These adverse reactions may be reversible if the drug is discontinued, but some medications produce permanent effects. This section focuses on drugs that have a profound or permanent effect on the small intestine, except for those causing erosive damage, as discussed earlier. The pathological and radiologic features of drug-related lesions of the intestinal tract have been reviewed. [172], [173]

Drugs Causing Ischemia

Mechanisms by which drugs and toxins can produce occlusive or nonocclusive intestinal ischemia include induction of arterial vasoconstriction, systemic or splanchnic hypotension, and thrombosis of mesenteric vessels (see Chapter 131). Regardless of cause, the mortality rate from small bowel ischemia progressing to bowel infarction ranges from 70% to 90%. [174], [175] Delays in presentation and diagnosis and coexistent health problems account for this high mortality. Patients with drug-induced mesenteric ischemia usually present with severe, poorly localized abdominal pain, low-grade fever, and hematochezia. Signs of peritonitis or abdominal distention secondary to ileus may be present. Evidence of intestinal perforation, obstruction, or ileus can be obtained by radiographic studies. The demonstration of bowel wall edema and thumbprinting, pneumatosis intestinalis, or portal venous gas are consistent with mesenteric infarction (Fig. 81-5). [174] Computed tomography is a reliable diagnostic method. [176], [177] Radiographic studies may be normal in patients with nonocclusive ischemia, such as occurs with digitalis-induced mesenteric spasm and antihypertensive medications. [178], [179] Mesenteric angiography may be needed to document digitalis-induced ischemia. [180]

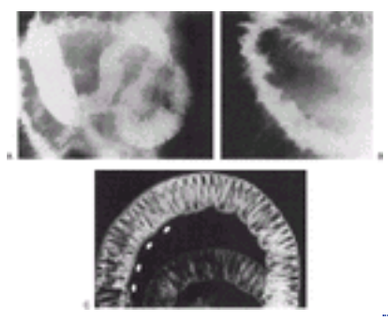

FIGURE 81-5. Acute spontaneous mesenteric venous thrombosis. (**A**) Involved jejunum shows separation of loops and thumbprinting. (**B**) Blurring of mucosal folds is seen in a distal zone of involvement. (**C**) Barium study of a surgical specimen shows thickening of mucosal wall and folds, thumbprinting, and pseudomembrane formation (*arrows*). (From Pringot J, Bodart P. Inflammatory diseases. In: Margulis AR, Burhenne HJ, eds. Alimentary tract radiology. St. Louis: CV Mosby, 1989:804.)

Besides measures specific to the offending agent, general supportive measures include administration of fluids and oxygen, correction of electrolyte and acid-base disorders, and antibiotic therapy. [174] Surgical resection of infarcted small bowel is necessary, although most patients are very high-risk surgical candidates.

Cardiac Drugs Intestinal ischemia or infarction may result from drugs that produce or potentiate arterial vasoconstriction or hypotension. [181] The incidence of these side effects is greatest when the splanchnic circulation is already compromised, such as in congestive heart failure. Antihypertensive agents and diuretics can induce intestinal ischemia secondary to hypotension and hypovolemia. Drugs with direct vasoconstrictive effects, such as norepinephrine, dopamine, and intraarterial or intravenous vasopressin, reduce intestinal blood flow and can cause mesenteric infarction. [182], [183] Digitalis glycosides can further reduce splanchnic flow in patients with congestive heart failure. Intestinal ischemia resulting from digoxin use may be reversed with nitroprusside and calcium channel blockers. [180], [184]

Cocaine Cocaine is a lipophilic drug that is readily absorbed by mucosal surfaces, including the intestinal mucosa. It has potent stimulatory effects on the central nervous system because of inhibition of presynaptic reuptake of norepinephrine, dopamine, and serotonin (5-HT) as well as increased synthesis of norepinephrine and dopamine. [185], [186] Excessive sympathetic stimulation produces peripheral vasoconstriction and tachycardia, which can cause hypertension and nonocclusive intestinal ischemia. [187] Rebound vasodilation after intense vasoconstriction can further compromise intestinal perfusion. Gastrointestinal manifestations of cocaine use include appetite suppression, nausea, vomiting and hyperperistalsis, perforated gastroduodenal ulcers (most common in crack users), and hepatotoxicity. [188] Intestinal ischemia is a serious but rare complication of cocaine and crack abuse. [189], [190], [191], [192], [193] and [194] Life-threatening gastrointestinal problems are more likely to be encountered by “body packers.” Such persons transport illicit drugs by ingesting drug-containing packets or condoms or by inserting them in the rectum. [187], [195], [196] Complications include mechanical intestinal obstruction and rupture of a packet, which can release a lethal quantity of cocaine. [196], [197] Signs of drug toxicity, mechanical intestinal obstruction, or marked leukocytosis, which may indicate the presence of gangrenous bowel, are indications for laparotomy. [182] Asymptomatic patients should be treated with activated charcoal to bind any leached drug and with mild cathartics to stimulate gastrointestinal transit. [182], [195] Abdominal radiographs may reveal evidence of intestinal obstruction or ileus as well the pathognomonic “double-condom sign.” [198]

Ergotamines Ergot alkaloids such as ergotamine, dihydroergotamine, methylergonovine, and methysergide are used in the symptomatic treatment or prevention of migraine headaches. [199] Common intestinal complications of ergots include abdominal pain, nausea, and vomiting. Symptomatic vasospasm affecting the extremities is a common complication of ergot toxicity, whereas severe splanchnic vasoconstriction is rare. [200], [201] There are several reports of bowel infarction after administration of large doses of ergots. [200], [201] Ergots have high affinity for a-adrenergic and 5-HT receptor subtypes. [202] Ergot-induced vasospasm is thought to occur as a result of peripheral adrenergic stimulation. [200], [202] The diagnosis of ergot-induced intestinal ischemia is based on the presence of abdominal symptoms in a patient taking ergotamines. Arteriographic demonstration of mesenteric vascular spasm and collateralization supports the diagnosis. [201] Discontinuation of ergots and supportive care with fluids are usually sufficient therapy. Intravenous sodium nitroprusside may be beneficial in severe cases. [201] Emergency laparotomy is essential if there is evidence of gangrenous bowel.

Oral Contraceptives Oral contraceptives have been reported to cause small intestine infarction and, more commonly segmental, colitis. [203] The mechanisms are not known, although mesenteric arterial occlusion [204], [205], [206] and [207] or mesenteric venous thrombosis [208], [209], [210] and [211] is often present. Progestins cause arterial occlusion, whereas estrogens can produce both arterial and venous occlusion. [212], [213] Mechanisms that have been implicated include hypercoagulability, reduced mesenteric venous blood flow, and endothelial proliferation. [206], [214] The risk is increased by ancillary factors such as collagen-vascular disease, hypercoagulable states, smoking, and hypertension. [215] The duration of contraceptive use is not an independent risk factor and does not correlate with the severity of symptoms. [206] The diagnosis should be considered in contraceptive users presenting with poorly localized colicky abdominal pain, bloody diarrhea, or hematochezia. Fever is often present, and presenting symptoms also may include nausea and vomiting. [207] Although abdominal pain may be present for several weeks or months, pain serious enough to warrant hospitalization is usually of recent onset. Results of laboratory studies, including platelet count, prothrombin time, and partial thromboplastin time, are usually normal. [207] The diagnosis depends on the demonstration of intestinal ulceration or ischemia in contraceptive users. Abdominal radiographs may demonstrate bowel wall thickening or ileus. Ulceration, which may be detected with contrast studies, is usually continuous in involved segments. [207] Oral contraceptives should be discontinued and supportive therapy initiated. Although mesenteric ischemia may be reversible, the mortality rate in severe cases is almost 50%. [207] The risk of thromboembolic complications decreases to normal levels within 1 month of discontinuation of oral contraceptives. [214]

Anticoagulants Gastrointestinal hemorrhage is a common complication of anticoagulant therapy with heparin or warfarin. Antiplatelet therapy with ticlopidine has been associated with chronic severe diarrhea that is related to altered motility but not to hemorrhagic complications. [226], [227] The incidence of bleeding depends on the intensity of therapy, the adequacy of monitoring and dosage adjustment, the route of administration, concurrent drug therapy, and the gender, age, and underlying condition of the patient. The incidence of gastrointestinal bleeding requiring transfusion for medical inpatients without predisposing illness in the Boston Collaborative Drug Surveillance Program was 1.2% and 0.2% for heparin and warfarin, respectively. [216] Minor gastrointestinal bleeding occurred in 8.3% and 3.3%, respectively. Gastrointestinal bleeding should be thoroughly investigated, even if it is a minor symptom, and regardless of the prothrombin time. [217], [218], [219], [220] and [221] Most episodes of gastrointestinal bleeding in patients who are taking anticoagulants are attributable to a demonstrable gastric or intestinal lesion. [220], [221] The most common hemorrhagic small intestine complication is spontaneous or trauma-induced intramural hematoma, [222] usually in the jejunum in the absence of abdominal trauma. The relative fixation of the descending duodenum is responsible for a higher susceptibility to intramural hematoma in response to blunt abdominal trauma. [222] Hematomas may cause colicky abdominal pain and symptoms secondary to intestinal obstruction. Biliary symptoms or pancreatitis may result from obstruction of the biliary or pancreatic ducts. Minor intestinal bleeding is detected in 25%, and major bleeding occurs in 3.5%. [223] Patients may present with an acute abdomen that can be differentiated from that owing to other causes by the more gradual onset of symptoms and the acute decrease in hematocrit. [224] Abdominal

tenderness, low-grade fever, and a palpable abdominal mass are common physical findings. Evidence of proximal small bowel obstruction may be present on plain abdominal radiographs. The most useful diagnostic test is an upper gastrointestinal series demonstrating the classical coiled-spring, picket-fence, or stack-of-coins sign (Fig. 81-6), caused by extravasation of blood into the valvulae conniventes, narrowing the lumen with spikelike projections of barium outlining the normal caliber of the lumen. [217, 222] Serial ultrasound examinations can be useful for monitoring the behavior of the hematoma. [225]

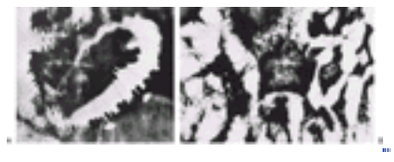

FIGURE 81-6. Small intestine ischemia. (**A**) Segmental ischemia in a picket-fence pattern of regular thickening of small bowel folds (*arrows*). (**B**) Complete resolution of the ischemic process is achieved after conservative therapy. (From Eisenberg R. Regular thickening of small bowel folds. In: Eisenberg R, ed. Gastrointestinal radiology: a pattern approach, 3rd ed. Philadelphia: Lippincott–Raven, 1996:471.)

