CHAPTER 30

Nicholas J. Talley and Gerald Holtmann

APPROACH TO THE PATIENT WITH DYSPEPSIA AND RELATED FUNCTIONAL GASTROINTESTINAL COMPLAINTS

Dyspepsia is a frequent reason for consultation in primary care and gastrointestinal practice. With the widespread availability and use of endoscopy, it has become evident that a structural explanation is found in only a minority of patients with dyspepsia. The application of appropriate diagnostic and therapeutic strategies in patients with either uninvestigated dyspepsia or documented functional (nonulcer) dyspepsia continues to be a challenge in clinical practice. This chapter aims to summarize the basis for a rational approach to the management of such patients.

CLINICAL PRESENTATION OF DYSPEPSIA

Symptoms

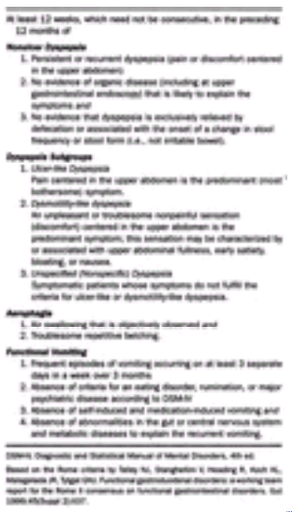
The term *dyspepsia* is derived from the Greek roots *dys* (“bad”) and *peptein* (“digestion”). Based on the consensus opinion of an international panel of clinical investigators, it is defined as persistent or recurrent pain or discomfort centered in the upper abdomen [1]; however, the definition does not exclude those who also have symptoms elsewhere. *Discomfort,* a subjective, negative feeling in the upper abdomen that does not reach the level of pain, may be characterized by one or more symptoms: early satiety, postprandial fullness, bloating, and nausea. *Heartburn,* a retrosternal burning discomfort that rises up toward the neck, is considered distinct from dyspepsia. Dyspepsia is not restricted to meal-related symptoms because patients with peptic ulcer disease often report pain that is not related to a meal. [1] Occasional episodes of dyspepsia often occur in otherwise healthy individuals, but clinically relevant dyspepsia is a relapsing or chronic condition, present for at least 12 weeks in the prior year. [2]

Diagnostic tests do not find a cause for dyspepsia in approximately 60% of studied patients. [1], [3], [4] The term *functional (or nonulcer) dyspepsia (NUD)* refers to relapsing or chronic dyspepsia in patients who lack an identifiable cause for their symptoms after a routine clinical diagnostic workup. [1], [5] Currently, patients with histological gastritis (or duodenitis) are not excluded from the NUD category because a link between these abnormalities and symptoms has not been convincingly established. NUD remains a somewhat confusing, although widely used, medical term. Some authorities who use it infer that the symptoms should resemble those of ulcer disease, [5] whereas others use the label to refer to symptoms that are not at all like those of an ulcer. [4]

The lack of a structural lesion does not mean that the symptoms are not real. Indeed, the lack of a clear association between structural lesions and symptoms has been noted in several other gastrointestinal (GI) disorders. For example, endoscopic studies have found that gastric and duodenal ulcer recurrences are frequent in asymptomatic subjects, [6], [7] and esophagitis and peptic ulcers were found in about 8% and 4% of totally asymptomatic subjects, respectively. [3]

Subgroups of Dyspepsia

Because NUD presumably affects a heterogeneous group of patients, attempts have been made to categorize them based on symptom clusters (Table 30-1). [1], [4], [8] Patients with NUD may be subdivided into at least the following symptom subgroups: ulcer-like, dysmotility-like, and unspecified dyspepsia (see Table 30-1). [1], [5], [8], [9]



At least 12 weeks, which need not be consecutive, in the preceding 12 months of

Rome/new Dyspepsia

1. Persistent or recurrent dyspepsia (pain or discomfort centered in the upper abdomen)
2. No evidence of organic disease (including at upper gastrointestinal endoscopy) that is likely to explain the symptoms and
3. No evidence that dyspepsia is exclusively relieved by defecation or associated with the onset of a change in stool frequency or stool form (i.e., not irritable bowel).

Dyspepsia Subgroups

1. Ulcer-like Dyspepsia
   Pain centered in the upper abdomen is the predominant (most troublesome) symptom.
2. Dysmotility-like dyspepsia
   An unpleasant or troublesome nonpainful sensation (discomfort) centered in the upper abdomen is the predominant symptom; this sensation may be characterized by or associated with upper abdominal fullness, early satiety, bloating, or nausea.
3. Unspecified (Nonspecific) Dyspepsia
   Symptomatic patients whose symptoms do not fulfill the criteria for ulcer-like or dysmotility-like dyspepsia.

Aerophagia

1. Air swallowing that is objectively observed and
2. Troublesome repetitive belching.

Functional Vomiting

1. Frequent episodes of vomiting occurring on at least 3 separate days in a week over 3 months
2. Absence of criteria for an eating disorder, rumination, or major psychiatric disease according to DSM-IV
3. Absence of self-induced and medication-induced vomiting and
4. Absence of abnormalities in the gut or central nervous system and metabolic diseases to explain the recurrent vomiting.

DSM-IV, Diagnostic and Statistical Manual of Mental Disorders, 4th ed.

Based on the Rome criteria by Talley NJ, Stanghellini V, Heading R, Koch KL, Malagelada JR, Tytgat GNJ. Functional gastroduodenal disorders: a working team report for the Rome II consensus on functional gastrointestinal disorders. Gut 1999;45(Suppl 2):II37.

TABLE 30-1 Criteria for the Clinical Categorization of Functional Gastrointestinal Disorders (Rome II)

The categorization of dyspepsia was introduced for the purposes of better targeting treatment to symptoms; for example, patients with dysmotility-like symptoms should respond best to prokinetics, whereas patients with ulcer-like dyspepsia should respond best to antisecretory therapy. Even though this categorization is widely used, its validity is a matter of debate. Several studies using standardized symptom questionnaires observed considerable overlap (10%–20%) and a lack of stability among the different dyspepsia categories. [8], [9], [10] and [11], [12] Previous categorizations generally focused on the presence or absence of specific symptoms, [1], [4] but the severity or predominance of pain versus discomfort may be more relevant, as is discussed in the section on pathogenesis. [2]

Misclassification of Gastroesophageal Reflux Disease as Dyspepsia Whether reflux-like dyspepsia should be considered a part of the spectrum of NUD and what symptoms should be included in this subgroup has been vigorously debated. [1], [4] Despite a lack of endoscopic evidence of esophagitis, pathological acid reflux is detectable in a subset of patients with reflux-like symptoms whether or not they have epigastric pain or discomfort. [13] Heartburn is considered to be of value in identifying true esophageal reflux. [1], [4], [5], [8] The absence of typical heartburn reliably indicates the absence of gastroesophageal reflux disease (GERD) [5], [14]; when present, heartburn is an insensitive indicator of reflux disease in comparison with 24-hour esophageal pH monitoring. [5], [14], [15] At least 20% of patients clinically classified as having NUD have pathological acid reflux, which may explain their symptom complex. [15] Other data suggest that a subset of patients with NUD who respond to acid-lowering therapy have frequent short reflux episodes. [16], [17] It is reasonable to conclude that patients who predominantly have typical reflux symptoms along with dyspepsia should be considered to have GERD, rather than NUD, until it can be proved otherwise. These patients often respond to a trial of acid suppression. Because the term *reflux-like dyspepsia* has resulted in substantial confusion, it should be abandoned. [1], [4]

Functional Vomiting, Rumination, and Aerophagy Dyspepsia and reflux are not the only symptom clusters arising from the foregut (see Table 30-1). *Aerophagy* is an excessive unconscious swallowing of air that results in belching and discomfort. These patients usually report transient improvement of symptoms after belching. [1] Postprandial belching from physiological air swallowing is normal and occurs up to three to four times per hour. Pathological aerophagy is suggested by a specific history and can be confirmed by observation. Because excessive gas is probably not present, it has been suggested that either disturbed upper GI tract motility or psychopathology accounts for the symptoms, but this has not been carefully studied. [1] Patients with *functional vomiting* have frequent episodes of vomiting, but clinical evaluation does not yield a structural or metabolic cause for the symptoms. Gastroparesis and chronic idiopathic intestinal pseudoobstruction should be excluded by appropriate testing (see Chapter 65 and Chapter 73), as should anorexia nervosa, bulimia nervosa, and panic attacks by the clinical assessment. *Rumination* in adults without mental retardation or neurological disease is an eating disorder, not a functional GI disorder. It is characterized by the regurgitation of recently swallowed food that occasionally may be rechewed and reswallowed. These patients may present with a history of considerable weight loss. [18] Symptoms usually do not occur during sleep and are sometimes falsely described or inappropriately labeled as chronic vomiting. [18] Reflux esophagitis and esophageal motor disorders must be excluded, but the history or observation is virtually diagnostic.

Irritable Bowel Syndrome Irritable bowel syndrome (IBS), which affects about one in six persons in the general population, is characterized by recurrent abdominal discomfort or pain and an erratic disturbance of defecation. [8], [10], [11] A positive diagnosis of IBS can be made based on a careful history. [1], [19] Of patients with NUD, at least one third have concurrent symptoms of IBS. [10], [11], [20], [21] Investigators using factor analysis have identified distinct symptom groupings consistent with IBS, NUD, and GERD in the population, although overlap exists. [22], [23] and [24] Because many patients do not mention bowel dysfunction unless specifically asked, an explicit inquiry should be made because the presence of concurrent IBS will influence management (see Chapter 86).

DYSPEPSIA IN THE GENERAL POPULATION AND CLINICAL PRACTICE

Prevalence and Incidence in the Population

Population-based studies from around the world have yielded prevalence rates of dyspepsia ranging from 7% to 60%. [24], [25], [26], [27], [28], [29], [30], [31], [32], [33], [34] and [35] This wide range is unlikely to reflect true variability in prevalence, but probably is explained by methodological differences. Indeed, when two different countries were studied with exactly the same methodology, similar prevalence rates for dyspepsia were observed. [8], [10]

Although prevalence has been extensively studied, few data are available for incidence. One 12- to 20-month population-based study from Olmsted County, Minnesota, identified an onset of symptoms compatible with NUD of approximately 9%, while the same number of subjects who initially reported symptoms became symptom free. [36] In a Swedish study, the calculated 3-month incidence of dyspepsia in previously asymptomatic subjects was under 1%. [21]

Dyspepsia in Clinical Practice and Health Care–Seeking Behavior

Although fewer than 50% of subjects with dyspepsia and IBS seek medical care, conservative estimates suggest that these disorders account for 2% to 5% of all consultations in family practice. [8], [10], [30], [37] Up to one third of these patients eventually may be referred to a gastroenterologist. [37] Although there is an association between the perceived intensity of abdominal (and extraintestinal) symptoms and health care–seeking behavior in NUD, [8], [10] psychological distress also may affect the utilization of health care services. [38], [39] Patients with dyspepsia have more concerns about the possible seriousness of their symptoms and are especially worried about cancer. [40] Moreover, consulters with dyspepsia have poorer coping capabilities, which may magnify their dyspeptic and psychological symptoms. [41]

CAUSES OF DYSPEPSIA

In patients with dyspepsia presenting for investigation, the four major causes of symptoms are chronic peptic ulcer disease, gastroesophageal reflux (with or without esophagitis), malignancy, and NUD. [13], [42], [43], [44], [45] and [46]

Structural Gastrointestinal Disease

The most important structural cause of symptoms to consider is *peptic ulcer disease* because definitive therapy is now available. [47] Symptoms discriminate poorly between peptic ulcer disease and NUD. [35], [48] Indirect evidence for the absence of ulcer disease includes the absence of *Helicobacter pylori* infection on noninvasive testing and no recent nonsteroidal antiinflammatory drug (NSAID) use, but normal upper GI endoscopy findings while the patient is off antisecretory therapy is the only defined diagnostic approach.

In Western countries, the prevalence of *gastric cancer* in previously uninvestigated dyspepsia has been reported to be 1% to 2%, but in persons younger than 55 years of age in most Western countries, gastric cancer is a rare cause of dyspepsia. [3], [49], [50] and [51] Nevertheless, the possibility of a gastric neoplasm must be considered for at least two reasons: Delayed diagnosis of early gastric cancer adversely affects patient prognosis, [52] and patient concerns about cancer promote health care–seeking behavior. [40]

At ultrasonography, *biliary tract disease* (gallstones) may be found in 1% to 3% of patients with dyspepsia but usually is incidental and not a cause of symptoms. [53], [54]

Although the prevalence of gallstones increases with age and is three times greater in female patients, there is no clear age-related increase in the prevalence of NUD and no gender difference. Cholelithiasis causes biliary pain, which is typically severe, constant pain in the epigastrium or right upper quadrant that persists for hours and occurs episodically. [55] In the absence of characteristic biliary pain, it is unlikely that gallstones are the cause of dyspepsia. [56], [57] and [58] Obtaining an accurate history is therefore key in differentiating biliary tract disease from NUD.

Chronic pancreatitis or *pancreatic carcinoma* may cause symptoms that occasionally are confused with those of NUD. [59], [60] Patients often have vague symptoms of insidious onset, but postprandial pain is usual that may radiate through to the back; these patients also may have a history of risk factors for pancreatitis, such as excess alcohol use. Weight loss, nausea, and diarrhea (steatorrhea) are typically late symptoms. Serum amylase and lipase levels are usually normal, but there may be glucose intolerance. In suspected cases, ultrasonography (including endoscopic ultrasonography), helical computed tomography (including thin sections of the pancreas), or magnetic resonance cholangiopancreatography (MRCP) will usually aid in the diagnosis.

Endoscopy-Negative Gastroesophageal Reflux

Because 60% of patients with true GERD are endoscopy negative, gastroesophageal reflux should be strongly suspected, despite the absence of esophagitis at endoscopy, in NUD patients with epigastric burning pain or discomfort that radiates up toward the throat and is relieved by antacids. [61], [62] Twenty percent of dyspeptic patients who were free of peptic ulcer and gallstones had abnormal esophageal acid exposure times. [15] Between 12% and 40% of patients with otherwise unexplained dyspepsia were found to have pathological gastroesophageal reflux [15], [16] and [17], [63], [64]; such patients should not be misclassified as having NUD.

Even if esophageal acid exposure lies within the conventional normal range, symptoms in some cases may be linked to reflux episodes. In a study of 771 consecutive patients referred for 24-hour esophageal pH monitoring, esophageal exposure to acid was normal in 60%, but 71% of these patients reported symptoms during reflux episodes. [16] In one of eight patients with normal esophageal exposure to acid, a significant association was found between symptoms and reflux episodes. The symptom cluster in these patients, which included belching, bloating, and nausea, did not differ between those with and those without pathological GERD. These results are consistent with the concept that *esophageal hypersensitivity* to acid is one of the major pathophysiological explanations of dyspepsia in the absence of pathological levels of acid reflux. [65], [66] Indeed, contact of the esophageal mucosa with acid (without induction of heartburn) causes a cerebral cortical response that is detectable with functional magnetic resonance imaging [67]; hence, esophageal acidification may alter the central processing of visceral afferents.

In patients with difficult-to-manage NUD, 24-hour esophageal pH testing (including an assessment of symptom association with acidification) may be of value to confirm nonerosive reflux disease. The symptomatic response to a short therapeutic trial with a high-dose proton pump inhibitor (PPI) has been advocated as a diagnostic measure for GERD patients, and this test does have good sensitivity and specificity. [68] However, the response to PPI therapy may be misleading in patients with suspected NUD because of the marked spontaneous fluctuations of symptoms in the condition.

Drug-Induced Dyspepsia

NSAIDs, including the cyclooxygenase-2 (COX-2)–specific NSAIDs, represent the most important cause of drug-induced dyspepsia. [69] Other drugs that may produce upper abdominal symptoms include iron or potassium supplements, digitalis, theophylline, and oral antibiotics, especially erythromycin and ampicillin. [70] Reducing the dose or discontinuing drug therapy usually relieves dyspepsia in such cases.

Psychiatric Disorders

Patients with constant pain do not have NUD; rather, these patients usually have a chronic pain syndrome. Similarly, patients with multisystem complaints of abdominal symptoms are more likely to have depression or somatoform disorder and should not be mislabeled as having NUD; these patients can benefit from formal psychiatric evaluation. Rarely, panic disorder can present with episodic upper abdominal distress. Eating disorders should be considered in any young patient presenting with significant weight loss in addition to dyspepsia. [70]

Other Disorders

Diabetes mellitus with underlying autonomic neuropathy can cause postprandial fullness, early satiety, nausea, and vomiting, but symptoms correlate poorly with gastroparesis. Poor glycemic control or psychiatric disorders may be of causal importance. [71] Furthermore, diabetic radiculopathy of the thoracic nerve roots can cause upper abdominal pain. [70] Metabolic disturbances (e.g., *hypothyroidism, hypercalcemia*) can produce upper GI distress. *Ischemic heart disease* sometimes presents with upper abdominal pain induced by exertion. *Intestinal angina* should be considered in older patients, particularly smokers; it typically presents with postprandial pain associated with a fear of eating and significant weight loss. [70] The prevalence of *celiac disease* in patients with dyspepsia may be approximately twice that in the general population in some parts of the world; [72] serologic screening (e.g., antiendomysial antibody) should be considered to allow diagnosis of an eminently treatable disease.

Malignancies such as colon cancer (e.g., involving the transverse colon), gastric lymphoma or sarcoma, esophageal cancer, pancreatic cancer, and ampullary cancer may cause upper abdominal distress that may initially be confused with NUD, although this occurrence is rare. [70] *Infiltrative diseases* of the stomach, including eosinophilic gastritis, Crohn's disease, sarcoidosis, tuberculosis, and syphilis, also may very rarely produce dyspepsia. [73] *Ménétrier's disease* often presents with upper abdominal symptoms; atrophic gastritis is an asymptomatic condition.

Abdominal wall pain from *muscle strain, nerve entrapment,* or *myositis* can be confused with NUD. Characteristically, there is localized tenderness that on palpation reproduces the pain, and the tenderness may be increased by tensing the abdominal muscles. [74]

PATHOGENESIS OF NONULCER DYSPEPSIA

Disturbed Motor Function

During the past 15 years, a role for gastric and intestinal dysmotility in the pathogenesis of NUD has been based on the observation that approximately 40% of patients seen at tertiary referral centers with NUD have delayed gastric emptying of solids, [75], [76], [77], [78], [79], [80], [81], [82], [83], [84], [85] and [86] and a similar number have antral hypomotility after meals. [80], [81] The prevalence of gastric motility disturbances in patients with NUD seen in the primary care setting is unknown but may be lower.

A link between symptoms and gastroparesis in NUD, however, is not always detected. [85], [86] An Italian study of more than 300 patients with NUD reported delayed gastric emptying in only one third and a clear association between delayed gastric emptying (radioisotope technique) and symptoms. [83] The probability of having delayed gastric emptying was more than doubled in female patients with severe postprandial fullness and was increased fourfold in female patients who reported vomiting. However, a larger study of patients with dysmotility-like dyspepsia assessed by a ^{13}C-octanoic acid gastric-emptying breath test failed to confirm these findings. [87] Thus, symptoms and delayed gastric emptying appear to be at best weakly linked.

Gastric antral hypomotility, characterized by either a decreased frequency or decreased amplitude of phasic pressure waves, is not a specific finding in NUD; such abnormalities have been observed in patients with peptic ulceration as well as in those with other diseases. [81], [88], [89] Prolonged ambulatory monitoring of small intestinal motility of patients with NUD has documented symptoms associated with burst activity and retrograde or nonpropagated phase III activity in some. [90] It is unlikely that this technique will identify specific motility patterns that are closely linked to dyspeptic symptoms. [91]

In patients with otherwise unexplained nausea, an elevated slow wave frequency with either a regular (*tachygastria*) or irregular (*tachyarrhythmia*) rhythm has been observed on electrogastrography (EGG). [92], [93] In 72 patients with NUD, the EGG findings were abnormal in 50% with delayed gastric emptying and in 22% with normal emptying. [93] Because gastric arrhythmias also have been documented in patients with severe nausea resulting from GERD [94] and other diseases, [95] the clinical significance of EGG abnormalities in NUD remains in question.

More recently, the concept of impaired fundus relaxation has been suggested as a potential mechanism of symptoms in NUD. After a meal, the fundus normally relaxes, preventing an uncomfortable sensation. [96] A failure of fundic relaxation has been associated with early satiety and weight loss in NUD (Fig. 30-1). [96] This study was conducted in highly selected patients; [96] weight loss is rare in NUD. Interestingly, this functional abnormality could be abolished by sumatriptan, a 5-HT 1 receptor agonist, and symptoms improved. [97] Further studies are needed to confirm this intriguing concept.

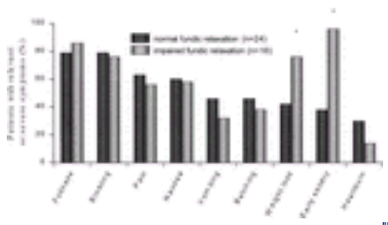


FIGURE 30-1. A study of postprandial fundic relaxation in 40 patients with nonulcer dyspepsia; gastric accommodation was impaired in 40% and was significantly associated with early satiety and weight loss. (From ref. [96] .)

Disturbed Sensory Function

In 1973, Ritchie [98] described lowered sensory thresholds to rectal balloon distention in a subset of patients with IBS, a disorder that frequently overlaps with NUD, and this finding was confirmed by others. [99] , [100] and [101] Moreover, a significant reduction in rectal sensation thresholds could be induced in patients with IBS who had normal baseline thresholds, but not in controls, [102] suggesting a disorder of visceral afferent function. Similarly, patients with NUD have a decreased threshold for the perception of mechanical gastric fundic and duodenal distention (Fig. 30-2). [103] , [104] , [105] , [106] and [107] Furthermore, sensory thresholds could be lowered in patients with NUD by intraduodenal lipid, but not glucose, infusion. [108] , [109] This phenomenon may explain the induction of symptoms after fatty meals reported by some patients with NUD. Nevertheless, approximately 50% of patients with NUD have normal gastric perception thresholds, and there is considerable overlap between healthy controls and patients, raising questions about the exact relevance of gastric hypersensitivity. [110] It has been shown that gastric mechanical thresholds normally increase (or adapt) after repeated distention or exposure to aspirin, but this does not occur not in patients with NUD, [111] , [112] suggesting that sensory dysfunction is one key abnormality in NUD.

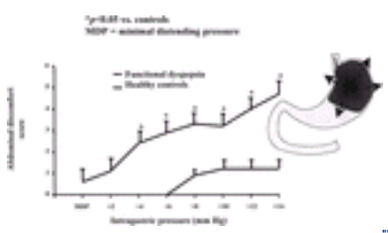

FIGURE 30-2. Gastric sensory thresholds assessed by a gastric barostat in patients with functional (nonulcer) dyspepsia and in healthy controls. (Adapted from Mearin F, Cucala M, Azpiroz F, et al. The origin of symptoms on the brain-gut axis in functional dyspepsia. Gastroenterology 1991;101:999.)

Although most studies have observed lowered gastric mechanosensory thresholds, the data regarding small intestinal sensory thresholds in NUD are more controversial. [113] Decreased thresholds for intestinal balloon distention have been observed in patients with NUD, although the method used (a latex balloon) may not have produced a well-standardized distention stimulus. [114] In contrast, Spanish studies [115] found isolated gastric but not intestinal hyperalgesia in NUD, and selective jejunal hyperalgesia in patients with IBS. [116] More recent studies, however, clearly identified lowered duodenal sensory thresholds in a group of patients with NUD that were independent of coexisting intestinal dysmotility (Fig. 30-3). [106] , [107]

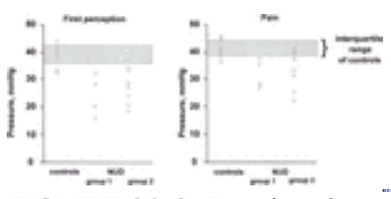

FIGURE 30-3. Duodenal sensory thresholds measured with a barostat placed in the third portion of the duodenum in healthy controls and in patients with nonulcer dyspepsia (NUD). Group 1 had abnormal intestinal reflexes, and group 2 did not. Note that patients with nonulcer dyspepsia in groups 1 and 2 had significantly lower first perception and maximally tolerated pressures with the barostat, and this was similar in those with or without altered intestinal reflexes. (From ref. [107] .)

A key question is whether lowered sensory thresholds in the stomach and duodenum are pathognomonic for NUD. The answer now appears to be no. Both abnormal rectal and esophageal sensory thresholds have been reported in patients with either IBS or NUD. [117] Furthermore, duodenal sensory thresholds were significantly lower in patients with either NUD or IBS and in patients with both conditions than in healthy controls. [20] Altered mechanical visceral sensory function is therefore most likely a nonspecific marker for functional GI disorders rather than an abnormality that directly explains the site and type of symptoms.

Although there are well-defined experimental animal models for the study of visceral hyperalgesia, [118] , [119] and [120] little is known about the mechanisms in humans. It is unknown whether altered sensation results from disturbed thresholds at the GI tract level (i.e., alterations of the mucosal mechanoreceptors, muscle, serosa, or supporting mesentery) or in the afferent nerve terminals, the vertebral ganglia, the spinal cord, the brainstem, and the cerebral cortex. Chronic gastric inflammation caused by *Helicobacter pylori* infection may theoretically be a cause of lower mucosal sensory thresholds, although no consistently significant differences in sensory thresholds between *H pylori*–positive and— negative patients with NUD and healthy controls have been observed. [107] , [121] , [122] and [123]

Mechanical or chemical stimulation of the dorsal root causes visceral hyperalgesia, [124] and it has been speculated that visceral hyperalgesia is associated with altered central projection of central (dorsal horn) neurons. [124] , [125] and [126] The prevalence of extraintestinal complaints, such as back pain and headache, is increased in NUD and IBS, [127] suggesting that central processing abnormalities may be linked also to the pathogenesis of symptoms. Positron emission tomography has revealed differences in cerebral blood flow between IBS patients and healthy controls anticipating rectal distention. [128] Such experiments have not been performed in patients with NUD, but it is reasonable to postulate that similar disturbances may exist in NUD.

Vagal and spinal afferents mediate visceral sensation. Altered vagal function in patients with NUD and IBS has been observed, [129] , [130] including an increase in the area of the antrum in fasting patients with NUD and diabetes mellitus in comparison with healthy subjects. [131] Symptoms of bloating and postprandial fullness are commonly reported by patients after vagotomy, and these symptoms may be linked to an impairment of vagally mediated fundic relaxation. [132] The normal fundic relaxation in response to a meal was observed to be significantly diminished in patients with a truncal vagotomy and in patients with NUD in comparison with healthy

controls. [133] Moreover, other indirect data suggest that the vagus nerve can inhibit the transmission of sensory information, and this inhibition may be impaired in NUD. [134]

Duodenogastric Reflux

Duodenogastric reflux has been postulated to be of importance in the pathogenesis of NUD. There is now convincing evidence that duodenogastric reflux is not more common in those with NUD than in controls, and it does not appear to be related to either symptoms or antral hypomotility. [89], [135], [136] and [137]

Gastric Acid

Basal and peak rates of acid output do not differ between patients with NUD and appropriate controls. [138], [139] However, acid secretion in response to gastrin-releasing peptide (GRP), which simulates the postprandial state, has been shown to be significantly increased in *H pylori*–infected duodenal ulcer patients and *H pylori*–infected healthy volunteers, [140] and more importantly, GRP-stimulated acid secretion was also significantly higher in *H pylori*–positive patients with NUD than in *H pylori*–positive healthy volunteers (Fig. 30-4). [140] Overall, about 50% of the patients with NUD had a disturbance of GRP-stimulated acid secretion similar to that of the patients with duodenal ulcer. Unfortunately, in the population studied, the background rate of peptic ulcer disease is particularly high, and this may have inadvertently contaminated the NUD group. [140] Furthermore, *H pylori*–negative NUD cases were not studied. Thus, the relevance of acid dysregulation in symptom generation in *H pylori*–infected patients with NUD remains to be determined.

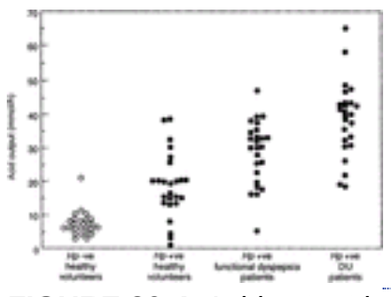

FIGURE 30-4. Acid output in response to gastrin-releasing peptide in *H pylori (HP)*–negative healthy volunteers, *H pylori*–infected healthy volunteers with functional (nonulcer) dyspepsia (*NUD*), and *H pylori*–infected patients with duodenal ulcer (*DU*). Note that the patients with NUD had a significantly increased acid output that was similar in a subset to that of patients with DU. (From ref. [140] .)

Whether NUD patients have gastric mucosal hypersensitivity to acid in NUD is not clear. George and colleagues [141] found that only 6 of 18 patients with NUD, 15 of whom had histological gastritis, had a positive symptom response to gastric instillation of acid, whereas 8 other patients had symptoms during the infusion of saline solution. Pentagastrin injection led to increased reports of pain in patients with NUD, although a histamine H_2 antagonist did not significantly reduce the pain. [142] Because pentagastrin may have other effects in addition to the stimulation of acid secretion, and acid secretion may not be blocked sufficiently by a histamine H_2 antagonist, these data are inconclusive. Esophageal sensory thresholds have been observed to decrease in normal controls during esophageal acid instillation, [143] suggesting that physiological esophageal acid reflux may trigger a decrease in sensory thresholds. In fasting dyspeptic patients, the clearance of exogenous acid infused into the duodenal bulb was shown to be impaired and was linked to the induction of nausea. [144]

Postinfectious Dyspepsia

H pylori infection is the most common cause of histological gastritis in humans [145], [146] and is found in approximately 40% of patients with NUD. [146], [147], [148] and [149] However, it is also common in asymptomatic subjects. [150] Because the prevalence of *H pylori* infection increases with age in those with and without NUD, [146], [149] studies reporting a higher prevalence of *H pylori* infection in patients with NUD [147], [151], [152], [153] and [154] have been criticized for including inappropriate comparison groups or failing to adjust for age, race, and socioeconomic status. [152], [154] In addition, there is a lack of convincing evidence to link *H pylori* with any specific symptom. [153], [154], [155], [156] and [157] In a systematic analysis that included 30 relevant observational studies involving approximately 3400 patients with NUD, and 11 additional studies with more than 6400 patients with uninvestigated dyspepsia, an association between *H pylori* infection and NUD was not confirmed. [158] The authors concluded that based on the available evidence, there is no strong association between *H pylori* infection and dyspepsia, but the evidence was insufficient to confirm or refute the existence of a modest association. Another issue in weighing any link between *H pylori* and NUD is biologic plausibility. Although chronic gastric inflammation is a potential cause of visceral hyperalgesia, [152] two studies failed to find a significant difference in sensory thresholds between *H pylori*–positive and–negative patients. [107], [121]

Thus, a causal relationship between *H pylori* colonization and NUD remains to be proved. However, the data do not exclude a role for *H pylori* infection as an initiating event in NUD in a predisposed individual, imilar to that proposed for postinfectious IBS. [159], [160] Similarly, a small subgroup of patients with NUD characterized by early satiety, nausea, weight loss, and impaired fundic accommodation may develop symptoms following a short episode of infectious gastroenteritis. [161]

Duodenitis

The prevalence of histological duodenitis in patients with NUD is between 14% and 83%, [162], [163] whereas the prevalence of macroscopic duodenitis in asymptomatic patients is 10%. [164] A duodenal ulcer may eventually develop in 48% of patients with duodenitis. [164], [165] It has been claimed that endoscopic irrigation of the duodenum with hydrochloric acid induces symptoms in patients with duodenitis, but unfortunately controls have not been not evaluated. [166] Based on the available evidence, erosive duodenitis appears to fall more within the spectrum of chronic duodenal ulcer disease and probably should not be considered part of NUD.

Psychosocial Factors and Alterations of the Central Nervous System

Individuals with NUD have been shown to be more psychologically disturbed, in terms of being more anxious and depressed, [167], [168], [169], [170], [171] and [172] and to score higher on measures of neuroticism [173] and somatization [127], [174], [175] and [176] than healthy controls. Other studies suggest that patients with NUD are no more psychologically disturbed than patients with organic bowel disease. [167], [177] In a case control study, Talley and colleagues [169] found similar levels of control of anger, anxiety, and unhappiness and of total emotional control over negative reactions in patients with NUD and control subjects. This subject remains controversial.

Most of these studies have included only individuals with NUD presenting for medical care. These studies, therefore, do not rule out the hypothesis that rather than causing symptoms, anxiety and depression simply make patients with NUD more likely to present their symptoms to a physician. [10] However, one large recent study was unable to confirm this concept. [178] Furthermore, in a follow-up study of patients with duodenal ulceration and NUD, abnormal personality patterns appeared to normalize after disappearance of the abdominal symptoms, [179] suggesting that psychological disturbances in some patients with NUD may be a consequence of the symptoms rather than of causal importance. Alternatively, both dyspepsia and psychological disturbances may be caused by another, unknown common environmental or genetic factor.

If psychological factors directly contribute to the development of symptoms in some patients with NUD, the precise mechanisms remain to be elucidated. In depressed patients, the hormonal response to a serotoninergic challenge is diminished. [180] A similar abnormality of central 5-hydroxytryptaminergic pathways may also exist in the functional GI disorders. Indeed, the prolactin response to buspirone, an azaspirone that stimulates central serotoninergic-1A receptors, was found to be significantly greater in patients with NUD than in healthy controls, and the difference correlated with the degree of delayed solid phase gastric emptying assessed scintigraphically. [180] These results require confirmation, however, because D-fenfluramine, a selective stimulus to central 5-hydroxytryptaminergic pathways, increased plasma prolactin and cortisol concentrations to a similar extent in patients with IBS and in controls, suggesting that central 5-hydroxytryptaminergic

pathways function normally in IBS. [181]

The role of stress in the pathogenesis of NUD remains controversial. Acute stress may result in decreased gastric contractility that precedes the onset of symptoms. [182], [183] and [184] It is not known, however, whether chronic dyspeptic symptoms are explained by such mechanisms. Indeed, patients with NUD, with or without antral hypomotility, have normal autonomic and humoral responses to experimental stress. [82] The stress of major life events, such as bereavement or divorce, has also been linked to NUD, although further studies are needed to evaluate this important area. [185], [186] Most studies have not focused on long-term stressors, and it is questionable whether experimental laboratory stressors reflect the stress of real life. Examinations, as an example of a real-life stressor, induced dyspeptic symptoms in medical students that were associated with personality traits, including anxiety. [187] Another study evaluated major life event stress in 100 patients with NUD, 100 patients with duodenal ulcer, and 100 healthy controls; the patients with NUD reported significantly more stressful life events. [188] It is notable, however, that most studies have not focused on long-term stressors and have not controlled for recall bias; abdominal symptoms may prompt patients more often to remember events that occurred in the past related to the occurrence of symptoms.