Conservative medical management is usually sufficient because most hematomas undergo spontaneous reabsorption, with resolution of symptoms within 3 weeks. Reversal of anticoagulation with fresh-frozen plasma and vitamin K, intravenous hydration, and continuous nasogastric suction are sufficient for management of most patients. Surgical intervention may be required if there is complete intestinal obstruction or if conservative medical management fails to resolve intestinal bleeding, obstructive symptoms, or fever. [219, 223]

Drugs Causing Motility Disorders

Drug-induced intestinal pseudoobstruction can occur as follows: with use of anticholinergic drugs; with use of drugs with anticholinergic effects such as phenothiazines and tricyclic antidepressants, opioids, verapamil, and clonidine; and, occasionally, with initiation of cyclosporine therapy. Neurotoxicity induced by such drugs as vincristine can also produce intestinal pseudoobstruction, [228] which frequently appears within 3 days of the initiation of therapy and resolves within 2 weeks after the cessation of therapy. Direct toxicity to the enteric nervous system is probable because evidence of peripheral nerve dysfunction is not always present in patients with this complication.

Persistent use of narcotic analgesics can produce the *narcotic bowel syndrome,* characterized by abdominal pain, intermittent vomiting, weight loss, and other symptoms suggestive of intermittent pseudoobstruction. [229] Poorly localized chronic abdominal pain that is colicky, with acute exacerbations, is typically the major symptom. The pain is initially responsive to narcotic analgesics, but, with continued narcotic use, progressively larger doses are required for pain relief. Although the differential diagnosis includes biliary colic, pancreatitis, peptic ulcer disease, and renal calculi, the history, physical examination, and laboratory tests are usually not consistent with these entities. Abdominal radiographs typically are consistent with ileus and, on rare occasions, with mechanical small bowel obstruction. [229] The diagnosis of narcotic bowel syndrome is readily made with an intake history of more than 2 weeks of moderate to heavy doses of narcotics and a workup that excludes more serious disorders. [229]

Narcotic withdrawal is essential for treatment of narcotic bowel syndrome. On withdrawal of these drugs, the patient may experience vomiting, diarrhea, and cramping resulting from increased intestinal motility. [229] These symptoms can be markedly reduced or abolished by the a_2-adrenergic receptor agonist, clonidine. [230, 231] Opiates are discontinued, and clonidine is gradually increased from 0.1 mg twice daily to 0.1 mg four times daily. [230] After 1 week of therapy, the dose is tapered over 3 days. Narcotic bowel syndrome and withdrawal symptoms can be successfully treated in 90% to 95% of patients with this regimen. Metoclopramide therapy has been of benefit in patients with cancer. [232]

Drugs Causing Malabsorption

Drug-induced malabsorption of nutrients, electrolytes, and concurrently used medications occurs by several different mechanisms. [178, 207, 233] These include the following: intralumenal interactions that interfere with the solubilization, digestion, or transport of nutrients; increased rate of intestinal transit; mucosal injury; direct inhibition of absorptive processes; and inhibition of gastric, biliary, or pancreatic secretions. Drugs that impede nutrient assimilation by direct interaction include the following: tetracycline, which chelates calcium ions; cholestyramine, which binds to iron and vitamin B_{12}; mineral oil, which reduces the solubilization of ß-carotene and fat-soluble vitamins; and aluminum and magnesium hydroxide, which precipitate calcium and phosphate ions. Prokinetic agents and cathartics can impair fat absorption by increasing intestinal transit. [234] Mucosal injury resulting in diminished nutrient absorption has been reported with drugs such as colchicine, neomycin, and methotrexate. Colchicine inhibits mitosis and brush border disaccharidases and impairs absorption of fat, vitamin B_{12}, ß-carotene, D-xylose, lactose, bile salts, and steroids. [235] Neomycin is thought to cause brush border damage by inhibiting enterocyte protein synthesis, [236, 237] as well as to impair micellar solubilization of bile salts, cholesterol, fatty acids, and fat-soluble vitamins by directly binding to bile salts. Azotorrhea and decreased D-xylose absorption also can occur with neomycin. The degree of malabsorption with neomycin is dose related and can be seen with as little as 3 g/d. [236] Discontinuation of the drug typically reverses the malabsorption and diarrhea.

Methotrexate decreases the height of intestinal microvilli and brush border membrane protein and lipid content. Other drugs that produce histological changes in the jejunal mucosa associated with fat malabsorption include methyldopa, [238] allopurinol, [239] and mefenamic acid. [240] The histological features of mefenamic acid enteropathy closely resemble those associated with celiac disease. Sodium aminosalicylate [241] and thiazide diuretics, which impair ileal vitamin B_{12} and sodium transport, respectively, are examples of drugs that directly inhibit nutrient transport.

Clofazimine, when used in high doses for the treatment of leprosy, can cause a distinctive enteropathy characterized by red brown birefringent crystals in the small bowel mucosa and submucosa as well as in the mesenteric lymph nodes. [242] Clofazimine enteropathy is associated with nonspecific clinical and radiologic signs including diarrhea abdominal pain, anorexia, vomiting, diarrhea, and weight loss but not clinically significant malabsorption. [243]

The clinical significance of drug-induced malabsorption is influenced by such variables as baseline nutritional status and dietary intake, underlying disorders that interfere with intestinal function, and pharmacological considerations such as drug dosage and schedule and duration of therapy. Awareness of the nutritional consequences of drug therapy facilitates the prevention and early detection of these disorders. For some drugs, prophylactic nutritional supplementation is reasonable. For example, patients treated on a long-term basis with sulfasalazine, phenytoin, or colestipol should receive folic acid, and patients receiving the latter two drugs should also receive vitamin D supplementation.

Chemotherapeutic Agents

Most chemotherapeutic agents produce cytotoxic effects in normal cells because they have low therapeutic indices. Cells that have a high turnover rate, such as those of the small intestine crypt epithelium, are particularly vulnerable to drugs that inhibit cell proliferation. The magnitude of gastrointestinal toxicity is highly variable among patients and is affected by dose, duration of treatment, specific agents used, concurrent radiotherapy, and nutritional status of the patient. Nausea and vomiting are common acute side effects of antineoplastic drugs and are mediated in part by the chemoreceptor trigger zone in the brain. These symptoms predominate in the early stages of therapy. After a single course of therapy, intestinal mucosal damage is usually evident within the first 3 days. Regeneration and repair occur rapidly after cessation of therapy, with grossly normal mucosa present by 14 days, although inflammatory changes may be present for several weeks. [244]

Erosive enteritis, with or without stomatitis, presents with abdominal pain, bleeding, vomiting, ileus, or diarrhea. It is most common with methotrexate therapy but is also seen with 5-fluorouracil, actinomycin D, doxorubicin, cytarabine (cytosine arabinoside; Ara-C), bleomycin, and vincristine. These chemotherapeutic agents are also associated with other complications. Methotrexate is also associated with malabsorption (discussed in the previous section). The erosive enteritis associated with cytarabine when it is used in combination regimens occurs within 8 to 11 days from the start of therapy and is associated with hypokalemia, hypocalcemia, PLGE, and a syndrome characterized by telangiectasis and intramural hematomas. [245] Recombinant interleukin-2, which is used for treatment of advanced renal cell carcinoma, has been associated with intestinal ischemia, necrosis, perforation, and diffuse bowel ulceration requiring surgery. [246] These complications have occurred with interleukin-2 alone or in combination with interferon-? or lymphokine-activated killer cells. Cyclosporine-induced vasoconstriction can contribute to the development of nonocclusive mesenteric ischemia in renal transplant recipients. [247] Vincristine can induce acute intestinal pseudoobstruction (as already discussed). Preconditioning for bone marrow transplantation with cyclophosphamide and total-body irradiation produces diffuse intestinal injury. Symptoms, including crampy abdominal pain, watery diarrhea, and anorexia, are common within the first 3 weeks after transplantation. Symptoms that persist beyond 3 weeks should be investigated to rule out enteric infection or other intestinal disorders. Neutropenic enterocolitis or typhlitis is most frequently encountered after chemotherapy for leukemia or lymphoma. Diffuse patchy mucosal necrosis involving the ileocecal region is associated with nonspecific symptoms and fever, nausea, vomiting, right lower quadrant

pain, and hematochezia. Colon complications resulting from these drugs are discussed in Chapter 85.

NECROTIZING ENTEROCOLITIS

NEC is also referred to as pigbel, enteritis necroticans, darmbrand, nonspecific jejunitis, epidemic regional jejunitis, Pasini regional jejunitis, and necrotizing jejunitis. Although there were numerous European outbreaks during and after World War II, [248] acute jejunitis is largely a problem in nonindustrialized nations. [249], [250] and [251] Outbreaks are most frequent in communities in which protein deprivation and poor food hygiene are prevalent. [252] The disease was a major cause of illness and death among children in the highlands of Papua New Guinea until immunization against the ß-toxin of the causative organism, *Clostridium perfringens,* was begun in 1980. [253] Isolated cases continue to be reported from industrialized nations, although detection of the causative organism is not always reported. [254], [255], [256] and [257] A well-documented case occurred in Atlanta, Georgia in a 12-year-old boy with poorly controlled diabetes who had eaten pig intestines (chitterlings). [257]

C perfringens type C (initially identified as *C welchii* type F) is a heat-resistant bacterium that can often be isolated from the tissues, stool, and food of affected patients. [258], [259], [260] and [261] One sixth of healthy persons were shown to harbor a less pathogenic strain. A similar illness attributed to pathogenic strains of this organism has been described in certain animal species. [262], [263] Immunization against the ß-toxin resulted in a reduction in hospital admissions for acute jejunitis to less than one fifth of previous figures. [253] These observations have firmly established that this organism is a causative agent of acute jejunitis. The agent has also been isolated from children in Bangladesh with nonnecrotizing diarrheal illnesses. [264] Nevertheless, there are patients who have an identical syndrome without evidence of *C perfringens* type C infection or the ß-toxin. [265] A newer cytotoxin isolated from *Bacillus cereus* has been identified as another putative cause of acute jejunitis. [266] Additional factors associated with development of acute jejunitis include ingestion of foods containing trypsin inhibitors (e.g., sweet potatoes), reduced gastric acidity, and reduced gastrointestinal motility. [257]

Acute jejunitis occurs sporadically and in epidemics. Illness is characterized by bloody diarrhea, fever, and abdominal pain, with a high mortality rate (58%). [252] Nonocclusive small intestinal ischemia resulting in necrosis of varying severity, with areas of full-thickness necrosis, is usually found. Early recognition, treatment with antibiotics, and surgical resection are essential for successful treatment.

Neonatal NEC is a disease of focal or diffuse small intestine ulceration and necrosis that is seen almost exclusively in premature infants and low-birth-weight neonates who have been fed enterally. Similar pathophysiological mechanisms may be operative in adult necrotizing enteropathies. The putative causes, clinical presentation, differential diagnosis, pathology, and management of NEC are discussed in several excellent reviews. [267], [268], [269] and [270]

The cause of NEC is unknown, but several factors appear to be implicated, including prematurity, intestinal ischemia, infectious agents and bacterial colonization, and the initiation of enteral nutrition. [271], [272] However, a randomized trial and subsequent reviews [273], [274] are at odds with earlier case control studies suggesting that stressed infants are at greater risk of developing NEC if enteral feedings are advanced rapidly or if excessive volumes are used. [275], [276], [277] and [278] The pathogenesis of NEC is clearly multifactorial, and susceptibility of individual patients to NEC is probably also dependent on unidentified host factors. [271], [272] Successful delineation of these factors and other pathogenic mechanisms should improve the ability to prevent and treat NEC and should provide insight into the mechanisms of similar disorders seen in adults.

PROTEIN-LOSING GASTROENTEROPATHY

Definition

PLGE is a syndrome characterized by enteric loss of plasma proteins in abnormal amounts. Many intestinal and extraintestinal diseases may be associated with PLGE, and treatment is aimed almost exclusively at the underlying disorder. The recognition of PLGE mandates a careful search for an associated illness.

The defining characteristic of PLGE is hypoproteinemia resulting from gastric or intestinal losses. Studies of iodine 131–labeled albumin secretion identified the stomach as the site of excessive protein loss in patients with hypertrophic gastritis and atrophic gastritis and the intestine as a site of loss in patients with inflammatory bowel disease. [280], [281] and [282]

Under physiological conditions, sloughed enterocytes and pancreatic and biliary secretions account for almost all the endogenous protein that is found in the intestine. Most of these proteins are digested, and the constituent amino acids are reabsorbed. [283], [284] Gastrointestinal loss of serum proteins, as indicated by measuring serum albumin kinetics, accounts for less than 10% of daily protein catabolism. [285], [286], [287], [288] and [289] This may increase four- to fivefold in patients with PLGE. Hypoproteinemia results if the capacity to increase protein synthesis is not sufficient to compensate for increased intestinal protein losses. For example, albumin synthesis is increased no greater than twofold in patients with PLGE. [290]

Etiology

Most gastrointestinal disorders associated with PLGE cause exudative protein losses secondary to ulcerative or nonulcerative enteropathies or secondary to lymphatic obstruction or increased lymphatic hydrostatic pressure (Table 81-3). Enteropathies resulting in PLGE include ulcerating gastrointestinal carcinomas and inflammatory disorders such as Crohn's disease and ulcerative colitis. Increased enteric protein loss and increased catabolism are the primary contributors to the hypoalbuminemia and reduced protein pools that are seen in these disorders. In the case of inflammatory bowel disease, the magnitude of enteric protein loss is most significant, and it is directly related to the extent and activity of mucosal inflammation. [291], [292]

Increased Interstitial Pressure
Congenital intestinal lymphangiectasia, mesenteric lymphatic obstruction, tuberculosis, sarcoidosis, lymphoma, retroperitoneal fibrosis, increased central venous pressure, constrictive pericarditis, congestive heart failure
Ulcerative Diseases
Erosive gastritis or enteritis, neoplasia-carcinoma or lymphoma, Crohn's disease, pseudomembranous enterocolitis, acute graft-versus-host disease
Nonulcerative Diseases
Giant hypertrophic gastropathy (Ménétrier disease), viral enteritides, bacterial overgrowth, parasitic diseases (malaria, giardiasis, schistosomiasis, helminth infections), Whipple disease (see also lymphatic obstruction), allergic enteritis, eosinophilic gastroenteritis, gluten-sensitive enteropathy, tropical sprue, systemic lupus erythematosus

TABLE 81-3 Causes of Protein-Losing Enteropathy

Nonulcerative diseases such as Ménétrier disease, [280] atrophic gastritis, tropical sprue, celiac disease, allergic gastroenteritis, eosinophilic gastroenteritis, collagenous colitis, and polyposis syndromes including Cronkhite-Canada syndrome, juvenile polyposis, and Peutz-Jeghers syndrome have also been associated with PLGE. [280], [293], [294], [295], [296], [297], [298], [299], [300] and [301] In addition to neurological symptoms, defects in glycoprotein biosynthesis (the carbohydrate-deficient glycoprotein syndromes) can also present with severe PLGE. [302]

Acute and chronic intestinal infections can result in PLGE, including acute staphylococcal, *Salmonella,* [283] and *Shigella* [303] infections. The incidence of PLGE is species and strain dependent; for example, *Shigella dysenteriae* type 1 infections cause greater loss of enteric protein than do other strains. [303] Both pseudomembranous colitis and asymptomatic colonization by *C difficile* can result in enteric loss of protein. [304], [305] In a study of elderly nursing home patients, PLGE was documented in all 12 patients with pseudomembranous colitis, in 6 of 14 with *C difficile* diarrhea, and in 6 of 12 colonized with *C difficile* without toxin or diarrhea. [305] Parasitic diseases with documented PLGE include *Strongyloides stercoralis* infection, [306] schistosomiasis, [307], [308] and giardiasis. [309], [310] and [311] Acute viral illnesses including cytomegalovirus, measles, and varicella also have been linked to PLGE. [312], [313], [314], [315] and [316] Small bowel bacterial overgrowth can also be associated with PLGE. [317]

PLGE has been well documented in patients with SLE. [318], [319], [320], [321], [322] and [323] It occurs most commonly in young women, and it may be the initial clinical manifestation of SLE. Fifty percent of these patients present with steroid-responsive diarrhea without steatorrhea. [324] Mixed connective tissue disease, [325], [326] Henoch-Schönlein purpura, [327] and other collagen-vascular diseases also can be complicated by PLGE. [328] Another cause of PLGE is secondary amyloidosis complicated by small intestinal tract ulcers, resulting from arteriole and lymphatic infiltration with amyloid deposits. [329],

[330] PLGE also has been seen in association with mesenteric vascular changes resulting from neurofibromatosis [331] and idiopathic mesenteric thrombophlebitis. [332]

Diseases that produce disruption of intestinal lymphatic vessels or obstruction of lymph flow are an additional cause of PLGE. Tortuous, dilated mucosal and submucosal lymphatic vessels are the hallmark of primary intestinal lymphangiectasia (see Chapter 72). Most patients with this disease present by 30 years of age with edema, diarrhea, hypoproteinemia, and lymphocytopenia resulting from epithelial leakage and lymphatic rupture. [333] A similar lesion has been implicated as the mechanism of enteric protein loss in some patients with systemic sclerosis and SLE. [334], [335]

Inflammatory granulomatous diseases such as sarcoidosis and mesenteric tuberculosis cause PLGE. [341], [342] By producing retroperitoneal lymph node enlargement or fibrosis, Whipple disease, [336], [337] lymphoma, [338] endometriosis of the small intestine, [339] and Crohn's disease [291], [340] impair lymphatic egress by causing mechanical obstruction or increased hydrodynamic pressure. Additional retroperitoneal processes, including pancreatitis, pancreatic cancer, and other retroperitoneal tumors, also can present with PLGE. Right-sided congestive heart failure, constrictive pericarditis, superior vena caval obstruction, and other causes of elevated central venous pressure [343], [344] commonly produce PLGE.