A potential link between childhood or adult sexual, emotional, or verbal abuse and functional GI disorders is based on studies in patients with IBS [189] and population-based surveys. [190] When standard criteria were applied, a surprisingly high prevalence (26%) of abuse in IBS patients (41% in women and 11% in men) was reported by subjects in a U.S. community. [190] Similarly, dyspepsia and heartburn were both significantly associated with abuse. [190] A causal link, however, has not been established, and notably, subjects with a history of abuse are more likely to seek medical treatment. [190]

Environmental Factors

The long-term use of NSAIDs causes asymptomatic mucosal lesions in up to 60% and ulcers in 10% to 30% of subjects treated; however, the role of aspirin and NSAIDs in NUD is not clear. Whereas acute dyspepsia can be induced by the ingestion of these drugs, including low doses of aspirin [9], [10] and COX-2 inhibitors, [69], [191] it is uncertain how often they cause chronic symptoms. [192], [193], [194], [195] and [196] In a random sample of 1644 residents in Olmsted County, Minnesota, aspirin (odds ratio, 1.8) and smoking (odds ratio, 1.5), but not alcohol (odds ratio, 0.9), were associated with dyspepsia. [196] However, after adjustments for nongastrointestinal somatic complaints, these environmental factors were no longer significant. [196] Most investigations have consistently failed to demonstrate that smoking and alcohol are important risk factors in NUD. [192], [193], [194], [195] and [196]

Some patients with NUD and IBS report specific food intolerances, but a convincing relationship between diet and chronic dyspepsia remains to be demonstrated. [197], [198] In one study, the main difference in eating pattern noted between NUD and controls was that a significantly lower percentage of patients with NUD regularly ate three meals per day. Also, dyspepsia patients in both groups associated certain eating habits and the consumption of specific foods with exacerbations of dyspeptic symptoms, which led to food avoidance in 80% of both groups. [198] In a cross-sectional survey from the United Kingdom, 20% of the population reported food intolerance, but food intolerance, as assessed by a double-blind, placebo-controlled food challenge, was confirmed in only 20%. [199] It is therefore unlikely that food intolerance is a major cause of symptoms in otherwise unexplained dyspepsia.

Coffee and decaffeinated coffee stimulate acid secretion. [194] Although the number of cups of coffee ingested has not been linked to NUD, [192], [193] coffee induced symptoms in 53% of patients with NUD and in 22% of healthy controls. [193] Whether coffee acts as a direct irritant or precipitates gastroesophageal reflux in NUD is unknown. [200]

A Proposed Disease Model

NUD is likely to be a multifactorial disorder. A subset of patients have atypical gastroesophageal reflux but are mistakenly labeled as having NUD. A small group (perhaps those at risk for future peptic ulceration) may have *H pylori*–induced dyspepsia that totally resolves after cure of the infection, because mucosal inflammation resets afferent pathways and symptoms persist despite healing of the gastritis. Acute resolving viral or bacterial infections in childhood or adulthood may be important in initiating visceral hypersensitivity or fundic failure of accommodation. These patients may be genetically predisposed to the development of an irritable gut, perhaps related to abnormal “hard wiring” in the enteric nervous system or higher centers (e.g., the personality trait neuroticism). A number of external factors then may be able to induce or modulate visceral hypersensitivity and altered intestinal reflexes, with or without secondary motor abnormalities, that lead directly to symptoms. It seems less likely that stress or personality traits alone can cause NUD, but they may promote abnormal processing of disturbed afferent signals, which then are interpreted as symptoms. Moreover, psychological status, stress, cultural and family factors, social support, and early childhood experiences are likely to influence the interpretation of symptom severity and health care seeking. Although speculative, this synthesis best fits current data. These concepts will of course have to be modified as new information becomes available.

DIAGNOSTIC APPROACH TO THE PATIENT WITH UNINVESTIGATED DYSPEPSIA

Identifying Patients with Structural Disease as a Cause of Dyspepsia

The diagnostic workup of patients with dyspepsia can be time-consuming and costly if undirected. Therefore, attempts have been made to limit diagnostic procedures to patients at higher risk for structural, potentially life-threatening disease. Age, symptom patterns, and *H pylori* status all have been evaluated as predictors of structural disease.

Age The risk for having a structural cause of symptoms increases with age. [3], [43], [44], [201], [202] A cutoff of 45 years has been traditionally applied in dyspepsia management strategies because the risk for gastric cancer in Western countries is extremely low in patients younger than 45 years. [43], [44] Patients older than 45 years with new-onset dyspepsia should undergo upper GI endoscopy. Because esophagogastroduodenoscopy (EGD) yielded only three gastric cancers in a sample of more than 7000 dyspeptic patients younger than 45 years without sinister symptoms, [49] the age of 50 or 55 years has been proposed by some as a more practical cutoff. [50], [203]

Pattern of Symptoms A long duration of symptoms in younger patients makes cancer an unlikely cause of symptoms. Dividing uninvestigated patients into ulcer-like, dysmotility-like, and nonspecific dyspepsia subgroups does not appear to identify subjects at higher risk for a structural lesion. [35], [48], [204], [205] and [206] Similarly, individual symptoms are of poor discriminating value. [206], [207] In subjects without alarm features, such as weight loss, bleeding, dysphagia, and recurrent vomiting, and who are younger than 45 years, gastric cancer is a very rare finding. [203]

H pylori *H pylori* infection and traditional NSAID use are strongly associated with peptic ulcer disease. [208] Restricting endoscopy to younger patients who test positive for *H pylori* by locally validated serology or a ^{13}C- or ^{14}C-urea breath test, to NSAID users, and to patients older than 45 years reduces the need for endoscopy by 20% to 40% without causing a relevant number of peptic ulcers or gastric cancers to be missed. [208], [209] This strategy, however, has several limitations; the accuracy of serology can be highly variable, and although peptic ulcer disease is declining overall in the developed world, an increasing proportion of patients have *H pylori*– and NSAID-negative ulcer disease. [210]

Endoscopy

Peptic ulcer disease, reflux esophagitis, and gastric or esophageal cancer are the most important conditions that must be ruled out to establish a firm diagnosis of NUD. Upper GI endoscopy remains the gold standard test and is superior to upper GI radiography. [211]

Not all structural abnormalities identified at endoscopy are clinically meaningful. In a study from Switzerland, reflux esophagitis or gastric and duodenal ulcers were found in 7% of asymptomatic subjects and in 24% of patients. [202] Similarly, in a large Norwegian population study, only peptic ulcers and duodenitis were definitely associated with dyspeptic symptoms, whereas other endoscopic and histological findings were not linked to dyspepsia. [3]

It is notable that some patients with a history of peptic ulceration continue to have dyspepsia even after cure of *H pylori* infection and in the absence of a persisting ulcer, which suggests that NUD has developed. [212], [213] If up to 50% of patients with duodenal ulcer have dyspeptic symptoms after apparent cure of their disease, [212] it can be speculated that the mechanisms causing ulcer dyspepsia are also linked to the pathophysiology of NUD.

Other Diagnostic Tests

Abdominal ultrasonography has a low yield and should not be ordered routinely. [35], [58], [70] Whereas endoscopy may yield pathological findings in about 50% of new patients with dyspepsia, an extended functional workup (including 24-hour esophageal pH recording, testing of gastric emptying, biliary scanning, and testing of lactose tolerance) will find abnormalities in only 50% of the remaining patients. [13] The true gain with these additional tests, however, is small. For example, identification of delayed gastric emptying by scintigraphy is unlikely to influence whether or not a prokinetic is prescribed because it has not been established that patients with delayed emptying respond better than those with normal emptying. [214] Similarly, although lactose deficiency may be present, dyspeptic symptoms often fail to respond to lactose withdrawal. A list of recommended tests to establish a diagnosis in dyspepsia is presented in Table 30-2.

Useful
1. A careful history that elicits the symptoms, and a relevant physical examination
2. Upper gastrointestinal endoscopy during a symptomatic period off acid suppression
3. Routine hematologic and biochemical tests (full blood count, ESR or CRP, serum glucose measurement, liver function tests, electrolytes and creatinine, calcium, thyroid function)
Optional
Helicobacter pylori testing
Ultrasonography of the gallbladder, liver, and pancreas
24-Hour esophageal pH testing
Uncertain Clinical Value
Gastric-emptying study
Fundus relaxation postprandially (e.g., by SPECT or ultrasound)
Electrogastrography
Gastroduodenal manometry
Water or nutrient load test

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; SPECT, single photon emission computed tomography.

TABLE 30-2 Diagnostic Studies to be Considered in the Patient with Suspected Nonulcer Dyspepsia

MANAGEMENT STRATEGIES

The initial management options are outlined in Table 30-3. Because only a few patients with dyspepsia have peptic ulcer, and even fewer have cancer, the American College of Physicians recommends empiric medical therapy (e.g., a histamine H_2 blocker) for 4 weeks for younger patients (i.e., younger than 45 years) without alarm features (option 1 in Table 30-3). [211] The use of PPIs has been extended to dyspepsia in clinical practice. The empiric therapy approach has been criticized, however, because it may promote the prolonged use of inappropriate medications, weaken the value of subsequent investigations, cause serious side effects (rarely), mask symptoms of serious disorders, and mask malignancy at subsequent endoscopy. [215], [216] Furthermore, if there is a high likelihood of symptom recurrence after the end of treatment, most patients will be investigated anyway, and resources will not be conserved. Lastly, this recommendation also fails to take into account the fact that dyspeptic patients with *H pylori*–related peptic ulcer usually have a potentially curable disease.

Exclude symptomatic gastroesophageal reflux, irritable bowel syndrome, and other conditions by history and examination.
Determine whether endoscopy is indicated immediately:
Age >50 y and new symptoms
Alarm symptoms or signs (e.g., weight loss, recurrent vomiting, bleeding)
If patient is young (<50 y) and no alarm features:
Option 1
Empiric therapy initially (e.g., antisecretory agent with optional endoscopy if fails to respond or promptly relapses)
Option 2
Test for *Helicobacter pylori* status (serology or breath test or stool antigen test).
If *H pylori* positive, empiric anti–*H pylori* treatment; if fails, go to option 1.
If *H pylori* negative, go to option 1.
Option 3
Prompt endoscopy for all patients.
Diagnose ulcer, cancer; treat appropriately.
Positively diagnose nonulcer dyspepsia and treat accordingly.

TABLE 30-3 Management Options for Uninvestigated Chronic Dyspepsia

Prompt endoscopy (option 3 in Table 30-3) has long been accepted as the gold standard approach. A large Danish randomized trial compared prompt endoscopy followed by targeted treatment with histamine H_2 receptor antagonists versus empiric histamine H_2 receptor antagonist treatment with diagnostic endoscopy reserved for those who failed therapy. [217] Two thirds of those randomized to empiric treatment eventually underwent endoscopy during the 1-year follow-up. It is noteworthy that the diagnosis of two cases of esophageal cancer was delayed 1 month by empiric treatment. After 1 year, the dyspeptic symptoms and functional status had improved similarly in both groups. Nevertheless, a significantly greater number of patients in the empiric treatment group were dissatisfied with their management and had lost more time from work, although this may reflect patient expectations before entry into the trial.

A number of management trials have now shown that empiric *H pylori* testing and treatment lead to outcomes similar to those observed after prompt endoscopy (option 2 in Table 30-3). The test and treat *H pylori* strategy was associated with a two-thirds reduction in subsequent endoscopies performed within 1 year. [218] In one controlled trial, fewer patients were satisfied with the *H pylori* test and treat strategy, [219] but other data suggest that this is not of major clinical concern. [218] In contrast, *H pylori* testing and referral of positive patients for endoscopy (versus acid suppression) was not cost-effective, and the outcomes were similar. [220] Thus, the *H pylori* test and treat strategy for dyspeptic patients younger than 45 years, with the use of office-based serology testing, appears to be safe and may result in lower costs than initial endoscopy with similar clinical outcomes. [218] For success, the test and treat strategy relies on a sufficient background prevalence of *H pylori* and peptic ulcer disease; the approach will fail if the prevalence of *H pylori* infection falls below 10% in the population. [215]

Endoscopy remains the gold standard approach and can be more cost-effective than other management strategies if the cost is below U.S. $500.00. [221]

Therapeutic Approach in Documented Nonulcer Dyspepsia

Placebo Several pharmacological treatments are now available for patients with NUD (Table 30-4), and most have been compared to placebo in controlled trials. The response to placebo in NUD ranges from 30% to 60%. [222], [223] This placebo response, however, may not reflect a nonspecific effect of treatment but rather spontaneous regression of the disease. Indeed, the course of NUD typically is characterized by relapsing and remitting symptoms, but during a 1-year period, more than 70% of patients will continue to have symptoms. [36], [224], [225] A major issue in the treatment of patients with NUD is improvement of the long-term outcome; unfortunately, most trials have focused on short-term results only. Moreover, the quality of the trials in this field has been highly variable. A systematic review in 1996 of all published trials concluded that most suffered from important weaknesses in study design and execution, such as failure to include validated outcome measures. [222]

First Line
Histamine H_2 receptor blocker*
Proton pump inhibitor
Anti-*Helicobacter pylori* therapy
Second Line
Tricyclic antidepressants (low dose)
Prokinetic (cisapride,† metoclopramide, domperidone)
5-HT_1 agonists (e.g., buspirone, sumatriptan)
Simethicone
Sucralfate
Uncertain or Unknown Efficacy
Promising new visceral analgesics
Serotonin type 3 (e.g., ondansetron, alosetron) or type 4 receptor antagonists
Promising new prokinetics
New serotonin type 4 agonists (e.g., tegaserod)
Gonadotropin-releasing hormone analogs
Somatostatin analogs
Unlikely to Be Beneficial
Antacids
Prostaglandin analogs
Motilinomimetics
Anticholinergics/antispasmodics
Nitrates

* Commonly prescribed, but trial data equivocal (although metaanalyses positive).

† Restricted access because of rare life-threatening cardiac side effects (long QT syndrome).

TABLE 30-4 Pharmacological Treatment for Nonulcer Dyspepsia

Antacids/Simethicone Randomized controlled studies have failed to show a significant benefit of antacid use over placebo. [226], [227], [228] and [229] Antacids are probably most effective in those with undiagnosed gastroesophageal reflux. [230] The potential role of gas retention and air swallowing in NUD was indirectly examined in one study, which observed a significantly greater improvement in symptoms during treatment with simethicone than with cisapride, [231] but more data are needed.

Acid Inhibition Controlled trials testing histamine H_2 receptor antagonists have yielded conflicting results. [222], [226], [228], [230], [232] These might be explained in part by the relatively small sample sizes, and thus inadequate study power, and the heterogeneity of the study populations. Metaanalysis suggested a benefit of histamine H_2 receptor antagonists over placebo, but only selected trials could be included, and studies with patients who had GERD symptoms were not specifically excluded. [232], [233], [234] and [235] The efficacy of the selective muscarinic blocking agent pirenzepine (still available in many countries, but not the United States) is questionable. [230], [233] It is notable that this drug has a lower acid-inhibitory potency than histamine H_2 blockers and has anticholinergic effects that decrease lower esophageal sphincter pressure. Reports have described greater relief of symptoms during treatment with a PPI than with placebo or ranitidine in uninvestigated dyspepsia [236] and NUD. [237] Several large placebo-controlled studies [238], [239] and [240] have provided further evidence that inhibition of acid secretion with a PPI relieves symptoms in a subgroup of patients with NUD. However, the therapeutic gain over placebo is modest and may in part be explained by contamination of the trials with GERD patients. Moreover, those with dysmotility-like dyspepsia may not respond better to a PPI than to placebo (Fig. 30-5). [239] A greater response to PPI than to placebo was observed in *H pylori*–infected patients in one trial, [237] but this was not confirmed by other, methodologically sound trials. [239], [240]

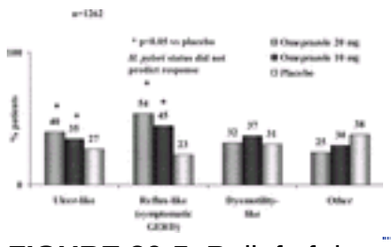

FIGURE 30-5. Relief of dyspepsia with a proton pump inhibitor versus placebo in nonulcer dyspepsia according to dyspepsia subgroup. *Ulcer-like,* predominant epigastric pain; *dysmotility-like,* nonpainful predominant symptom; *reflux-like,* symptomatic reflux. (Data from ref. [239].)

Cytoprotection Sucralfate stimulates mucosal prostaglandin synthesis and release of cytokines and has cytoprotective properties in experimental models. [241] One placebo-controlled study [242] reported significant improvement of symptoms in 77% of patients treated with sucralfate, versus 56% of patients in the placebo group. An open study that directly compared sucralfate with ranitidine [243] noted superior symptom improvement in patients treated with sucralfate. Other studies of NUD failed to detect a significant effect of sucralfate compared with placebo. [243], [244] Whether this drug is truly superior to placebo remains uncertain. Rebamipide, a cytoprotective drug available in the Far East, was not superior to placebo in NUD. [223] Misoprostol is also not efficacious in NUD. [245]

Prokinetic Drugs Two classes of prokinetic drugs have been widely used in NUD: the dopaminergic receptor blockers metoclopramide and domperidone, and cisapride, a 5-HT_4 agonist that also has 5-HT_3 antagonist actions. Indeed, many studies have demonstrated significant improvement of symptoms during treatment with these prokinetic agents, [84], [230], [233], [246], [247] although not all the results have been positive. [246], [248], [249] A comparison of cimetidine and cisapride demonstrated a significantly better response to therapy with the prokinetics, [250] and a trial comparing cisapride to metoclopramide favored cisapride. [251] There is reasonable evidence that cisapride is superior to placebo in NUD, [230], [233] but many of the published trials have had major design limitations, and a funnel plot suggested that the apparent beneficial effects of prokinetics may be the result of publication bias. [235] Large uncontrolled studies suggest that up to 80% of patients with uninvestigated dyspepsia respond to cisapride, but patients responding do not appear to be characterized by a specific symptom profile. [252] The mechanisms by which prokinetics relieve symptoms is uncertain; alterations of gastric emptying have not been convincingly directly linked to an improvement of symptoms, but few studies have assessed gastric emptying before and after therapy. [246] The safety profile of the current prokinetics limits their use. Metoclopramide can induce side effects through its central antidopaminergic mechanism; these include dystonic reactions, drowsiness, increased prolactin levels, and rarely, particularly in the elderly, tardive dyskinesia. Cisapride has been withdrawn because of QT prolongation and life-threatening arrhythmias (including sudden death). Domperidone, available in Canada and Mexico, also increases prolactin levels and may be proarrhythmic. Tegaserod, a well-tolerated partial 5-HT_4 agonist with no cardiac toxicity, is being tested in NUD. Erythromycin, a motilin agonist that initiates phase III activity in the antrum and small bowel, [253] has not been evaluated in NUD, and the drug often induces nausea. A new motilinomimetic, ABT-229, was not superior to placebo in NUD patients with or without delayed gastric emptying, and higher doses caused worse outcomes. [254] The cholecystokinin receptor antagonists loxiglumide and dexloxiglumide accelerate gastric emptying and may be of benefit in NUD, but development of cholelithiasis is a potential limitation. [255], [256]

Fundus-Relaxing Drugs It has been suggested that fundic relaxation following a meal is impaired in a subset of patients with NUD who have early satiety. [96] Hence, drugs that relax the gastric fundus may have therapeutic potential in the syndrome. [97], [257] Administration of the 5-HT_{1A} receptor agonist sumatriptan has been shown to induce relaxation of the gastric fundus, permitting larger intragastric volumes to accumulate before thresholds for perception or discomfort are reached. [97] Other fundus-relaxing drugs include buspirone (a 5-HT_{1A} agonist), clonidine (an a-adrenergic agonist), and citalopram (a selective serotonin reuptake inhibitor). Randomized controlled trials are needed to confirm beneficial treatment effects, but preliminary data are promising. [257], [258]

Treatment Targeting *H pylori* Most of the earlier studies of the effects of *H pylori* eradication in patients with NUD had important methodological limitations (i.e., lack of randomization or lack of a placebo control, application of inadequate outcome measures, failure to eradicate infection, lack of adequate follow-up after therapy, or inadequate study power). [147], [259] More recent studies have assessed the long-term outcome of eradication therapy, but the results have been mixed despite greater methodological rigor. [260], [261], [262], [263], [264], [265], [266], [267], [268], [269], [270], [271] and [272] Three large, properly designed studies failed to demonstrate a significant benefit of *H pylori* eradication, [269], [271], [272] whereas one observed a small but statistically significant benefit of *H pylori* eradication (Fig. 30-6). [270] However, the latter study showed a remarkably low placebo response rate, perhaps because peptic ulcers actually developed in a high proportion of those with persistent *H pylori* infection during follow-up. Although follow-up endoscopy was not routinely undertaken, a duodenal ulcer was found in four of six symptomatic patients who failed *H pylori* eradication and underwent endoscopy. [270] The metaanalyses have produced contradictory conclusions; one suggested a small but significant effect of *H pylori* eradication therapy in NUD, [273] whereas another failed to detect a relevant benefit but was less comprehensive. [274] Long-term outcome studies are not available.

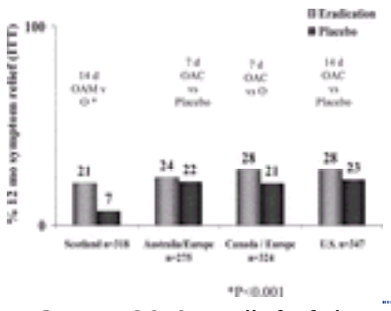

FIGURE 30-6. Relief of dyspepsia at 12 months after randomization to *H pylori* eradication therapy or a control group (omeprazole or placebo in four high-quality trials). *A,* amoxicillin; *C,* clarithromycin; *M,* metronidazole; *O,* omeprazole. (Data from the following trials: Scotland, [270] Australia/Europe, [271] Canada/Europe, [269] and the United States. [272])

H pylori eradication should be considered for patients with NUD. Perhaps 1 in 15 will be cured with just one course of therapy, [273] but most will not respond. The disadvantages include side effects of therapy, a lack of improvement after treatment, which is conducive to patient dissatisfaction, and the potential (albeit controversial) small risk for the development of esophagitis after treatment. These issues must be explained to and considered by any patient contemplating eradication therapy for NUD. [275]

Visceral Analgesic Drugs Agents that reduce gut visceral hypersensitivity are currently being assessed in NUD and IBS. [276] In two double-blinded, placebo-controlled trials, fedotozine (a peripheral ?-receptor agonist) was superior to placebo in relieving epigastric pain and nausea and registered better global symptom scores. [277], [278] Although the effect was statistically significant, the differences were numerically small, and the drug is no longer under study. In recent years, the potential role of serotonin receptors in modulating gut sensation has been recognized. [276], [279] 5-HT $_3$ receptors appear to play a role in the altered nociception that occurs during gastrointestinal inflammation, [280] and 5-HT $_3$ antagonists may modulate peripheral gut sensory nerve transmission. [281] One study observed a reduction of concomitant dyspepsia symptoms in patients with IBS during treatment with ondansetron, a 5-HT $_3$ antagonist. [282] Another trial, with alosetron, demonstrated a modest benefit in NUD over placebo. [283] However, the development of severe constipation and ischemic colitis in patients with IBS led to the withdrawal of alosetron. Leuprolide acetate, a gonadotropin-releasing hormone analog, has been shown in two randomized placebo-controlled trials to improve symptom scores during a 3-month period in women with severe functional GI complaints. [284], [285] Its mode of action is unknown, but ovarian hormone release is reduced, and such hormones may modulate GI smooth muscle function. The role of the gonadotropin-releasing hormone analogs remains to be established; moreover, their inconvenient mode of administration as well as significant side effects resulting from chemical castration is likely to restrict their application substantially.

Antispasmodic Drugs Because pyloric or antral spasm has not been documented in NUD, it is not surprising that neither dicyclomine nor trimebutine was more efficacious than placebo in small crossover studies. [230] Anticholinergic agents combined with a benzodiazepine have not been tested in NUD; such drugs should be used sparingly if at all because of their potential for habituation.

Antinauseant Drugs Antinausea drugs include the prokinetics and 5-HT $_3$ antagonists (discussed above) and the antihistamines and phenothiazines (e.g., prochlorperazine). Benzodiazepines may also help reduce nausea by their sedative effects. Although the therapeutic gain with nonspecific antinauseants has not been formally tested in patients with NUD, the histamine H $_1$ antagonists dimenhydrinate and cyclizine decrease gastric dysrhythmias and may be worth a trial. [286]

Antidepressant Drugs The data on the efficacy of antidepressants and other psychotropic agents in NUD are very limited. However, in one placebo-controlled trial, the antidepressant mianserin (a combined 5-HT $_2$, 5-HT $_3$, and a $_2$-adrenergic antagonist) was superior to placebo in a heterogeneous group of patients with functional gastrointestinal disorders. [287] Furthermore, the tricyclic antidepressant imipramine at a relatively low dose of 50 mg daily was clearly superior to placebo in patients with noncardiac chest pain. [288] A study of seven patients reported significantly less severe symptoms after 4 weeks of treatment with amitriptyline, but interestingly, the symptom improvement during treatment was not associated with a normalization of the perceptual responses to gastric distention. [289] In a metaanalysis, tricyclic antidepressants were of benefit in IBS (including NUD). [290] There are as yet no data on the effects of selective serotonin reuptake inhibitors (SSRIs) in patients with NUD. [291] Regarding the use of antidepressants, it is important to note that tricyclics (but not the SSRIs) appear to be effective at doses well below those currently used for the treatment of depressive disorders, and they appear to be effective in NUD, even in patients without obvious psychiatric abnormalities. In patients with symptoms resistant to standard therapy, a trial of a low-dose tricyclic antidepressant or an SSRI is justified.

Complementary and Alternative Medicine Limited placebo-controlled trials have reported improvement of symptoms in NUD and IBS during treatment with herbal preparations. [292], [293] The findings of these studies must be confirmed independently. Major problems of alternative medicines are related to a lack of standardization of the compounds, the inclusion of multiple potentially active extracts, and lack of knowledge about their long-term safety and precise mechanisms of action. Acupuncture and acupressure can reduce chemotherapy-induced and postoperative nausea and vomiting but have not been tested in NUD. [2] The value of gastric pacing in NUD is also unclear. [2]

Psychological Therapies Few controlled trials have evaluated the efficacy of psychological therapies in NUD. Haug and colleagues [294] observed significantly greater improvement of symptoms in patients treated with cognitive psychotherapy than in a control group that received no specific treatment. In a randomized trial of patients with NUD receiving either psychodynamic interpersonal psychotherapy or supportive therapy, small but significant advantages were observed in the psychotherapy arm compared with the controls in both the gastroenterologists' and the patients' total symptom scores; 1 year after treatment, the symptom scores were similar (Fig 30-7). [295] Another trial suggested that hypnotherapy may be efficacious in NUD. [296] However, trials of psychological treatment have generally been suboptimal, and direct comparisons with pharmacological therapies (including cost-effectiveness data) are lacking. [297]

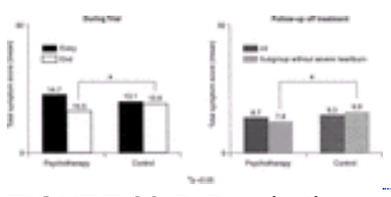

FIGURE 30-7. Psychotherapy in functional dyspepsia: results from a randomized controlled trial of 95 patients who failed conventional therapy at the end of treatment and 12 months later. Psychotherapy was superior to supportive therapy at the end of treatment, but scores 1 year after therapy were similar (except in a subgroup analysis of those without severe heartburn). (From ref. [295].)

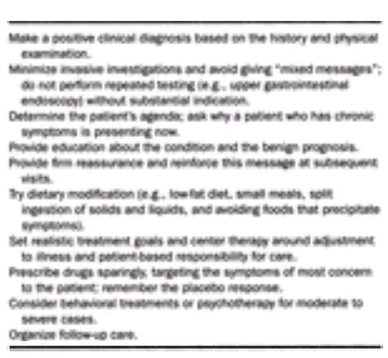
Treatment of Aerophagy Treatment of excessive unconscious air swallowing is difficult. Stress reduction (e.g., relaxation or cognitive-behavioral therapy) and dietary modifications (avoiding sucking on sweets or chewing gum, eating slowly, encouraging small swallows at meal time, and avoiding carbonated beverages) sometimes may help. Simethicone and activated charcoal are not of established value. Tranquilizers or prokinetics sometimes may be of benefit. [1]

Management Guidelines

A management algorithm is shown in Figure 30-8.

FIGURE 30-8. Management algorithm for patients presenting with new-onset dyspepsia who have not been previously evaluated. *GERD,* gastroesophageal reflux disease; *Hp, Helicobacter pylori*; *IBS,* irritable bowel syndrome; *NSAID,* nonsteroidal antiinflammatory drug; *PPI,* proton pump inhibitor. (Modified from American Gastroenterological Association medical position statement. Gastroenterology 1998;114:579.)

Patients with New-Onset (Uninvestigated) Dyspepsia The medical history is important. If typical reflux symptoms, heartburn, or acid regurgitation is the predominant complaint, a diagnosis of gastroesophageal reflux rather than NUD should be made and appropriate treatment instituted. A short trial of high-dose PPI therapy may be useful as a diagnostic test. Similarly, if bowel dysfunction is linked directly to the epigastric pain or discomfort, a diagnosis of IBS should lead to reassurance, explanation, dietary modification, and selective pharmacological therapy or stress management, which constitute the mainstay of treatment for patients with IBS (see Chapter 86). Patients older than 45 years with unexplained dyspepsia and those with alarm symptoms should undergo prompt upper GI endoscopy, and management should be based on the findings. In patients without alarm features, management should depend on the degree of uncertainty that both patient and physician are willing to accept. The use of a locally validated noninvasive *H pylori* test and initiation of anti– *H pylori* treatment in infected subjects constitute a reasonable initial approach, unless *H pylori* is uncommon in the background population. [215] Anti– *H pylori* therapy should relieve symptoms in most patients with peptic ulcer and substantially eliminate the ulcer diathesis. Noninvasive testing, however, may result in an inappropriate number of subjects being unnecessarily treated. Moreover, symptoms may recur even in patients cured of peptic ulcer disease [212]; reflux disease, for example, may be unmasked in some patients. [275] No agent has been approved by the Food and Drug Administration for use in NUD. If empiric therapy is considered in the uninvestigated patient who is negative for *H pylori,* the major first-line drugs remain histamine H_2 blockers or, increasingly, PPIs. Patients who fail to respond within 8 weeks or who rapidly relapse may require endoscopy. In patients with documented NUD after endoscopy, a positive clinical diagnosis and firm reassurance remain the key steps in management, especially if the principles of management outlined in Table 30-5 are adhered to.



Make a positive clinical diagnosis based on the history and physical examination.
Minimize invasive investigations and avoid giving "mixed messages"; do not perform repeated testing (e.g., upper gastrointestinal endoscopy) without substantial indication.
Determine the patient's agenda; ask why a patient who has chronic symptoms is presenting now.
Provide education about the condition and the benign prognosis.
Provide firm reassurance and reinforce this message at subsequent visits.
Try dietary modification (e.g., low-fat diet, small meals, split ingestion of solids and liquids, and avoiding foods that precipitate symptoms).
Set realistic treatment goals and center therapy around adjustment to illness and patient-based responsibility for care.
Prescribe drugs sparingly, targeting the symptoms of most concern to the patient; remember the placebo response.
Consider behavioral treatments or psychotherapy for moderate to severe cases.
Organize follow-up care.

Peyrin-Biroulet L.

TABLE 30-5 Management Principles in Nonulcer Dyspepsia

Patients Who Fail to Respond Failure to respond to treatment may raise two questions: Is the diagnosis of NUD correct, and was the treatment chosen appropriate? If a diagnostic workup has not been done, testing (including upper GI endoscopy and occasionally other investigations as outlined above) should be performed. Once structural lesions have been definitely excluded, treatment should be adjusted (e.g., a short trial of high-dose acid suppression, with dose reduction if successful). Combination therapy (e.g., an antispasmodic plus an antisecretory agent) or simethicone or sucralfate is not established as beneficial but may be worth a trial. If early satiety is a prominent symptom, consider a trial of buspirone, sumatriptan, or clonidine. Another option is to initiate low-dose treatment with a tricyclic antidepressant or an SSRI in full dose. With such therapy, it is important to inform the patient about potential side effects to ensure compliance.

Patients with Recurrent or Relapsing Symptoms In most patients, symptoms improve after an initial course of treatment. Because NUD and related functional disorders are characterized by chronic relapsing symptoms, it is highly probable that symptoms will recur after the end of treatment. No long-term strategy has been tested adequately in these patients. If symptoms have responded initially to a specific treatment but recur (usually after weeks or even months), another course of the same treatment is justified. Some patients have frequent symptom relapses that affect their quality of life, and in such cases, intermittent drug treatment can be helpful. Alternatively, consider prescribing on-demand therapy (self-directed therapy only when symptoms develop); this strategy has not been tested in NUD but is successful in nonerosive GERD. [298] The patient also should be advised to return for reevaluation if the pattern of symptoms changes or the symptoms do not respond to therapy.

Intractable Nonulcer Dyspepsia A small group of patients, usually concentrated at tertiary referral centers, do not respond to therapeutic measures, and their quality of life is affected considerably. [299] Rare causes of dyspepsia must be excluded, but once a comprehensive evaluation has been undertaken, repeated diagnostic testing should be avoided because this undermines patient confidence. The patient with intractable symptoms can benefit from an ongoing relationship with a physician who demonstrates a commitment to the patient's well-being. The physician should set realistic goals. For example, although improvement in functional status and quality of life is usually possible, complete symptom relief is usually not, and the patient must be made aware of the realities. The patient should be encouraged to become a partner in all management decisions. Regular brief visits will provide useful psychosocial support. It is important to rule out comorbid major psychiatric disease. Specific behavioral therapy (e.g., psychotherapy or cognitive-behavioral therapy) can reduce anxiety levels and encourage health-promoting behaviors in patients with intractable complaints, giving them greater control over their symptoms. In patients who require continuous therapy, drug holidays should be used to confirm that the therapy is still of value.

PROGNOSIS

A firm diagnosis of NUD after endoscopy is generally a safe one; few patients are later found to have an ulcer or other structural disease. Population-based studies have demonstrated a considerable turnover of subjects with abdominal symptoms; up to one third may lose their symptoms for years. [36] Patients with NUD seen at tertiary centers represent a subgroup with relatively intractable symptoms, and in this group, evidence that spontaneous remissions occur is only anecdotal. Whereas treatment may relieve symptoms for a limited period, cure cannot be expected.

CHAPTER 31

Ray E. Clouse

APPROACH TO THE PATIENT WITH DYSPHAGIA OR ODYNOPHAGIA

SYMPTOM DEFINITIONS

Dysphagia and odynophagia are common complaints that usually merit prompt investigation and management. The term *dysphagia,* derived from Greek roots, literally means to “eat badly” or “with difficulty.” In common practice, dysphagia has become an umbrella term encompassing the sensations (short of pain) associated with abnormal bolus transit from mouth to stomach, as well as other signs or symptoms accompanying abnormal transit. In a sense, dysphagia has syndromic overtones. The term *odynophagia,* from Greek roots meaning to “eat with pain,” refers more specifically to pain during any component of the swallowing process. The two terms are not synonymous and may reflect different underlying disorders, yet they have overlapping differential diagnoses.

Dysphagia is represented by two principal types: oropharyngeal dysphagia and esophageal dysphagia. The differentiation is more than semantic; this convenient segregation reflects differences in pathophysiology, differential diagnosis, investigation, and management. For the purposes of this chapter, the initiation of swallowing is considered to occur at the pharyngeal phase, when velopharyngeal closure, laryngeal elevation and closure, opening of the upper esophageal sphincter, tongue loading and pulsion, and pharyngeal clearance result from highly coordinated central events. Bolus preparation and movement during the oral phases of swallowing are discussed in less detail. Abnormalities preceding the pharyngeal phase can be detected by bedside evaluation and radiologic imaging, if required.