Clinical Features

The major clinical manifestation of PLGE is dependent edema resulting from decreased plasma oncotic pressure. Although all plasma proteins are usually lost, selective loss of low-molecular-weight proteins may occur without lymphatic obstruction. Proteins such as albumin, immunoglobulins (IgM, IgG, and IgA but not IgE), fibrinogen, ceruloplasmin, and a_1-antitrypsin that have long circulating half-lives and a limited capacity for increased synthesis are most likely to exhibit depressed levels. Decreased levels of proteins other than albumin are rarely symptomatic, although in the setting of lymphatic obstruction, symptomatic lymphopenia and steatorrhea may be present.

Diagnosis

Edema and hypoproteinemia resulting from enteric protein loss are presenting manifestations of disease, but they are often minor aspects of the underlying disease. The diagnosis should always be considered in hypoalbuminemic patients if other causes such as malnutrition or protein loss from other sites are not apparent. If it is necessary to document intestinal protein losses, the preferred method is to quantitate fecal a_1-antitrypsin concentration or clearance. Alternative methods employing radiolabeled substrates for quantitating enteric protein loss remain useful research tools, but they are seldom used for clinical purposes. Clinical studies indicate that PLGE can be diagnosed and the sites of albumin loss can occasionally be determined scintigraphically using ^{99m}Tc-labeled albumin or dextran. [345], [346], [347], [348], [349] and [350]

a_1-Antitrypsin is particularly valuable because it constitutes approximately 4% of serum proteins, has a molecular weight similar to that of albumin, is resistant to proteolysis, is not actively absorbed or secreted, is normally present in low quantities in stool, and is easy to assay. The test cannot be used for analyzing gastric protein losses or losses in patients with Zollinger-Ellison syndrome because a_1-antitrypsin is degraded at a pH below 3. [351] The a_1-antitrypsin concentration in stool and the plasma clearance of a_1-antitrypsin were compared in healthy persons and in consecutive patients with chronic diarrhea, malabsorption, or unexplained hypoalbuminemia. [352] The plasma clearance is the product of daily stool volume and stool a_1-antitrypsin concentration divided by the serum a_1-antitrypsin concentration. [353] In contrast to earlier studies, [354], [355] and [356] there is ample evidence that analysis of fecal a_1-antitrypsin concentration is not a reliable substitute for measurement of a_1-antitrypsin clearance. [352] There is a highly significant correlation between a_1-antitrypsin clearance and serum albumin concentration and fecal loss of radiolabeled albumin. When the a_1-antitrypsin clearance was elevated more than threefold, serum albumin levels were less than 3.0 g/dL. a_1-Antitrypsin clearance levels may be increased in otherwise healthy persons with diarrhea secondary to ingestion of lactulose, sorbitol, sodium sulfate, or phenolphthalein. [352] Clearance levels also may be overestimated if hematochezia or meconium is present.

Therapy

There is no specific therapy for PLGE. Optimal therapy of the primary illness is the only effective remedy. In the case of Ménétrier disease, octreotide and eradication of *Helicobacter pylori* may reduce enteral protein losses. [357], [358] Prophylactic measures to avoid complications resulting from peripheral edema should be instituted. In the setting of lymphangiectasia, reduction of lymphatic transport may reduce enteric protein loss. Low-fat diets supplemented with medium-chain triglycerides may be beneficial in this setting. [359], [360] Surgical drainage of dilated lymphatic channels (lymphovenous anastomosis) is occasionally helpful. [340], [361]

CHAPTER 82

Steven M. Cohn and Elisa H. Birnbaum

COLON: ANATOMY AND STRUCTURAL ANOMALIES

ANATOMY OF THE COLON

The colon is a tubular organ that extends from the ileocecal valve to the proximal rectum. It is approximately 3 to 5 feet in length. Its principal functions are absorption of water and electrolytes as well as storage of intralumenal contents to permit controlled elimination of the feces. The terminal ileum enters the cecum on its posteromedial border at the ileocecal valve. The cecum is a large, blind pouch, approximately 7.5 to 8.5 cm in diameter, which projects from the antimesenteric side of the ascending colon. The colon progressively diminishes in size toward the sigmoid colon, which is approximately 2.5 cm in diameter and is the narrowest portion of the colon. This size discrepancy accounts for the fact that cecal tumors often grow to be large and bulky before the onset of symptoms but sigmoid tumors are symptomatic at smaller sizes. In addition, tension on the bowel wall is directly proportional to the diameter of the bowel. This is explained by the law of LaPlace: T = PR, where *T* is tension in the wall of the bowel, *P* is internal pressure, and *R* is the radius of the bowel. Because the cecum has the largest diameter, it is usually the first part of the bowel to rupture as a result of distal obstruction.

The omentum is attached to the transverse colon on its anterior superior edge. The ascending colon, descending colon, rectum, and posterior surface of the hepatic and splenic flexures are fixed retroperitoneal structures. The cecum, transverse colon, and sigmoid colon are intraperitoneal and are prone to volvulus because of their location and relative lack of fixation.

The longitudinal muscle is an incomplete layer and is seen as three bands of muscle, called teniae coli, located 120 degrees apart around the circumference of the colon. The teniae converge proximally at the appendix as distinct bands and disappear at the level of the sacral promontory. Haustra coli are sacculations between the teniae and are separated by crescent-shaped folds called plicae semilunares. Appendices epiploicae are fatty appendages covered by peritoneum and have no anatomic or pathological significance.

P>The rectal wall consists of mucosal, submucosal, inner circular, and outer longitudinal muscular layers (Fig. 82-1). There is no serosal layer in the rectum. The rectum is approximately 12 to 15 cm in length and extends from the sigmoid colon to the anal canal, following the curve of the sacrum. The proximal rectum begins at the sacral promontory (third sacral vertebra), at which point the teniae fan out to form a complete layer of longitudinal muscle.

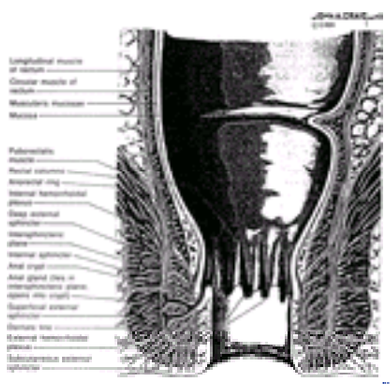

FIGURE 82-1. Anorectal anatomy. Copyright 1985. Novartis. Reprinted with permission from Clinical Symposia 37/6, illustrated by John A. Craig, M.D. All rights reserved.

The anal canal is approximately 4 cm long and appears as a collapsed anteroposterior slit in the normal patient (see Fig. 82-1). The anal verge is the junction between anal and perianal skin. Anal epithelium (anoderm) lacks hair follicles, sebaceous glands, and sweat glands. The dentate line is a true mucocutaneous junction located 1 to 1.5 cm above the anal verge. A 6- to 12-mm transitional zone exists above the dentate line, in which the squamous epithelium of the anoderm becomes cuboidal and then columnar epithelium. The columns of Morgagni are 8 to 14 mucosal folds located just above the dentate line that are surrounded by anal crypts. Small, rudimentary glands open into some of the crypts. These glands go through the internal sphincter into the intersphincteric groove but do not penetrate the external sphincter. The anorectal ring is 1 to 1.5 cm above the dentate line and is the palpable upper border of the anal sphincter complex. The anatomic anal canal extends from the anal verge to the dentate line. The surgical anal canal extends from the anal verge to the anorectal ring.

Arterial Supply

The superior mesenteric artery arises from the ventral surface of the aorta below the celiac axis, passes behind the pancreas, and crosses in front of the third portion of the duodenum (Fig. 82-2). The cecum, ascending colon, and transverse colon are supplied through its ileocolic and middle colic branches. Cadaver studies have shown that the right colic artery frequently arises from the ileocolic artery in the majority of patients and arises from the superior mesenteric artery in less than 15% of patients. [1]The inferior mesenteric artery arises from the infrarenal aorta and supplies the descending colon, sigmoid colon, and upper rectum through its left colic, sigmoidal, and superior rectal branches.

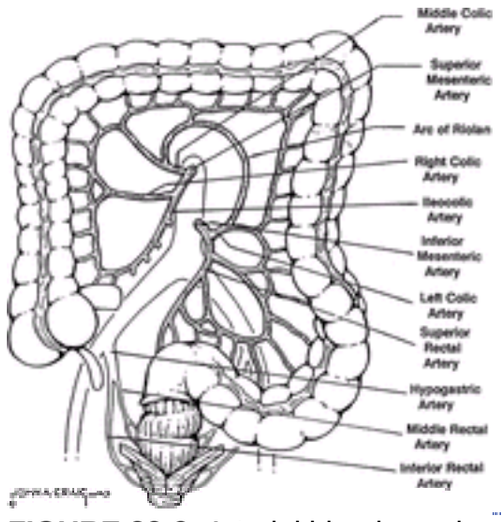

FIGURE 82-2. Arterial blood supply of colon and rectum. (From Kodner IJ, Fry RD, Fleshman JW, Birnbaum EH. Colon, rectum and anus. In: Schwartz SI, ed. Principles of surgery, 6th ed. New York: McGraw-Hill, 1993.)

Collaterals exist between the superior and inferior mesenteric arteries in the region of the splenic flexure. [2] The arcades of the ileocolic, right, middle, and left colic arteries are peripherally connected by the marginal artery of Drummond, which runs along the mesenteric border of the colon and provides the vasa recta to the colon. The arc of Riolan is a tortuous, inconstant vessel that exists between the left colic branch of the inferior mesenteric artery and the middle colic branch of the superior mesenteric artery. It is frequently referred to as the meandering mesenteric artery and is best visualized if there is an occlusion of either the inferior or superior mesenteric artery.

The terminal branch of the inferior mesenteric artery becomes the superior rectal artery, which descends in the sigmoid mesocolon and bifurcates at the level of the third sacral vertebra (Fig. 82-3A). Branches of the superior rectal artery supply the upper and middle rectum. The middle rectal arteries arise from the internal iliac arteries, and the inferior rectal arteries are branches of the internal pudendal arteries. These arteries supply the lower two thirds of the rectum. [3] The middle sacral artery arises just before the aortic bifurcation and provides very little blood supply to the rectum. Anastomosis exists between the middle and superior rectal arteries; there are no anastomoses with the inferior rectal arteries. Preservation of the middle rectal arteries is necessary to maintain viability of the rectal stump after high ligation of the inferior mesenteric artery. [3]

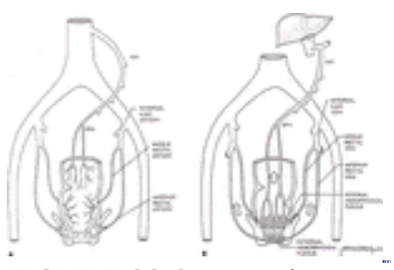

FIGURE 82-3. Vascular supply of the anus and rectum. **A**: Arterial supply. **B**: Venous drainage. *IMA*, inferior mesenteric artery; *IMV*, inferior mesenteric vein; *SRA*, superior rectal artery; *SRV*, superior rectal vein. (From Kodner IJ, Fleshman JW, Fry RD. Anal and rectal cancer principles of management. In: Schwartz SI, Ellis H, eds. Maingot's abdominal operations, 9th ed. Norwalk, CT: Appleton & Lange, 1989.)

Venous Drainage

The veins draining the colon follow the same course as the corresponding arteries except for the inferior mesenteric vein. The inferior mesenteric vein drains the descending colon, sigmoid colon, and proximal rectum and runs in a retroperitoneal location to the left of the ligament of Treitz, at which point it enters the splenic vein. The superior mesenteric vein drains the cecum, ascending colon, and transverse colon and joins the splenic vein to form the portal vein.

The venous drainage of the rectum enters the portal or systemic (caval) system. The upper and middle rectum are drained by the superior rectal vein, which enters the portal system through the inferior mesenteric vein (Fig. 82-3B). The lower rectum and upper anal canal are drained by the middle rectal vein, which empties into the internal iliac veins and then into the caval system. The inferior rectal veins drain the lower anal canal and empty into the pudendal veins, which empty into the caval system through the internal iliac veins. Rectal tumors can metastasize through venous channels into either the portal or systemic venous systems.

Three submucosal internal hemorrhoidal complexes are located above the dentate line. Hemorrhoidal tissue receives its blood supply from the superior, middle, and inferior rectal arteries. The left lateral, right posterolateral, and right anterolateral internal hemorrhoids drain into the superior rectal vein (Fig. 82-3B). The external hemorrhoids are located below the dentate line and drain into the pudendal veins. There is communication between the internal and external plexi, and mixed internal-external hemorrhoids result if these communications become engorged (see Chapter 92).

Lymphatic Drainage

Colonic mucosa has rich vascular plexi but no lymphatics. Lymphatic capillaries encircle the colon in the submucosal and muscularis mucosae layers. This segmental architecture limits longitudinal intramural extension of tumors, and circumferential extension results in annular lesions. Lymphatic vessels follow the blood supply of the colon.

Lymph nodes are located on the bowel wall (epicolic), along the inner margin of the bowel (paracolic), around the named mesenteric arteries (intermediate), and along the origin of the superior and inferior arteries (main) (Fig. 82-4). Lymph from the upper and middle rectum drains into the inferior mesenteric nodes. The lower rectal lymphatics follow the superior rectal artery and enter the inferior mesenteric nodes. Lymph from the lower rectum can also flow laterally along the middle and inferior rectal arteries, posteriorly along the middle sacral artery, or anteriorly through channels in the rectovesical or rectovaginal septum. [4] These channels drain to the iliac nodes and subsequently to periaortic lymph nodes.

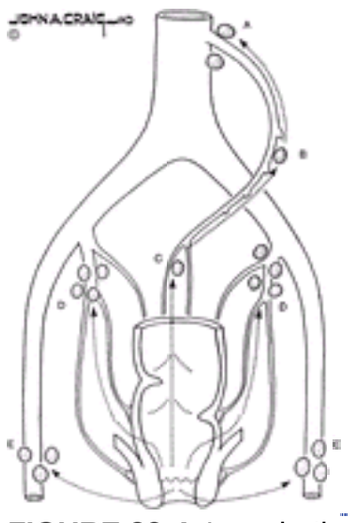

FIGURE 82-4. Lymphatic drainage of the rectum and anus. *A*, nodes at origin of inferior mesenteric artery; *B*, nodes at origin of sigmoid branches; *C*, sacral nodes; *D*, internal iliac nodes; *E*, inguinal nodes. (From Kodner IJ, Fleshman JW, Fry RD. Anal and rectal cancer: principles of management. In: Schwartz SI, Ellis H, eds. Maingot's abdominal operations, 9th ed. Norwalk, CT: Appleton & Lange, 1989.)

Lymphatics from the anal canal above the dentate line drain through the superior rectal lymphatics to the inferior mesenteric lymph nodes or laterally to the internal iliac lymph nodes. Below the dentate line, the lymphatics drain primarily to the inguinal nodes but they can drain to the inferior or superior rectal lymph nodes as well. [4]

Nerve Supply

The sympathetic and parasympathetic nerves to the colon follow the course of the blood vessels. Sympathetic nerves inhibit and parasympathetic nerves stimulate peristalsis. Sympathetic fibers to the right colon originate in the lower six thoracic segments and travel in the thoracic splanchnic nerves to the celiac and then to the superior mesenteric plexus. Sympathetic supply to the left colon and rectum originates in the first three lumbar segments. These nerves join the preaortic plexus and become the inferior mesenteric plexus below the bifurcation of the aorta. The parasympathetic supply to the right colon is presumed to come from the right vagus. The parasympathetic nerves to the left colon ascend from the pelvis, pass through the sigmoid mesocolon, and spread out toward the sigmoid and the descending colon.

The rectum is innervated by both sympathetic and parasympathetic nerves. [5] Sympathetic nerves from thoracolumbar segments unite below the inferior mesenteric artery, forming the inferior mesenteric plexus, and descend to the superior hypogastric plexus below the aortic bifurcation. The nerves bifurcate and descend in the pelvis as the hypogastric nerves, supplying sympathetic innervation to the lower rectum, bladder, and sexual organs, in both males and females. Injury to the inferior mesenteric plexus can result during ligation of the inferior mesenteric artery at its origin.

Parasympathetic fibers from the second, third, and fourth sacral roots (the nervi erigentes) unite with the hypogastric nerves anterior and lateral to the rectum, forming the pelvic plexus. [5] The periprostatic plexus arises from the pelvic plexus. Mixed fibers from these plexi innervate the rectum, internal anal sphincter, prostate, bladder, and penis. The pudendal nerve (originating from the second, third, and fourth sacral nerves) mediates sensory stimuli from the penis or clitoris through the dorsal nerve. Damage to the periprostatic plexus may occur during dissection of the rectum. Injury to the pelvic autonomic nerves may result in bladder dysfunction, impotence, or both.

Below the dentate line, afferent fibers of the inferior rectal and perineal branches of the pudendal nerve convey cutaneous sensations of temperature, pain, and touch. Numerous free nerve endings make this area very sensitive to sensations. [6] Above the dentate line, a poorly defined dull sensation, experienced if the mucosa is pinched or if internal hemorrhoids are ligated, is probably mediated by parasympathetic fibers.

HISTOLOGY

The colonic wall consists of mucosa, submucosa, inner circular muscle, outer longitudinal muscle, and serosa (Fig. 82-5). The colonic mucosa is similar in organization to the small intestine mucosa except that it lacks villi. The mucosa is lined by a simple columnar epithelium that forms straight tubular crypts that are about 0.5 mm in length (Fig. 82-6). The lamina propria extends from the simple columnar epithelium to the muscularis mucosae and contains many cells involved in immunologic functions of the gut (see Chapter 7). Numerous immunoglobulin-secreting plasma cells, macrophages, and lymphocytes are present, in addition to abundant lymphoid nodules that often extend through the muscularis mucosae into the underlying submucosa (Fig. 82-7). Subepithelial fibroblasts surround each crypt and produce the collagen table as well as many of the extracellular matrix components that underlie the basal lamina of the epithelium (Fig. 82-8). These fibroblasts and the extracellular matrix that they secrete appear to have an important role in regulating cell proliferation and differentiation events within the overlying epithelium. [7], [8], [9], [10] and [11] The submucosa contains numerous small veins, arteries, and lymphatic channels surrounded by loose connective tissue. The inner circular muscle fibers form a continuous layer around the colon. The outer longitudinal smooth muscle fibers are condensed into three bands (teniae coli) equidistant around the circumference of the colon. Haustra are the bulging sacculations that form between adjacent teniae coli. The serosa is a mesothelial-derived cell layer that covers the peritoneal surface of the colonic wall. Therefore, regions of the ascending colon, the descending colon, and the rectum that lie outside the peritoneal cavity have no outer serosal layer (see section " Anatomy").