Patients with *oropharyngeal dysphagia* typically describe food lodging or sticking in the back of the throat or cervical esophageal region and accurately localize the site of swallowing error as demonstrated radiologically. [1] The symptom may be perceived as low as the level of the suprasternal notch, but oropharyngeal dysphagia rarely is referred to more distal locations. [2] Hesitation with swallowing, frequent and repeated attempts at swallowing, and throat clearing may accompany the dysphagia. Not only does the patient sense or demonstrate abnormal pharyngoesophageal transit, but tracheobronchial aspiration may occur (with coughing or choking during or after swallows), reflecting a failure of coordination of bolus transit and laryngeal closure. Related symptoms include a rough or dysphonic voice after eating; hoarseness may reflect the underlying neuromuscular disorder. Poor neuromuscular coordination or high pressure within the bolus from mechanical obstruction can disrupt protection of the nasopharynx and result in nasopharyngeal regurgitation. Consequently, the spectrum of symptoms associated with oropharyngeal dysphagia can be dramatic and severe. These associated symptoms often are absent, and characteristics of the dysphagia itself commonly are used for establishing the diagnosis. Such characteristics, besides location of the symptom, include onset of dysphagia within 1 second of swallowing, inability to swallow any liquids or solids once a food bolus is lodged, and expectoration rather than regurgitation of the bolus. [3]

Esophageal dysphagia reflects disorders of the esophageal body and esophagogastric junction as well as anatomic areas abutting these regions, such as the gastric cardia and mediastinum. Obstructing lesions in the proximal esophageal body can produce symptoms mimicking oropharyngeal dysphagia; more distal processes produce esophageal dysphagia with distinctive characteristics. The most telling feature differentiating esophageal from oropharyngeal dysphagia is the sensing of abnormal bolus transit at a retrosternal site. Unfortunately, distal esophageal processes can refer symptoms proximally to the cervical esophageal region and suprasternal notch in nearly 30% of cases. [2], [4], [5] This fact alone is responsible for most of the clinical difficulty in segregating types of dysphagia by means of historical features. In contrast to oropharyngeal dysphagia, esophageal dysphagia is not immediate, typically is not associated with tracheobronchial aspiration, and is more likely to allow further ingestion of liquids to alleviate the dysphagia sensation. Additionally, patients with esophageal dysphagia are more likely to try repeated or forceful swallowing to dislodge or advance food boluses. When bolus impactions occur, patients with esophageal dysphagia regurgitate foamy, bland secretions or ingested liquids that have been retained above the impacted food.

Both dysphagia and odynophagia occur with or shortly after the initiation of a swallow. Pain and discomfort in the neck or retrosternal region present between swallows occur through different mechanisms and reflect an expanded differential diagnosis. The *globus sensation,* a sense that something is lodged continuously in the throat, must be differentiated from dysphagia or odynophagia before an improper investigation is undertaken. [6] The globus sensation typically is sensed in the midline at the laryngeal level, but it can lateralize in as many as 20% of patients. [7] The sensation classically is reported as a “lump in the throat,” but a feeling that a foreign body, sharp object, or food particle is lodged also is a compatible description. [6] Most notably, the globus sensation does not interfere with swallowing; although 20% of patients note something abnormal during food swallows, the original symptom abates during the process. [8] Globus may accompany a variety of disorders also producing dysphagia, such as gastroesophageal reflux disease (GERD) and distal esophageal motility disorders, and up to 45% of the general population may have intermittent symptoms resembling globus. [9] The persistent symptom, however, most often reflects a functional gastrointestinal disorder. [10], [11] A summary of the features differentiating functional globus from oropharyngeal dysphagia is provided in Table 31-1. *Xerostomia* also can be confused with oropharyngeal dysphagia if the medical history is not obtained carefully.

TABLE 31-1 Features Distinguishing Oropharyngeal Dysphagia and Functional Globus

MECHANISMS RESPONSIBLE FOR SYMPTOM PRODUCTION

Sensory information from the pharyngeal and very proximal esophageal regions is carried by cranial nerves V, X, and XI. Both discomfort and pain can be elicited from the posterior pharynx and hypopharynx by noxious mucosal stimulation. Pressure on the pharyngeal surfaces is readily perceived, and minor alterations in bolus pressure dynamics may be sufficient to trigger dysphagia in some conditions. Proximal esophageal distention just distal to the upper esophageal sphincter results in upper sphincter hypertonicity, but symptoms have not been linked directly to this motor response. [12] The nasal and tracheobronchial symptoms associated with the oropharyngeal dysphagia syndrome are provoked by noxious stimulation of cranial nerve V innervating nasal passages and activation of the cough reflex, respectively. Little is known about the perception of oropharyngeal dysphagia in patients with normal swallowing dynamics.

Esophageal sensation occurs via vagal and spinal afferent pathways modulating motor activity, although noxious stimuli are carried almost exclusively through spinal afferents. [13], [14] At the spinal level, afferents from each esophageal region are widely distributed and overlap innervation from other organs, such as the heart. [15] This convergence of input contributes to the similarity in the presentations of esophageal and cardiac symptoms. [16] Fine perception of abnormal bolus movement normally is not present in the esophageal body, and retention of a nonobstructing solid bolus in the distal esophagus is poorly recognized. [17] As further evidence, capsule-shaped pH transmitters can be attached to the distal esophageal mucosa and produce few symptoms. [18] Consequently, factors beyond bolus retention must be necessary for dysphagia in most cases. Distention of esophageal regions proximal to a lodged bolus may be one important factor. Increased intraesophageal pressure encountered in achalasia before the esophagus becomes markedly dilated may stimulate the sensation of dysphagia. [19] Motility alterations in the esophageal body in response to transient obstruction also may have a sensory counterpart, but it is difficult to attribute dysphagia to specific esophageal body motor patterns alone. Both hypomotility and hypermotility ranging from mild to marked are encountered during the routine manometric evaluation of patients not reporting dysphagia at the time of the investigation. The exception is the achalasia patient, whose intraesophageal pressure is increased during the study. [19], [20]

In some instances, esophageal dysphagia is produced by mucosal damage. Mucosal inflammation may be partly responsible for the nonobstructive dysphagia seen with GERD. [21] Similarly, mucosal damage overlying strictures or tumors may augment sensation through the effects of inflammation on visceral sensitivity. [22] In patients who have rings or strictures with little or no associated mucosal injury, dysphagia occurs when food boluses completely and transiently obstruct. Symptoms are corroborated radiographically with brief impaction of radiopaque solid boluses in the narrowed region. Symptoms are alleviated with dissolution of the bolus, and dysphagia is not reproduced with liquids or solids that pass freely. Consequently, with many esophageal abnormalities producing dysphagia, symptoms do not occur until the lumenal diameter is less than 13 mm, a size at which conventional food boluses (e.g., bread, meat) become at least transiently impacted. [23] Persistent obstruction from food bolus impactions produces additional uncomfortable symptoms arising from proximal esophageal regions.

Sensitivity to these mechanisms varies considerably from patient to patient. The variation in part may reflect hypersensitivity or hyposensitivity accompanying specific conditions or disease processes. [13] Aging, connective tissue diseases (particularly those overlapping with scleroderma), diabetes, and other conditions associated with esophageal hypomotility are associated with hyposensitivity to experimental stimuli, such as acid instillation and balloon distention. [13], [24], [25] and [26] Although it has not been established, such patients may be poorly sensitive to transit abnormalities and underreport dysphagia. Likewise, as the esophagus develops secondary hypomotility and dilates in response to chronic obstruction, the sense of dysphagia dissipates in compensation. In contrast, hypersensitivity to acid and distention stimuli in the functional esophageal syndromes and spastic disorders may help explain the esophageal dysphagia occurring in these conditions. [27], [28] A sense of abnormal transit is reported, yet convincing evidence of an obstructing lesion or mucosal injury often is lacking. [6]

Odynophagia only occasionally accompanies dysphagia and appears to occur through separate mechanisms. With the exception of pain accompanying acute esophageal obstruction, odynophagia requires afferent input not resulting from abnormal bolus transit alone. In the esophageal phase of swallowing, odynophagia may require direct invasion or irritation of intramural nerves, as occurs with malignancies or deep inflammatory processes. Sensory stimulation resulting from some forms of esophagitis also can be responsible for this symptom (e.g., caustic or infectious esophagitis).

DIFFERENTIAL DIAGNOSES

The approach to the patient with dysphagia or odynophagia begins with a consideration of the differential diagnoses. Diagnostic possibilities vary markedly between oropharyngeal and esophageal dysphagia, further emphasizing the importance of characterizing dysphagia by type.

Oropharyngeal Dysphagia

Symptoms of abnormal transit in any part of the gut can be produced by disturbed motor function or by structural lesions. Oropharyngeal dysphagia is a manifestation of motor dysfunction rather than of structural disease specific to the oropharynx or its neighboring structures in a ratio of approximately 4:1. [29] Motor dysfunction results from a variety of neurological, striated muscle, and systemic disorders (Table 31-2). Structural lesions are less commonly responsible for oropharyngeal dysphagia, but they can be intrinsic or extrinsic to the pharyngoesophageal region—indenting, invading, or encircling the structures. Many of the responsible disorders listed in Table 31-2 have additional manifestations that assist in limiting the differential diagnosis.

TABLE 31-2 Causes of Oropharyngeal Dysphagia

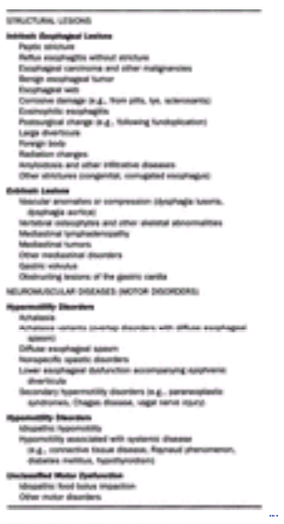
Despite the range of diagnostic possibilities, most patients presenting with oropharyngeal dysphagia have had a cerebrovascular accident—Parkinson disease being responsible for much of the remainder. [30] Either clinical or videofluoroscopic evidence of swallowing dysfunction can be found in more than 50% of patients after acute stroke, and chest infection (implying tracheobronchial aspiration) occurs in nearly a third. [31], [32], [33] and [34] Dysphagia typically dissipates during the 6 months following the event, but symptoms and signs of oropharyngeal dysfunction persist in 10% to 15% and gradually appear in a small percentage initially free of dysphagia. [35] Laryngopharyngeal sensory deficits accompanying motor dysfunction and thereby impairing the appropriate response to aspiration may be factors in the poor outcome of stroke victims with oropharyngeal dysphagia. [36] Some patients with documented swallowing dysfunction have none of the classical symptoms of oropharyngeal dysphagia, and pulmonary or nutritional complications dominate because of diminished sensation from nerve damage or a reduced level of consciousness.

Pharyngolaryngeal cancer surgery is an important structural cause of difficult oropharyngeal dysphagia. Symptoms result from obstruction at the pharyngoesophageal junction or reduced tongue driving force, in the case of resection at the base of the tongue. [37] The importance of the tongue as a pressure generator in the process of swallowing is highlighted in these patients. The esophagus is anchored at the cricoid cartilage, and osteophytes at the fourth through seventh cervical vertebrae can sufficiently impede normal physiology to produce dysphagia. [38] This degree of advanced osteophyte formation is typical of diffuse idiopathic skeletal hyperostosis, or Forestier disease, a disorder that affects 12% of the population and can manifest clinically as dysphagia. [39], [40] Careful documentation with videofluoroscopy of the role of skeletal abnormalities in altering swallowing dynamics and bolus transit is necessary before the symptom can be attributed to this condition. [39], [41]

Esophageal Dysphagia

In contrast to oropharyngeal dysphagia, wherein motility disorders top the differential diagnosis, esophageal dysphagia is most often caused by structural lesions. As with oropharyngeal dysphagia, the range of possibilities is broad (Table 31-3). Esophageal strictures associated with GERD are common, increase in frequency with age, and are not associated with a significant heartburn history in 25% of patients. [42] Nonobstructive dysphagia is reported to some degree in nearly a third of patients

undergoing preoperative evaluation for antireflux surgery. [43] Distal esophageal rings, particularly mucosal rings at the squamocolumnar junction (Schatzki rings), also are common; some indentation of the barium column is detected at this level during radiographic evaluation in as many as 14% of individuals. [23], [44] Malignant esophageal neoplasms typically present with dysphagia. The diagnosis of esophageal adenocarcinoma is rapidly increasing, particularly in middle-aged white men. Other structural explanations listed in the table are uncommon; vascular anomalies are rare. [45], [46] and [47] The ability of proximal gastric disorders (e.g., gastric volvulus) to produce this presentation should be considered in the appropriate setting when the cause of esophageal dysphagia is unclear. [48]



STRUCTURAL LESIONS
Intrinsic Esophageal Lesions
Peptic stricture
Reflux esophagitis without stricture
Esophageal carcinoma and other malignancies
Benign esophageal tumor
Esophageal web
Corrosive damage (e.g., from pills, lye, sclerosants)
Eosinophilic esophagitis
Postsurgical change (e.g., following fundoplication)
Lesga diverticula
Foreign body
Radiation changes
Amyloidosis and other infiltrative diseases
Other strictures (congenital, corrugated esophagus)
Extrinsic Lesions
Vascular anomalies or compression (dysphagia lusoria, dysphagia aortica)
Vertebral osteophytes and other skeletal abnormalities
Mediastinal lymphadenopathy
Mediastinal tumors
Other mediastinal disorders
Gastric volvulus
Obstructing lesions of the gastric cardia
NEUROMUSCULAR DISEASES (MOTOR DISORDERS)
Hypermotility Disorders
Achalasia
Achalasia variants (overlap disorders with diffuse esophageal spasm)
Diffuse esophageal spasm
Nonspecific spastic disorders
Lower esophageal dysfunction accompanying epiphrenic diverticula
Secondary hypermotility disorders (e.g., paraneoplastic syndromes, Chagas disease, vagal nerve injury)
Hypomotility Disorders
Idiopathic hypomotility
Hypomotility associated with systemic disease (e.g., connective tissue disease, Raynaud phenomenon, diabetes mellitus, hypothyroidism)
Unclassified Motor Dysfunction
Idiopathic food bolus impaction
Other motor disorders

TABLE 31-3 Causes of Esophageal Dysphagia

Esophageal dysmotility can be classified in two predominant categories, hypomotility and hypermotility (Fig. 31-1). [13], [27] Hypomotility of either the smooth muscle esophageal body (also called *ineffective esophageal motility* [49], [50]) or lower esophageal sphincter (LES) represents failure of the contractile mechanisms through neurogenic or myogenic processes. The outcome is feeble or absent esophageal peristalsis and loss of resting tone in the LES. Systemic disorders associated with hypomotility have been mentioned previously, but most hypomotility is idiopathic. [51], [52] These processes predispose to GERD, and impairment of bolus clearance often is conspicuous. Nevertheless, dysphagia typically is not attributed to hypomotility, even when severe, without careful exclusion of structural explanations that include reflux esophagitis.

FIGURE 31-1. A method of categorizing dysmotility in the distal esophagus and lower esophageal sphincter (LES) based on the principal type of motor dysfunction. Hypermotility may result from inhibitory nerve deficiency or an imbalance between inhibitory and contractile influences. Some patients have a mixture of hypomotility and hypermotility features and cannot be classified solely into one branch of the scheme. (From ref. [27].)

In contrast, hypermotility results from deficient inhibitory nerve influence. [53] Nonpropulsive, uncoordinated contractions disrupt bolus transit; incomplete LES relaxation produces functional obstruction and dysphagia. Consequently, achalasia, diffuse esophageal spasm, and related patterns of severe hypermotility belong in the differential diagnosis (see Fig. 31-1). [13], [27] A variety of nonspecific spastic disorders, including high-amplitude peristaltic contractions (“nutcracker esophagus”), other vigorous contraction wave abnormalities, and isolated hypermotility features of the LES (increased basal pressure or incomplete relaxation), have been found in patients with otherwise unexplained dysphagia. [27], [54], [55] Transit disruption is less common with these findings, and dysphagia may be related to the hypersensitivity that often accompanies the disorders. [27] Spastic disorders typically have no underlying pathological explanation, and their presence neither precludes a functional diagnosis for the presenting complaints nor excludes the possibility that associated psychological factors are contributing to symptoms. [6], [27], [56], [57] Nevertheless, because esophageal dysphagia can represent serious structural explanations, a thorough investigation is required before a functional diagnosis is assigned. Less classified motor abnormalities also have been reported (e.g., lower esophageal muscular rings). [44], [58]

Odynophagia

Pain during the oropharyngeal phase of swallowing has been attributed to a variety of processes, particularly malignancies, foreign body ingestion, and mucosal inflammation and ulceration. Oropharyngeal odynophagia may indicate deeper invasion of sensory nerves or extrinsic structures, and a careful evaluation for structural lesions should be undertaken. Odynophagia occurring later in the swallowing process most commonly is caused by specific types of mucosal damage: caustic injury and infection. It also accompanies tumors and other processes associated with deep mural injury, such as radiation damage, deep peptic ulceration, and idiopathic ulcer (in immunosuppressed patients)—processes more likely to produce chronic or persistent symptoms. Odynophagia rarely results from uncomplicated reflux disease. Chest pain is reported by up to half of patients with achalasia at some period during the course of the illness. [59], [60] This pain typically is not directly related to swallowing, runs a course separate from that of dysphagia, is influenced in a limited fashion by treatment for achalasia, and usually is not confused with purer presentations of odynophagia. [60]

The most common causes of acute esophageal odynophagia in immunocompetent subjects are infection with *Candida albicans* or herpes simplex virus and pill-induced injury. [61], [62] Esophagitis with other infectious causes can have a similar presentation; these include bacteria, fungi, cytomegalovirus, and varicella-zoster virus. [63] In fact, the entire range of opportunistic esophageal infections encountered in immunosuppressed individuals may be responsible for this symptom (see Chapter 61). Whereas herpes simplex virus is the most common viral cause of esophagitis in immunocompetent subjects, cytomegalovirus is a more common offender in the immunosuppressed. [64] In this latter group, however, *Candida* remains the most common cause of infectious esophagitis. [63] Pill-induced caustic injury to the esophagus has been associated with more than 70 medications, including aspirin, potassium supplements, tetracycline, ferrous sulfate, quinidine, alendronate, and nonsteroidal antiinflammatory drugs. [62], [65], [66] Tissue injury to the esophagus from caustic medications can be deep, and odynophagia that becomes severe over 3 to 4 days is a common component of the presentation (see Chapter 63).

APPROACH TO THE PATIENT WITH DYSPHAGIA

Dysphagia is a common clinical problem. Nearly one in five subjects older than 50 years of age describes the symptom in epidemiologic surveys. [67], [68] Dysphagia is the second most common indication for endoscopy in the United States, [69] and a mechanism responsible for the symptom can be found in most cases, even those initially labeled psychogenic. [70], [71] Consequently, a systematic approach to the differential diagnosis that results in a well-planned investigation is important. A variety of algorithms have been recommended, but each depends on a carefully obtained medical history as the initial step. [72], [73], [74] and [75] The physical examination is more likely to provide useful information in patients with oropharyngeal dysphagia.

The Medical History and Physical Examination of the Patient with Dysphagia

Establishing the type of dysphagia, either oropharyngeal or esophageal, is of primary importance. Differentiating historical features have been outlined in the opening paragraphs of this chapter. Patients with oropharyngeal dysphagia may have symptoms of oral dysfunction that further support the diagnosis (e.g., poor handling of the food bolus with drooling and spillage, piecemeal swallowing, and dysarthria). When the type of dysphagia remains unclear, discerning the outcome after the ingestion of specific foods or liquids can be helpful. Asking for a description of recent meals and resulting symptoms may keep the patient focused on the specific events of swallowing. Additionally, offering the patient a small quantity of water to swallow during the interview may clarify the medical history through first-hand observation.

Certain features in the medical history can help narrow the differential diagnosis of oropharyngeal dysphagia. Proximal dysphagia for solid foods alone is suggestive of restrictive processes, such as strictures, webs, and tumors. Odynophagia in association with oropharyngeal dysphagia also has implications (see below). A sudden onset of symptoms suggests an acute neurological insult, and a short but progressive course typifies malignancy, whereas an insidious presentation reflects inflammatory processes, such as myopathies. Delayed expectoration is suggestive of a retaining pharyngeal diverticulum.

Historical evidence and physical findings corroborating a neurological, muscular, or systemic disease should be sought when oropharyngeal dysphagia is suspected, with the large differential diagnosis outlined in Table 31-2 taken into account. Inquiries should be made about any past history of cerebrovascular accidents or neurological disability that preceded or accompanied dysphagia, and a comprehensive neurological examination is essential (for a further elaboration of the physical findings accompanying oropharyngeal dysphagia of neurological causes, see Chapter 59). The medication history should be reviewed for agents that can either cause or exacerbate dysphagic symptoms, including those with adverse neuromuscular effects (e.g., sedatives, narcotics, muscle relaxants) or that cause xerostomia (e.g., anticholinergics, antihistamines, antidepressants). [76] The neck should be examined for masses, thyromegaly, or lymphadenopathy. The presence and degree of tracheobronchial aspiration (including aspiration pneumonia) should be extracted from the history to determine the severity of the dysphagia syndrome. Likewise, limitations of food intake and their impact on weight should be assessed based on the available information. Determining the need and urgency for nonoral feeding is a primary component of the oropharyngeal dysphagia evaluation. [77]

If esophageal dysphagia is suspected, the medical history can help narrow the differential diagnosis and direct the investigative approach. [78] Features or established diagnoses of systemic disorders associated with esophageal dysphagia (see Table 31-3), particularly connective tissue diseases and Raynaud phenomenon, should be sought. [79], [80] Historical aspects favoring structural diagnoses lead to early endoscopy, biopsy, and dilation. Features favoring a motility disorder may indicate barium radiography and manometry, either early in the evaluation or for completion of the workup. Although presentations of the disorders listed in Table 31-2 are quite variable from patient to patient, certain features of common diagnoses can be helpful in establishing the initial impression (Fig. 31-2). [78] Structural esophageal lesions typically result in dysphagia after ingestion of solid foods but not after liquids alone. Bulky foods of larger caliber, such as meats and bread, more reliably reproduce the symptom. In contrast, precipitants of dysphagia from esophageal motility disorders are more variable.

FIGURE 31-2. Features of the medical history that help focus the differential diagnosis of common causes of esophageal dysphagia.

At least 95% of patients with achalasia have dysphagia, but the course frequently is nonprogressive. [59] This may leave a large number of patients without a diagnosis, an undesirable outcome in light of the treatment options available for this disorder. Because heartburn also can be reported by achalasia patients, some are followed for years with a presumptive diagnosis of GERD before the correct diagnosis is established. [81], [82] Conventional investigative tests such as endoscopy or barium radiography were not helpful prospectively in as many as a third of achalasia patients eventually presenting for manometry, with which the diagnosis was secured. [82] A careful medical history can enhance suspicion of achalasia. Dysphagia typically is for liquids as well as solid foods, although one third of patients may report dysphagia for solid foods alone. Regurgitation of esophageal contents is reported by 60% to 90% of subjects, a feature that can be differentiated from gastroesophageal regurgitation by the bland, nonacidic characteristics of the regurgitated material and the ability of the patient to reswallow the bolus without aversion. Maneuvers performed by the patient during meals to increase intraesophageal pressure and enhance esophageal emptying frequently can be elicited (e.g., straightening the back, raising the arms above the head, and forceful swallowing). [13], [59] The ability to retain and regurgitate large quantities of ingested food or foamy saliva from a dilated esophagus also characterizes achalasia.

Approach to the Patient with Oropharyngeal Dysphagia

The evaluation of oropharyngeal dysphagia has three important components: (1) determining the structural and physiological abnormalities responsible for symptoms, (2) discovering the underlying disorders (including neurological and muscular disorders) responsible for these findings, and (3) evaluating the safety and practicality of oral feeding. [77], [83] The second of these is largely determined from the history and physical findings, as described previously, in conjunction with appropriate laboratory investigation. The other two are most commonly and effectively accomplished by following a protocol for videofluoroscopic swallowing evaluation—referred to as a *modified barium swallow*. [1], [73], [84] The examination is structured to detect and analyze functional impairment of the swallowing mechanism and provides evidence for each of the four categories of oropharyngeal swallowing dysfunction: (1) inability to initiate or excessive delay in the initiation of pharyngeal swallowing, (2) aspiration of the ingestant, (3) nasopharyngeal regurgitation, and (4) residue of ingestant within the pharyngeal cavity after swallowing. [73] Because it is widely available, characterizes swallowing dysfunction well, and can examine the short-term effects of swallowing interventions (compensatory or corrective swallowing strategies, diet modifications), the modified barium swallow presently is considered the most applicable initial test in patients with a compatible presentation. [71]

Videofluoroscopy also can detect structural abnormalities potentially responsible for symptoms, but it is less satisfactory than endoscopic evaluation. Transnasal fiberoptic pharyngoscopy/laryngoscopy (nasoendoscopy) is the optimal method for the direct inspection of mucosal surfaces in the region, and when combined with a swallowing assessment protocol, it provides at least indirect evidence of all categories of swallowing dysfunction except possibly nasopharyngeal regurgitation. [85], [86], [87] and [88] Nasoendoscopy or indirect laryngoscopy typically is performed early in the evaluation of oropharyngeal dysphagia and is especially important if the symptoms suggest a mucosal lesion. Nasoendoscopy also can be used to assess sensory function by applying pulses of air to the mucosa innervated by the superior laryngeal nerve and evoking glottic adduction. [88], [89] and [90] Thus, in centers where nasoendoscopy combined with a swallowing assessment can be performed, the approach may provide much of the same information as videofluoroscopy and has the unique advantages of portability, repeatability without radiation exposure, and technical success in patients with a reduced sensorium. [87], [91], [92] This approach is less effective than videofluoroscopy in determining the cause of swallowing dysfunction, and nasoendosopy does not obviate the need for videofluoroscopy in all subjects—providing merit to each test in clinical practice. In contrast, manometry has contributed little to the routine evaluation of the patient with oropharyngeal dysphagia despite its capacity to quantify contraction strength. [93], [94] It is complementary to videofluoroscopy when the two are performed concurrently, and this approach or possibly even manometry alone can be helpful in differentiating obstruction at the level of the upper esophageal sphincter from weak pharyngeal propulsive forces. [95], [96]

In the systematic assessment of patients with oropharyngeal dysphagia, a specific diagnosis of the underlying cause will be detected in many instances, and the mechanism responsible for the symptom will be detected in nearly all. [71] Important therapeutic recommendations can arise from the evaluation, even when a specific diagnosis is not established. The algorithm shown in Figure 31-3 demonstrates how these outcomes are accomplished. If local lesions are detected by direct mucosal visualization, further study of swallowing mechanisms may not be required. The videofluoroscopic examination may uncover rings, webs, strictures, posterior pharyngeal diverticula, or tumors that are amenable to specific surgical or endoscopic interventions. However, oropharyngeal dysphagia should not be attributed to

some common radiologic findings without careful consideration of alternative explanations. Such findings include cricopharyngeal bars, prominent vertebral osteophytes, and lateral pharyngeal diverticula. The first of these is found in more than 15% of evaluated dysphagic patients, correlates poorly with the symptomatic state, and precludes detection of the true explanation for dysphagia in the vast majority if alternative explanations are not pursued. [97], [98] Some authorities believe that dysphagia should not be attributed to a cricopharyngeal bar unless no other explanation is available and coexistent pharyngeal dysfunction is present to accentuate the importance of the bar. [73] The swallowing evaluation also may reveal disorders responsive to cricopharyngeal myotomy or other, less invasive approaches that reduce upper sphincter pressure. [99] The success of myotomy is greatest in situations in which the cricopharyngeal opening is limited but pharyngeal function is preserved. [100] Examples include Zenker diverticulum, primary cricopharyngeal dysfunction, and postcricoid stenosis. Success in neurogenic dysphagia can reach 60%, but predictors of response are not readily available. [73] Reviews of this treatment in relation to specific underlying disorders should be consulted. [73], [101], [102]

FIGURE 31-3. Approach to the patient with oropharyngeal dysphagia. The modified barium swallow (videofluoroscopic swallowing evaluation) is a key element in the evaluation of most patients, providing useful information for both diagnosis and management. Nasoendoscopy accompanied by a swallowing protocol is an alternative method to reach similar end points. *EGD,* esophagogastroduodenoscopy. (Adapted from ref. [73].)

The detection of aspiration during videofluoroscopy is a predictor of pneumonia risk and future hospitalization, although false negatives also are common with this test in patients with stroke and other forms of neurogenic dysphagia. [33], [103], [104] Aspiration during nasoendoscopic swallowing assessment has similar predictive value, as does bedside evaluation examining oxygen desaturation with water swallowing. [91], [105] As a minimum, compensatory swallowing strategies are required, and oral feeding may be prohibited. If aspiration is demonstrated with all food consistencies despite compensatory maneuvers, nonoral feeding typically is instituted; this approach may not prevent subsequent aspiration pneumonia, however. [106], [107] and [108] The videofluoroscopic study or nasoendoscopy with swallowing evaluation also is used to direct specific compensatory or corrective swallowing strategies that may reduce the risk for aspiration. [91] Swallowing therapy techniques that have been employed are listed in Table 31-4, and of these, the evidence most strongly favors the efficacy of diet modifications in reducing the risk for subsequent aspiration pneumonia. [73], [109] Although many of the maneuvers listed in Table 31-4 affect the occurrence of aspiration during a brief swallowing evaluation, such as the modified barium swallow, their actual ability to reduce subsequent morbidity is less established. Nevertheless, potential benefits at low cost drive the recommendation for their use. [73], [77], [110] After all, the first-year mortality caused by aspiration pneumonia in patients with stroke approaches 20%, and subsequent annual mortality from this complication remains 10% to 15%. [30]

CATEGORY OF TECHNIQUE	SPECIFIC EXAMPLE
Swallowing maneuver	Supraglottic swallow
	Supersupraglottic swallow
	Effortful swallow
	Mendelsohn maneuver
Postural adjustment	Head tilt
	Chin tuck
	Head rotation
	Head rotation with extrinsic pressure on thyroid cartilage
	Lying on side, elevation
Facilitatory techniques	Strengthening exercises
	Biofeedback
	Thermal stimulation
	Gustatory stimulation
Dietary modification	Thickening liquids
	Thinning liquids

From refs. 1, 161, 162; table adapted from ref. 73.

TABLE 31-4 The Spectrum of Swallowing Therapy Techniques

Other interventions for oropharyngeal dysphagia depend on the specific diagnosis that is derived from this initial evaluation, and the reader should refer to discussions of the disorders at other locations in this text. Certain combinations of videofluoroscopic findings can help determine the underlying disorder correctly. [30] Some systemic or neurological disorders that produce oropharyngeal dysphagia can be treated, and treatment results in a reduction of swallowing symptoms, although this response is not uniform. For example, reduction in dysphagia from Parkinson disease is inconsistent with levodopa treatment despite improvement in other neurological features of the illness. [111], [112]

Approach to the Patient with Esophageal Dysphagia

Endoscopy has become the primary tool for investigating esophageal dysphagia, not only for its accuracy, but also for its therapeutic potential. [113] Barium radiography once was recommended as the initial test in all patients with dysphagia, but the popularity of this approach is waning. The safety of endoscopy, its high diagnostic yield, and its provision for mucosal biopsy and dilation of commonly encountered structural lesions favor its use over radiographic screening when esophageal dysphagia is suspected. Likewise, barium radiography is not sufficiently sensitive to the range of tissue damage resulting from GERD, a common cause of esophageal complaints. [114] Barium radiography with fluoroscopy does retain a role in the evaluation of esophageal dysphagia (Fig. 31-4). Strictures that can be overlooked at endoscopy, particularly those having a lumenal diameter of more than 10 mm, are detectable. [115], [116] and [117] Barium studies are more sensitive than endoscopy to distal rings and to achalasia and can fully establish the level of dysphagia if symptoms are reproduced during the study. [115], [118] The sensitivity of barium radiography for motor disorders and structural lesions is further enhanced if barium-impregnated solids are employed. [119], [120] Although the barium swallow may be required ultimately to establish a diagnosis, its benefits do not overshadow the utility of endoscopy in the typical case, and the American Gastroenterological Association in a practice guideline has recommended endoscopy as the initial investigative test in esophageal dysphagia. [113] Achalasia suspected from the outset is an exception. [113] Compatible radiographic findings can be confirmed by manometry, and endoscopy can be reserved until the treatment plan for newly established achalasia is designed (see Chapter 59).

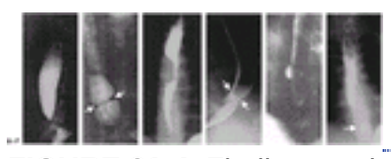


FIGURE 31-4. Findings on barium radiography can help establish the diagnosis in patients with esophageal dysphagia and unrevealing endoscopy. **A:** Absent peristalsis and barium retention above a closed lower sphincter suggest achalasia in this patient with minimal esophageal dilation. **B:** A lower esophageal (Schatzki) ring (*arrows*) causing intermittent dysphagia was not appreciated at endoscopy. **C:** Findings at endoscopy were completely normal in this patient with mediastinal adenopathy producing extrinsic compression of the midesophagus. **D:** A stricture with a lumenal diameter of 12 mm (*arrows*) was not appreciated on the initial

endoscopic evaluation. **E:** This epiphrenic diverticulum was overlooked at endoscopy, yet once discovered, it prompted manometric evaluation, and a severe distal spastic disorder was discovered. **F:** Endoscopy was unrevealing in a patient with a medical history confusing for oropharyngeal versus esophageal dysphagia, but a barium pill (12.5-mm diameter) lodged at the esophagogastric junction (*arrow*) reproduced symptoms and led to reevaluation and dilation.

Once structural explanations for esophageal dysphagia are excluded, the evaluation should proceed with esophageal manometry. [121] Manometry is sensitive to conventional hypermotility and hypomotility disorders but will not establish a conclusive diagnosis or have treatment implications in all patients with otherwise unexplained esophageal dysphagia—even when food bolus impactions have occurred. Nevertheless, manometry is indicated if only to detect the reasonable proportion of patients with achalasia who would be overlooked by other investigative tests. [82], [121] Manometry occasionally fails to establish the diagnosis of achalasia because of seemingly normal LES relaxation, arguably the most important diagnostic criterion; this artifactual error can be reduced if a sleeve sensor is used, if an averaged value is recorded for LES relaxation nadir pressure, or if high-resolution manometric methods are employed. [122], [123] and [124] Manometry also will detect spastic disorders, all of which may be associated with dysphagia. [27] Although the demonstration of a direct relationship between symptoms and these motor disorders often is less convincing, the findings may help direct therapeutic trials. [27]

Dysphagia to some degree is the most common complication of antireflux surgery, its occurrence predicted with any reliability only by the presence of preoperative dysphagia. [125] The technical skill of the surgeon is more important than the degree of existing hypomotility in producing this adverse outcome. [126] Early symptoms, even when severe (<5% of patients), may dissipate within 8 to 12 weeks after the operation with resolution of local inflammatory response. [127], [128] Periodic dilation with a 16- to 20-mm-diameter bougie or balloon may suffice. [128] Persistent dysphagia, occurring to at least mild degree in up to 24% of patients, [129] most often is related to suboptimal surgical technique. In cases requiring reoperation, transdiaphragmatic migration of the fundoplication, slipped or misplaced fundoplication, twisted fundoplication, or residual paraesophageal hernia can explain this symptom. [130] Physiological failure of the procedure with persistent reflux is reported following a small percentage of operations, and reflux-related explanations for dysphagia must be excluded.

Multivariate analysis of manometric features in postoperative dysphagia suggests that both the degree of obstruction and the degree of peristaltic competency participate in symptom production, both delaying transit across the lower sphincter. [131], [132] The last may be of particular importance. [132] In practice, endoscopy and barium videofluoroscopy are the principal evaluation tools, the emphasis being on detecting an abnormal postoperative appearance and on evaluating the degree of retention. [133] Manometry has a limited role unless used in conjunction with videofluoroscopy or high-resolution techniques, procedures that remain primarily investigational. [19], [132] Dilation for persistent dysphagia is effective in half of subjects when the fundoplication is intact; evidence of slipped fundoplication predicts a poor response, and reoperation can be avoided in some with pneumatic dilation. [129], [134]

Patients with suspected esophageal dysphagia who remain without a diagnosis following endoscopy, barium radiography, and esophageal manometry probably benefit little from additional testing. Ambulatory pH monitoring to define nonobstructive dysphagia from endoscopy-negative reflux disease may have a role that could be obviated with a therapeutic trial of antireflux treatment. When additional evaluation is desired, further efforts at reproducing dysphagia during videofluoroscopy with the use of barium-impregnated liquids or solids might be considered. Reproducing dysphagia in the absence of a transit abnormality helps establish a functional diagnosis and provides alternative therapeutic approaches.