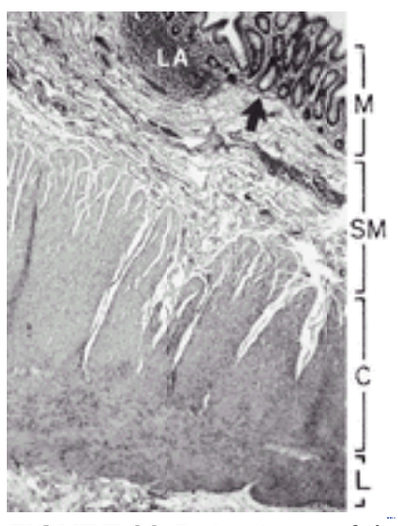

FIGURE 82-5. Anatomy of the colonic wall. The muscularis mucosae is indicated (*arrow*). (*C*, circular smooth muscle layer; *L*, longitudinal smooth muscle layer; *LA*, lymphoid aggregate; *M*, mucosa; *SM*, submucosa. FIGURE 82-6. Histology of the colonic mucosa. Straight, simple colonic glands (*G*) extend from the muscularis mucosae (*arrows*) to the lumenal surface of the colon. Note the numerous small arteries, veins, and lymphatics coursing through the loose connective tissue stroma in the submucosa. (Paraffin-embedded 4-µm section stained with hematoxylin and eosin, original magnification ×100.)

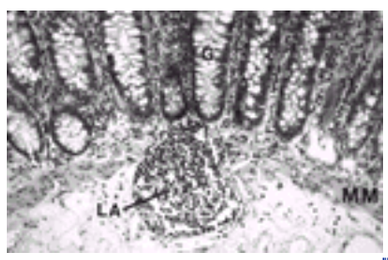

FIGURE 82-7. A lymphoid aggregate (*LA*) arises in the lamina propria and extends through the muscularis mucosae (*MM*) into the submucosa. (Paraffin-embedded 4-µm section stained with hematoxylin and eosin, original magnification ×200.)

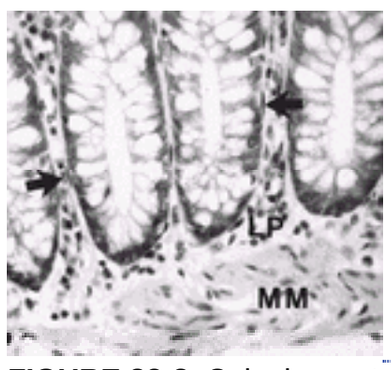

FIGURE 82-8. Colonic crypts. Note the subepithelial fibroblasts (*arrows*). Numerous plasma cells, macrophages, and lymphocytes are seen in the lamina propria (*LP*). (*MM*, muscularis mucosae. Paraffin-embedded 4-µm section stained with hematoxylin and eosin, original magnification ×400.)

The colonic epithelium undergoes continuous and rapid renewal; epithelial cells are sloughed from the flat lumenal surface of the colon and are replaced by replication of the descendants of epithelial stem cells located in the bottom one third of each crypt. There are three principal, differentiated epithelial cell types present in the adult colonic epithelium: absorptive colonocytes, goblet cells, and enteroendocrine cells. All these cell lineages appear to be derived from a common epithelial cell stem cell precursor. Undifferentiated cells, replicating cells, and enteroendocrine cells predominate near the base of each colonic gland (crypt). [12] Cells belonging to each of the principal cell lineages differentiate during a highly ordered migration away from the zone of proliferation. The average life span of goblet cells and absorptive cells, from their birth deep in the crypt to the point where they are sloughed into the lumen, is approximately 6 days. [13] Some enteroendocrine cell subtypes appear to have a much longer life span, suggesting that their migration up the crypt to the surface epithelium must be uncoupled from that of adjacent epithelial cells. [13] Animal studies using X-linked enzyme markers, chimeric mice, and transgenic mice have suggested that the epithelial cell population of each small intestine or colonic crypt is derived from a single stem cell or, at most, a very small number of stem cells. [14], [15], [16], [17] and [18] If normal homeostasis of the epithelial cell populations within the colonic mucosa is to be maintained, the rate of epithelial cell production within each crypt must be closely matched to the rate of cell loss from the surface epithelium. Although the mechanisms that regulate epithelial cell renewal have yet to be fully elucidated, a number of peptide growth factors are emerging as important potential regulators of the dynamic balance between cell proliferation and cell loss in the intestinal and colonic epithelium (see Chapter 23). [19]

One of the principal functions of absorptive columnar cells is the regulation of water and electrolyte content of the feces. The mature adult absorptive columnar cell in the colon absorbs sodium, chloride, and water; potassium and bicarbonate are secreted (see Chapter 14). [20] In contrast to the enterocytes of the small intestine, however, colonocytes are not able to absorb significant amounts of glucose or amino acids. Under normal conditions, lipid absorption is complete in the small intestine, but under pathological conditions in which lipid absorption in the small intestine is incomplete, the surface columnar cells of the colon have a limited capacity for uptake of fatty acids and subsequent packaging of them into chylomicrons. [21] As these cells differentiate during their migration up the crypt, they develop short microvilli and clear, apically oriented vesicles containing a fibrillar, glycoprotein-rich secretory product that may contribute to the glycocalyx. [21] These apical vesicles are lost, and microvilli elongate and increase in number as the maturing absorptive cells emerge onto the surface epithelium (Fig. 82-9). At this point, alkaline phosphatase activity appears on the brush border, and the basolateral membranes have acquired a considerable amount of Na^+,K^+-ATPase activity, reflecting their function in water and electrolyte transport.

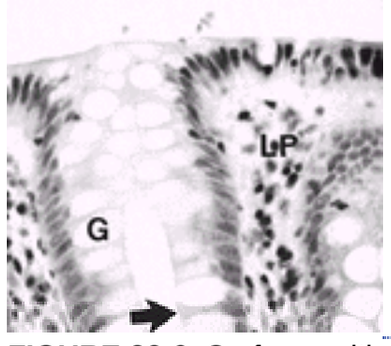

FIGURE 82-9. Surface epithelium of the colon. The mature absorptive columnar epithelial cells (*arrow*) lose their apical vesicles as they migrate into the upper regions of the colonic glands and emerge onto the lumenal surface. Goblet cells (*G*) elongate as they emerge onto the surface epithelium because of accelerated secretion of their mucus granules. (Paraffin-embedded 4-µm section stained with hematoxylin and eosin, original magnification ×400.)

Goblet cells are flask-shaped cells with large apical vesicles that store and secrete mucus. [22] Mucus secreted by the goblet cell forms a viscous gel that functions as a lubricant and also protects the surface epithelium against adherence of invading pathogens. Mucins are a family of large, sulfated glycoproteins that are synthesized in the rough endoplasmic reticulum (see Fig. 82-9). Glycosylation and sulfation of these proteins occur posttranslationally in the Golgi apparatus. The composition of mucus shows regional variability along the cephalocaudal axis of the gut. [22] The membrane-bound vesicles bud off the Golgi apparatus and are slowly transported to the apical cell surface, where they secrete their contents into the lumen by exocytosis. Mucus granules accumulate during the migration of goblet cells toward the

lumenal surface of the colon, distending the apical aspect of the cell and giving it its broad, flasklike appearance. As goblet cells emerge onto the surface epithelium, the secretion of mucus occurs more rapidly, depleting the apically stored granules and causing the goblet cells to elongate (see Fig. 82-9). Increased cholinergic stimulation can cause accelerated secretion of mucus from crypt-associated goblet cells, leading to deep invaginations of the apical surface. Certain components of mucus may become depleted in pathological conditions such as ulcerative colitis (see Chapter 83).

Originally thought to be of neuroectodermal origin, the enteroendocrine cells found in the intestinal and colonic epithelium are now recognized to arise from the same common stem cell precursor as the other principal cell lineages found in the gut epithelium. A number of different enteroendocrine cell types are found within the colonic epithelium, including L cells, which contain both enteroglucagon and peptide YY (PYY); cells that secrete only PYY; EC1 cells, which secrete serotonin, substance P, and leuenkephalin; pancreatic polypeptide-secreting cells; and rare somatostatin-secreting cells. [23], [24] These enteroendocrine cells are characterized by their polygonal shape, their broad base, and the numerous membrane-bound secretory granules present in their basilar portions (Fig. 82-10). Enteroendocrine cells are identified in pathological specimens using argentaffin or agyrophilic silver staining techniques or through immunohistochemical methods using antibodies to the particular neuroendocrine products stored in each enteroendocrine cell subtype. The narrow apical process of the enteroendocrine cell communicates with the lumen of the crypt and may serve to sense changes in the lumenal environment. Each enteroendocrine cell is joined to other adjacent cells in the epithelium through junctional complexes located near the apical pole. [13] Despite these intracellular attachments, each enteroendocrine cell appears to migrate within the glandular colonic epithelium independent of its neighbors (see previous discussion of migration). The regulatory peptides or bioamine products stored in the basally located secretory granules are secreted through the basolateral membrane and act through paracrine or endocrine mechanisms as mediators of gastrointestinal secretion, absorptive function, and motility in response to lumenally or basolaterally derived signals (see Chapter 8). Enteroendocrine cells are more numerous in the appendix and the rectum than in the rest of the colon. This may explain, in part, the more frequent occurrence of certain subtypes of neuroendocrine tumors at these sites.