Symptomatic Treatment of Dysphagia

A thorough investigation of dysphagia reveals a diagnosis in a large proportion of cases, and therapy is directed at the specific diagnosis. In some instances, empiric interventions are employed for both diagnosis and treatment. A specific explanation for oropharyngeal dysphagia cannot be found in a reasonable minority of patients with this syndrome, even when abnormalities in swallowing physiology are defined by the modified barium swallow. Compensatory or corrective swallowing strategies and dietary manipulations are the principal empiric interventions (outlined above), aimed at reducing aspiration risk and avoiding nonoral feeding. The empiric use of botulinum toxin or cricopharyngeal myotomy is ill-advised without convincing evidence of restrictive obstruction at the upper sphincter level because of the potential for added morbidity. [100], [135], [136] Botulinum toxin injection can reduce all indicators of swallowing dysfunction in appropriately selected patients, but the response durability still is being evaluated. [137] Balloon catheter or Savary dilation of the cricopharyngeus more recently has been reported for patients with primary cricopharyngeal dysfunction, and the morbidity associated with the approach is low. [138], [139] There is no evidence that this less invasive approach is effective for oropharyngeal dysphagia unless similar selection criteria are used as for the other techniques. Other empiric therapies are not offered routinely in the management of oropharyngeal dysphagia.

For esophageal dysphagia, empiric strategies include dilation, antireflux therapy, and treatments aimed at sensorimotor dysfunction. The value and safety of dilation with a large-caliber (=14-mm-diameter) bougie or balloon when no abnormality is detected at endoscopy or by videofluoroscopy can be debated, as dilation is not without risk. [113], [140] Dysphagia was significantly reduced in a small group of patients with no obstructive lesions who were randomized to dilation with a 16.7-mm Maloney dilator versus those who underwent dilation with a small-caliber (8.7-mm-diameter) bougie. [141] The benefits were sustained in 80% of initial responders. Empiric use of an 18-mm dilator in an uncontrolled study of patients with esophageal dysphagia for solid foods yet negative endoscopic and radiologic evaluations produced immediate response in 95% of subjects and a sustained response for nearly 2 years in 68% of the initial responders. [142] By comparison, dysphagia resolved in only 12% of the patients with dysphagia for both solid foods and liquids when managed in the same fashion. Although the risk for perforation or significant bleeding approximates 1% when standard dilation is performed for a variety of benign indications, [140] the complication rate is undoubtedly lower when empiric dilation is performed. These findings suggest that dilation with a large-caliber dilator is reasonable as a therapeutic trial in patients with significant symptoms from unexplained esophageal dysphagia, especially if the clinical presentation resembles that of a stricture or ring.

Antireflux therapy, specifically antisecretory therapy, probably is offered to many patients with investigation-negative esophageal dysphagia, but a reasonable estimate of its efficacy is unknown. Esophageal prokinetics, such as the 5-HT $_4$ agonist cisapride, increase midesophageal contraction pressures and could conceivably benefit patients with unexplained esophageal dysphagia, [143] but serviceable reports to support this possibility are unavailable. Glucagon inhibits LES contraction and has been used acutely in patients with idiopathic food bolus impactions. The limited benefits of this approach may be related to the negative effects of glucagon on esophageal body motility. [144] Smooth muscle relaxants, such as nitrates, calcium channel blockers, and peppermint oil, effectively decrease LES pressure or reduce distal esophageal contraction amplitudes and improve transit symptoms in achalasia. [145], [146], [147] and [148] These agents have been tried in patients with spastic disorders with limited benefit. Most trials have studied effects on pain rather than dysphagia, and benefits may be better for transit symptoms. Antidepressants, particularly the tricyclic antidepressants, reduce many unexplained esophageal symptoms, including those associated with spastic esophageal disorders. [6], [27] These agents may alter esophageal sensation or the central processing of visceral afferent input. [6], [149], [150] Although most measured outcomes from antidepressant use have focused on pain, the general cluster of esophageal symptoms, including dysphagia, appears to be responsive when the symptoms represent a functional esophageal disorder. [151], [152] Antidepressants typically are reserved for patients without significant transit delay, with no other explanation for dysphagia on thorough investigation, and in whom enhanced tolerance to the symptom would be a suitable outcome.

APPROACH TO THE PATIENT WITH ODYNOPHAGIA

Odynophagia is an uncommon medical problem in comparison with dysphagia, but its presence usually indicates a significant underlying and definable disorder. The symptom can range from dull discomfort to intense pain that interferes with any swallowing attempt.

The Medical History and Physical Examination of the Patient with Odynophagia

Determining the presence of odynophagia is important in all patients who present with esophageal complaints. The most important characteristic is the temporal relationship of pain to swallowing: early, in the oropharyngeal phase, or later, in the esophageal phase. The characteristics used in differentiating types of dysphagia are helpful in making this determination. When odynophagia is described as accompanying the oropharyngeal phase, malignancy, foreign body, infection, or other causes of inflammation become more likely. Exposure histories that predispose the patient to mucosal irritation, such as prior radiation therapy or corrosive ingestion, should be elicited. A history of tobacco and alcohol use, risk factors for head and neck malignancy, should be recorded, and the physical examination should proceed with these diagnostic possibilities in mind. Nasoendoscopy or indirect laryngoscopy is essential when odynophagia is present in this swallowing phase.

When odynophagia originates in esophageal locations, the medical history should focus on factors predisposing the patient to opportunistic infection, including systemic illnesses, immunosuppressive treatment, and antibiotic use. Symptoms of esophageal disease develop in as many as 30% to 40% of patients with acquired

immunodeficiency syndrome (AIDS) at some point in the course of the illness. [153] The possibility of foreign body ingestion and the use of caustic medications should be carefully explored. Ingestion of pills at bedtime, while reclining, or with little water intake should be determined. The use of caustic medications may not readily be recalled, for example, by young patients using doxycycline for acne management. A list of caustic medications that have been associated with esophageal damage is provided in Chapter 63.

Investigation of Odynophagia

Whether oropharyngeal or esophageal in location, odynophagia typically requires a careful examination of the muscosal surface with direct visualization and biopsy if necessary. This is accomplished with nasoendoscopy, indirect laryngoscopy, or esophagoscopy depending on the nature of the odynophagia. The investigation is altered if a foreign body is the suspected cause of oropharyngeal odynophagia. [154], [155] and [156] Plain films of the neck with soft tissue technique, including lateral views, are indicated, but many foreign bodies are radiolucent (see Chapter 63). Sharp or pointed objects lodged at or above the cricopharyngeus should be removed with use of the laryngoscope or by someone experienced in direct laryngoscopy. [154], [155] Blunt objects retained in this region, such as coins, mandate protection of the airway during removal. In some instances, the foreign body may have become dislodged, leaving residual odynophagia from laceration. Nevertheless, inspection is required, and oral contrast studies (which can interfere with direct mucosal inspection) are not indicated in managing oropharyngeal or esophageal foreign bodies. [154]

The approach to esophageal odynophagia depends on a combination of the acuity of the presentation, the suspected diagnosis, and the setting (immunocompetent or immunocompromised host). Chronic processes often indicate invasion of or extension of mucosa-based processes into the deep esophageal layers. Both radiologic imaging (chest radiography, computed tomography, barium radiography) and endoscopy may be needed to establish the diagnosis and the extent of esophageal or mediastinal involvement. In immunocompetent patients with this presentation, initial testing is driven by the suspected diagnosis, and algorithms defining the most expedient or cost-effective approach are not available.

Provided a history of foreign body ingestion is absent, acute esophageal odynophagia in immunocompetent subjects most often reflects infectious or pill-induced esophageal damage. Evidence for either can be detected by endoscopy or barium radiography, and despite the recognized radiologic patterns of mucosal damage in these forms of esophagitis, [157], [158] endoscopy is more sensitive to mucosal damage. Because of the high incidence of esophageal complaints and disease in AIDS patients, management approaches have been studied. *Candida* infection is very common, and empiric treatment of AIDS patients with oral thrush is recommended. [63], [159] Further investigation, including biopsy, is delayed until a poor response to empiric treatment is determined. Barium radiography is not worthwhile if diagnostic testing is required. A randomized trial comparing barium radiography with endoscopy in symptomatic patients with human immunodeficiency virus infection confirmed the higher sensitivity and utility of the latter technique. [160] In general, cultures taken at the time of endoscopy are less useful than histological study of biopsy specimens because of their inability to differentiate colonization from the pathogen responsible for infection, their lower sensitivity, and the delay in obtaining results. Treatment for odynophagia in this setting is directed by the specific diagnosis (see Chapter 61).

CHAPTER 32

Donald O. Castell and Philip O. Katz

APPROACH TO THE PATIENT WITH UNEXPLAINED NONCARDIAC CHEST PAIN

Recurring unexplained chest pain located in the substernal area in patients in whom a cardiac etiology has been excluded has been a source of clinical uncertainty for more than a century. Although this phenomenon is frequently called *noncardiac pain*, we prefer the term *unexplained chest pain (UCP)* because even patients with normal coronary arteries occasionally have evidence of myocardial ischemia (i.e., microvascular angina or “syndrome X”). [1], [2] Unexplained retrosternal chest pain is a problem commonly seen in clinical practice, causing anxiety for both patient and physician because of the uncertainty regarding possible underlying coronary artery disease.

UCP remains a difficult and challenging problem for the gastroenterologist because these patients are often referred for evaluation of the esophagus once a cardiac etiology has been excluded. Up to 13% of people in a survey of U.S. households reported chest pain of unknown cause, and up to 44% of these respondents were seeking care for their pain. [3] The differential diagnosis centers around ruling out cardiac disease because this is the most serious cause of pain. The importance of excluding a cardiac etiology is reinforced by a study showing that when cardiac disease is ruled out, almost no cardiac fatalities occur during 7-year follow-up. [4] Coronary artery and esophageal disease coexist; 50% of patients with proven angina secondary to coronary atherosclerosis may have gastroesophageal reflux disease (GERD). [5] Establishing an esophageal origin of chest pain with a high degree of certainty results in less frequent pain and fewer visits to the physician. [6]

After coronary artery disease has been ruled out, a search for an esophageal cause, particularly GERD, should be aggressively pursued because this condition is eminently treatable. GERD can be diagnosed with a therapeutic or diagnostic trial of medication or by an abnormal finding on ambulatory pH monitoring with symptom correlation. The yield of endoscopy is low in the evaluation of chest pain compared to that in typical reflux disease. [7] If GERD is excluded, the presence of an esophageal motility abnormality or visceral hypersensitivity can be pursued with manometry and provocative testing with edrophonium [8] or balloon distention. [9]

OVERVIEW AND SCOPE OF THE PROBLEM

Approximately 1,500,000 million patients per year undergo cardiac catheterization for recurring chest pain. [10] In 30% or more of these, the findings are normal. Many other patients undergo a noninvasive cardiac evaluation that is considered to exclude coronary artery disease, leaving at least 450,000 new patients with unexplained chest pain seen annually in the United States. Our own review of 635 patients seen during a 10-month period in the emergency department at the Graduate Hospital (Philadelphia) with substernal chest pain showed that for 75%, the final diagnosis was noncardiac (Fig. 32-1). A recent multicenter review of more than 10,000 patients evaluated in emergency departments for substernal chest pain revealed that 55% had no evidence of any cardiac abnormality when followed for at least 6 months. [11] The cost of caring for these patients is exceptionally high, likely to be more than $2 billion a year.

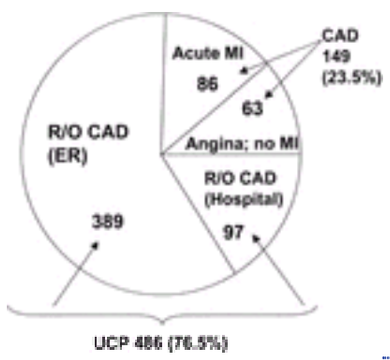

FIGURE 32-1. Discharge diagnosis for 635 consecutive patients seen in the emergency department at Graduate Hospital for acute substernal chest pain. Coronary artery disease (*CAD*) was excluded (*R/O*) in 76.5% either in the emergency department evaluation or after brief admission to the hospital. The diagnosis of these patients remains unexplained chest pain (*UCP*). CAD was diagnosed in the hospital as either acute myocardial infarction (*MI*) or persistent angina in a total of 23.5% of the patients.

DIFFERENTIAL DIAGNOSIS

The clinical history often does not easily differentiate coronary from esophageal pain in patients with UCP. In one study, 25% of patients with chest pain evaluated by a cardiologist were given a mistaken diagnosis of coronary artery disease based on the clinical presentation compared to the final angiographic findings. [12] Gastroesophageal reflux can be induced during exercise [13] and present with exertional chest pain that mimics angina pectoris. In fact, changes in ST-T waves indistinguishable from those of coronary chest pain may be seen during exercise testing.

If the history shows other key esophageal symptoms, such as heartburn, dysphagia, regurgitation, and odynophagia, an esophageal cause should be suspected. Heartburn is strongly predictive of GERD in these patients. Features that also suggest an esophageal origin include pain lasting more than 2 to 3 hours, pain that does not radiate laterally, meal-related pain, pain that is relieved by antacids, or pain that awakens the patient. None of these are 100% specific, however, and further evaluation is always required; cardiac disease must be ruled out.

The absence of esophageal symptoms decreases the likelihood of an esophageal cause of chest pain. However, up to 50% of patients who prove to have coronary artery disease will have one or more symptoms typical of esophageal disease, and many will have concurrent coronary artery disease and GERD. [14] It is well-known that mitral valve prolapse and esophageal abnormalities can coexist. As many as 80% of patients with mitral valve prolapse have been shown to have abnormal esophageal motility, often consistent with that seen in diffuse esophageal spasm. [15]

Because the history cannot definitely differentiate cardiac from esophageal pain, a cardiac evaluation is recommended as the initial approach in patients with unexplained substernal pain. The nature of the workup is determined by numerous factors, including the patient’s age and other cardiac risk factors. Although a noninvasive workup with an electrocardiogram, exercise testing, and perhaps echocardiography may be reasonable in ruling out cardiac disease in a person younger than 40 years, coronary angiography remains the gold standard. It is our policy to leave this decision to cardiac specialists.

Patients with normal coronary arteries or insignificant (<50%) lumenal narrowing have an excellent prognosis; a mortality rate of less than 1% from cardiac causes was seen in a 7-year follow-up study. [4] A normal angiogram allows the physician to reassure patients that their recurring chest pains are not life threatening. Despite

this reassurance, most patients continue to have recurring chest pain and a compromised lifestyle, and many continue to believe that they have heart disease even after coronary artery disease has been ruled out. [16]

The direct cost of caring for these patients was estimated to be $4,000 per patient or more than $300 million dollars per year in 1988. [8] It is likely that the actual number of patients and the total costs have become considerably higher as health care costs have risen dramatically. Because of this continued morbidity and cost, providing an accurate and thorough diagnosis is important in caring for these patients.

Despite the difficulty of determining the cause from the history, evaluation after cardiac disease has been excluded is centered on ruling out diseases of the upper gastrointestinal tract, biliary tree, chest wall, and pulmonary system that may present with chest pain.

DIAGNOSTIC APPROACH

A suggested diagnostic approach is illustrated in Figure 32-2. Peptic ulcer disease and biliary tract disease rarely present with chest pian. Therefore, the frequency of these abnormalities in patients with UCP is quite low. In the absence of a history of coexistent right upper quadrant pain after meals (biliary colic), jaundice, or classical ulcerlike dyspepsia, a routine evaluation for these diseases is not warranted. As noted above, endoscopy is usually unrevealing.

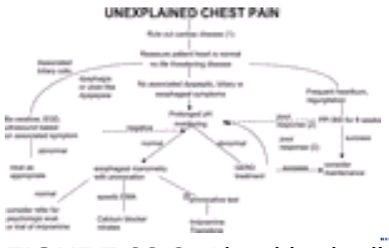

FIGURE 32-2. Algorithmic diagnostic/therapeutic approach to patients with unexplained chest pain. Initial evaluation to exclude cardiac disease depends on (1) testing individualized for each patient, usually in consultation with a cardiologist, and (2) ambulatory pH monitoring with esophageal and intragastric electrodes while the patient is on therapy to evaluate the adequacy of gastric acid suppression and control of reflux before an alternative diagnosis is considered. Spastic esophageal motility abnormality (*EMA*) includes diffuse esophageal spasm, nutcracker esophagus, and hypertensive lower esophageal sphincter. A therapeutic trial with a proton pump inhibitor (*PPI*) given twice daily before meals (*BID*) is particularly indicated in patients with associated symptoms suggesting gastroesophageal reflux disease (*GERD*).

If the patient has dysphagia, consider esophagogastroduodenoscopy/barium swallow as the initial approach to evaluate the patient for stricture, mass lesion, or other obstruction, such as a ring. If heartburn is present, the diagnosis of GERD is more likely, and early endoscopy is probably not necessary because endoscopic esophagitis is seen in fewer than 10% of patients with UCP. [7] In the absence of dysphagia, endoscopy may not be useful. Abdominal ultrasonography should be used judiciously in these patients because biliary disease may be asymptomatic (i.e., “silent” gallstones), and experience suggests that in the absence of biliary colic, cholecystectomy is not helpful.

Ambulatory pH monitoring is the preferred technique to document reflux and demonstrate a correlation between reflux and symptoms. Several investigations have shown that up to 50% of patients with UCP have an acid-induced esophageal abnormality: increased esophageal acid exposure, a high symptom index (a correlation of episodes of reflux with chest pain) without an increased frequency of reflux (the “acid-sensitive” esophagus), or exercise-induced reflux. [5] /SUP>, [7] , [17] Studies have suggested that a trial of proton pump inhibitor (PPI) therapy may be more appropriate (see section “ Treatment”).

Esophageal manometry has been used extensively in the evaluation of patients with UPC; however, its usefulness is debated. About 25% to 30% of patients have some type of abnormal esophageal motility during stationary manometry (Fig. 32-3) [18] ; however, few have pain during motility testing, so that it is difficult to establish the clinical significance of an abnormal test result. We believe it is useful to attempt to induce the patient’s pain by using various provocative tests. The most widely used approach is to induce pain with an intravenous injection of edrophonium (Tensilon; Hoffman-LaRoche, Nutley, New Jersey). In up to 30% of patients, typical chest pain is reproduced when a 10-mg dose is given by intravenous push. [8] The high-amplitude contractions induced by edrophonium are not the cause of the pain; normal subjects do not have pain, and the patients’ motility changes are the same as those in normal subjects. This suggests heightened visceral sensitivity (of unknown cause). Edrophonium does not cause coronary artery narrowing or affect the pulmonary circulation; therefore, when the pain is reproduced, the esophagus can be implicated as the source. The sensitivity of provocative testing may be increased by using progressive balloon distention. Patients with UCP have a lower threshold for pain during balloon distention than normal subjects—that is, they experience pain with a lesser degree of distention. [9]

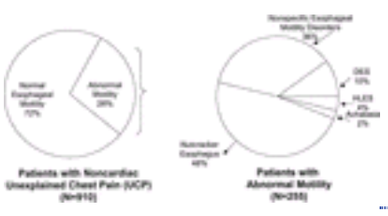

FIGURE 32-3. Esophageal motility abnormalities identified in 255 of 910 patients with unexplained chest pain following exclusion of coronary artery disease. *DES*, diffuse esophageal spasm; *HLES*, hypertensive lower esophageal sphincter. (From ref. [18] .)

PATHOGENESIS

As noted above, it is likely that as many as 50% of patients with UCP have GERD; in one placebo-controlled study, 80% of patients with documented GERD had a clinical response to omeprazole. [19] Once GERD has been excluded, the pathogenesis of UCP remains elusive. The high-amplitude contractions, such as those seen in “nutcracker esophagus,” have been suggested by some to indicate an esophageal cause; however, they have been suggested by others to represent a clinically unimportant finding or a secondary response to stress-induced panic. In a study in which ten subjects with UCP underwent simultaneous measurement of intralumenal pressure and pH and ultrasonographic imaging of the esophagus for 24 hours, [20] muscle thickness was assessed by ultrasonography during chest pain and asymptomatic baseline and control periods. Sustained esophageal contractions averaged 68 seconds. Five patients had a positive chest pain response to edrophonium provocation, and all had sustained esophageal contractions during the pain. Sustained esophageal contractions of shorter duration (mean, 24 seconds) were seen in a few asymptomatic periods. Healthy subjects and patients without chest pain did not have sustained contractions. Muscle thickness was increased during both chest pain and asymptomatic periods. Thus, the magnitude of the contraction was not predictive of the occurrence of pain, which corroborates the findings of stationary esophageal manometry.

It has been suggested that UCP is a disorder of visceral hypersensitivity. We evaluated the role of repeated esophageal acid sensitization in the production of chest pain. [21] Esophageal acid exposure in the 30 minutes preceding episodes of chest pain associated with reflux (pH < 4) was compared with acid exposure in the 30 minutes preceding episodes of chest pain not associated with reflux. In 51 patients, 129 pain events were recorded; 34 events were associated with episodes of reflux, and 95 were not. In the episodes of chest pain associated with reflux, significantly more total esophageal acid exposure time was observed in the 30 minutes preceding the index event than in those pain events not associated with reflux (6.8 ± 1.9 minutes versus 0.6 ± 0.6 minutes, $P < .001$). Also, more individual episodes of reflux occurred in the 30 minutes preceding the index pain event in the 34 events with a positive symptom correlation than in the 95 events with a negative symptom correlation.

We have also found that a shorter duration of esophageal acid infusion is needed to induce chest pain when the time interval since a previous infusion is shorter. [22] In an older study in which a modified Bernstein test was used, a repeated infusion at a pH of 1 or 1.5 resulted in a greater frequency of chest pain than a single infusion. [23] In addition, prior acid infusion into the esophagus reduces the volume threshold at which chest pain is first perceived when an intraesophageal balloon is inflated. [24] These studies support other evidence that a hypersensitive esophagus may be an important variable in the production of chest pain.

TREATMENT

Recurring substernal chest pain, when it remains truly unexplained after evaluation by numerous health care providers, produces considerable anxiety for the patient. With the background of a negative cardiac evaluation, treatment begins with reassurance to the patient that the heart is normal and that a life-threatening illness is not present. If an esophageal abnormality is found and the patient is made aware that the esophagus is the cause of pain, the patient is better able to accept the symptoms and experiences fewer limitations in daily life as a result of the pain. [6]

It is common practice to treat UCP secondary to GERD with traditional antireflux therapy. Uncontrolled observations with both histamine H_2 receptor antagonists and PPIs have suggested that this is an effective approach. The only double-blinded, randomized, placebo-controlled trial [19] compared omeprazole and placebo in 36 patients with UCP and GERD documented by 24-hour ambulatory pH testing. Patients received either omeprazole (20 mg twice daily) or placebo for 8 weeks and kept a diary of the frequency and severity of daily chest pain scored on a scale of 0 (none) to 10 (worst possible). This study confirmed clinical experience in that a significant decrease in chest pain was achieved in 81% of patients with omeprazole, versus 6% with placebo (Fig. 32-4); both the number of days with chest pain (39% ± 7.2% versus 10% ± 6.9%, $P = .006$) and the severity of pain (40.7 ± 8.1 versus 14.8 ± 8.2, $P = .03$) were reduced. This study included both male and female patients (female-to-male ratio of 2:1), and almost all had normal findings on endoscopy (90%). The study supports the use of PPIs in higher doses in patients with UCP who have known nonerosive GERD, the typical population seen in clinical practice. The study also reinforces the need and value of excluding GERD in this population.

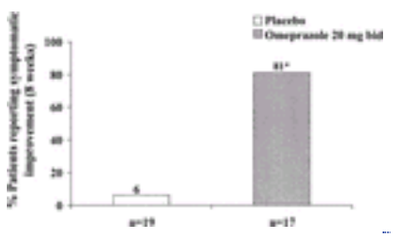

FIGURE 32-4. Percentage of 36 patients with unexplained chest pain and abnormal findings on pH monitoring reporting symptomatic improvement after 8 weeks on omeprazole therapy versus placebo. (From ref. [19] .)

The Omeprazole Test

Fass et al. [25] examined the value of empiric therapy in a randomized, double-blinded, placebo-controlled trial of a short course of high-dose omeprazole as a diagnostic test for GERD in 37 patients with UCP (the “omeprazole test”). Coronary artery disease was excluded by cardiac catheterization or a noninvasive workup and consultation with a cardiologist. To be enrolled, patients had to have chest pain at least three times a week and be able to record symptoms accurately. Before the study, all participants underwent upper gastrointestinal endoscopy and 24-hour ambulatory pH monitoring and kept a diary of the frequency and severity of chest pain. Patients were randomized to either placebo or omeprazole (40 mg in the morning and 20 mg in the evening) for 7 days, followed by a crossover after a 2-week washout period during which baseline symptom assessment was repeated. Of the 37 patients, 23 (62.2%) were classified as positive for GERD and 14 as negative for GERD, based on the presence of erosive esophagitis or abnormal results of 24-hour pH monitoring without calculation of a symptom index.

The result of the treatment trial (the omeprazole test) was considered positive for GERD if the baseline chest pain score was reduced by more than 50% after treatment with omeprazole or placebo. A positive omeprazole result was noted in 18 (78%) of the GERD-positive patients and in only 2 (14%) of the GERD-negative patients, which translated to a sensitivity of 78.3% (95% confidence interval [CI], 61.4–95.1) and a specificity of 85.7% (95% CI, 67.4–100) in comparison with upper gastrointestinal endoscopy and ambulatory pH monitoring for the diagnosis of GERD. An economic analysis performed later estimated that this 1-week omeprazole trial could save $573.00 per patient with UCP, assuming that the patient would be evaluated by endoscopy, esophageal manometry, and ambulatory pH monitoring. Such a treatment trial could result in an 81% reduction in the number of endoscopies and a 79% reduction in the use of ambulatory 24-hour esophageal pH monitoring in this patient population.

This is the best-designed study in which researchers have attempted to investigate this difficult issue. It was blinded, randomized, and controlled with placebo. All patients received all diagnostic and therapeutic interventions. However, the population studied was almost exclusively male (unusual for UCP, in which the gender distribution is usually 50:50), and the frequency of endoscopic esophagitis was higher (35%, or eight patients) than in other large studies of patients with UCP (<10%). [7] , [19] It is particularly important to be aware of the frequency of pain in these patients. All had chest pain at least three times a week. The frequency of heartburn was high, so that the pretest probability of GERD was high. In general, patients with UCP have pain less frequently (often less than once a week) and have less frequent heartburn, and a 1-week trial therefore may not be sufficient to evaluate improvement. Whether a longer trial would suffice has not been studied. The study does not allow us to examine treatment after the omeprazole test. It remains to be shown whether this PPI test will be useful in those patients with less frequent pain and whether the results can be extrapolated to women with chest pain.

It is not clear what is the best dosage of PPI to use. Higher doses appear to be needed than are used to treat patients with heartburn. Whether a PPI twice daily (before breakfast and dinner) or a regimen including a PPI twice a daily plus a histamine H_2 receptor antagonist at bedtime [26] provides the “best” outcome of aggressive acid suppression is not known.

The sensitivity and specificity of prolonged ambulatory pH monitoring are the subject of considerable debate. Beedassy et al. [21] evaluated the results of monitoring 104 consecutive patients with UCP and normal coronary arteries documented by catheterization. The percentage of time that the pH was less than 4 in patients (upright, recumbent, and total) and the symptom correlation with a pH of less than 4 (symptom index) were reviewed. In 51 (45%) of the patients, the percentage of time when the pH was less than 4 during the study was abnormal. Patients with a high symptom index (27) were more likely to have an abnormal pH result. These results confirm those of previous studies showing that pH monitoring is the most sensitive traditional diagnostic test in patients with UCP.

Fass et al. [28] evaluated the ability of 24-hour ambulatory esophageal pH monitoring to predict a reduction in chest pain with treatment in 23 patients with GERD-related UCP. Twenty-two of the patients were men, and all had had at least three episodes of chest pain a week for a minimum of 3 months before the study. Of the 23 patients, 15 (64%) had abnormal results of 24-hour pH monitoring based on the time of esophageal acid exposure at a pH of less than 4. No comment was made about a positive symptom index. All were treated with omeprazole (40 mg in the morning and 20 mg in the evening). A significant correlation ($r = 0.51$, $P < .02$) was found between the results of 24-hour ambulatory esophageal pH monitoring and the change in symptom intensity score with treatment. This study suggests the value of prolonged ambulatory monitoring, both from the standpoint of the frequency of an abnormal study and its potential value in predicting the response to treatment. A positive symptom index during pH-metry should provide the best predictor of outcome of PPI therapy.

If patients do not respond to a trial of antireflux therapy, an evaluation with prolonged ambulatory pH monitoring performed with dual esophageal and gastric pH electrodes while therapy is continued is the procedure of choice. [29] This allows assessment of pH control and symptom correlation. In the event that gastric pH control is incomplete, especially overnight, [30] esophageal acid exposure continues, [31] or symptoms persist in association with continued reflux, higher-dose PPI therapy or the combination of a PPI twice daily plus a histamine H_2 receptor antagonist at bedtime can be considered. If the results of pH testing are negative, further evaluation should include esophageal motility testing and provocation with edrophonium (and balloon, if available). Patients without heartburn or regurgitation (or other symptoms to suggest GERD) should be evaluated earlier with pH monitoring. Patients successfully treated with acid suppression should be considered for long-term maintenance with PPI therapy, although no specific study has addressed this issue.

Other Treatments

Many patients with UCP do not have GERD. Although in 25% to 35% a motility abnormality is detected on esophageal manometry and in approximately 20% pain is provoked by stimulation with edrophonium, treatment of this group has been difficult. At least one placebo-controlled study suggests that a calcium channel blocker may be effective for patients with nutcracker esophagus. [32] Nitroglycerin has been shown to reduce the pain and simultaneous contractions in patients with diffuse esophageal spasm. [33], [34] A more recent uncontrolled study has suggested that endoscopic injection of botulinum toxin may be effective in these patients. [35] Double-blinded, placebo-controlled studies are limited in number and have shown minimal success; however, these agents should be considered in patients with abnormal esophageal contractions.

A 50-mg dose of imipramine at bedtime results in significant improvement in patients with UCP who do not have reflux disease. [36] Anxiolytics [37] or the antidepressant trazodone (100–150 mg/d) [38] has been shown to be helpful in decreasing symptoms associated with abnormal esophageal contractions. It is likely that these agents, particularly imipramine, act to alter visceral sensation. [39] The reports lend support to the suggestion that pain or hypersensitivity in these patients is mediated by abnormal visceral nociception. Many patients have high scores on somatization and depression scales during psychological testing, so the agents may also relieve these symptoms.

Prakash and Clouse [40] have reported a long-term experience of tricyclic antidepressants in 21 outpatients with UCP, normal coronary arteries, and no or an incomplete response to antireflux therapy. Patients were observed for a minimum of 6 months (median, 2.7 years; range, 0.8–8.6 years), and all received tricyclic antidepressants continuously. Five patients had had abnormal pH readings, and aggressive PPI or surgery had failed in all. Only six (28.6%) had an anxiety or affective disorder. Seventeen (81%) showed improvement or complete remission during initial treatment with 20 to 75 mg (median, 50 mg) of amitriptyline, imipramine, nortriptyline, or desipramine daily. Only 3 of the 17 whose condition improved required a change because of side effects.

In follow-up, five (29%) patients discontinued treatment after 0.5 to 2.7 years with long-term relief of chest pain. In one, the pain recurred. Seven (41.2%) were in treatment almost continuously for a mean of 2.6 ± 0.6 years. Five patients discontinued medication (despite pain relief) because of side effects. Overall, 13 (76.5%) of 17 experienced sustained improvement (>6 months). None of these 13 required further investigation or treatment for chest pain during follow-up.

Several potentially important points are made. Long-term tricyclic agents are tolerated well by these patients, and pain is relieved. Although these observations are uncontrolled, they offer some promise for patients in whom antireflux therapy fails or who do not have GERD, which underscores the importance of a thorough evaluation. Patients do not have to have psychiatric disturbances to respond to these agents. Regardless of their mechanism, the agents offer promise. They are inexpensive and generally well tolerated.

Another interesting treatment modality was tested by Van Peski-Oossterbaan and colleagues. [41] Seventy-two patients with UCP (normal coronary arteries) and without major depression, psychosis, organic brain syndrome, or use of psychoactive substances were randomized to no treatment or to cognitive-behavioral therapy (4 to 12 weekly sessions of 45 to 60 minutes each), during which the patients were instructed in relaxation techniques, counseled, and shown how to identify defined irrational beliefs about UCP. The patients were evaluated at 6 and 12 months for frequency of chest pain and use of medical services. A clear advantage of the cognitive-behavioral treatment was found in comparison with no treatment, inasmuch as 50% of those treated were free of chest pain at 6 months, versus 6.1% of those untreated (P <.001). Forty-eight percent were free of pain at 12 months in the treated group, versus 13% of those untreated (P <.001). Visits to their general practitioners were unchanged. Patients appeared to have high levels of baseline functioning and were educated. The study was not blinded. Nevertheless, the result reinforces those of other case reports and the clinical impression that nonpharmacological intervention may be of value in selected patients. This time-intensive method should not be ignored as definitive treatment.

SUMMARY

Published studies support the clinical impression that PPIs are the drug of choice for GERD-related UCP. The recent literature encourages the use of a trial of a PPI as a useful diagnostic test for GERD in patients with UCP who have chest pain more than three times a week and other symptoms suggestive of GERD. Tricyclic antidepressants and behavior modification appear useful in patients who do not have GERD, underscoring the importance of a thorough assessment in these patients. Further research is needed to elucidate the respective role of esophageal sensory and contraction abnormalities in the pathogenesis of this complex syndrome.

CHAPTER 33

Grace H. Elta

APPROACH TO THE PATIENT WITH GROSS GASTROINTESTINAL BLEEDING

Gastrointestinal (GI) bleeding is a common clinical problem requiring more than 300,000 hospitalizations annually in the United States. The annual rate of hospitalization for upper GI bleeding has been estimated at 36 to 102 patients per 100,000 members of the general population and is twice as common in men as in women. [1], [2] Lower GI bleeding is less common; the estimate from a large health maintenance organization of cases of acute lower GI bleeding leading to hospitalization was 20 per 100,000. [3] The rates of acute upper and lower GI bleeding are both increased in patients taking aspirin, and the risk appears to dose related. [4], [5] Calcium antagonists, which also inhibit platelet aggregation, may increase GI bleeding, [6], [7] whereas nitrovasodilator drugs may decrease the risk. [8]

During the last 10 years, hospitalization days have significantly decreased, and most patients with upper GI bleeding undergo endoscopy within 24 hours after admission. [9] Of these endoscopic procedures, 20% to 35% include endoscopic hemostatic therapy. An important change in the management of nonvariceal upper GI bleeding has been the use of upper GI endoscopy to assess the risk for rebleeding, allowing outpatient care of selected patients with significant cost savings. [10], [11] Because the cost of a hospital bed accounts for most of the hospital cost of providing care for patients with upper GI hemorrhage, shortening the length of stay or eliminating the need for hospitalization can significantly lower costs. A comparison of the costs of care for patients with acute upper GI bleeding showed that gastroenterologists provide more cost-effective care than internists or surgeons. [12] The cost savings associated with a shortened length of stay reflected the time interval between endoscopy and discharge; the time to endoscopy did not differ among services.

Mortality rates from upper GI hemorrhage vary from 3.5% to 7% in the United States, [1], [2] and [3], [13] although a large study from the United Kingdom reported a mortality rate of 14%. [14] The mortality rate for lower GI bleeding has been reported at 3.6%; although similar to upper GI bleeding, it is markedly higher in patients who begin bleeding after hospitalization. [3] The early and accurate diagnosis of patients with severe bleeding can facilitate therapeutic maneuvers, leading to lower mortality rates. [15] This trend appears to have developed with the use of therapeutic endoscopic techniques. [16]

CLINICAL PRESENTATION

The overall strategy for management of GI bleeding starts with an assessment of the patient to determine how much blood has been lost and whether the bleeding is ongoing. This is followed by resuscitation because the dire consequences of GI bleeding are those of shock. A brief history and physical will often determine whether the source of bleeding is in the upper or lower GI tract and whether the bleeding has ceased, which happens in 80% of patients. The need for urgent versus elective endoscopy can then be determined (although in upper GI bleeding, urgent endoscopy has been proposed for all patients to facilitate triage and decreased resource utilization). If endoscopy is to be performed electively, empiric medical therapy for the most likely diagnoses can be started to decrease the risk for rebleeding. Once a definitive diagnosis is made, specific medical, endoscopic, angiographic, or surgical therapy can be performed.

Patient Assessment

The first step in assessing the bleeding patient is to determine the urgency of the situation. Agitation, pallor, hypotension, and tachycardia may indicate shock requiring immediate volume replacement. Patients with severe blood loss may actually have bradycardia rather than tachycardia secondary to vagal slowing of the heart. [17] Shock occurs when blood loss approaches 40% of the total blood volume. If no evidence of hypotension is found, the orthostatic vital signs can help diagnose lesser degrees of intravascular volume depletion. Postural hypotension with a decrease in systolic blood pressure of 10 mm Hg or more usually indicates at least a 20% reduction in blood volume. In the acutely bleeding patient, intravenous access should be established. If the patient has signs of shock or continues to bleed, a large-bore central intravenous line is useful. Blood samples for an assessment of hematocrit, platelets, and coagulation factors and for blood typing and cross-matching should be sent immediately to the laboratory.

The initial hematocrit obtained for a patient with acute bleeding poorly reflects the degree of blood loss. Because the hematocrit is expressed in terms of erythrocyte volume as a percentage of the total blood volume, it does not drop until the blood volume has been restored. This repletion of blood volume from extravascular fluid begins immediately but takes 24 to 48 hours to equilibrate completely. An acutely bleeding patient can be evaluated more effectively by monitoring the blood pressure and pulse and looking for gross evidence of ongoing bleeding than by assessing laboratory tests.

Resuscitation

Patients with severe acute GI bleeding require admission to an intensive care unit. Fragile patients with a history of cardiopulmonary disease may require measurement of capillary wedge pressure. The intravascular volume should be replenished with normal saline solution to prevent the consequences of shock while blood is being cross-matched for transfusion. This allows adequate circulation of the remaining erythrocytes. The oxygen-carrying capacity of blood can be maximized by administering supplemental oxygen. In rapidly bleeding patients, oxygen availability is markedly decreased during early hemorrhage, reflecting primarily a decreased cardiac output. The decrease in oxygen-carrying capacity of the blood caused by a decrease in hemoglobin is less important. Metabolic acidosis has been measured in patients with acute hemorrhage, reflecting poor tissue perfusion. [18] Close attention to vital signs, urine output, and central vascular pressure is mandatory.

The specific criteria that define when a patient requires transfusion vary according to the age of the patient, whether concomitant cardiopulmonary disease is present, and whether the bleeding continues. In general, the hematocrit should be maintained above 30% in elderly patients and above 20% in young, healthy patients. With continued evidence of bleeding, the decision to transfuse cannot be based on the hematocrit alone. Unstable vital signs and gross evidence of active bleeding, such as hematemesis, bright red blood in the nasogastric aspirate, or hematochezia, are better requisites for transfusion. The hematocrit is a poor index for following the patient's need for additional transfusions. The plasma volume after acute GI bleeding is often overexpanded by intravenous fluids; the immediate posttransfusion hematocrit may underestimate the final value. Overuse of transfusions is probably more common than underuse.

In general, packed erythrocytes are the preferred form of blood transfusion. Whole-blood transfusions should be reserved for the unusual circumstances of massive blood loss and rapid, high-volume replacement, which increases the need for coagulation factor replacement. Preferably, blood volume has already been replenished with saline solution by the time banked blood is available. The use of packed cells also spares components for the blood bank. If the results of coagulation tests are abnormal, as is the case in many patients with cirrhosis, fresh-frozen plasma and platelets may also have to be administered. Even patients with initially normal coagulation factors and platelet counts eventually need plasma and platelet transfusions if they are transfused repeatedly. Patients who require massive transfusions (>3000 mL) should receive warmed blood to prevent decreases in body temperature. [19] Rarely, in massively transfused patients, calcium supplementation may be

necessary to counter the effects of calcium-binding agents in banked blood.

Location of Bleeding

In patients with obvious upper GI bleeding who present with hematemesis, a nasogastric tube should be placed to further assess the rate of ongoing blood loss. When upper GI bleeding is suspected, as in the patient with melena or with a history of previous epigastric symptoms or disease, a nasogastric tube aspirate demonstrating blood confirms the upper tract as the source. However, the nasogastric aspirate may be a negative in a patient with duodenal bleeding presenting with melena when a competent pylorus prevents duodenogastric reflux. [20] A negative nasogastric aspirate does not preclude the upper gut as the source of bleeding. Melena usually indicates an upper GI source (i.e., above the ligament of Treitz), although bleeding may be from the small bowel or proximal colon. Melena occurs when hemoglobin is converted to hematin or other hemochromes by bacterial degradation. This can be produced experimentally by the ingestion of as little as 100 to 200 mL of blood. [21] If the volume of a lower GI hemorrhage is too small to cause hematochezia but sufficient to supply enough hemoglobin for degradation, and if colonic motility is sufficiently slow, bleeding from the small bowel or proximal colon may cause melena. This is an uncommon occurrence because small bowel bleeding is rare and colonic sources bleed slowly, causing Hemoccult-positive stools, or bleed rapidly enough to cause hematochezia.

Another indication of an upper GI source of bleeding is a mildly elevated level of blood urea nitrogen (BUN). [22] Some of this azotemia is caused by the absorption of blood, but the experimental ingestion of blood results in lower elevations in BUN of shorter duration, suggesting that part of the azotemia is secondary to hypovolemia. [23] A study has confirmed that the BUN-to-creatinine ratio is higher in upper GI than in lower GI bleeding but is a poor discriminator. [24] Testing for occult blood in nasogastric aspirates is rarely necessary because the blood is often obvious. The one occasion on which occult blood testing is helpful is when a coffee ground appearance of the aspirate may be produced by some foods. A simple positive test for occult blood may merely indicate nasogastric tube trauma. When occult testing of gastric aspirates is used, it is important not to rely on standard stool kits, which may yield false-negative results in acidic solutions. [25]

Hematochezia usually indicates a lower GI source. However, 11% of patients with rapid bleeding from an upper GI source pass bright red blood rectally because of rapid GI transit. [26] Placement of a nasogastric tube and an endoscopic examination should be considered if there is any question about the location of bleeding in a patient with hematochezia.

ACUTE UPPER GASTROINTESTINAL BLEEDING

Upper GI bleeding is a common clinical problem, causing 10,000 to 20,000 deaths each year in the United States. Forty-four percent of hospitalizations for upper GI bleeding are for patients older than 60 years of age. [1] Approximately 80% of upper GI bleeding episodes are self-limited and require only supportive therapy. [27] Patients with continued or recurrent bleeding have mortality rates of 25% to 30%. [1], [27]

Prognostic Indicators

Several prognostic indicators in upper GI bleeding have been identified. The most important is the cause of bleeding. Variceal hemorrhages have much higher rebleeding and mortality rates than other conditions. Mortality from variceal hemorrhage during the initial hospitalization is at least 30%, with rebleeding rates of 50% to 70%. [28] A reduction in the mortality rates associated with variceal bleeding would lower the overall mortality of upper GI bleeding because varices account for approximately 10% of all bleeding episodes. [29]

Stigmata of recent bleeding that can be visualized at endoscopy, such as active arterial spurting, oozing of blood, a visible vessel, or a fresh or old blood clot, are important predictors of outcome in peptic ulcer bleeding (Table 33-1). A visible vessel is described endoscopically as an elevated, dark red, blue, or gray mound that protrudes from the ulcer crater and is resistant to washing. The endoscopic diagnosis of a visible vessel has been validated by pathological correlation in a group of gastric ulcer patients who required surgical resection, although this visible vessel is actually an organizing clot plugging a side hole in the bleeding artery located just below the ulcer base. [30] The evolution of the endoscopic appearance of visible vessels, or sentinel clots, has been described as an initial large, red clot that becomes darker and smaller with time, eventually replaced with a white plug of fibrin and platelets that finally disappears. [31] The dark, small sentinel clot that is not oozing, also described as a bare visible vessel, and older stigmata in the form of a flat, black eschar or white clot, have lower rates of rebleeding. [32] Controversy regarding the evolution of vessel color and the variable risks associated with the color of the visible vessels continues. [33]

STIGMATA OF HEMORRHAGE	INCIDENCE (%)	REBLEEDING (%)
Spurting arterial bleeding	8	85–100
Nonbleeding visible vessel	17–50	18–55 (mean, 43)
Adherent clot (no visible vessel)	18–26	24–41
Other stigmata	12–18	5–9
No stigmata	10–36	0

Adapted from Johnston JH. Endoscopic risk factors for bleeding peptic ulcer. Gastrointest Endosc 1990;36:516.

TABLE 33-1 Stigmata of Hemorrhage and the Risk for Rebleeding

Despite the lack of uniform endoscopic descriptions and risks for rebleeding depending on the type of visible vessel, the presence of a visible vessel in an ulcer crater at endoscopy predicts an increased risk for required surgical intervention and increased mortality. [34] The incidence of rebleeding in patients who have ulcers with visible vessels is up to 50%, whereas no rebleeding is observed in patients with no stigmata of recent bleeding. [35] When endoscopy is performed within 6 to 24 hours after admission, visible vessels are found in 20% to 50% of bleeding ulcers.

The identification of predictors of recurrent hemorrhage may direct the need for therapeutic endoscopic techniques, which can lower the mortality rate for patients with ulcers that have stigmata of recent bleeding. [36] Which stigmata indicate a requirement for therapy in patients with bleeding ulcers? More than 30 randomized trials have been reported, and although results have varied, most authorities recommend treatment of actively bleeding (i.e., spurting or oozing) visible vessels and nonbleeding visible vessels that are raised and cannot be washed off. [37] Adherent clot should be aggressively washed off to assess a possible underlying vessel if there is clinical evidence of major hemorrhage, such as hypotension, significant hematemesis, or a transfusion requirement of more than two units.

Other prognostic indicators include the following:

Severity of the initial bleed. Severity is assessed by the transfusion requirement, the presence of bright red blood in the nasogastric aspirate, or the presence of hypotension (Table 33-2). [38]

NASOGASTRIC ASPIRATE	STOOL COLOR	MORTALITY RATE (%)
Clear	Red, brown, black	10
Coffee grounds	Brown or black	10
	Red	20
Red blood	Black	10
	Brown	20
	Red	30

Adapted from Silverstein FE, Gilbert DA, Tedesco FJ. The national ASGE survey on upper gastrointestinal bleeding. Gastrointest Endosc 1981;27:73.

TABLE 33-2 Prognostic Value of the Severity of Upper Gastrointestinal Bleeding

Age of the patient. Patients older than 60 years have been shown to have higher mortality rates than their younger counterparts, although this indicator may not be independent from concomitant disease. [1]
Concomitant disease. Diseases such as chronic renal failure and severe cardiopulmonary disease affect the ultimate outcome.

Onset of bleeding during hospitalization. Patients who begin to bleed while hospitalized have a mortality rate of 25%, whereas the rate is only 3.7% for patients who start to bleed before admission. [2]
Giant ulcers. Patients with giant ulcers (diameter >2.0 cm) have mortality rates as high as 40%. [39]
Emergency surgery. Patients requiring emergency surgery have a surgical mortality as high as 30%, compared with 10% for those undergoing elective surgery.

Diagnostic Approach

Patients with self-limited, minor bleeding and other more serious medical problems may not require endoscopy. However, for most patients, even those with relatively minor bleeding, an accurate diagnosis or localization of the source is desirable to direct further management.

History and Physical Examination As initial resuscitative measures are being implemented, a history should be taken and a physical examination performed. Even experienced gastroenterologists can guess the cause of bleeding only 50% of the time after a careful history and physical examination. However, the history may raise specific diagnostic possibilities. A history of peptic disease or dyspeptic symptoms suggests ulcer bleeding. The recent use of nonsteroidal antiinflammatory drugs (NSAIDs) must always be determined. A history of ingesting alcohol or a caustic substance is important to obtain. A history of cirrhosis or symptoms of cirrhosis such as ascites may suggest the need for urgent endoscopy to diagnose variceal bleeding. Other medical problems, such as prior aortic graft surgery, coagulopathies, cancer, or recent nose bleeds, may suggest likely diagnoses. Physical examination of the skin may provide diagnostic clues. Stigmata of cirrhosis, evidence of underlying malignancy (e.g., Kaposi sarcoma), or hereditary vascular anomalies may be revealed. The finding of lymphadenopathy or abdominal masses may suggest malignancy. Abdominal tenderness in the epigastrium is common in peptic disease. Hepatic or splenic enlargement may indicate liver disease or certain malignant disorders. When patients present with upper GI bleeding, a rectal examination may indicate the magnitude of blood loss by demonstrating maroon stool or melena in patients with severe bleeding or normal-colored stool in patients with minimal or recent bleeding.
Endoscopy Endoscopy has replaced barium contrast studies for the diagnosis of upper GI bleeding. The greater accuracy and therapeutic potential of endoscopy generally makes it the diagnostic procedure of choice. [40] Diagnostic endoscopy is viewed as a safe and simple procedure by patients and physicians, although morbidity rates of 1.0% and mortality rates of 0.1% have been reported. Endoscopy is contraindicated for an uncooperative patient or a patient with a suspected perforated viscus. Endoscopy can locate precisely the site of bleeding when bleeding continues or the stigmata of bleeding persist. In patients with massive hemorrhage, the source of bleeding occasionally cannot be discerned by endoscopy. In patients whose bleeding has stopped and in whom no stigmata of bleeding remain, a significant lesion seen on endoscopy (e.g., a clean ulcer base) is the presumed source. If more than one lesion or no lesion is identified, a definitive diagnosis cannot be made, and these patients must be restudied if they bleed again. Up to 24% of patients presenting with melena will have a nondiagnostic upper GI endoscopy, with the most common source of bleeding being the right side of the colon. [41] It is important not to mislead those caring for the patient by overstating the certainty of the localization or diagnosis of the bleeding site. The timing of the diagnostic endoscopy depends on the severity and suspected cause of the hemorrhage. Patients who fail to stop bleeding with simple supportive care require urgent endoscopy to guide further therapeutic techniques. Patients with underlying cirrhosis should undergo endoscopy as close to the bleeding episode as possible because they often have more than one source of potential hemorrhage and the diagnosis of bleeding varices alters future approaches to treatment. For most patients whose bleeding ceases, diagnostic endoscopy can be postponed for 24 hours without seriously altering diagnostic accuracy or clinical outcome. [42]
Angiography Angiography is used as a diagnostic examination for acute upper GI bleeding only if endoscopy has failed. The bleeding must be arterial and at a rate of at least 0.5 to 0.6 mL/min to detect extravasation. Angiography represents a therapeutic alternative for the delivery of intraarterial vasopressin in stress gastropathy or for embolization of bleeding ulcers or neoplasms in inoperable patients. Angiography may be used to diagnose difficult cases of recurrent GI bleeding from an unknown source. It provides an accurate diagnosis for 50% to 75% of patients but is associated with a serious complication rate of about 2%. Complications of angiography are related to catheter placement (e.g., dissection, thrombosis, false aneurysm) or to the contrast material (e.g., allergic reactions, renal failure). When embolic occlusion of vessels is used, the complication rate increases because of ischemic necrosis and perforation, although the use of minicoils instead of fluid embolization agents has reduced the risk. [43]

Causes and Therapy

The three major causes of upper GI bleeding are peptic ulcer disease, gastric erosions, and varices (Table 33-3). Their distribution depends on the patient population studied. In all endoscopic series, no diagnosis is made in 10% to 15% of patients, and as many as 20% to 30% of patients have more than one diagnosis. The endoscopically examined patients with no diagnosis of disease have an excellent prognosis.

DIAGNOSIS	PERCENTAGE OF TOTAL DIAGNOSES (%)
Duodenal ulcer	24.3
Gastric erosions	23.4
Gastric ulcer	21.3
Varices	10.3
Mallory-Weiss tear	7.2
Esophagitis	6.3
Erosive duodenitis	5.8
Neoplasm	2.9
Stomal ulcer	1.8
Esophageal ulcer	1.7
Miscellaneous	6.8

TABLE 33-3 Final Diagnosis of the Cause of Upper Gastrointestinal Bleeding in 2225 Patients

Peptic Ulcer Bleeding Duodenal, gastric, and stomal ulcers account for about 50% of upper GI bleeding episodes. Although several effective therapies have been developed for peptic ulcer disease during the past 20 years, these advances have had little or no impact on hospitalization rates for bleeding ulcers. Perhaps the reason is that ulcers can bleed without a prior history of peptic symptoms. [44] There also may be an increase in upper GI bleeding in the elderly because of the widespread use of NSAIDs, including aspirin. [45] Ulcers that are located high on the lesser curve of the stomach or on the posteroinferior wall of the duodenal bulb are more likely to rebleed. [46] Bleeding tends to occur when an ulcer erodes into the lateral wall of a vessel. The vessel often loops up to the floor of the crater and commonly protrudes with an aneurysmal dilatation. A vessel with an eccentric breach is thought to be more likely to be associated with continued or recurrent bleeding than a transected vessel because retraction contraction of a severed vessel is an important mechanism of hemostasis. [47] Patients with continued or recurrent ulcer bleeding have increased mortality rates. [48] Therapy is therefore directed at stopping bleeding and preventing recurrent bleeding.
Cessation of bleeding: endoscopic methods. The physician should perform lavage with tap water at room temperature for the important task of monitoring the rapidity of bleeding. Although lavage with iced saline solution and levarterenol has been suggested for vasoconstriction, controlled trials have not shown therapeutic benefit, and ice water increases patient discomfort. [49] A large-bore orogastric tube should replace the diagnostic nasogastric tube when cleaning for subsequent endoscopy is needed. Aliquots of 100 to 500 mL of water are instilled and removed, preferably by gravity drainage to prevent extensive suction trauma. For patients with persistent or recurrent hemorrhage from peptic ulcer disease, endoscopic control of bleeding, which is safer than emergency surgery, should be attempted. [50] Endoscopic methods can be divided into thermal and nonthermal (i.e., injection therapy) types. They are described in detail in Chapter 148. Numerous randomized controlled trials have documented the efficacy of injection therapy for bleeding peptic ulcers and for nonbleeding visible vessels. [51], [52] Nonthermal methods include injection of sclerosing agents such as alcohol or ethanolamine, injection of vasoconstrictors such as epinephrine, or injection of normal saline solution. [53] Because the choice of agent does not seem to alter efficacy, it is presumed that the mechanism of action of injection therapy is local tamponade. In contrast to thermal therapy, in which precise localization of the bleeding vessel is desirable, injection therapy is feasible even in an actively bleeding patient in whom visualization may be difficult. A spray of 3% hydrogen peroxide has been suggested as a means of clot dissolution to allow endoscopic visualization. [54] Comparisons of thermal and injection therapies suggest that they are equally effective. [55], [56] and [57] Some endoscopists use a combination of injection and thermal therapy, with initial injection to slow the bleeding or “clear the field” followed by coagulation of the identified vessel. Thermal methods include the neodymium:yttrium-aluminum garnet (Nd:YAG) laser, the heater probe, the argon plasma coagulator, and multipolar electrocoagulation. In this technique, direct probe pressure is used to tamponade the bleeding vessel, followed by raising the tissue temperature to coagulate and seal the vessel. Controlled trials of multipolar electrocoagulation show efficacy in reducing further bleeding, transfusion requirement, and need for surgery in actively bleeding ulcers and in nonbleeding visible vessels. [58], [59] A similar technique that uses pure thermal energy is the heater probe, which has also been efficacious in the treatment of bleeding ulcers and nonbleeding visible vessels. [60], [61] The major advantage of these two devices is that they are portable and relatively simple to use. The Nd:YAG laser is as effective as the heater probe and multipolar electrocoagulation, but its immobility, requirement for trained support personnel, and greater equipment expense reduce its attractiveness. [62] The argon plasma coagulator is the newest member of the thermal armamentarium. Although not as well studied, it appears to be equally as effective as other thermal methods. [63] Although most studies have not shown a reduction in mortality rates with endoscopic therapy, [64] a metaanalysis of numerous trials suggested a reduction, although this reached statistical significance

only for laser therapy. [16]

Cessation of bleeding: when endoscopy and medical therapy fail. After endoscopic treatment to control bleeding from peptic ulcers, bleeding recurs in 15% of patients. [48] A randomized controlled trial of repeated endoscopic treatment versus surgery for patients with recurrent ulcer bleeding concluded that endoscopic re-treatment is superior to surgery. [65] If hemorrhage is not stopped or if bleeding recurs again, surgery should be considered early because the risk for death increases as the patient becomes more unstable. Peptic ulcer bleeding is effectively treated with surgery, and this is safer than other therapeutic alternatives, such as angiography. Unlike bleeding from gastric erosions, bleeding from ulcers is not effectively stopped with intraarterial vasopressin, presumably because of the large size of the bleeding vessel in peptic ulcer disease. [66] Embolization by means of an angiographic catheter with polyvinyl alcohol particles or microcoils can be successful but requires significant expertise and causes complications. [67] This procedure should be reserved for the patient who is too unstable to undergo surgery.

Prevention of recurrent hemorrhage: pharmacological therapy. Most peptic ulcer rebleeding occurs within the first 3 days after presentation. The therapeutic goal is to prevent clot dissolution and allow healing of the underlying lesion. In vitro data show that coagulation and platelet function are better at neutral pH. [68] Although clot is not dissolved by acid, it is dissolved by gastric juice, suggesting that pepsin degradation may be important. [69] Because the activity of pepsin is pH dependent, it is reasonable to assume that a clot cannot dissolve if the gastric juice pH is high. Historically, multiple trials using histamine H_2 antagonists agents failed to demonstrate any improvement in survival for patients with upper GI bleeding. [70] Early studies of more potent acid suppression with continuous intravenous histamine H_2 antagonists or with proton pump inhibitors (PPIs) also failed to show efficacy. [71], [72] However, both of these studies included all bleeding ulcer patients, the majority of whom are at low risk for rebleeding, so that an insufficient number of patients may have been studied. In a comparison of omeprazole and placebo in high-risk ulcer patients with bleeding stigmata at endoscopy who were not treated endoscopically, high-dose omeprazole (40 mg twice daily) significantly lowered the rates of further bleeding and surgical intervention. [73] Although it is unlikely to replace endoscopic therapy, this study demonstrated the efficacy of potent acid suppression, perhaps through the stabilization of clotting activity. A placebo-controlled trial of high-dose infusion omeprazole after endoscopic treatment of bleeding peptic ulcers demonstrated a substantial reduction in the risk for rebleeding. [74] Potent acid suppression with high-dose intravenous or oral proton pump inhibition is now the mainstay of medical treatment for peptic ulcer bleeding (Table 33-4).

Decreases rebleeding and need for surgery	High-dose proton pump inhibitors
Efficacy not proven	Somatostatin Prostaglandins Tranexamic acid Intravenous vasopressin
Not effective	Histamine H_2 antagonists

TABLE 33-4 Medical Therapy for Peptic Ulcer Bleeding

Other drugs, such as somatostatin, [75], [76] prostaglandins, [77] tranexamic acid (an antifibrinolytic agent), [78] and intravenous vasopressin, [79] have not been proved to alter the course in bleeding ulcer patients. Mucosal protective agents such as sucralfate have not been studied in bleeding patients. It has been demonstrated that in patients without stigmata of recent hemorrhage, immediate refeeding and subsequent discharge are as safe as delayed refeeding for 36 hours. [80] The prevention of rebleeding by therapeutic endoscopic methods in high-risk ulcers with stigmata of bleeding is widely accepted. [81] However, some issues remain. First, the lack of standardized definitions of the various stigmata of recent hemorrhage and sufficient knowledge about each of their natural histories continues to be a problem. [82] Second, therapeutic endoscopy adds to the risk of the endoscopic procedure, with a risk for precipitating bleeding as high as 20% and with perforation occurring in as many as 1% of patients. Third, therapeutic endoscopy adds to the cost of treatment unless it successfully decreases the need for surgery or shortens the hospital stay and therefore must be applied judiciously.

Hemorrhage from Gastric Erosions The term *gastritis* should be reserved for the pathologist; *gastric erosions* or *gastropathy* should be used by the endoscopist. Histologically, gastritis is defined by epithelial distortion and inflammatory cell infiltrate, which may be chronic (i.e., predominantly plasma cells) or acute (i.e., polymorphonuclear cells). There may be biopsy evidence of severe histological gastritis with a normal endoscopic appearance. [83] This type of gastritis is not associated with upper GI hemorrhage. Endoscopically, gastropathy is defined by the gross appearance of mucosal hemorrhages, erythema, and erosions. An erosion is technically a break in the mucosa that does not cross the muscularis mucosae. Practically, most endoscopists define an erosion as an area of adherent hemorrhage or a defect in the mucosa with a necrotic base that is less than 3 to 5 mm in size and without significant depth. This type of gastric erosion may lead to upper GI bleeding and has several different causes. [84]

Drug-induced gastropathy. Gastropathy induced by aspirin or other NSAIDs is common. In almost all normal volunteers challenged with aspirin, mild hemorrhagic gastropathy develops that involves the proximal or entire stomach within 24 hours. [85] The bleeding associated with this acute damage is minimal and only rarely clinically apparent. If the aspirin is continued, adaptation and healing occur. In a smaller percentage of individuals continually exposed to NSAIDs, chronic erosive gastropathy, predominantly involving the antrum, or frank ulcer disease eventually develops. [86] This common type of erosive gastropathy is usually a self-limited disease that heals rapidly after removal of the offending agent. Interventional treatments such as therapeutic endoscopy or surgery are rarely required. Bleeding from NSAID-induced gastric erosions usually resolves spontaneously, and most of the serious upper GI bleeding associated with NSAID intake is the result of NSAID-induced peptic ulcers. [87] Although they have not been well studied in the treatment of bleeding from NSAID-induced gastric erosions, the use of high-dose PPIs seems reasonable. A more important issue in the management of NSAID-induced gastropathy is prophylaxis. Prostaglandins have been shown to be effective in preventing acute erosions from NSAIDs and in preventing chronic ulcers. [88] Although it has been difficult to demonstrate prevention of serious ulcer sequelae, such as hemorrhage or perforation, [89] a large study of more than 8500 patients did show a 40% reduction in serious NSAID-induced upper GI complications by misoprostol. [90] Prophylactic treatment with histamine H_2 blockers appears effective in duodenal disease but not in the stomach, [91] and sucralfate is not effective. [88] Omeprazole prevents damage in healthy volunteers [92] and is more effective than ranitidine for preventing ulcers. [93] It remains unclear who should receive prophylaxis because significant upper GI bleeding does not develop in most patients on NSAIDs, and routine prophylaxis with prostaglandins or PPIs would be extremely expensive. It seems reasonable to recommend additional treatment with prostaglandins or PPIs for the patient who has already demonstrated significant upper GI bleeding but requires continued NSAID intake. Additionally, treatment of concomitant *Helicobacter pylori* infection also decreases the risk for recurrent bleeding. [94] Another alternative is to change the NSAID to a less damaging agent, such as enteric-coated aspirin, which has been shown to cause fewer ulcers and less gastropathy in normal volunteers and patients with chronic rheumatic diseases. [95] Although less well studied, it has been suggested that the nonacetylated salicylates may also be gastric sparing. [96] Much better studied are the new specific cyclooxygenase-2 (COX-2) inhibitors, which have been shown to decrease not only gastric erosions but also upper GI tract bleeding. [97] An uncommon cause of drug-induced erosive gastropathy is hepatic artery pump chemotherapy. This treatment may cause hemorrhagic gastropathy, duodenitis, and frank ulcer disease. [98] The pathogenesis is presumably direct tissue injury from the chemotherapeutic agents or from ischemia secondary to catheter placement. Little is known about the management of this entity.

Gastropathy related to alcohol intake. Historically, it was thought that alcohol ingestion caused gastric erosions. In animal models, absolute alcohol causes severe hemorrhagic gastropathy, although lower doses of intragastric alcohol can produce adaptive cytoprotection. [99] These lower doses are closer to those obtained in human alcohol use. Alcohol consumption is a risk factor for upper GI bleeding only when it is excessive, four or more drinks per day. [100] Perhaps the historical "alcohol-induced gastritis" was actually the result of portal hypertension in patients with alcoholic liver disease. A recent endoscopic evaluation of GI hemorrhage in alcoholics found the causes to be peptic ulcer disease and disorders related to portal hypertension. [101]

Portal gastropathy. Portal gastropathy has been described as a diffuse erythematous, reticular, or mosaic pattern of the gastric mucosa. [102] The endoscopic spectrum of portal gastropathy includes a snakeskin appearance, with more severe cases having small areas of intense erythema (e.g., scarlatina rash), frank petechiae, or multiple bleeding spots. Vascular ectasia may be present throughout the stomach or show an antral predilection. Hyperdynamic congestion has been the presumed cause, [103] with a controversial role suggested for prior variceal sclerotherapy. [104] Increased gastric blood flow without congestion may also exist. [105] Although mild cases of portal gastropathy have a nonspecific appearance and no clinical consequences, the more severe variants are associated with overt and chronic bleeding. [106] The prevalence of portal gastropathy in patients with cirrhosis is 80%, with acute bleeding occurring in only 2.5% and chronic bleeding in 11%. [107] Portal gastropathy does not respond to treatment with acid suppression, although potent acid suppression has not been studied. Decreasing the portal pressure with propranolol is efficacious in the prevention of rebleeding. [108], [109] Portal systemic shunting in the unusual patient who has continued significant blood loss has been effective. [110] A transjugular intrahepatic portal systemic shunt (TIPS) would likely have similar efficacy.

Stress gastric erosions. An important cause of gastric erosions that cause major hemorrhage is illness severe enough to require an intensive care unit hospitalization, or "stress gastritis." It occurs in patients with respiratory failure, hypotension, sepsis, renal failure, thermal burns, peritonitis, jaundice, or neurological trauma. [111] The risk for bleeding in an individual patient varies with the number of such conditions. Endoscopic evidence of gastropathy is found in almost all intensive care unit patients, although only 2% to 10% of these patients have significant bleeding. [112] All treatment modalities for significant bleeding from stress erosions are associated with high failure rates and significant morbidity. Endoscopic therapy is usually the first and safest choice, although it has not been specifically studied in stress gastric erosions. The presence of multiple bleeding sites precludes its use in some patients. In contrast to the treatment of bleeding ulcers, angiographic control of gastric mucosal bleeding reportedly has a good success rate, perhaps because of the small vessel size in these superficial lesions. Intraarterial vasopressin controls hemorrhage in 80% to 90% of successfully catheterized patients with gastric erosion. [113] Unfortunately, even skilled angiographers can catheterize only 75%

of patients. Intravenous infusion of vasopressin has not been as well studied but is also reported to be effective. [114] The operative mortality rate is extremely high for patients bleeding from stress gastric erosions, and rebleeding after surgery is common; surgery is reserved as a last alternative. [115] The major emphasis in the management of stress gastric erosions is prophylaxis. Although there has been some controversy about the cost-effectiveness of treating all patients at risk, [116] a review of all studies strongly supports routine prophylaxis for all patients ill enough to be in an intensive care unit. [117] The use of high-dose antacids, [118] histamine H_2 blockers, [119] or sucralfate [120] in patients at risk has decreased the incidence of bleeding. Misoprostol is as effective as high-dose antacids in preventing stress erosions, although both caused diarrhea in 25% of patients. [121] Because high-dose antacids cause considerable side effects and nursing inconvenience, intravenous histamine H_2 blockers, PPIs, and sucralfate are more popular. Sucralfate administered through the nasogastric tube also appears as effective as high-dose antacids and is cheaper than intravenous histamine H_2 blockers. [122] However, a large multicenter trial showed a significantly lower rate of clinically important bleeding with ranitidine than with sucralfate. [123] This study also challenged a previous suggestion that agents such as sucralfate, which improve the mucosal defense without altering intragastric pH, may result in lower rates of nosocomial pneumonia in patients on respirators. [124] The validity of the hypothesis that gastric bacterial overgrowth occurs with acid-reducing therapy and that endotracheal intubation establishes a pathway for colonization of the respiratory tract continues to be questioned. [123], [125]

Esophageal Varices The first episode of upper GI hemorrhage from esophageal varices is associated with a mortality rate of 21% to 50%, and in years past, two thirds of these patients died within 1 year. [28] These bleak mortality figures may have improved slightly in more recent studies, [126] although a variable delay in trial entry makes comparison of mortality rates among studies difficult. [127] This high mortality rate attests to the difficulty of managing acute variceal bleeding and preventing further bleeding. It also may explain why so many therapeutic alternatives have been proposed. Most patients with varices have underlying cirrhosis, and this contributes to the high mortality rate; 40% die of associated medical problems. It has been estimated that one fourth to one third of patients with cirrhosis hemorrhage at least once from varices. [128] Despite the increasing array of therapeutic options for variceal hemorrhage, there has been little change in long-term survival.

Determinants of variceal rupture. Portal hypertension must be present with pressures of 12 mm Hg or greater for varices to develop. However, the degree of pressure elevation does not correlate with the risk for rupture. [129] Portal pressures may be similar in patients with no evidence of varices and in those with large varices. Once a threshold portal pressure develops that permits varices, other factors control their formation and their risk for rupture. It has been suggested that directly measured intravariceal pressure may correlate better with the risk for hemorrhage. [130] The portal pressure measured within 48 hours after the bleeding event may also correlate better with bleeding. A higher risk for rebleeding has been demonstrated in patients admitted with variceal hemorrhage who have higher portal pressures. [131] Esophagitis has not been shown to predispose to variceal bleeding, even though intuitively it seems reasonable that erosions on top of esophageal varices may cause a vessel to bleed. This remains somewhat controversial. [132] Gastroesophageal reflux as measured by a pH probe is not more common in patients with a history of variceal bleeding than in controls. [133] As in other types of GI bleeding, the recent use of aspirin predisposes to a first episode of variceal bleeding. [134] An important predictor of variceal hemorrhage is the size of the varices. Several studies have shown that large varices are more likely to bleed than small ones. [135] Wall tension is a function of diameter and wall thickness, and it is not surprising that larger varices are more likely to rupture. Another endoscopic finding of value in predicting variceal bleeding is the appearance of the vessel wall. Certain colors of varices are thought to indicate impending hemorrhage. The red color sign is the result of microtelangiectasia of the varix. Variants of this sign are red wale marks, which look like whip marks; cherry red spots 2 mm in diameter; hemocystic spots, which are round, crimson projections larger than 4 mm that look like blood blisters; and diffuse redness. All the red color signs and a blue color are thought to be risk factors for bleeding. Red color signs have been correlated with increased variceal pressure as assessed by direct needle puncture. [136] When examined by endoscopic ultrasonography, hemocystic spots appear as saccular aneurysm projections on the variceal surface. [137] The white nipple sign on a varix, thought to be a platelet-fibrin plug, is considered diagnostic of previous bleeding but not predictive of rebleeding. [138] The presence of cutaneous vascular spiders also correlates with a risk for hemorrhage from esophageal varices. [139] A prognostic index for variceal hemorrhage based on the three variables of variceal size, presence of red wale marks, and a modified Child classification of underlying liver disease was able to identify subsets of patients with a 1-year incidence of bleeding ranging from 6% to 76%. [140] The value of these predictors of variceal rupture depends on the usefulness of prophylactic therapy for variceal bleeding (Table 33-5).