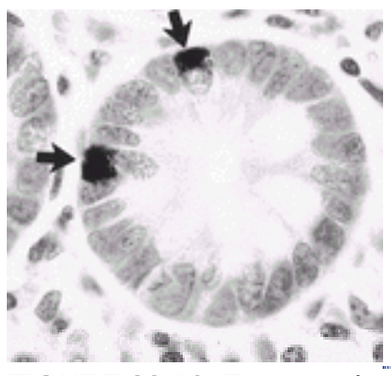

FIGURE 82-10. Enteroendocrine cells (*arrows*) seen in a cross-section of a colonic crypt have a narrow apical process and a broad base filled with membrane-bound granules containing the neuroendocrine secretory product. (Paraffin-embedded 4-µm section, argentaffin stain, Fontana-Masson technique, original magnification ×1000.)

The appendix is similar in histological organization to the rest of the colon. The mucosa of the appendix consists of deep folds lined by a columnar epithelium forming simple tubular or forked glands. [21] This epithelium contains abundant goblet cells and enteroendocrine cells. Numerous lymphoid nodules are found in the lamina propria. The normal histological architecture of the adult appendix is often replaced by fibrous scar tissue as a result of subclinical bouts of appendicitis.

COLONIC DEVELOPMENT

The primitive foregut, midgut, and hindgut develop during the fourth week in utero. The midgut lengthens, herniates out of the abdominal cavity, and rotates 90 degrees counterclockwise around the superior mesenteric artery during the sixth week in utero. By the tenth week, the midgut rotates an additional 180 degrees as it returns to the abdominal cavity. The cecum descends to the right iliac fossa, where it becomes fixed. The base of the small bowel mesentery then runs from the ligament of Treitz in the left upper quadrant to the ileocecal valve in the right lower quadrant. [25], [26]

The small intestine, distal to the entrance of the common bile duct, cecum, appendix, ascending colon, and proximal transverse colon arise from the midgut and are supplied by the superior mesenteric artery. The distal transverse colon, descending colon, sigmoid colon, rectum, upper portion of the anal canal, and part of the lower urogenital tract are derivatives of the hindgut and are supplied by the inferior mesenteric artery. The lower third of the anal canal is ectodermal in origin and is supplied by branches of the internal pudendal artery.

The cloaca is located at the distal end of the hindgut and by the end of the sixth week is separated by the anorectal septum into a ventral urogenital sinus and a dorsal rectum. [27] The anal membrane covering the cloaca ruptures at the end of the eighth week, forming the anal canal. The dentate line is the approximate location of the transition from endoderm to ectoderm, at the junction of the upper two thirds of the anal canal with the lower one third.

The enteric nervous system forms during early fetal life. Neural crest cells, precursors of ganglion cells, migrate from cephalad to caudad during the first 12 weeks in utero. [28] The migration from the midtransverse colon to the anus takes 4 weeks to complete. Smooth muscle cells begin to appear within the mesenchymal layer around the tenth week of gestation. The developing circular muscle layer spreads cranially. The outer longitudinal bands of smooth muscle (teniae coli) and haustra begin to appear between the tenth and eleventh weeks of gestation. [29] By the twelfth week of gestation, Auerbach and Meissner plexi and the circular and longitudinal muscle layers of the colon are well formed, and colonic motility may be observed in isolated fetal colon as early as this developmental stage. [29], [30]

Failure of the neural crest cells to complete their cephalocaudal migration results in a congenital absence of the myenteric plexus in a distal segment of bowel and is thought to be the cause of Hirschsprung disease (see section “Structural and Congenital Abnormalities”). In vitro studies have suggested that components of the extracellular matrix, including laminin and type IV collagen, promote neuronal outgrowth, migration, and survival. Qualitative differences in laminin and type IV collagen have been found in some patients with Hirschsprung disease, suggesting a potential role for abnormalities in fetal extracellular matrix components in the pathogenesis of this disease. [31] Studies using the lethal spotted (ls) mouse, a model for Hirschsprung disease, confirm the importance of nonneural crest–derived tissue components in directing appropriate migration of ganglion cell precursors during normal embryogenesis. [32], [33] Mice that are homozygous for the ls mutation are born without ganglion cells in the distal bowel. Experiments with aggregation chimeras formed from homozygous ls and wild-type mice demonstrate that the aganglionic phenotype results from a defect in mesenchymal cells rather than an intrinsic abnormality of the neural crest–derived neuroblasts. [33]

A number of other genes involved in the susceptibility and development of Hirschsprung disease have also been identified. A recessive susceptibility locus for Hirschsprung disease that encodes the endothelin-B receptor has been mapped to human chromosome 13q22. [34] Targeted and naturally occurring mutations of the mouse endothelin-B receptor gene or in the mouse endothelin-3 ligand gene also result in aganglionosis and a megacolon phenotype as well as defects in development or migration of other neural crest–derived cell lineages, including epidermal melanocytes. [35], [36] Together, these studies suggest that defects in the endothelin-B receptor or its ligand can cause a hereditary form of Hirschsprung disease. Other studies have identified mutations in the RET receptor tyrosine kinase gene located on human chromosome 10q11.2 in an autosomal-dominant form of Hirschsprung disease. [37], [38], [39], [40], [41] and [42] The ligands for this receptor are members of the glial cell line–derived neurotrophic factor family. Over 30 distinct missense and deletion mutations distributed along the entire length of the receptor have been identified in cases of Hirschsprung disease. Most RET mutations associated with Hirschsprung disease result in loss of receptor function. [39] In contrast, mutations in this gene which result in a constitutively active receptor have been found associated with multiple endocrine neoplasia type 2 syndromes (see Chapter 128). [39], [42] RET mutations are found in approximately 10% to 20% of sporadic cases and 50% of patients with a familial history of Hirschsprung disease. [39], [40] and [41] Segregation analysis in a Mennonite family has indicated the existence of other major loci for susceptibility to Hirschsprung disease. [34] These findings confirm the multigenic nature of this disease.

In many respects, the development of the colonic epithelium parallels that of the small intestine epithelium (Fig. 82-11; see Chapter 72). At 8 to 9 weeks of gestation, the developing colon consists of a pseudostratified columnar epithelium several cell layers deep, with a slitlike lumen surrounded by mesenchymal tissue forming a simple tubular structure. [43], [44] and [45] Epithelial ridges form between 10 and 11 weeks of gestation, giving the colonic lumen a stellate appearance. Small secondary

lumens form at the base of the pseudostratified epithelium and subsequently extend to the primary lumen, resulting in the formation of broad primary villi. Between the thirteenth and fifteenth weeks of gestation, the formation of cystlike spaces within these primary villi and the accompanying upward growth of mesenchymal tissue result in the division of primary villi into numerous secondary villi. During this developmental stage, epithelial cells near the bases of the primary villi undergo rapid proliferation and bud into the surrounding mesenchyme to form the developing colonic crypts. Numerous goblet cells, columnar epithelial cells with well-developed microvilli, and enteroendocrine cells can be observed in the epithelium by this time. [23], [46] The fetal enteroendocrine cell population has been found to secrete a variety of neuroendocrine mediators, some of which may have important trophic effects on the developing epithelium. The mesenchymal tissue underlying the developing colonic epithelium appears to play a crucial role in the induction of appropriate regional differentiation in the gut epithelium. [47]

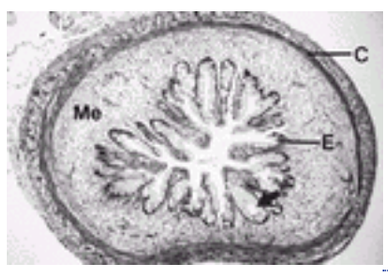

FIGURE 82-11. Human fetal colon at 14 weeks of gestation. Note the villus architecture of the developing epithelium. The circular smooth muscle layer is already well formed. *Arrowhead*, secondary lumen; *E*, columnar epithelium; *C*, circular smooth muscle layer; *Me*, mesenchymal tissue. (Paraffin-embedded 4-µm section stained with hematoxylin and eosin, original magnification ×100.)

Some studies suggest that homeotic genes of the CDX family may regulate regional specificity of the stem cells in the developing gut. [48], [49] and [50] Prominent supranuclear inclusion bodies can be observed in the principal epithelial cells lining the fetal colon. These inclusion bodies were originally termed meconium corpuscles because it was thought that they arose from uptake of lumenal contents present in the developing colon. However, more recent studies have found that these membrane-bound inclusion bodies are a result of apoptosis, emphasizing the role of programmed cell death in the morphologic restructuring of the epithelium that occurs during fetal life. [51] Colonic villi are present through at least week 29 of gestation but are not found in the colon of full-term infants. [46], [52] During fetal life, the colonic epithelium is also similar to the developing small intestine in its biochemical characteristics. For instance, the initial appearance and the activity of many brush border hydrolases found in the fetal colonic epithelium, including sucrase-isomaltase complex and at least five dipeptidases, are similar to those found in the developing small intestine. [43], [52], [53], [54] and [55] By full term, however, the activities of these brush border hydrolases have declined to levels similar to those found in the adult colon.

STRUCTURAL AND CONGENITAL ABNORMALITIES

Congenital abnormalities of the intestine are common; most arise from errors in rotation or fusion of the mesenteries or from failure of neural crest cells to complete their migration during fetal colonic development. Imperforate anus, duplication, and malrotation are usually identified in the neonatal period. Hirschsprung disease may present in the neonatal period, in childhood, or, more rarely, in the young adult.