Factors correlated with risk for bleeding	Variceal size
	Red marks on varices
	Severity of liver disease
Probably correlated with bleeding	Intravariceal pressure
	Portal pressure during hospitalization for bleeding
	Cutaneous spider angiomata
Not correlated with bleeding	Esophagitis
	Degree of portal pressure elevation over 12 mm Hg

TABLE 33-5 Predictors of Variceal Rupture

Management of acute variceal hemorrhage. Variceal bleeding is often the most rapid type of upper GI hemorrhage. The emphasis in acute management is on resuscitation. More than 90% of episodes of variceal bleeding cause a drop in the hematocrit to below 30%, so that transfusions are required. However, as in upper GI hemorrhage with other causes, 70% to 80% of cases resolve without specific intervention. Urgent endoscopy is indicated for a patient with a suspected variceal source because the methods of treating the acute bleeding episode and preventing recurrent bleeding differ from those for upper GI bleeding with other causes. In more than half to two thirds of patients with cirrhosis who present with bleeding, the sources are nonvariceal, and many of these patients have more than one lesion. [141] For this reason, early endoscopy is mandatory to determine the site and cause of bleeding. In the acutely bleeding patient, intravenous octreotide, a synthetic analog of somatostatin, is often begun as soon as the diagnosis is made. This newer agent has replaced vasopressin because of its ease of use, although vasopressin has been the historical treatment to which octreotide has been compared. The efficacy of both of these agents has been difficult to demonstrate convincingly. Compared to placebo, somatostatin has had conflicting results, [142], [143] although it has been shown to be equally efficacious with terlipressin and vasopressin. [144], [145] Several studies combining sclerotherapy with octreotide (or vapreotide) versus sclerotherapy alone found less bleeding with combination therapy and no difference in mortality rates. [146], [147], [148] and [149] Historically, vasopressin was used for splanchnic arteriolar vasoconstriction resulting in decreased portal pressure, although it remains controversial whether this effect is maintained in the face of severe hemorrhage. [150] Although early trials appeared to show marginal efficacy for vasopressin, [151] cardiovascular complications were common. This led to the concomitant use of nitroglycerin, which both decreased complications and improved efficacy. [152] An alternative to vasopressin for control of variceal hemorrhage is a synthetic analog of vasopressin, terlipressin, which is reportedly more effective than placebo or vasopressin although not yet available in the United States. [153] When combined with nitroglycerin, it is as effective as balloon tamponade [154] and may be as effective as sclerotherapy. [155] Pharmacological constriction of the lower esophageal sphincter with metoclopramide lowers intravariceal pressure, [156] although this is more effective when combined with intravenous nitroglycerin. [157] Only limited data are available regarding metoclopramide in the treatment of bleeding varices. [158] After supportive medical therapy and octreotide infusion have been started in the patient with variceal bleeding, the next step in management is urgent band ligation or sclerotherapy. If a skilled endoscopist is not available or, rarely, if the bleeding is too rapid to permit endoscopy, balloon tamponade is indicated. Variceal band ligation is a superior alternative to sclerotherapy for acutely bleeding patients and for the prevention of rebleeding (see Chapter 147) (Fig. 33-1). Ligation of varices has a significantly lower complication rate than sclerotherapy [159], [160], [161], [162] and [163] and may further lower the rebleeding rate [159], [160], [162] and improve survival. [159] Variceal ligation also requires fewer sessions to achieve variceal obliteration and is now technically simpler with multiple-shoot devices. [164] The combination of band ligation and sclerotherapy compared to ligation alone has had conflicting results. Some studies show no benefit for the combined therapy and a higher complication rate than that for ligation alone. [165], [166] Other studies suggest that combined therapy may be more effective at variceal eradication, [167], [168] with a decrease in recurrent bleeding. [169] Although emergent sclerotherapy has a success rate for controlling bleeding of 85% to 95%, [170], [171] it is now relegated to rapidly bleeding patients in whom visualization is insufficient for band ligation or to patients with varices too small to ligate. A new ligation technique in which tiny detachable snares are used to treat esophageal varices has been developed [172] and appears comparable to band ligation therapy. [173]

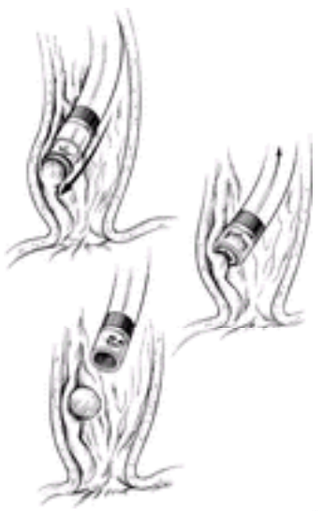

FIGURE 33-1. Endoscopic band ligation involves the application of a small suction chamber to a standard endoscope tip, which allows the varix to be pulled into the stretched band. A trigger device then releases the band around the varix base, causing subsequent necrosis and scarring.

Emergency sclerotherapy in cirrhotics with upper GI hemorrhage is associated with bacteremia, and the administration of prophylactic antibiotics after emergency endoscopy decreases the incidence of clinical infections. [174] Antibiotic prophylaxis is now recommended for all patients with cirrhosis who present with upper GI bleeding. [175] When endoscopic and medical therapy fails to control variceal bleeding, balloon tamponade is indicated as a temporizing maneuver. Balloon tamponade with the Sengstaken-Blakemore tube is effective in achieving hemostasis in 70% to 90% of patients. [176] Unfortunately, hemostasis is often temporary, with rebleeding occurring in 30% to 50% of patients after the balloon is deflated. An adapted Sengstaken-Blakemore tube with an esophageal aspiration port or the Minnesota tube with a built-in esophageal port is probably the most popular device (Fig. 33-2). [177] The complication rate of balloon tamponade is 10% to 30%; complications include esophageal perforation, aspiration pneumonia, malfunction requiring replacement, chest pain, gastric erosion, and agitation. [178] Endotracheal intubation before balloon insertion has been recommended to decrease complications. [179]

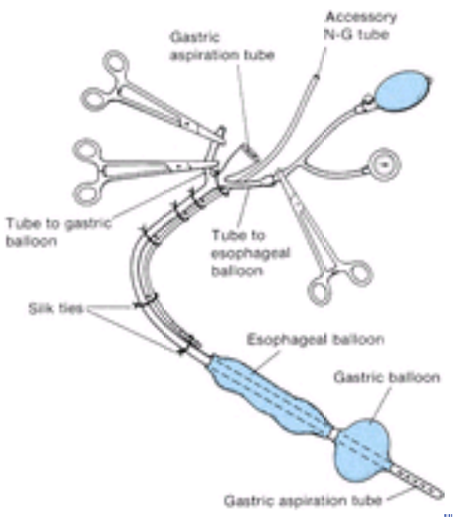

FIGURE 33-2. Modified Sengstaken-Blakemore tube. Also available is the Minnesota tube, which has a built-in esophageal port. (Adapted from ref. [177].)

TIPS, a nonsurgical method of creating portosystemic shunting, has gained popularity. [180] TIPS has been used to manage acute variceal hemorrhage and prevent rebleeding. An expandable metallic stent is placed between the hepatic and portal veins within the liver by means of an angiographically guided catheter (Fig. 33-3). Technical success is achieved in 93% to 96% of patients, with a 10% to 15% procedure complication rate and a 25% incidence of hepatic encephalopathy. [181], [182] In one third of patients, TIPS stenosis or occlusion develops by 1 year of follow-up, although this is successfully treated by redilation or placement of an additional stent. TIPS has been proposed as an effective bridge to liver transplantation because it avoids surgery in patients with advanced liver disease. [183]

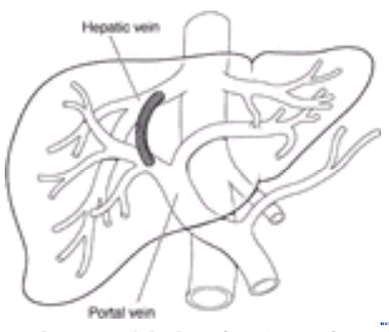

FIGURE 33-3. The transjugular intrahepatic portosystemic shunt (TIPS) is a metal expandable stent that is placed angiographically between branches of the hepatic and portal veins to create a nonsurgical shunt between the portal and systemic venous systems.

The surgical shunting of portal blood to the systemic circulation to control ongoing hemorrhage from varices is reserved for patients resistant to other therapies and has become quite uncommon since the advent of TIPS. The mortality rate for these emergency shunts is as high as 50% to 80%, which has dampened enthusiasm for the procedure. [184] This mortality rate is in contrast to that of surgery to prevent recurrent variceal bleeding. Although a better survival rate for emergency shunting has been reported, the study may have included patients who would have been controlled with other, simpler techniques at other centers. [185] Staple gun transection of the esophagus has been advocated as the simplest type of emergency surgery for active variceal bleeding and has been proposed as the salvage procedure of choice after failure of acute sclerotherapy. [186] However, because of lower postsurgical rebleeding rates, portosystemic shunts continue to be favored by many surgeons.

Prevention of recurrent variceal hemorrhage. One third of patients surviving a variceal hemorrhage rebleed within 6 weeks. [28] Death from bleeding occurs in 40% to 60% of these patients. Prevention of recurrent hemorrhage is an important part of therapy. Therapies to prevent rebleeding include band ligation or sclerotherapy, medical therapy with propranolol or nitrates, TIPS, and rarely surgical shunts. An improvement in the mortality rate is particularly difficult to demonstrate with all these methods, suggesting that the risk for death is more likely correlated to the severity of the underlying liver disease than to rebleeding. Endoscopic therapy is thought to be superior to medical management for the prevention of rebleeding, although controversy continues on this point. Controlled trials of ß $_1$-blockade compared with sclerotherapy showed lower rebleeding rates with sclerotherapy, [187] and a metaanalysis confirmed this superiority, although there was no difference in survival. [188] Combination therapy with nadolol and nitrates proved superior to sclerotherapy, with fewer complications and a lower rebleeding rate. [189] Since variceal banding has replaced sclerotherapy at most centers for the prevention of rebleeding, the combination of nadolol plus nitrates must be compared to band ligation before the ultimate role of medical versus endoscopic therapy for the prevention of rebleeding is determined. The risk for rebleeding is greatest in the first few weeks after the initiation of a endoscopic therapy regimen, before the varices are obliterated. Propranolol has been advocated for the reduction of rebleeding rates during endoscopic sclerotherapy before variceal obliteration, although the results have been conflicting. [190], [191] A study of variceal ligation versus ligation plus nadolol and sucralfate showed that the combination of ligation and medical therapy decreased both variceal and nonvariceal bleeding. [192] Subcutaneous octreotide has also been combined with endoscopic therapy to prevent rebleeding. [193] Propranolol was proposed more than 20 years ago to prevent rebleeding in patients who had already presented with variceal hemorrhage. [194] Propranolol decreases portal pressures in laboratory animals and humans, although the response is not uniform. [195] Despite early controversy, subsequent studies and several metaanalyses show efficacy with propranolol in doses that reduce the heart rate by 25%. [196] Nadolol is a popular alternative to propranolol because it has to be administered only once daily and is not metabolized by the liver. Isosorbide mononitrate has been shown to be as effective as propranolol [197] and has been used in patients who either cannot tolerate propranolol or do not respond to it satisfactorily. The combination of propranolol and isosorbide mononitrate enhances portal pressure reduction compared to propranolol alone [198] and has better efficacy in the prevention of rebleeding. [199] Despite some early concerns about the effect of nitrates on renal function and ascites, the combination of nadolol and isosorbide-5-mononitrate appears safe. [200] TIPS has

been compared to sclerotherapy and band ligation for the prevention of rebleeding. [201], [202], [203] and [204] TIPS has also been compared to a combination of endoscopic and medical therapy with either sclerotherapy plus propranolol or band ligation plus propranolol. [205], [206] Most of these trials showed less rebleeding in the patients receiving TIPS, although survival rates and costs were similar and the incidence of encephalopathy was higher with TIPS treatment. It appears that once the acute variceal bleeding episode has been controlled with endoscopic treatment, the choice for prevention of rebleeding is either further band ligation to achieve obliteration, band ligation plus medical therapy, TIPS, or medical therapy alone with a combination of nadolol and isosorbide mononitrate. Surgical shunts decompress the portal system by diverting blood into the systemic circulation. Several types of shunts have been used, including end-to-side portacaval, side-to-side portacaval, mesocaval, and splenorenal shunts. Multiple studies have confirmed their efficacy in preventing rebleeding. [207] Unfortunately, encephalopathy developed postoperatively in 10% to 40% of patients. This led to the development of the distal splenorenal (i.e., Warren) shunt, which spares portal blood flow to the liver (Fig. 33-4). The proponents of this shunt continue to report lower rates (4%–15%) of encephalopathy. [208] This has been confirmed in some controlled trials, [209], [210] although other studies comparing nonselective and distal splenorenal shunts have shown similar rates of operative mortality, late mortality, incidence of encephalopathy, and shunt occlusion. [211], [212] It appears that the incidence of encephalopathy is more related to the severity of underlying liver disease than to the type of surgery performed. Some surgeons reserve the selective shunt for patients with preserved hepatopetal (i.e., intestine-to-liver) blood flow, although this may be unnecessary. A partial portacaval shunt (i.e., small-diameter or H-graft) has also been advocated as a mechanism to preserve hepatic portal blood flow and decrease postoperative encephalopathy. [213], [214] This shunt reportedly does not compromise subsequent liver transplantation, although it may have a higher incidence of occlusion and encephalopathy than the distal splenorenal shunt. [215]

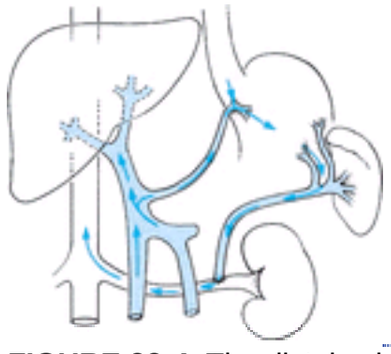

FIGURE 33-4. The distal splenorenal shunt was designed to prevent diversion of gut venous flow to the liver.

Despite the efficacy of all shunts in preventing rebleeding, controlled trials have not shown improved mortality rates. [216] A randomized comparison of surgical shunt with the effects of sclerotherapy showed similar survival and efficacy in the prevention of variceal rebleeding, with sclerotherapy having lower costs. [217] Most physicians favor endoscopic therapy as the initial therapy, with surgery reserved for the patients who fail an adequate attempt at variceal obliteration. For patients who are transplantation candidates or have poor hepatic function, TIPS is generally preferred to surgical shunt. For patients with well-preserved hepatic function, controversy continues about the choice of endoscopic treatment or surgery. [218], [219] Two other surgical methods of portal decompression have been used. The Sugiura procedure involves esophageal transection with paraesophagogastric devascularization. [220] Many modifications of this esophageal transection and devascularization procedure exist. The results of the Sugiura procedure in patients with nonalcoholic liver disease have been excellent, but some surgeons have documented high rebleeding rates. [221] A procedure that has not been extensively studied is splenopneumopexy. [222] This can be performed in patients with diffuse splanchnic venous thrombosis when alternative shunts are not technically possible. It involves resection of part of the left diaphragm with apposition of the abraded surfaces of the spleen and left lung to allow decompressive collaterals to form. Hepatic transplantation is the accepted treatment for otherwise healthy patients with end-stage liver disease. When these patients present with bleeding varices, management of the bleeding should avoid abdominal operations, which makes transplantation more difficult.

Prophylactic treatment of variceal hemorrhage. Because 30% of cirrhotics experience variceal hemorrhage and the mortality rate associated with even one episode is very high, prevention is important. Prophylactic portacaval shunts have successfully prevented bleeding but do not improve survival. [223] The benefit of not bleeding may be offset by the operative morbidity and mortality, and this surgical treatment has completely fallen out of favor. Less invasive methods of prophylactic therapy include endoscopic and medical treatment. It was hoped that identification of a group of cirrhotics at high risk for variceal bleeding (e.g., those with large varices with red color signs) would select a subset of patients who would benefit from preventive sclerotherapy. However, results of multiple trials continue to be contradictory, with most studies failing to show benefit. [224], [225], [226], [227], [228] and [229] Prophylactic sclerotherapy is not routinely recommended, although the safer procedure of band ligation has been advocated. [230] A recent comparison of band ligation to propranolol for the prophylaxis of variceal bleeding in patients with grade 3 or 4 varices showed superiority for endoscopic treatment. [231] Confirmation of this result is needed before band ligation can be routinely recommended. Propranolol or nadolol is the least invasive therapy of the prophylactic alternatives and therefore the most attractive, but results of controlled trials have been controversial. [232] However, several controlled studies and two metaanalyses concluded that nonselective ß-adrenergic antagonists have a beneficial effect in prophylaxis of a first variceal hemorrhage. [233], [234] and [235] This relatively complication-free treatment can be recommended for patients with large or moderately sized varices. Cirrhotic patients with small or no varices should be followed for the development of varices. The best clinical predictor of the presence of varices is splenomegaly or a platelet count below 88,000/mm^3. [236], [237] A prospective screening study suggests that patients should undergo endoscopy annually if the initial endoscopy reveals small (grade 1) varices, and that screening every other year is adequate for patients with no varices. [238] In the 3% to 20% of patients who cannot tolerate propranolol, isosorbide-5-mononitrate is an effective alternative. [197] Because combination therapy with propranolol and isosorbide mononitrate is more effective in reducing portal pressure, [198] it may become the standard for prophylaxis of first variceal hemorrhage.

Gastric Varices Gastric varices usually accompany esophageal varices, although they may occur alone. In a study of 568 patients with portal hypertension, primary gastric varices were present in 20% of patients, and secondary gastric varices, which developed after treatment of esophageal varices, occurred in 8% of patients. [239] Risk factors for hemorrhage from gastric fundal varices are similar to those for esophageal variceal bleeding: larger variceal size, the presence of red marks, and relatively severe underlying liver disease. [240] Several classification schemes that depend on the variceal location have been suggested, [239], [241] and it appears that the various subsets have different natural histories and responses to treatment. [239], [242] Gastric varices that develop after sclerotherapy for esophageal varices are referred to as *secondary,* although the propensity for this to occur is controversial. [243] Gastroesophageal varices that cross the gastroesophageal junction along the lesser curvature are most common and often disappear spontaneously with the obliteration of esophageal varices. Gastroesophageal varices that cross the junction along the greater curvature are less common but are associated with a higher incidence of bleeding and are much less likely to disappear after esophageal variceal obliteration. Isolated gastric varices that do not connect with esophageal varices usually occur in the gastric fundus and are the most difficult to treat endoscopically. [244] Isolated gastric varices located elsewhere in the stomach or duodenum (i.e., ectopic varices) are more commonly secondary varices, occur most often in the antrum, and rarely bleed. Isolated gastric varices in the fundus may be the result of splenic vein thrombosis, which can be verified with angiography. These patients are best treated with simple splenectomy that adequately decompresses their varices. They have an excellent prognosis because they do not have underlying liver disease. [245] Splenic vein thrombosis may occur as a complication of pancreatitis secondary to contiguous inflammation from the body and tail of the pancreas. [246] Bleeding gastric varices commonly are associated with large esophageal varices and are the result of underlying liver disease. When patients with gastroesophageal varices bleed, they are more likely to bleed from their esophageal varices, although bleeding gastric varices are associated with higher transfusion requirements. [239] Acute sclerotherapy to stop bleeding is reportedly effective for all types of gastric varices. [247] Sclerotherapy to prevent rebleeding has been advocated for gastric varices that cross the esophageal junction but persist after esophageal variceal obliteration, [239] although sclerotherapy in the stomach may have a higher complication rate. Alternative endoscopic treatments for gastric varices include injection of thrombin, [248] snare ligation, [249] and a combination of sclerotherapy with percutaneous transhepatic obliteration. [250] Injection of cyanoacrylate glue is reportedly effective [251], [252] and may be superior to sclerotherapy with ethanolamine. [253] Shunting with TIPS [254], [255] or surgery may be the best treatment for preventing rebleeding from gastric varices, especially from isolated fundal varices.

Mallory-Weiss Tear Mallory-Weiss tears occur near the gastroesophageal junction in the gastric or esophageal mucosa. They are caused by retching, perhaps with forceful gastric mucosal prolapse as identified at endoscopy. [256] They account for 5% to 10% of cases of upper GI hemorrhage. [257] There is usually a history of vomiting foodstuffs before hematemesis, although bleeding can occur with the first emesis. Many patients with Mallory-Weiss tears have a history of alcohol intake or have portal hypertension. [258] The bleeding usually resolves with conservative management, although endoscopic therapy may be required. [259] Rarely, patients with rebleeding or uncontrollable hemorrhage require oversewing of the bleeding mucosa or angiographic treatment.

Esophagitis and Esophageal Ulcers Esophagitis and esophageal ulcers account for approximately 8% of cases of upper GI hemorrhage. The primary cause of these lesions is peptic reflux, but other causes include irradiation, infectious esophagitis associated with pathogens such as *Candida* or herpesvirus, pill-induced damage, and sclerotherapy-induced ulcers. The presentation of bleeding esophageal lesions is similar to that of peptic ulcer disease. Persistent or recurrent bleeding should be treated aggressively with therapeutic endoscopic or angiographic techniques because esophageal lesions are less amenable to surgery than peptic ulcer disease. When the ulcer is caused by sclerotherapy, the physician must be certain of the source of bleeding because recurrent varices are managed differently.

Sucralfate has been suggested for the treatment of these chemically induced ulcers, although a controlled trial did not prove efficacy. [260] Omeprazole was found effective in the treatment of sclerotherapy-induced ulcers in an uncontrolled trial. [261]

Erosive Duodenitis Hemorrhage resulting from erosive duodenitis is closely related to duodenal ulcer bleeding but is usually less severe because the lesions are shallower and involve smaller vessels. It accounts for approximately 5% of cases of upper GI hemorrhage. The hemorrhage usually occurs in patients with a history of peptic ulcer disease or similar risk factors. Bleeding from duodenitis is almost always self-limited, rarely requiring therapeutic endoscopic intervention.

Neoplasms Neoplasms of the stomach, esophagus, or duodenum are uncommon causes (2%–5%) of upper GI hemorrhage. Bleeding from these lesions is usually self-limited, and treatment is ultimately in the hands of the oncologist or surgeon. If persistent or recurrent bleeding occurs in a patient unsuitable for surgical resection, endoscopic therapy or angiographic arterial embolization may be used. [262], [263] Intraarterial vasopressin is not usually effective because of the large size of the bleeding vessels.

Angiodysplasia and Gastric Antral Vascular Ectasia Vascular ectasia or angiodysplasia, which occurs less commonly in the stomach or duodenum than in the colon, is the cause of upper GI bleeding in 5% to 7% of patients (see Chapter 130). [27], [264] Often found in patients of advanced age, it has been associated with chronic renal failure, hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome), and prior radiation therapy. [265], [266] Angiodysplasia has also been associated with aortic valve disease, although this remains controversial. [267] The diagnosis is usually made endoscopically by visualizing small, punctate, bright red, vascular mucosal lesions. Controlled studies of therapeutic alternatives are not available, but most clinicians would first attempt endoscopic coagulation techniques. These have been successful, although associated with high rebleeding rates in patients with hereditary (Osler-Weber-Rendu) lesions. [268] In cases of vascular ectasia associated with chronic renal failure and its attendant prolonged bleeding time secondary to platelet dysfunction, estrogen-progesterone therapy has been reported beneficial. [269] Similar efficacy has been reported in patients with normal renal function and chronic GI blood loss from vascular ectasia. [270] This suggests that the abnormal platelet function present in renal failure may not be a prerequisite for estrogen-progesterone treatment. One controlled crossover trial confirmed this efficacy. [271] An unusual variant of gastric vascular ectasia is the watermelon stomach, [272] also called *gastric antral vascular ectasia (GAVE)*. The endoscopic appearance is a jagged column of vessels that run along the top of longitudinal rugal folds, traversing the antrum and converging on the pylorus. This vascular aggregate resembles the stripes on a watermelon. Endoscopic biopsy or resected specimens show dilated mucosal capillaries with focal thrombosis and fibromuscular hyperplasia of vessels in the lamina propria. The condition has been associated clinically with hypochlorhydria, systemic sclerosis, and portal hypertension. [273], [274] Although GAVE occurs in patients with cirrhosis, it is distinct from portal gastropathy and does not appear to respond to lowering portal pressures. [275] Endoscopic coagulation treatment with the Nd:YAG laser, multipolar electrocoagulation, argon plasma coagulator, or heater probe may be useful. [276] Estrogen-progesterone treatment has also been effective in decreasing blood loss, [277] even in patients with underlying cirrhosis. [278]

Aortoenteric Fistula Aortoenteric fistulae usually involve the aorta but occasionally arise from branches of the celiac axis. Most aortoenteric fistulae are secondary to prior aortic Dacron graft surgery, [279] although they may occur as primary fistulae caused by atherosclerotic vessels or more rarely mycotic aneurysms, tuberculosis, or syphilis. [280] Aortoenteric fistulae almost always involve the third portion of the duodenum, although they may rupture into the jejunum, ileum, stomach, and colon. In patients with Dacron grafts, the fistula usually arises from the proximal portion of the graft and may be associated with false aneurysms. The classical clinical presentation is a “herald” bleed that occurs and stops spontaneously hours or occasionally weeks before the exsanguinating hemorrhage. A high index of suspicion is necessary to make the diagnosis because the fistula is difficult to discern by x-ray film, endoscopy, and angiography. Arteriography is often not helpful and may delay surgery. Abdominal computed tomography may demonstrate evidence of the fistula. If there is a history of aortic Dacron graft surgery in a patient presenting with GI hemorrhage, endoscopy should be performed to rule out other causes of bleeding, and the endoscopist should attempt to reach the third portion of the duodenum in an effort to visualize the fistula. If not identified, a fistula should be the presumed source of bleeding, and the patient should undergo surgery.

Hematobilia and Hemosuccus Pancreaticus *Hematobilia* is defined as hemorrhage into the biliary tract from any cause. Hemorrhage traversing the pancreatic duct has been called *hemosuccus pancreaticus,* although it is often included with hematobilia because it exits the ampulla. The mortality associated with hemorrhage from both these sites is significant (20%–50%). The most common cause of hematobilia is prior liver or biliary tree trauma, including prior percutaneous liver biopsy or transhepatic cholangiography. Extrahepatic or intrahepatic aneurysms of the hepatic artery or its branches are often caused by the trauma and may communicate with the bile ducts. Angiographic treatment with embolization is usually effective. [281] Less common causes of hematobilia are extrahepatic or intrahepatic tumors, gallstones, and cholecystitis. Hemosuccus pancreaticus represents bleeding from peripancreatic blood vessels into a pancreatic duct. Blood emanates from digested peripancreatic pseudoaneurysms or veins that rupture into a pseudocyst or from true aneurysms of the peripancreatic vessels that rupture into pancreatic parenchyma and ducts. [282] This usually occurs in patients with a history of chronic pancreatitis and pseudocysts. The diagnosis may be made by endoscopy, with visualization of blood coming from the papilla, although it is easily missed when the bleeding has ceased. Angiography is indicated to define the bleeding site and may be used for treatment by embolizing the vessel. [283] If embolization therapy is not successful, surgery may be required.

Dieulafoy Disease The Dieulafoy lesion is defined as a ruptured, thick-walled artery that is larger than other surrounding submucosal vessels, with little or no associated ulceration. The cause of bleeding is not thought to be a primary ulcerative process but rather pressure erosion of the overlying epithelium by this ectatic vessel. [284] The Dieulafoy vessel usually occurs in the fundus, although up to 34% of the lesions develop outside the stomach. [285] Endoscopically, it appears as a round mucosal defect with a protruding artery at the base. Patients present with hematemesis or melena without any relevant history. Endoscopic injection therapy, electrocoagulation techniques, band ligation, and hemoclipping have been successful in stopping bleeding in most patients, although surgery is occasionally required. [285], [286]

Factitious Bleeding or Bleeding from Nongastrointestinal Sources Some patients present with hematemesis or melena that does not originate from a GI source. Usually, it is caused by swallowing blood from epistaxis, hemoptysis, or oral lesions. These diagnoses are best determined by a careful history and physical examination. Endoscopy to rule out GI sources may be required if the diagnosis remains uncertain. Rarely, patients present with factitious bleeding. They may cause themselves to bleed by venopuncture and then swallow the blood before presentation. A high index of suspicion is necessary to make this diagnosis.

ACUTE LOWER GASTROINTESTINAL BLEEDING

Lower GI bleeding is defined as bleeding from a source below the ligament of Treitz. The annual incidence of lower intestinal bleeding is estimated to be 20 to 27 per 100,000 adults at risk. [3] When patients hospitalized for GI bleeding are identified, lower GI sources account for one fourth to one third of all bleeding events. [287], [288] Lower GI bleeding is more common in men than in women, and the incidence rate increases with age, with more than a 200-fold increase noted from the third to the ninth decade of life. [3] Overall mortality rates for lower GI bleeding are consistently below 5%, which is lower than mortality rates for upper GI bleeding.

Diagnostic Approach

The diagnosis should be sought in all patients with lower GI bleeding unless their overall prognosis is too poor to warrant further tests. In most patients whose bleeding ceases spontaneously, an elective colonoscopy after routine preparation is indicated. Patients with continued bleeding require urgent diagnosis. If a perianal or rectal source is suspected, simple proctoscopy can be performed quickly and may provide the diagnosis. For most colonic bleeding, a more thorough examination is required. Unless the bleeding is massive, rapid intestinal lavage allows adequate preparation for urgent colonoscopy. For patients who are bleeding too rapidly for a cleaning preparation or when urgent colonoscopy is not available, angiography is indicated. As with upper GI bleeding, most angiographers prefer prior radiolabeled nuclide scans to demonstrate active bleeding and direct the examination, [289] although the value of this practice has been questioned. [290] Before angiography, nasogastric lavage and even upper GI endoscopy should be considered to rule out an upper GI source of bleeding.

History and Physical Examination A thorough history and physical examination often point to the correct diagnosis. For example, a prior diagnosis of hemorrhoids or inflammatory bowel disease is important. Symptoms that are associated with bleeding, such as abdominal pain or diarrhea, suggest specific diagnoses. A recent history of anorexia or weight loss or an abdominal mass found during physical examination may indicate an underlying malignancy.

Colonoscopy Colonoscopy has replaced the barium enema study in the diagnostic evaluation of lower GI bleeding. Several series have demonstrated the superior diagnostic sensitivity of colonoscopy, even in comparison with double-contrast barium enema studies. When the indication for the diagnostic study is GI bleeding, a colonoscopy is usually indicated regardless of the result of the barium study because false-negative results occur in 10% to 20% of barium studies, and abnormal findings on a barium study lead to colonoscopy for biopsy or therapeutic maneuvers. For these reasons, most clinicians favor colonoscopy as the primary examination. In the occasional patient in whom complete colonoscopy is not technically feasible or the colonoscopy is nondiagnostic, a barium study is helpful. Patients with rapid, ongoing blood loss require diagnostic angiography or urgent colonoscopy after purge. Although the traditional view is that colonoscopy in patients with severe hematochezia is impractical because of inadequate visualization, colonoscopy is feasible and useful after prior rapid cleaning. [287], [288] Urgent colonoscopy made a final diagnosis of colonic lesions in 74% to 90% of patients. In one series that included prior upper GI endoscopy, upper GI lesions were diagnosed in 11%, presumed small bowel lesions in 9%, and no lesion in 6% of 80 patients with ongoing hematochezia. [26] This diagnostic accuracy is better than that of arteriography.

Radionuclide Scans The site of GI bleeding can be localized by scanning for extravasation of intravascular radioactively labeled blood. Technetium Tc 99m sulfur colloid scans are obtained shortly after injection. The use of erythrocytes labeled with ^{99m}Tc-pertechnetate allows repeated scanning over 24 to 36 hours after injection to detect intermittent bleeding. These techniques can reveal bleeding when the rate of blood loss is as low as 0.5 mL/min and have no associated morbidity. In comparison with surgical pathology, they have a sensitivity of 88% for correct localization of the bleeding site. [291] The major disadvantage of radionuclide scans is that they localize the bleeding to an area of the abdomen but do not diagnose the specific location or the responsible lesion. For this reason, radionuclide studies are

often used to determine which patients have sufficient ongoing bleeding to warrant angiography, although their value as an angiography screen has been questioned.[292] However, they may allow more selective angiographic studies, decreasing the dye load. In the rare situation in which massive hemorrhage makes endoscopy impossible, angiography should be obtained immediately and not be delayed by prior radionuclide scans.

Angiography In the rapidly bleeding patient, angiography offers accurate diagnosis and therapy. For patients in whom active bleeding cannot be demonstrated, some advocate an aggressive diagnostic angiographic approach based on pharmacological techniques with heparin or streptokinase.[293] When dye extravasation is not demonstrated, angiography can lead to a presumptive diagnosis such as angiodysplasia. Rare small bowel lesions such as arteriovenous malformations or neoplasms may be demonstrated. Selective arterial embolization with polyvinyl alcohol particles or microcoils is beginning to replace intraarterial vasopressin in the treatment of lower GI hemorrhage.[294] Although intraarterial vasopressin is effective in 70% to 90% of cases, bleeding recurrence is high and the elderly may not tolerate the cardiovascular complications of vasopressin.[295] The use of 3F coaxial catheters allows placement of the microcatheter through an outer 5F diagnostic catheter close to the extravasating artery to deliver an embolic agent, thereby lowering the risk for bowel ischemia.[296] Microcoils are becoming the embolic agent of choice because they are easy to inject and provide reliable arterial occlusion, and flow distal to the coil occlusion can be maintained. Patients who fail angiographic therapy require surgery.

Causes and Therapy

The diagnostic certainty regarding the source of acute colonic bleeding is problematic in much of the literature on lower GI bleeding.[297] A definitive diagnosis is made when endoscopic or angiographic evidence of active bleeding is found, or endoscopic evidence of stigmata of recent bleeding. A presumptive diagnosis is made when a tagged red blood cell scan is positive and colonoscopy shows a potential bleeding site in the area of the positive scan. Historically, the two major causes of acute lower GI bleeding were thought to be diverticulosis and angiodysplasia. However, more recent studies utilizing colonoscopy for diagnosis report angiodysplasia much less often (Table 33-6).[3],[288] Diverticulosis remains the most frequent cause of gross lower GI bleeding, although diverticula are also found incidentally in up to 66% of patients with other bleeding sources. In contrast to patients with upper GI bleeding, patients with lower GI bleeding are less likely to present with shock and have lower transfusion requirements. Like upper GI bleeding, lower GI bleeding stops spontaneously in approximately 80% of cases.

DIAGNOSIS	PERCENTAGE OF TOTAL DIAGNOSES (%)	MEAN (%)
Diverticulosis	20–55	33
Angiodysplasia	3–37	8
Cancer/polyp	8–30	19
Colitis*	6–22	18
Anorectal	0–9	4
Others†	3–14	8
Unknown	1–25	16

* Includes inflammatory bowel disease, infectious colitis, ischemic colitis, radiation colitis, vasculitis, and inflammation of unknown etiology.

† Includes postpolypectomy bleeding, aortoenteric fistula, trauma from fecal impaction, and anastomotic bleeding.

Adapted from ref. 297.

TABLE 33-6 Final Diagnosis of Major Lower Gastrointestinal Bleeding from Seven Studies

Diverticular Bleeding Diverticular bleeding occurs in only 3% of patients with diverticulosis. However, it is the most common cause of major lower GI hemorrhage because of the high prevalence of diverticulosis in the Western world (see Chapter 87). Despite the left-sided preponderance of diverticula, angiographic studies have demonstrated that 70% of bleeding diverticula occur in the right side of the colon.[298] In contrast, studies in which colonoscopy was used in a limited number of patients suggest that bleeding diverticula are more likely to be left-sided.[299],[300] Although most patients with diverticular hemorrhage have always been managed nonoperatively,[301] colonoscopic treatment of bleeding further decreases the need for surgical intervention.[304] Diverticula are usually located in the colonic wall at the sites of penetration of nutrient vessels. Bleeding presumably results from a colonic artery that penetrates into the dome of the diverticulum. The artery ruptures into the diverticular sac and causes copious bleeding. Clinical evidence of associated diverticulitis or inflammation is usually not present, and vessel rupture is thought to be the result of pressure erosion. Diverticular bleeding presents with acute, painless, maroon to bright red hematochezia, although melena may occur. Diverticulosis is not thought to be a cause of Hemoccult-positive stool or slow bleeding.[302] If the initial bout of diverticular bleeding ceases spontaneously, no further therapy is indicated because bleeding does not recur in most patients. Of the 75% to 80% of patients in whom bleeding ceases, 65% to 75% will not have a recurrence, and 25% to 35% will have repeated episodes of diverticular hemorrhage.[3],[303] Urgent colonoscopy after purge with endoscopic treatment of diverticular bleeding for patients with active bleeding or stigmata of bleeding has been shown to be highly effective in decreasing the need for surgical intervention compared to historical controls.[304] Endoscopic treatment has not been compared to angiographic intervention, which is reported to be effective in 93% of patients in whom embolization was possible and in 76% on an intention-to-treat basis.[305] Any patient in whom endoscopic or angiographic control of diverticular bleeding fails should undergo urgent surgery to remove the portion of the colon bearing the bleeding site. Additionally, patients with recurrent diverticular bleeding should undergo elective surgery if their general medical condition and anticipated life span warrant such aggressive therapy. Accurate preoperative localization of the bleeding site with either angiography or colonoscopy reduces postoperative rebleeding rates by directing the resection to the appropriate segment of colon. Subtotal colon resection is recommended for patients with recurrent bleeding but no demonstration of a bleeding site and may be associated with lower rebleeding rates than limited colon resection without increasing morbidity or mortality.[306] Surgical mortality rates for recent series are between 5% and 10%.[307]

Angiodysplasia Vascular ectasia, or angiodysplasia, is a common cause of acute major lower GI hemorrhage and slow intermittent blood loss (see Chapter 130). Of 80 patients with lower GI angiodysplasia, 46% presented with acute hemorrhage and 54% presented with chronic or occult blood loss.[308] The percentage of cases of acute lower GI bleeding that have been attributed to angiodysplasia varies widely in the literature, from 10% to 40%.[309],[310] Most vascular ectases are degenerative lesions associated with aging. Two thirds of patients with colonic angiodysplasia are older than 70 years of age. These lesions are different from the congenital vascular lesions that occur throughout the GI tract in various age groups. Angiodysplastic lesions are usually multiple, less than 5 mm in diameter, and involve primarily the cecum and right side of the colon. A clinical association with aortic value stenosis is recognized,[311] although the validity of the association continues to be controversial.[312] It has been reported that aortic valve replacement decreases bleeding frequency.[313] Acquired von Willebrand disease secondary to aortic stenosis, which is corrected after valve replacement, has been the hypothesized link between bleeding angiodysplasia and aortic valve disease.[314] The pathogenesis of angiodysplasias is unknown, but one theory is that repeated, partial, intermittent obstruction of the submucosal veins where they pierce the muscle layers of the colon leads to dilation and tortuosity of the vessels.[315] Eventually, the entire arteriolar-capillary-venular unit dilates, creating a small arteriovenous communication. The predilection for the right side of the colon of these degenerative lesions may reflect the greater tension in the cecal wall than in the rest of the colon. The diagnosis of vascular ectasia can be made by colonoscopy or angiography. A sensitivity of 70% for helical computed tomographic angiography has been reported in the diagnosis of colonic angiodysplasia by the demonstration of vessel accumulation in the colon wall, an early-filling vein, and an enlarged supplying artery.[316] The diagnostic sensitivity of colonoscopy is 80% to 90%, and colonoscopy has the advantage of therapeutic potential.[26] Naloxone may enhance the appearance of both normal colonic vasculature and ectasias.[317] The sensitivity of angiography for angiodysplasia appears to be much lower, although no data based on pathology as the gold standard are available. The earliest angiographic sign is a densely opacified, dilated, tortuous, slowly emptying intramural vein. A vascular tuft represents a more advanced lesion, and an early-filling vein reflects an arteriovenous communication and is a late sign.[318] All diagnostic modalities frequently identify the lesions without demonstrating active bleeding. Because active bleeding is infrequently identified and because these lesions appear to be common in the elderly without a history of significant blood loss, a definitive diagnosis is difficult. Nevertheless, if no other source of GI bleeding is identified in a patient with recurrent or persistent GI bleeding sufficient to require transfusions or cause significant anemia, the presence of angiodysplasia is an indication for treatment. Angiographic embolization and endoscopic techniques of hemostasis are both successful for controlling continued gross hemorrhage.[319] Electrocoagulation techniques, including heater probe, hot biopsy with monopolar coagulation, multipolar coagulation, Nd:YAG laser, and the argon plasma coagulator, have all been used successfully for the treatment of bleeding angiodysplasia. Rebleeding rates of 10% to 30% have been reported.[320] Options then include further endoscopic therapy or surgery. Complications of endoscopic therapy are uncommon but include induction of bleeding and perforation. A retrospective comparison of medical therapy, coagulation techniques, and surgery showed a significant decrease in transfusion requirements for all three types of management of angiodysplasia.[321] Specimen injection techniques have demonstrated incidental angiodysplastic lesions in as many as 50% of surgically resected colons from autopsy specimens.[322] It seems prudent to reserve endoscopic therapy for lesions causing significant blood loss or anemia. For chronic or recurrent bleeding caused by angiodysplasia, estrogen-progesterone therapy is successful in decreasing transfusion requirements. If therapeutic colonoscopy and estrogen-progesterone therapy fail to prevent recurrent bleeding, a hemicolectomy or colectomy is indicated, depending on the localization of these lesions.

Neoplasms and Postpolypectomy Bleeding Benign and malignant neoplasms of the colon are common and, like diverticula and angiodysplastic lesions, occur predominantly in the elderly. They usually present with small degrees of intermittent bleeding or Hemoccult-positive stools. However, neoplastic lesions are the cause of acute lower GI bleeding in 2% to 26% of cases.[287] The diagnosis is made by colonoscopy, and the treatment is surgical or colonoscopic excision. Small bowel tumors are rare but may be diagnosed by small bowel x-ray films or enteroclysis. Occasionally, angiography may be required to make the diagnosis. A history of

intermittent small bowel obstruction is a clue to a small bowel tumor as the cause of lower GI bleeding. Postpolypectomy bleeding accounts for 2% to 5% of cases of acute lower GI bleeding. [3], [288] A review of patients with postpolypectomy hemorrhage noted that half of the patients required transfusions; the presentation time from polypectomy ranged from 0 to 17 days, with a median of 5 days. [323] Most patients had been on NSAIDs/aspirin or anticoagulants. Endoscopic therapy successfully treats more than 95% of patients. [324]

Perianal Disease Hemorrhoids and anal fissures are the most common causes of minor intermittent lower GI bleeding. Most young and middle-aged persons with rectal bleeding do not even seek medical care. [325] Only rarely is the amount of bleeding severe enough to cause iron deficiency anemia or acute and severe enough to mandate transfusions. Massive hemorrhage from simple hemorrhoids is rare. Bleeding is usually from internal hemorrhoids and is painless. The characteristic clinical history is the presence of bright red blood on the toilet tissue or around the stool but not mixed in the stool. Bleeding often occurs with straining or the passage of hard stool. A similar history is common in patients with bleeding from anal fissures, with the exception that anal fissures are often painful. Because rectal polyps and carcinomas may present with a similar bleeding history, patients should be evaluated with flexible sigmoidoscopy, including retroflexion of the flexible sigmoidoscope in the rectum to examine the proximal anal canal. Careful external examination of the external anal canal is also necessary. Perianal disease is treated with sitz baths, bulk-forming agents, avoidance of straining, and ointments or suppositories. It is unknown whether actual therapeutic benefit is obtained with locally applied medications containing lubricants and hydrocortisone, but many patients report symptomatic relief. When bleeding or other symptoms continue to be troublesome, hemorrhoidal banding, coagulation techniques, or surgery may be indicated. [326]

Meckel Diverticulum Meckel diverticulum is the most frequent congenital anomaly of the intestinal tract, with an incidence of 0.3% to 3.0% in autopsy reports. It develops from incomplete obliteration of the vitelline duct, leaving an ileal diverticulum. Approximately 50% of these diverticula contain normal ileal mucosa, and most of the remaining 50% contain gastric mucosa or may occasionally contain duodenal, colonic, or pancreatic ectopic mucosa. The gastric mucosa is capable of acid secretion, which can result in ulceration of adjacent ileal mucosa. Most Meckel diverticula remain asymptomatic and do not require surgical excision when discovered incidentally. [327] Bleeding, the most common complication, usually occurs in childhood, although bleeding may rarely occur in adults. [328] Patients present with painless bleeding that may be dark or bright red, although its appearance is classically described as “currant jelly.” The diagnosis can be made by scanning with radioactively labeled technetium, but false-negative results are not uncommon, and false-positive results have also been reported. [329] It has been suggested that the administration of pentagastrin or cimetidine before the scan may improve sensitivity of the test. [330], [331] Barium filling of the diverticulum may occur, especially with an enteroclysis. Mesenteric angiography may demonstrate the site of bleeding. Surgical excision is the treatment of choice.

Inflammatory Bowel Disease Bleeding from inflammatory bowel disease is usually minimal to moderate, although it reportedly accounts for 2% to 6% of all cases of acute lower GI bleeding. [3], [297] A review of acute major GI hemorrhage in inflammatory bowel disease suggests that it is much more common in Crohn’s disease than in ulcerative colitis. [332] However, acute lower GI bleeding accounts for only 1% of hospital admissions for Crohn’s disease. Surgery is required for treatment in 20% to 35% of cases. [333]

Colitis Secondary to Ischemia, Infections, or Irradiation *Ischemic colitis* is a common entity in the elderly (see Chapter 131). It is usually caused by “low-flow states” and small vessel disease rather than by large vessel occlusion. Any segment of the colon may be involved, although the most common areas are the splenic flexure, descending colon, and sigmoid colon. The typical presentation is mild, cramping abdominal pain localized to the lower left side, followed within 24 hours by rectal bleeding or bloody diarrhea. The blood loss is characteristically minimal, although ischemic colitis causes 3% to 9% of all cases of major lower GI bleeding. [3], [297] Plain abdominal films may show the classical “thumb-printing” lesion of the colon. The diagnosis is best made by colonoscopy and biopsy. Most cases resolve spontaneously with observation and medical support. Surgery is reserved for the rare circumstance of clinical deterioration with fever and a rising leukocyte count or persistent hemorrhage. *Infectious colitis* caused by *Campylobacter jejuni, Salmonella* species, *Shigella* species, invasive *Escherichia coli* or *E coli* 0157:H7, or *Clostridium difficile* often presents with bloody diarrhea. The degree of blood loss is rarely significant. The diagnosis is made by sigmoidoscopy or colonoscopy with biopsy and stool culture. Treatment is not required or is determined by the specific pathogen. *Radiation-induced colitis* is a chronic or recurrent problem that may follow irradiation immediately or several years later (see Chapter 132). The blood loss is rarely massive but may cause iron deficiency or a need for intermittent blood transfusions. The diagnosis is based on a history of prior irradiation with endoscopic biopsy confirmation. Medical treatment with bulk-forming agents or sulfasalazine has not been successful. Intrarectal instillation of formalin will stop bleeding in 75% to 80% of patients. [334] Endoscopic coagulation treatment with the Nd:YAG, argon, or KTP (potassium [K] titanyl phosphate) laser, bipolar electrocoagulation, and treatment with the heater probe have also been successful in 65% to 90% of patients. [335], [336], [337] and [338] These endoscopic treatment modalities appear safer and technically easier than formalin instillation. Decreased transfusion requirements have also been reported after treatment with estrogen-progesterone and hyperbaric oxygen. [339], [340] Surgical intervention is difficult because of the radiation damage to local tissue, with substantial morbidity reported. [341]

Intussusception Intussusception may present with maroon stools and is almost always accompanied by cramping abdominal pain. Uncommon in adults, it usually has a leading point, such as a polyp or malignancy. The diagnosis may be suggested by plain abdominal films and the finding of a sausage-shaped mass during physical examination. Barium enema studies may be useful for diagnosis and in children may be used for therapeutic reduction. The treatment of intussusception in adults is usually surgical.

Portal Hypertension and Rectal Varices Ileal or colonic varices, which tend to occur around ostomies, [342] may present with massive lower GI bleeding. [343] The diagnosis is often made by angiography, and the treatment is decompression of the portal hypertension by surgery, TIPS, or propranolol and nitrates. Rectal varices may also present with gross lower GI bleeding. Variceal ligation has been used to stop bleeding, although decompression of portal hypertension is probably superior for preventing rebleeding. Multiple colonic vascular ectases in patients with portal hypertension can cause hematochezia or Hemoccult-positive stools; the condition is called *portal colopathy*. [344]

Other Causes Several rare causes of lower GI bleeding deserve brief mention. Solitary rectal ulcer, which may be associated with an internally prolapsing rectal mucosa, causes lower GI bleeding, although the bleeding is rarely massive. [345] Aortoenteric fistulae, not associated with prosthetic grafts, have been described in the ileum and colon. The diagnosis is usually made by angiography, and the treatment is surgery. NSAIDs predispose patients to lower GI bleeding by two mechanisms: causing small bowel or colon ulcers [346], [347] and interfering with platelet function. [348], [349] Metronidazole may be effective in decreasing GI blood loss from NSAID-induced enteropathy. [350]

BLEEDING FROM AN UNKNOWN SOURCE

There are always a few unfortunate patients with chronic bleeding (obscure-occult) or recurrent acute bleeding (obscure-overt) in whom a diagnosis cannot be made despite upper and lower GI x-ray studies, endoscopy, and angiography. It has been estimated that in as many as 5% of patients, a source of bleeding cannot be identified despite extensive examination. [351] The cause of GI bleeding from an obscure origin in most patients is thought to be vascular ectasia. [352] Unfortunately, many of these lesions are too small to be detected by angiography and can be missed or not reached by endoscopy. [353] They usually are degenerative lesions that develop with aging. Rarely, arteriovenous malformations or vascular fragility syndromes may be associated with elastic tissue disorders, such as pseudoxanthoma elasticum and Ehlers-Danlos syndrome, or with skin-associated vascular anomalies, such as heredity hemorrhagic telangiectasia or blue rubber bleb syndrome (see Chapter 49 and Chapter 130). [354], [355] and [356]

The failure to make a diagnosis in some patients with chronic or recurrent bleeding reflects the relative inaccessibility of the small bowel. In young patients, a radionuclide scan for Meckel diverticulum is valuable. The most useful approach for identifying small bowel sources of bleeding is enteroscopy, which may replace a “second look” upper GI endoscopy. [357] Small bowel enteroscopy by the “pull” or Sonde technique has been successful in diagnosing the cause of bleeding from obscure origins in 25% to 40% of patients whose condition has eluded all other diagnostic tests. [358], [359] This is a tedious and time-consuming test for both patient and physician; in three fourths of the patients, the ileum is reached after an average intubation time of 6 hours. Other drawbacks include the lack of intervention capability, inability to view the lumen completely (estimated at 50%–70%), and lack of availability of the technique. Much more commonly applied is “push” enteroscopy with a pediatric colonoscope or a modified, longer upper GI endoscope (see Chapter 139). This has the advantage of allowing therapeutic maneuvers and is widely available. [360], [361] Diagnostic yields of 30% to 45% are reported. [362], [363] Up to half of the diagnoses made at push enteroscopy are within the reach of a standard upper GI endoscope, demonstrating the value of repeated expert upper GI endoscopy. [364] Push enteroscopy and Sonde enteroscopy have been combined to increase the diagnostic yield to 58%. [365] Capsule endoscopy may become important in visualizing the portion of the small bowel that is not within reach of the push enteroscope.

Enteroclysis, or a small bowel infusion x-ray study, provides better radiographic images of the small bowel than traditional small bowel follow-through. Unfortunately, it is an uncomfortable examination requiring intubation of the patient through the mouth, with fluoroscopic positioning of the tip of the tube at the duodenojejunal junction. Barium is then rapidly injected to fill the small bowel. Methylcellulose and water with or without parenteral glucagon are also given to achieve a double-contrast effect. [366], [367] A combination of push enteroscopy and enteroclysis, in which the enteroclysis tube is inserted on withdrawal of the enteroscope, provides a better diagnostic yield in a more comfortable and convenient single diagnostic setting. [368] Diagnostic angiography in the patient who is not actively bleeding may also reveal vascular anomalies or small bowel tumors not identified by other tests. [369]

Intraoperative small bowel enteroscopy has a high success rate in identifying bleeding lesions, although the operative morbidity may be significant, [370] and after seemingly appropriate surgery, rebleeding occurs in 26% of patients overall and in 39% of patients with small bowel vascular abnormalities. [371], [372] Intraoperative

angiography with methylene blue injection and intraoperative scintigraphy have also been used in locating small bowel angiodysplastic lesions. [373], [374]

Push enteroscopic cauterization of small intestinal angiodysplasias has been shown to be effective in decreasing blood transfusion requirements. [375], [376] If this is unsuccessful or not feasible because multiple lesions are present, surgical resection of the involved segments may be necessary. A trial of estrogen-progesterone therapy for the possible underlying diagnosis of vascular ectasia may be worthwhile, even in some patients without a definite diagnosis. Unfortunately, the condition of a few patients with bleeding from an unknown source defies diagnostic efforts, or they patients are too ill for surgery and are relegated to receive transfusions as needed.

CHAPTER 34

David A. Ahlquist

APPROACH TO THE PATIENT WITH OCCULT GASTROINTESTINAL BLEEDING

By definition, occult gastrointestinal (GI) bleeding is hidden and not apparent on stool inspection. It occurs commonly, but a test is required for its detection. Elevated fecal blood levels are found in about 1 of 20 adults on prevalence screens [1], [2], [3] and [4] and probably occur episodically in all persons. Although often insignificant, occult GI bleeding may herald a health-threatening lesion arising at any level from mouth to rectum. As such, the clinician is challenged when faced with occult GI bleeding.

The critical metabolic sequela of occult GI bleeding is iron deficiency. Iron deficiency afflicts 20 million people in the United States alone, and its global prevalence is estimated at 15%. [5], [6] It is the most common cause of anemia and often results from occult GI blood loss. [7] The management of iron deficiency depends on the cause, and a GI origin should always be considered.

Fecal occult blood testing is widely used to screen for colorectal cancer and to evaluate iron deficiency and anemia. A rational assessment and treatment of occult GI bleeding are based on an appreciation of the pathophysiology of occult blood loss, available diagnostic tools, and therapeutic principles.

QUANTIFYING BLOOD LOSS

Given a typical daily stool mass of 150 g (150 mL) and a circulating hemoglobin (Hb) of 15 g/dL, the following equivalences can be calculated: 2 mL of fecal blood loss per day = concentration of 2 mg of Hb per gram of stool = total daily Hb loss of 300 mg = daily iron loss of 1 mg.

Depending on the rate and site of GI bleeding, enterocolic transit time, efficiency of lumenal Hb metabolism, and degree of fecal mixing, blood loss may be visually gross or occult. At one extreme, large amounts of blood may be lost into the proximal GI lumen and remain occult. A bolus of more than 150 mL of blood in the stomach or cecum is required to consistently produce melena or hematochezia. [8], [9] Fecal Hb concentrations may approach those of circulating blood without being visibly apparent. [10] On the other extreme, a mere drop of blood from anorectal lesions may be visible as a bright red streak on the stool surface.

Fecal blood is not simply present or absent; the levels range in a continuum from normal to pathologically elevated. Fecal blood loss quantified in healthy volunteers averages 0.5 to 1.5 mL/d (0.5–1.5 mg of Hb per gram of stool), [11], [12] and [13] with levels below 2 mL/d found in 95% (Fig. 34-1).

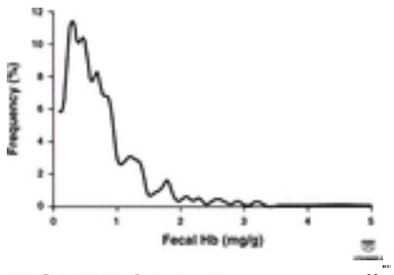

FIGURE 34-1. Frequency distribution of fecal occult blood levels in 900 asymptomatic subjects undergoing colorectal cancer screening as quantified by the HemoQuant assay. In more than 95%, the fecal hemoglobin levels are below 2 mg/g, which is considered to be the upper limit of normal.

GASTROINTESTINAL HEMOGLOBIN METABOLISM

The degree of Hb disassembly during GI transit and fecal storage affects measurements because available fecal blood tests target different components of the Hb molecule (Table 34-1). An appreciation of enterocolic Hb metabolism helps to clarify test limitations and is useful in selecting a test appropriate to the clinical indication.

TABLE 34-1 Effect of Gastrointestinal Bleeding Site on Metabolic Fate of Intralumenal Hemoglobin

Heme is cleaved from Hb by enzymes in the upper gut. [14] Some heme, probably less than 15%, is absorbed intact in the proximal small intestine. [15], [16], [17], [18] and [19] Heme absorption may increase threefold in iron deficiency [20] and decrease after gastrectomy. [21] In the colon, from 1% to 99% of heme is converted by bacteria to porphyrins. [16], [22] Heme-derived porphyrins escape detection by guaiac tests. [10], [13], [18]

The globin chains of Hb are digested by upper gut proteases. Because immunoassays for Hb are directed against globin antigens, they are insensitive for upper GI bleeding. [23], [24] and [25] Immunoassays fail to detect ingested blood in quantities up to 100 mL. [24], [26] Hb globins are also metabolized by colonic bacteria, and immunoassays are less likely to detect bleeding from the right side of the colon than from the left. [27] Furthermore, immunoreactivity is progressively lost during fecal storage.

IRON METABOLISM AND DEFICIENCY

Occult GI bleeding may be compensated for by increased iron absorption or mobilization of body iron stores, which in turn stimulates erythropoiesis. However, if iron loss from occult bleeding chronically exceeds intestinal iron absorption, iron stores become depleted, and iron deficiency with attendant anemia and other metabolic sequelae ensues. The time required for iron deficiency to develop depends on the rate and chronicity of occult bleeding.

Iron Absorption

Ordinarily, 1 to 2 mg of iron is absorbed daily, which represents about 10% of that in a typical Western diet. [28] Both heme and elemental forms of iron are absorbed primarily in the duodenum and proximal jejunum. Elemental iron absorption may be increased up to tenfold by iron deficiency, anemia, hypoxia, liver disease, increased erythropoiesis, and an elevated lumenal iron concentration. [5], [28], [29] It is facilitated by reducing substances, bile, pancreatic juice, gastric acid, and a nonacidic gastric modulator. [5], [30], [31], [32] and [33] Iron absorption is impeded by various mucosal diseases of the upper small intestine and by certain lumenal substances, such as phytates in cereals, tannic acid in tea, and oxalates, that chelate iron. [28], [29], [34], [35] and [36] Selective iron malabsorption occurs rarely secondary to an inherited defect of transferrin function [37] or to an acquired autoimmunity to the transferrin receptor. [38]

Iron Loss

A physiological mechanism does not exist for iron excretion. Under normal circumstances, absorption of dietary iron (average, 1–2 mg/d) equals or just exceeds iron loss through normal daily occult GI bleeding (average, 1 mg/d). Trace amounts of iron are also lost through cutaneous desquamation and intestinal epithelial sloughing. Menorrhagia often contributes to iron deficiency in premenopausal women. [39] Although excessive bleeding can occur from the airway, from the urinary tract, or from multiple phlebotomies, these are uncommon causes of iron deficiency, and, if present, clinically apparent. [5] Excessive iron loss through occult GI bleeding, the most common cause of iron deficiency, is the most difficult to recognize. As a general rule, daily GI blood losses of at least 5 to 10 mL are required to overcome compensatory absorptive increases and lead to a negative iron balance.

Iron Storage

Most body iron, about 75%, is stored in metabolically active forms, with roughly 70% in Hb and 5% in myoglobin and various tissue enzymes. [5] The remaining 25% of body iron is metabolically inactive and stored in a soluble complex with ferritin or in a particulate state as hemosiderin, especially in hepatocytes and in the reticuloendothelial cells of the liver, bone marrow, and spleen. [5] A small amount of ferritin is present in plasma and correlates well with total body iron stores. [40]

Metabolic Consequences of Iron Deficiency

Iron is present in all human cells and is of vital importance for oxygen transport and many metabolic functions. This ubiquitous metal is essential for nearly half of the enzymes of the Krebs and tricarboxylic acid cycles, for DNA synthesis, and for many other cellular processes. [5], [41] It is not surprising that the clinical and metabolic manifestations of iron deficiency are so generalized. The fatigue associated with iron deficiency should be recognized as a pancellular phenomenon and results not only from anemia [42], [43] but also from dysfunction in nonhematologic tissue. [44], [45]

Characteristic mucocutaneous findings may be present (see section “ Clinical Manifestations of Blood Loss”). Gastric atrophy with achlorhydria and a spruelike small intestinal lesion with malabsorption may occur with iron deficiency and resolve with iron replacement. [46], [47], [48] and [49] Iron deficiency has also been causally linked to certain behavioral, immunologic, and developmental abnormalities. [50], [51], [52], [53] and [54]

ETIOLOGY OF BLOOD LOSS

Many of the lesions that cause gross bleeding (see Chapter 33) can also cause occult bleeding. The mechanisms of occult GI bleeding necessarily involve a disruption of the epithelium and subepithelial blood vessels and can be categorized as inflammatory, infections, vascular, neoplastic, and other (Table 34-2). The prevalence of responsible lesions varies by age and geography. For example, occult bleeding in infants commonly arises from milk-induced enteritis, [52] but in the elderly from peptic ulcer disease or neoplasms. [7], [13], [55], [56] Although rare in temperate climes, hookworm infestation is the most common cause of harmful occult bleeding in tropical and subtropical regions. [57]

Inflammatory Causes	**Tumors and Neoplastic Causes**
Acid peptic disease	Primary GI cancer at any site
Large hiatal hernia (Cameron erosions)	Metastases to GI tract
Crohn’s disease	Large polyp at any site
Chronic ulcerative colitis	Lymphoma
Mild enterocolitis	Leiomyoma
Whipple disease	Leiomyosarcoma
Sprue	Lipoma
Eosinophilic gastroenteritis	Other
Meckel diverticulum	**Drugs**
Solitary colon ulcer	Nonsteroidal antiinflammatory drugs
Other	Other
Infectious Causes	**Miscellaneous Causes**
Hookworm	Long-distance running
Strongyloidiasis	Extra-GI bleeding
Ascariasis	Benign infiltrative lesions
Tuberculous enterocolitis	Factitious cancer
Amebiasis	Artifact
Other	
Vascular Causes	
Angiodysplasia and vascular ectasia	
Gastroesophageal varices and congestive gastropathy	
Hemangiomata	
Blue rubber bleb nevus syndrome	
Watermelon stomach	
Other	

GI, gastrointestinal.

TABLE 34-2 Disorders that May Present as Occult Gastrointestinal Bleeding with or without Iron Deficiency

Inflammatory Causes

In Western countries, erosions or ulcerations of the esophagus, stomach, and duodenum are the most common GI lesions associated with occult bleeding and iron deficiency (see Chapter 60 and Chapter 66). Iron deficiency has been attributed to such acid peptic disease in 30% to 70% of adult cases and is often asymptomatic. [7], [24], [25], [55], [56] Acid peptic disease, particularly reflux esophagitis, [58] may also underlie iron deficiency in children. Most peptic disease is associated with drug use (see below) or *Helicobacter pylori* gastritis (see Chapter 68). In some populations, *H pylori* disease is pandemic and contributes to widespread iron deficiency. [59], [60] Studies suggest that the iron deficiency resulting from *H pylori* infection may occur in the absence of erosions or ulcers and resolves with antibiotic therapy. [61]

The association between large diaphragmatic hernias and iron deficiency anemia has long been known. [62], [63] and [64] In up to 10% of iron-deficient patients, a large diaphragmatic hernia is found. [7], [55] Blood loss is caused by longitudinal mucosal erosions (Cameron erosions) located in the proximal stomach and is thought to be secondary to mechanical trauma resulting from breathing. [65], [66]

Many inflammatory GI conditions of the small bowel and colon may cause occult bleeding (see Chapter 83 and Chapter 85). Bovine milk may produce occult bleeding and iron deficiency in infants as a consequence of inflammation throughout the gut, which resolves after the ingestion of milk is stopped. [67] Meckel diverticulum may cause occult bleeding in children and young adults. [52] Crohn's disease and chronic ulcerative colitis uncommonly present with occult bleeding alone. [7], [55] Occult blood loss may occur with celiac sprue, Whipple disease, eosinophilic gastroenteritis, radiation enteritis, and solitary colon ulcer.

Infectious Causes

Whereas occult bleeding may accompany many acute infectious enterocolitides (see Chapter 74), it may be chronic and lead to iron deficiency in such conditions as GI tuberculosis (see Chapter 75), amebiasis (see Chapter 125), ascariasis (see Chapter 126), and *H pylori* gastritis (see above). However, the most common infectious cause of harmful occult bleeding worldwide is hookworm (see Chapter 126).

Several hundred million people are infected with hookworm globally, and the prevalence in some tropical countries exceeds 80%. [57] The major and often the only manifestation is iron deficiency, which exacts an enormous socioeconomic toll in lost work productivity. Daily occult fecal blood loss averages more than 12 mL in most hosts, may exceed 100 mL, correlates with the hookworm burden, and drops precipitously after use of a vermifuge. [57], [68]

Vascular Causes

Varices are occasionally incriminated as the source of occult bleeding and have been reported in up to 3% of patients with iron deficiency. [7], [13] The attendant congested mucosa in the gastroduodenum [69] or colon [70] may account for occult blood loss with portal hypertension.

Vascular malformations (see Chapter 130) are found in up to 6% of adults with iron deficiency anemia [7], [24], [25], [55], [56] and are a common explanation for occult bleeding of obscure origin. [71], [72] and [73] GI bleeding remains occult in many patients with acquired or hereditary (e.g., hemorrhagic telangiectasia [Osler-Weber-Rendu syndrome]) vascular malformations. [74] An increasingly recognized and endoscopically treatable vascular lesion is watermelon stomach, which characteristically presents with iron deficiency anemia in older women. [75], [76] Clinically significant occult bleeding has been described from other vascular lesions, including post-radiation telangiectases [77] and lesions associated with the blue rubber bleb nevus syndrome, [78] scleroderma, [79] Turner syndrome, [80] and Klippel-Trenaunay syndrome. [81]

Tumors and Neoplasms

GI tumors are second only to peptic disease as a cause of occult bleeding leading to iron deficiency in adults in Western countries. [7], [24], [25], [55], [56] Because of the importance of fecal occult blood testing in the detection of colorectal adenocarcinoma and adenomas, these lesions are discussed separately (see section "Occult Bleeding Patterns" under "Fecal Blood Screening for Colorectal Neoplasia"). Colorectal cancer is the most common malignant lesion to cause occult bleeding in Western countries, followed by primary cancers in the stomach, esophagus, and ampulla. [7], [13], [24], [25] /SUP>, [55], [56], [82] Lymphomas, lipomas, leiomyomas, leiomyosarcomas, hamartomas, juvenile polyps, and metastatic lesions to the gut can also produce occult bleeding (see Chapter 80, Chapter 89, and Chapter 91).

Drugs

Any ingestant that directly or indirectly injures the GI tract may cause abnormal occult bleeding. Ethanol may lead to hemorrhagic gastritis only at high concentrations, [83], [84] and the contribution of social drinking to occult bleeding is probably minor. Anticoagulants appear to unmask bleeding from preexisting lesions rather than produce bleeding per se. [85], [86] Certain antibiotics, potassium preparations, antimetabolites, and other drugs may damage the epithelium, but few data on occult bleeding are available.

Aspirin and related nonsteroidal antiinflammatory drugs (NSAIDs) are responsible for most cases of drug-induced occult GI bleeding, owing to widespread use. In the United States, more than 30 billion NSAID tablets are consumed annually. [87] Except for acetaminophen and sodium salicylate, all NSAIDs may cause blood loss. [88], [89] At therapeutic doses, some NSAIDs induce more bleeding than others. [89] The new cyclooxygenase-2 inhibitors are much less toxic to the mucosa than conventional NSAIDs. [90], [91] NSAIDs most commonly ulcerate the stomach but may injure the GI tract at any level and cause bleeding. [89], [92] NSAID gastroenteropathy results from the inhibition of epithelial cyclooxygenase and loss of mucosa-protective prostaglandins. [93] The NSAID dose influences the amount of mucosal injury and blood lost. [85], [87] Those taking therapeutic amounts of aspirin lose on average 2 to 5 mL of blood daily, and some more than 30 mL/d. [85], [87], [94] Fecal blood levels are rarely elevated in those taking low-dose aspirin for cardiovascular prophylaxis. [86], [95]

Miscellaneous Causes

Iron deficiency may develop in long-distance runners and compromise performance. [96] Occult GI bleeding appears to be a major cause. [97], [98] In elite class runners, both gastric and colonic erosions have been identified and have been shown to resolve when running is stopped. [99], [100] Occult GI bleeding is less likely to occur with other endurance activities. [101], [102]

Fecal occult blood levels may be elevated in patients who swallow blood from tracheobronchial, dental, oronasopharyngeal, or factitious sources. Infiltration by benign conditions such as endometriosis, [103] amyloidosis, [104] and splenosis [105] may cause hemorrhage and chronic occult bleeding. Stools sampled from toilet water may be contaminated by blood in the urine or menstrual blood. [106] Finally, numerous substances other than blood may react with guaiac and other tests to produce false-positive results (see section "Fecal Blood Testing").

CLINICAL MANIFESTATIONS OF BLOOD LOSS

Symptoms

Occult GI bleeding in most cases is clinically silent and unsuspected. However, predominant manifestations of the underlying GI disease may be responsible for occult bleeding. Also, characteristic symptoms and signs of iron deficiency may occur secondary to chronic occult blood loss from any cause. Fatigue with exercise intolerance is the most frequent symptom of iron deficiency and can be disabling. [41], [42], [43], [44] and [45] Rapid palpitations and exertional dyspnea are also common features of advanced iron deficiency. Less common overt sequelae of iron deficiency may be present; for example, iron deficiency may contribute to a restless leg syndrome. [107]

Pica, or compulsive eating, may occur in roughly 50% of patients with iron deficiency. [108], [109] Pagophagia, or ice eating, is the most frequent form, and some afflicted persons have consumed more than 9 kg of ice daily. Other variants of pica include ingestion of soil (geophagia), laundry starch, brittle or crunchy foods ("gooberophagia"), and chalk. Such bizarre behavior resolves with iron repletion.