Omphaloceles and Gastroschisis

Abdominal wall defects are present at birth. Omphaloceles are identified by a mass of bowel and viscera in the central abdomen covered by a translucent membrane. The size of the defect varies, and it can be associated with other congenital anomalies. Gastroschisis is usually a small defect that occurs at the junction of the umbilicus and normal skin. Although no membrane covers the bowel, there are usually no associated anomalies. Both omphaloceles and gastroschisis require immediate surgery. Only in gastroschisis are reduction of the bowel and primary closure of the defect usually possible. If the bowel is edematous and thickened or the defect is too large to close primarily, a Silastic silo can be constructed to achieve gradual reduction of the bowel (see Chapter 72 for a more complete discussion).

Hirschsprung Disease and Congenital Megacolon

Hirschsprung disease is a result of the failure of neural crest cells (precursors of ganglion cells) to complete their caudal migration during normal colonic development (see section “ Colonic Development”). The aganglionic segment does not relax and causes a functional obstruction. The normal proximal bowel hypertrophies and eventually dilates. The rectosigmoid is involved in approximately 75% to 80% of cases. [56] The entire colon and various lengths of small bowel are aganglionic in 5% to 10% of cases. [57] A very short aganglionic segment is the typical finding in adult Hirschsprung disease.

Delayed passage of meconium and abdominal distention are often the presenting symptoms in the newborn. [58] Chronic constipation, abdominal distention, volvulus, or perforation may be symptoms of the disease in a child. Hirschsprung disease in the adult is rare but must be considered in the evaluation of patients with chronic constipation dating back to childhood. [59], [60], [61] and [62] Patients with total colonic aganglionosis may present with less dramatic intermittent symptoms of constipation. [57]

Digital rectal examination aids in the diagnosis. The rectal vault is empty in patients with Hirschsprung disease and is full of stool in patients with idiopathic megacolon. Abdominal radiographs usually show colonic dilation and a paucity of gas in the rectum. Barium enema may suggest the presence of a short, narrow segment or transition zone (Fig. 82-12). Patients with total aganglionosis or very short segment Hirschsprung disease may have a normal-appearing barium enema. Newborns may have a normal-appearing barium enema because the proximal bowel has not had time to dilate.

FIGURE 82-12. Radiologic study from a patient with Hirschsprung disease. The short, collapsed, aganglionic segment (*arrows*) is evident on this radiograph of a barium enema performed on a 28-month-old infant with constipation. The colon proximal to the aganglionic segment is often dilated and filled with stool.

Anorectal manometry may be useful in the evaluation of patients with suspected Hirschsprung disease but is difficult to perform in the newborn and is reserved for older infants and children. Typically a normal sphincter profile (resting pressure of 40–80 mm Hg and squeeze pressure of 80–160 mm Hg) and an abnormal rectoanal inhibitory reflex are seen in patients with Hirschsprung disease. The rectoanal inhibitory reflex is the normal relaxation of the internal sphincter in response to rectal

distention. The internal sphincter does not relax in response to rectal distention in patients with Hirschsprung disease, and an abnormal reflex during manometry aids in the diagnosis. [63], [64] This reflex is easily identified using anal manometry with a manometric catheter and a balloon to distend the rectum. When the rectal balloon is distended, the manometry tracing will reveal a normal external sphincteric contraction but no compensatory relaxation of the internal anal sphincter. The rectoanal inhibitory reflex may be normal in patients with short-segment Hirschsprung disease. These patients may have a short segment as their primary disease or the short segment may be residual disease after surgery. High anal resting pressures and impaired rectal emptying may be seen.

Histological evaluation is necessary to make the diagnosis of Hirschsprung disease. Hyperplasia or hypertrophy of nerve fibers can be seen, but ganglion cells are absent in the submucosa and myenteric plexus of these patients. Mucosal pinch biopsy specimens are not adequate for diagnosis because sufficient submucosa must be present in the biopsy specimen in order to conclude that ganglion cells are absent. Suction biopsies are simple to perform, but the mucosa and submucosa must be identifiable to have an adequate specimen. Full-thickness rectal biopsy samples may be necessary for confirmation. Routine hematoxylin and eosin staining misses ganglion cells in almost 40% of normal patients. [65] Acetylcholinesterase staining has been found to be more accurate in identifying patients with Hirschsprung disease. Acetylcholinesterase-positive nerve fibers are increased in number in the lamina propria and muscularis propria in these patients. A positive diagnosis may be obtained even by evaluation of superficial suction biopsy samples.

Colostomies are usually performed after the diagnosis is made in newborns. This allows a period of stabilization and growth before definitive repair. A colostomy may be used in the older child or adult to allow hypertrophied bowel to resume a more normal caliber. Pull-through operations (Swenson technique, Duhamel procedure, or Soave procedure) have been devised to anastomose normally innervated bowel to the anus with or without resection of the abnormal bowel. [58], [59], [60] and [61] Intraoperative biopsy results must demonstrate the presence of ganglion cells at the level of the colostomy and the proximal margin of the colonic resection. Rectal myectomy may be curative in patients with short-segment Hirschsprung disease.

Intestinal Duplications

Intestinal duplications are rare congenital anomalies that can occur anywhere along the gastrointestinal tract. There are many theories regarding the cause of intestinal duplication, including failure of the bowel to recanalize in utero, caudal twinning, and incomplete separation of the notochord from the entoderm. The resultant structures may either be tubular, communicating with the intestinal lumen, or, more commonly, closed cystic duplications. These cysts are lined with gastrointestinal mucosa and contain a layer of smooth muscle within their walls. Duplications are usually found on the mesenteric side of the intestine. They frequently share a common wall and blood supply with the involved bowel. All regions of the gastrointestinal tract may be involved; the esophagus and ileum are the most commonly involved sites. The colon and rectum account for 5% to 10% of all gastrointestinal duplications. [66]

Duplications are usually symptomatic during childhood. They can produce symptoms of obstruction, volvulus, or hemorrhage. Duplications in adults are often asymptomatic and may be discovered incidentally. They can be complicated by infection, bleeding, or malignant degeneration. Plain abdominal radiographs, barium enemas, and computed tomography scans may reveal soft tissue masses or the point of communication with normal bowel. Evaluation of the genitourinary tract should be performed to rule out associated anomalies.

Resection is indicated for rectal duplications because of the risk of neoplasia, even for asymptomatic duplications. Cystic duplications can often be excised. Dividing the common wall is the treatment for tubular duplications. Mucosal excision may be necessary if heterotopic gastric mucosa is present. [66]

Malrotation

Malrotation occurs if the midgut fails to complete the 270-degree counterclockwise rotation as it returns from herniation (10–12 weeks of gestation). [26], [67] The base of the small bowel mesentery normally stretches from the ligament of Treitz in the left upper quadrant to the ileocecal valve in the right lower quadrant. In malrotation, the entire midgut and its vascular pedicle have a narrow-based mesenteric attachment in the right upper quadrant. The duodenojejunal junction (ligament of Treitz) comes to lie to the right of the spine. The cecum and right colon overlie the duodenum in the right upper quadrant, and Ladd bands form over the duodenum in an attempt to peritonealize the cecum. Associated anomalies, such as small bowel atresias, intussusception, Hirschsprung disease, and abdominal wall defects, have been reported in 30% to 60% of patients. [67], [68]

Most infants present with evidence of malrotation within one month of birth. [67], [68] The clinical picture is one of a high small bowel obstruction, volvulus, or ischemia. One should suspect the diagnosis in an infant with bilious vomiting and a flat abdomen. Bloody stools indicate vascular compromise. Less severe forms of malrotation can present in childhood or into adulthood.

Plain abdominal radiographs may show evidence of a complete gastric or duodenal obstruction with a paucity of gas in the distal small bowel. A barium upper gastrointestinal series shows the ligament of Treitz to the right of midline. A barium enema is rarely needed, but it may demonstrate the cecum in the right upper quadrant.

The treatment of malrotation is operative. Most neonates with an obstruction from malrotation have a midgut volvulus. [68] The volvulus is reduced by untwisting it in a counterclockwise rotation. [69] Ladd bands overlying the right colon and duodenum are lysed. The duodenum is placed in the right upper quadrant and the cecum in the left upper quadrant. An appendectomy is performed because the alteration in anatomy would make future diagnosis of appendicitis difficult. [68]

Imperforate Anus

Imperforate anus occurs in 1 of 20,000 live births and is associated with other congenital anomalies in 50% of cases. Genitourinary anomalies and sacral abnormalities are frequently seen. Cardiac and gastrointestinal anomalies (primarily esophageal atresia) are also associated with imperforate anus.

Imperforate anus is classified according to the relationship of the rectum to the levator ani muscles. [70] High lesions are those in which bowel of normal or greater caliber terminates above the levator muscle complex. The rectum often ends in the prostatic urethra in males. In low lesions, the rectum terminates distal to the levators, often ending in a fistula. Low lesions are more common in females. Fistula tracts may connect the distal rectum with the perineum, vagina, or other hollow organs. Intermediate lesions are found within the levator complex and may be associated with a partial anal canal or perineal fistula.

The diagnosis is usually made by physical examination at birth. Most infants with imperforate anus fail to pass meconium at birth unless a fistula is present. Radiography can be used to determine the type of defect. Air invertograms can be used to identify the location of the rectum in relation to the perineum but are difficult to interpret. Fistulography may be performed, and computed tomography and magnetic resonance imaging are useful in evaluating high lesions. The urinary tract should be evaluated with an intravenous pyelogram and voiding cystourethrogram because of the associated urogenital anomalies.