Physical Findings

Telltale findings may suggest both the presence and cause of iron deficiency. Papilledema, hearing loss, cranial nerve palsies, and retinal hemorrhages occur rarely with severe iron deficiency and

may resolve with iron repletion. [5], [110] More characteristic of iron deficiency are various epithelial abnormalities. Fingernails and toenails may become brittle, longitudinally furrowed, or spooned, [111] changes called *koilonychia*. Glossitis may occur with erythema and loss of the lingual papillae. [112] Scaling or fissuring of the lips, called *cheilitis,* and atrophic rhinitis may also result from iron deficiency. The association of esophageal webs with iron deficiency is known as *Paterson-Kelly syndrome* or *Plummer-Vinson syndrome*. [113], [114] These proximal esophageal webs may cause dysphagia, are more common in women, and may resolve with iron therapy. [5], [115]

ASSESSMENT AND DIAGNOSTIC STRATEGIES

Occult GI bleeding may be evidenced either indirectly by laboratory confirmation of iron deficiency or directly by measurement of fecal blood. Neither approach is infallible, and they should be viewed as complementary. Iron deficiency would not be present if enteric blood loss were quantitatively minor or of short duration. Negative fecal blood test results may be caused by intermittent bleeding or analytic limitations of the tests. It is important to appreciate the strengths, limitations, and complementarity of the laboratory techniques used to establish occult bleeding. The subsequent GI evaluation should be tailored to the clinical setting.

Blood and Bone Marrow Tests for Iron Deficiency

Although it is a late-stage manifestation, hypochromic microcytic anemia is often the first clue to the presence of iron deficiency. [5] The characteristic erythrocyte morphology on peripheral smear is now more commonly detected by automated calculations that reveal a low mean corpuscular Hb concentration (MCHC) and low mean corpuscular volume (MCV). Anisocytosis, or variability in cell size, is also common in iron deficiency anemia and is reflected by an elevated red cell distribution width (RDW). However, these red cell changes are present in fewer than 70% of persons with iron deficiency anemia, [116] and they may occur in patients with anemia of chronic illness, thalassemia, or sideroblastic anemia. [5], [116], [117] The status of iron stores must be evaluated to determine the cause of microcytic anemia.

Unlike iron deficiency, other causes of hypochromic microcytic anemia are associated with normal or increased tissue iron stores. [5], [116], [117] Although typically decreased in iron deficiency, serum iron levels and transferrin saturation correlate rather poorly with marrow iron stores, are influenced by many medical conditions, and are also commonly low in anemia of chronic illness, the most troublesome differential diagnosis. [5], [116], [117] In contrast, serum ferritin levels correlate well with tissue iron stores and better discriminate iron deficiency anemia from other types of anemia. [5], [117] Serum ferritin levels fall well before anemia develops, and a low serum ferritin level is pathognomonic for iron deficiency. Inflammatory, malignant, liver, and renal disease can elevate serum ferritin and uncommonly cause a falsely normal serum level when marrow iron stores are absent. [5], [116], [117] Under such conditions, erythrocyte ferritin, [118] serum transferrin receptor, [119] or erythrocyte protoporphyrin [120], [121] levels may more accurately reflect body iron stores. Iron deficiency occasionally presents with normal levels of ferritin or other blood markers, and a bone marrow study is indicated if uncertainty remains. Although the gold standard for iron deficiency is the absence of bone marrow hemosiderin by Prussian blue staining, this invasive procedure is seldom required.

Fecal Blood Testing

Four fecal occult blood tests (guaiac, immunochemical, heme-porphyrin, and radiolabeled erythrocyte tests) are commercially available, each with advantages and disadvantages.

Guaiac Tests Guaiac preparations have been employed to detect blood for more than a century [122] and remain the most widely used type of fecal blood test. Guaiac-impregnated pad tests, such as Hemoccult, were developed in the 1960s. [123] These pad tests are elegantly simple, inexpensive, and highly portable, and a sophisticated laboratory is not required for interpretation. Guaiac, a leuco-dye, is a colorless compound that becomes colored in the presence of adequate peroxidase-like substances (e.g., Hb) and hydrogen peroxide. There appears to be no consistent fecal Hb level above which guaiac test results become positive and below which they remain negative. [10], [13], [123], [124], [125] and [126] In general, the rate of fecal blood loss must exceed 10 mL/d before a Hemoccult test result is positive at least half the time. [10], [13], [124], [125] Guaiac test results may be positive in stools with less than 1 mg of Hb per gram [10] or remain negative in those with more than 80 mg/g. [10], [127] Hemoccult sensitivity is enhanced by wetting the fecal smear before adding the peroxide catalyst [128] or by hydrating the stool before smearing. [10] Also, the native water content of stools affects Hemoccult reactivity—wetter stools are more likely to yield positive results than drier stools. [10], [13] Another major explanation of the variability in guaiac test reactivity is degradation by the fecal flora of heme to porphyrin, which does not possess peroxidase-like activity. This accounts for the relative insensitivity of guaiac tests for occult bleeding arising from the right side of the colon and more proximal gut. [13], [16], [22], [24], [129], [130] Conversion of heme to porphyrin continues during fecal storage and causes a corresponding fall in Hemoccult positivity. [10], [131] Thus, guaiac tests tend to underestimate enteric blood loss, especially with bleeding from proximal lesions or with stored specimens. Several factors besides wet stools can produce chemical false-positive reactions. Certain fruits and vegetables have peroxidase-like activity, and diet restriction reduces Hemoccult false positives. [132] Whether oral iron causes guaiac false positives is debated. [133], [134] Other factors reported to cause a color reaction include sucralfate, [135] cimetidine, [136] halogens, [137] and toilet bowl sanitizers. [138] Factors that inhibit guaiac reactivity, in addition to dry stools and heme degradation, include ascorbic acid, [139] antacids, [140] heat, acid pH, and defective reagents. [141] Maneuvers to increase guaiac sensitivity, such as hydrating the smeared fecal aliquot before testing or reconfiguring reagent concentrations, often succeed at the expense of specificity. [128], [142], [143]

Immunochemical Tests Immune detection of fecal blood, studied for more than three decades, is relatively inexpensive and simple to perform. [23], [24], [25], [26] and [27] The antihemoglobin or anti-albumin antibodies used in these assays do not react with nonhuman blood, diet peroxidases, or medications, [144], [145] and burdensome dietary preparations are avoided. The metabolism of antigens during transit or storage compromises the immune detection of fecal blood. These tests detect as little as 0.3 mg of blood added to a stool, but they fail to detect fecal Hb after the ingestion of 20 to 100 mL of blood. [23], [26], [130] It is not surprising that immunochemical tests are less likely to detect upper GI than colorectal bleeding. [23], [24] and [25], [130] Although immunochemical tests promise to improve specificity, reactions to certain fecal constituents may cause false positives at rates comparable to those of guaiac tests. [26], [146], [147] Like guaiac tests, immunochemical tests are qualitative, variably sensitive, and affected by the anatomic site of bleeding and by storage. Immunochemical tests have also been developed to detect blood leukocyte proteins, such as calprotectin [148] and lactoferrin. [149] However, such tests are insensitive for the detection of GI bleeding per se and correlate poorly with hemoglobin-directed fecal blood tests. [150]

Heme-Porphyrin Assay The quantification of fecal blood provides meaningful diagnostic information because the predictive value of an elevated level depends on the degree of elevation. [151], [152] A heme-porphyrin–based assay, [10], [16] HemoQuant (Mayo Medical Laboratories, Rochester, Minnesota; SmithKline BioSciences, Van Nuys, California; Nichols Laboratory, Los Angeles, California), is quantitative, noninvasive, specific for heme, chemically sensitive, and suitable for automation. HemoQuant involves the fluorometric assay of heme and heme-derived porphyrin. Unlike guaiac and immunochemical tests, the HemoQuant test includes that fraction of heme already degraded to porphyrin during fecal storage [13] or enterocolic transit. [10], [13], [16], [22] Because of this feature, its sensitivity for proximal GI bleeding is higher than that of guaiac and immunochemical tests. [13], [24] The heme-porphyrin test may be affected by red meat, but not by other dietary peroxidases, medications, or fecal contaminants. [10], [13], [16], [18] HemoQuant results are calculated as Hb equivalents and reported as milligrams of Hb per gram of stool. Fecal Hb concentrations from 0.01 to 500 mg/g are accurately measured, [10], [11], [12], [13], [14], [15] and [16] and values below 2 mg/g are considered normal. [13], [151], [152] HemoQuant has been validated by the recovery of blood added to stools, [10] recovery of ingested blood, [16], [18], [24], [130] and close correlation with other quantitative assays. [16], [17] HemoQuant is currently performed for commercial use in reference laboratories only, and the inevitable 2- to 4-day delay in results necessitated by specimen shipment is a distinct inconvenience.

Radiolabeled Erythrocyte Technique The fecal recovery of intravenously injected ^{51}Cr-labeled erythrocytes has been used to quantify enteric blood loss for more than four decades. [11], [12] After chromium enters the gut lumen, its reabsorption is negligible, and therefore it has proved to be a valid quantitative marker for GI bleeding. However, some have questioned its accuracy at very low levels of bleeding because of the biliary excretion of free chromium. [153] The test is expensive, requires 3 to 5 days of whole-stool collections, and is impractical for large-volume routine use. Slow enterocolic transit may cause falsely low results. [154]

Specimen Collection and Sampling Accurate fecal blood testing requires control of each step of the testing process. The common practice of sampling stools from the toilet water introduces potential measurement error caused by leaching of blood into the water [138] or by contamination with menstrual or urinary blood, [106] urinary reducing substances, [137], [139] or toilet bowl sanitizers. [138] The use of a collection device prevents these artifacts. [138] Because blood is nonuniformly distributed within the fecal specimen, [155] testing of multiple aliquots or multiple stools reduces sampling error. [151], [156] Guaiac-based tests have been developed to detect blood in the toilet water or on stool wiped from the perineum, but few published data are available. Reports on the testing of stool obtained from digital examination are conflicting. [157], [158] and [159] Some studies suggest that adequate stool is obtained in fewer than half of digital examinations [159] and that the digital approach lowers test specificity. [160]

Test Selection No single fecal blood test is appropriate for all applications. Test selection should be guided by a judicious consideration of test performance characteristics, availability, and cost relative to the clinical indication (Table 34-3). A simple, inexpensive, qualitative test may be preferred to screen for colorectal bleeding. Immunochemical or guaiac tests are appealing for such screening because they preferentially detect colorectal bleeding. The heme-porphyrin assay offers no advantage over these simpler tests in screening for colorectal lesions. [143], [161] However, to evaluate iron deficiency or anemia, the heme-porphyrin assay is most useful because it accurately quantifies lumenal blood loss regardless of the site of bleeding. [13], [24], [130] The radiolabeled erythrocyte technique yields similar quantitative information, [17] but it is time-consuming, much more expensive, and logistically burdensome. Guaiac and immunochemical tests would appear less suitable in the evaluation of anemia because they are qualitative and insensitive for upper GI bleeding. [13], [24], [130], [152] In a study of anemic patients with hemorrhagic lesions in the proximal gut, the heme-porphyrin test detected 88%, guaiac testing 26%, and immunochemical testing of stools 2%. [24]

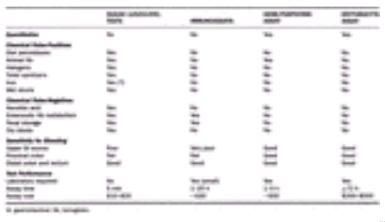

TABLE 34-3 Comparative Features of Fecal Occult Blood Tests

Patient Evaluation

In practice, abnormal occult GI bleeding comes to the attention of clinicians after a positive fecal blood test result has been obtained for a patient undergoing colorectal cancer screening, after iron deficiency anemia has been encountered, and, less commonly, after fecal blood tests have been applied to investigate a patient presenting with GI symptoms. The diagnostic strategy should be tailored according to the setting.

Abnormal Fecal Blood Test Results in an Asymptomatic Patient without Anemia This common situation is encountered almost exclusively as a result of colorectal cancer screening because there are very few other reasons to routinely check fecal occult blood levels (see section " Fecal Blood Screening for Colorectal Neoplasia"). The major responsibility is to exclude a colorectal cancer, although this finding can be expected in only 2% to 10% of cases with positive test results. [1], [2], [3] and [4] Most agree that colonoscopy and other structural approaches are more sensitive and specific for colorectal neoplasia, [161], [162] but these interventions are also invasive and more expensive. Because of the relatively lower prevalence in most Western countries of malignancies proximal to the colon, physicians could justifiably stop their evaluation after colon studies in the absence of symptoms or anemia. [163] However, a good case can be made for additionally checking the serum ferritin level because this is inexpensive, introduces essentially no morbidity, and may point to an indolent proximal GI lesion. If the ferritin level is low, esophagogastroduodenoscopy (EGD) is the preferred next step because the false-negative rate of barium roentgenography of the stomach for peptic and other lesions is so high (see Chapter 138, Chapter 139, Chapter 148, and Chapter 152). If this result is negative, a radiograph of the small intestine is appropriate. If all GI studies are unrevealing, periodic hematologic follow-up is in order. Finally, in populations with a high prevalence of gastric or esophageal cancer, it may be prudent to routinely extend the evaluation to the upper gut if the results of colorectal studies are negative. The common practice of having all patients admitted to the hospital undergo fecal occult blood testing is of uncertain value. Utilization studies indicate that such testing is inappropriate in most cases because of an absence of valid indications, the presence of serious comorbidities, and inadequate patient preparation. [164], [165]

Occult Bleeding in the Anemic Patient Unless menorrhagia, gross hematuria, frequent blood donations, or another source of extraintestinal blood loss is clinically apparent, most patients found to have iron deficiency with or without anemia should undergo an aggressive GI evaluation. Because a GI lesion is found in most men and postmenopausal women with new-onset iron deficiency anemia, [7], [55], [56], [166] it can be argued that fecal blood testing is superfluous and that GI studies should be performed regardless of fecal blood test results. However, nutritional inadequacy, iron malabsorption, or extraintestinal bleeding may be the critical etiologic factor in some patient groups with iron deficiency anemia. Fecal blood testing may be helpful to assess the contribution of enteric blood loss in selected groups with iron deficiency, including children, menstruating women, postgastrectomy patients, immigrants from underdeveloped countries, strict vegetarians, frequent blood donors, and patients with steatorrhea. For example, menstruating women with new-onset iron deficiency often demonstrate occult fecal blood loss and, subsequently, are found to harbor hemorrhagic GI lesions. [167] Thus, it should not be assumed that menstrual blood loss alone accounts for iron deficiency in this large subset of patients. Most adults with new-onset iron deficiency anemia are found to have culprit hemorrhagic lesions in the proximal gut (Table 34-4). [24], [25], [167], [168], [169], [170] and [171] However, roughly 15% of patients with lesions seen on EGD also have potential sources of blood loss on colonoscopy. [25], [167], [168], [169], [170] and [171] Most upper GI lesions in patients with iron deficiency are peptic in nature, whereas most colorectal lesions are neoplastic. [7], [24], [25], [167], [168], [169], [170], [171] and [172]

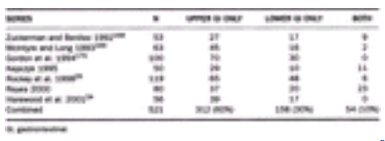

TABLE 34-4 Anatomic Site of Occult Gastrointestinal Bleeding in Patients with Iron Deficiency Anemia

A practical schema for evaluating adults with iron deficiency anemia and occult GI bleeding is shown in Figure 34-2. The large majority of lesions causing occult bleeding in anemic patients can be demonstrated by routine endoscopic procedures. At many centers, extended or push enteroscopy is used only if the results of the initial evaluation by routine EGD, colonoscopy, and small bowel radiography are negative; endoscopically treatable lesions, especially vascular ectasia, are not uncommonly discovered. [71], [163], [173] Some advocate extended upper GI endoscopy rather than conventional EGD for the initial evaluation as a more cost-effective strategy. [62], [72], [174] For immigrants from tropical or subtropical regions, a stool examination for hookworm or other parasite ova should be considered early in the evaluation of anemia.

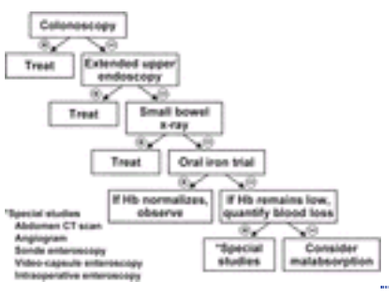

FIGURE 34-2. Diagnostic schema for asymptomatic adult patients with iron deficiency anemia and occult gastrointestinal bleeding. *CT,* computed tomography; *Hb,* hemoglobin.

Because further studies for obscure bleeding sources are more invasive, expensive, and less revealing of lesions, it is often justifiable to observe a response to iron therapy before further studies are undertaken. NSAIDs should be strictly avoided during such a trial. Anemia will resolve and no serious pathology will emerge over time in most such patients. [175] In patients who fail to respond to iron therapy, confirmation of GI blood loss with valid fecal blood testing is desirable before further evaluation. If GI bleeding is established, special diagnostic studies may prove helpful, including universal (Sonde) enteroscopy, [176] angiography (see Chapter 130 and Chapter 159), abdominal computed tomography, and, in rare situations, surgical exploration with intraoperative endoscopy. [73] Laparoscopically assisted panenteroscopy may provide a less invasive future alternative to intraoperative endoscopy. [177] A pill-sized videocapsule device may allow noninvasive interrogation of parts of the small intestine that cannot be reached by conventional endoscopes. [178] Radioisotope blood loss scans have no role in the evaluation of occult bleeding.

Occult Bleeding in the Patient with Gastrointestinal Symptoms Few data are available on the use of fecal blood testing to evaluate patients with GI symptoms in the absence of iron deficiency or anemia, although some suggest that a positive stool result increases the likelihood that organic disease is present. [179] The sequence of diagnostic testing should be initially directed to the anatomic level suggested by the symptoms. Site-specific symptoms in patients with iron deficiency are predictive of abnormalities in the corresponding portion of the bowel. [62], [166] Clinical judgment is required to determine the extent of evaluation in such instances.

FECAL BLOOD SCREENING FOR COLORECTAL NEOPLASIA

Fecal blood screening for colorectal cancer is widely practiced, and U.S. surveys suggest that roughly 30% of adults have undergone such screening. [180], [181] and [182] This section deals only with fecal testing, not with other approaches to the detection of colorectal neoplasia (see Chapter 89, Chapter 91, Chapter 140, Chapter 152, and Chapter 155).

Occult Bleeding Patterns

Fecal blood levels vary widely in colorectal cancer [13, 128, 151, 155, 161, 183] and commonly fall within the normal range (Fig. 34-3). Occult bleeding increases with neoplasm size, surface ulceration, and stage. [13, 161, 184, 185, 186] and [187]

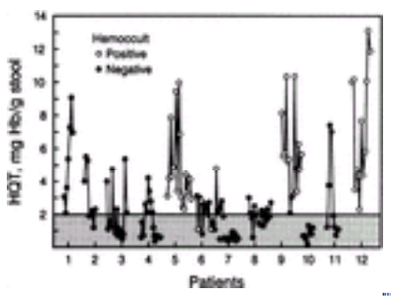

FIGURE 34-3. Occult blood levels in stools collected for 2 weeks from 12 patients with asymptomatic primary colorectal adenocarcinoma as determined by HemoQuant (*HQT*) and Hemoccult. The shaded zone below a HemoQuant level of 2 mg of hemoglobin per gram of stool represents the conventional normal range. (From ref. [151].)

Although it is well established that symptomatic colorectal polyps may bleed, [129] less is known about occult bleeding with asymptomatic polyps. Quantitative studies have shown fecal blood distributions to be comparable in asymptomatic groups with and without adenomas. [126, 161, 183] Roughly 5% of patients with endoscopically proven polyps are guaiac positive, [161, 186] a positivity rate similar to that of the general population. Although many polyps found on fecal blood screening are probably incidental, [161, 184] about 20% of large adenomas may be associated with elevated fecal blood levels. [161] Fecal blood appears to be a poor marker for adenomas, especially small ones.

Test Validity

Validity is a function that combines sensitivity, specificity, and predictive value, and it varies with the techniques used and populations studied. Validity must be high if a screening test is to perform effectively and efficiently. The sensitivity, or detection rate, ranges in patients with symptomatic colorectal cancer from 40% to 97%. [13, 27, 144, 180, 186, 187] Rigorous prospective studies comparing fecal blood levels against structural gold standards (e.g., colonoscopy) yield average sensitivity estimates for widely used guaiac tests of about 26% (range, 22%–50%) for asymptomatic colorectal cancers (Table 34-5). [161, 189, 190, 191, 192, 193, 194] and [195] The newer immunochemical and guaiac tests may yield somewhat higher cancer detection rates. [142, 143, 196] However, fecal blood levels from patients with asymptomatic colorectal neoplasms often fall within the normal range (Fig. 34-3), and detection by any fecal blood test is not possible if neoplasms do not bleed.

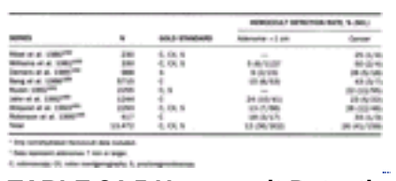

TABLE 34-5 Hemoccult Detection Rates for Asymptomatic Colorectal Neoplasms Based on Comparison against Structural Gold Standards in the Screening Setting*

Screening specificity, the rate of negative tests in those without cancer, ranges from 90% to 98%, [1, 2, 3] and [4, 180] which translates to false-positive rates of 2% to 10%. The positive predictive value, or probability that a positive test result will yield a colorectal cancer, depends on both test specificity and cancer prevalence. For commonly used guaiac tests in the screening setting, the positive predictive value in colorectal cancer averages 5% (range, 2%–18%). [1, 2, 3] and [4, 161, 180] Most positive test results yield no pathology and are considered false positives.

Many asymptomatic colorectal cancers are unfortunately missed by fecal blood screens, and most positive screening test results are caused by trivial conditions other than cancer. Sensitivity can be increased only by reducing specificity, and vice versa (see Fig. 34-4).

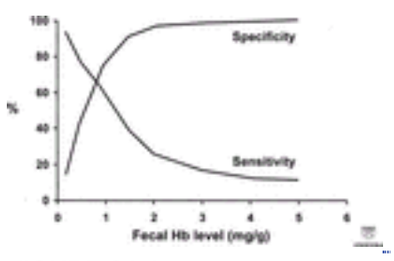

FIGURE 34-4. Fecal hemoglobin screening for colorectal cancer detection showing inverse relationship between sensitivity and specificity. Quantitative stool testing was performed in 2293 persons who also underwent colorectal evaluation by diagnostic gold standards. (From Ahlquist DA, Gilbert JA. Novel fecal markers for colorectal cancer screening: future considerations. Dig Dis 1996;14:132.)

Test Compliance

Screening effectiveness requires not only a high level of test validity but also a compliant population. Operationally, the neoplasm detection rate is the product of test sensitivity and the compliance rate in the target population. Compliance rates have been as low as 19% in general populations and as high as 97% in carefully instructed outpatients using a stool collection device, [138, 180, 197] but compliance averages 30% to 60% in community-based programs. [180, 197] Compliance varies with demography, educational effort, and setting. [197, 198] Physician compliance in screening programs also varies. [180, 199]

Test Effectiveness and Cost

Fecal occult blood screening reduces colorectal cancer mortality by 15% to 30% when regularly applied for more than 10 years (Fig. 34-5). [1, 2] and [3] Because of low detection rates for precursor adenomas, such screening has little influence on cancer incidence. [1, 2] and [3, 200] The benefit is achieved primarily by the detection of early-stage cancer. [201] Screening is ineffective when test intervals exceed 2 years [202, 203] or when compliance is low. [204, 205] and [206]

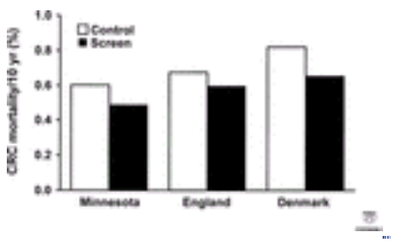

FIGURE 34-5. Colorectal cancer mortality during 10 to 14 years in controlled trials with Hemoccult screening: screened versus control groups. [1], [2] and [3]

Based on mathematical models, [204] the cost-effectiveness of fecal blood testing is comparable to that of other approaches to colorectal cancer screening. [207], [208] However, the measures of effectiveness are lowest with fecal blood testing, and its comparable cost-effectiveness ratio is carried by lower estimated costs. [201] Program costs of fecal blood screening are strongly leveraged by the false-positive rate and the resultant high cost of downstream colonoscopies.

Guidelines for Colorectal Cancer Screening

Because colorectal cancer is so prevalent in the United States, its incidence increases sharply after age 50 years, and its early detection confers a favorable prognosis, the American Cancer Society and the National Cancer Institute recommend annual fecal blood testing alone or in combination with sigmoidoscopy every 5 years for average-risk persons 50 years of age or older. If fecal blood testing is to be practiced for cancer detection, clinicians should be aware of the test limitations and inform their patients accordingly, understand the common causes of occult GI bleeding, and follow a rational strategy in evaluating positive test results.

Future Approaches to Stool Screening

In comparison with structural screening approaches, such as colonoscopy, stool testing has several advantages. Stool testing is noninvasive, requires no cathartic preparation, and can be done without a formal health care visit. Markers with performance characteristics better than occult blood could improve the effectiveness and appeal of stool screening. Exfoliated markers represent rational alternative candidates. [209], [210] Unlike blood, exfoliated markers enter the colorectal lumen continuously with cell shedding, which enhances sensitivity, and have the potential to be unique to neoplastic tissue, which enhances specificity. Neoplasm-associated DNA alterations are a particularly promising class of exfoliated markers, given the known genetic defects in colorectal cancer and the exquisitely sensitive assay techniques available.

Early clinical studies with DNA-based stool testing suggest good sensitivity and specificity for colorectal cancer [211], [212] and apparently much higher rates of polyp detection than are achieved with fecal blood testing. [211] However, large comparative studies in representative general populations must be conducted to corroborate these findings before practice implementation can be justified.

THERAPEUTIC CONSIDERATIONS

The treatment of abnormal occult GI bleeding is dictated by the clinical setting. The critical first step in the management of newly discovered occult bleeding is to exclude a serious underlying lesion. For patients with positive screen test results but normal structural colorectal studies, it is often appropriate to check whether iron stores are low. If concomitant iron deficiency exists, then an aggressive search for the GI bleeding source is warranted. Specific medical or extirpative therapy of the lesion may not only prevent lesion-associated morbidity but also definitively stop further iron loss (see other chapters for lesion-specific treatments). For patients with persistent bleeding from diffuse or inaccessible vascular malformations, nonspecific medical treatment with systemic estrogen, aminocaproic acid, or somatostatin has been attempted. [213]

Whether the bleeding source is correctable or not, a cornerstone of treatment is the replenishment of iron stores. Some patients with chronically bleeding lesions, such as radiation enteritis or Cameron erosions, [65], [77] may be appropriately managed with long-term iron replacement alone because satisfactory medical cures are lacking and surgical approaches may be associated with unwanted morbidity. Uncommonly, blood transfusions are indicated initially in those with severe anemia and cardiovascular compromise.

Oral iron therapy with ferrous sulfate tablets is the preferred approach in most patients with iron deficiency because it is cheap, effective, and usually well tolerated. Other oral preparations include ferrous fumarate, ferrous gluconate, and preparations with added ascorbic acid or other absorption enhancers. [5] Dietary iron replacement is usually inefficient and impractical. For example, it has been calculated that a daily consumption of 5 kg of red meat would be required to provide 60 mg of iron, [117] which is the amount contained in one 325-mg tablet of ferrous sulfate. A maximal adult dose of ferrous sulfate is 325 mg three times daily, and absorption is not appreciably increased with higher doses. [5] With iron replacement, a peak in reticulocytosis occurs after 7 to 10 days, the Hb level usually normalizes within 2 months, and epithelial abnormalities resolve within months. It should be emphasized that the Hb level normalizes well before body iron stores are repleted. [6] If blood loss is not ongoing, satisfactory iron replacement usually requires 3 to 6 months. The serum ferritin level can be used to monitor the adequacy of iron replenishment.

Side effects of oral iron develop in 10% to 20% of patients, appear to be dose-related, are similar for the different preparations, and result in discontinuation in about 8%. [214] In a large prospective study, [214] the side effects most commonly reported included constipation in 13%, diarrhea in 6%, heartburn or epigastric pain in 5%, and nausea in 4%. The side effects of oral iron therapy can often be avoided simply by lowering the dose to one tablet daily or every other day. Caution should be taken not to overreplace body iron stores because excess iron may cause oxidative stress and contribute to a long-term risk for inflammatory, cardiovascular, and neoplastic disease. [54], [215], [216] There is no justification for iron supplementation in iron-replete individuals.

Parenteral iron is indicated in patients with iron malabsorption and in those who do not comply with or cannot tolerate oral iron. [217] Because parenterally administered iron salts are toxic, iron must be injected in a complexed form. Parenteral iron preparations vary in their bioavailability, degradation kinetics, dosimetry, and side effects. [5], [218], [219] The iron complex is taken up by reticuloendothelial tissues and slowly converted to bioavailable iron. Fatal idiosyncratic reactions occur rarely with parenteral iron dextran. [5] In about 10% of patients, a serum sickness-like illness develops with fever, myalgias, arthralgias, lymphadenopathy, and urticaria. [5] As a guiding principle, oral iron is equally effective in correcting iron deficiency anemia and is safer in most cases. [5], [217]

CHAPTER 35

Dean L. Antonson, James K. Madison, and Renée L. Young

APPROACH TO THE PATIENT WITH UNINTENTIONAL WEIGHT LOSS AND EATING DISORDERS

Body weight is determined by the interplay of calorie intake, activity level, and metabolic rate. Significant alterations involving any of these factors may result in weight loss. This chapter focuses on the patient who presents with unexplained weight loss (i.e., the extent to which any of these factors has been affected is not readily apparent). The first part of the chapter explores unintentional weight loss caused by evolving disease states; the second part focuses on intentional weight loss resulting from eating disorders. Eating disorders present initially as unexplained weight loss because these patients tend to hide their eating behaviors. The patient with unintentional weight loss is not dieting to lose weight, whereas the patient with an eating disorder is in relentless pursuit of this goal. A careful and thorough diet history, therefore, will allow one to begin to separate these patients. A thoughtful and deliberate investigative approach to testing is required for the former patient. Simple screening laboratory tests and referral to an eating disorder center are required for the latter.

UNINTENTIONAL WEIGHT LOSS

Unexplained weight loss in patients is one of the common enigmas presented to the physician. Patients experiencing weight loss are typically alarmed because of underlying fears of malignancy or other serious diseases. Physicians realize that unintentional weight loss is a nonspecific manifestation of many conditions. The evaluation of this problem challenges the physician by its broad range of diagnostic possibilities and seemingly endless differential diagnoses. Cost-efficient medicine makes an efficient diagnostic strategy essential.

Body weight tends to remain constant for long periods of time, although fluctuations in weight on a day-to-day basis are common and reflect deviations in food, water, and salt intake. Weight loss is generally defined as continued loss of more than 5% of body weight, and it is especially of concern when progressive and persistent.

Weight loss is a nonspecific clinical sign with multiple causes. Six major studies of involuntary weight loss have been published since 1981 (Table 35-1). [1], [2], [3], [4], [5] and [6] The causes of weight loss varied widely; approximately 50% of cases could be attributed to cancer or other diseases, [1], [2], [3], [6] and 20% to 60% to psychiatric conditions. [4], [5] The mortality rates of patients presenting with unexplained weight loss ranged from 9% to 25% in the first year and were 38% in 2 years. [1], [2] and [3] In the first three studies cited, mortality rates were lower in patients without defined physical causes of weight loss. [1], [2] and [3] The conclusions from these six studies are the following:

1. Malignancy is not the most common cause of weight loss and is usually diagnosed early in the evaluation period.
2. In most cases of unexplained weight loss, the cause is established initially without extensive evaluation.
3. Psychiatric causes are common, especially in the elderly population.

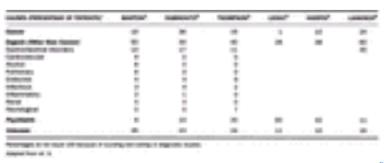

TABLE 35-1 Clinical Studies Evaluating Causes of Unintentional Weight Loss

Etiology

The differential diagnosis of unintentional weight loss is lengthy and, most simply, can be categorized physiologically as follows:

1. Decreased caloric intake because of an altered perception of smell or taste, anorexia, nausea, or an altered perception of satiety
2. Acceleration or alteration of metabolism caused by tumor cells, excess thyroid hormones, or exercise
3. Increased loss of calories in the urine or stool secondary to diabetes mellitus or malabsorption. [7]

Morley [8] has categorized the major causes of weight loss in the geriatric population as either social, psychological, medical, or age-related (Table 35-2). Robbins [9] has published a mnemonic consisting of the nine *D*s of weight loss in the elderly population (Table 35-3); Wise and Craig [10] have added a tenth *D* for “don’t know.”

Social
Isolation
Poverty
Inadequate education
Lack of transportation
Unavailability of preferred foods
Urban decay
Psychological
Depression
Schizophrenia
Bereavement
Bulimia
Manipulation
Sociopathy
Late-life mania
Dementia
Conversion reaction
Anorexia nervosa
Anxiety
Alcoholism
Late-life paranoia
Excessive burden of life (food refusal)
Medical
Increased metabolism—hyperthyroidism, pheochromocytoma, Parkinson disease
Anorexia—drugs, abdominal ischemia, cancer, hyperparathyroidism
Swallowing problems—dysphagia, cerebrovascular accident
Malabsorption—gluten enteropathy
Increased metabolism and anorexia—COPD, cardiac cachexia
Age-Related
Impaired olfactory sensitivity
Appetite suppression
Impaired taste sensitivity

COPD, chronic obstructive pulmonary disease.

TABLE 35-2 Causes of Weight Loss in the Geriatric Population

Dentition
Dysgeusia
Dysphagia
Diarrhea
Disease (chronic)
Depression
Dementia
Dysfunction
Drugs
Don't know

Adapted from refs. 8 and 9.

TABLE 35-3 Ten *D* s of Weight Loss in the Elderly Patient

Medical Causes

Cancer. Malignancy is frequently, but erroneously, thought to be the most common cause of weight loss in the patient without other signs and symptoms (see Table 35-1). [11] However, this diagnosis should be considered early because of the gravity of cancer. Mechanisms of weight loss resulting from malignancy vary, and often more than one factor is present. Anorexia is common in most types of cancer. The ectopic production of hormones such as bombesin, which produces anorexia by sending satiety messages to the central nervous system, [8] or interleukin [1] or tumor necrosis factor (cachectin), another anorectic agent, [12], [13] may cause anorexia. Increased metabolism may play a role in some cancers (e.g., lymphoma, leukemia).

Infection and renal, pulmonary, and cardiac diseases. *Infection* with human immunodeficiency virus (HIV) should be considered, especially in patients in high-risk groups. Fungal infections, tuberculosis, parasitic infections (including amebic abscess), and subacute bacterial endocarditis are often hidden infections that can be associated with weight loss. An early manifestation of *uremia* is anorexia. Patients with *end-stage lung disease* or chronic obstructive pulmonary disease frequently experience increased dyspnea when eating and hence quit eating or limit their intake. The use of accessory muscles of respiration in pulmonary diseases consumes excess calories and potentiates weight loss. *Congestive heart failure* may lead to weight loss through increased metabolic demands, loss of appetite, dietary restrictions, and an inability to find palatable foods that are low in sodium and heart healthy. Atherosclerotic disease can lead to abdominal angina from decreased blood flow to the intestinal tract during digestion.

Endocrine diseases. Unexplained weight loss is one of the hallmarks of undiagnosed or untreated *diabetes mellitus*. This weight loss is usually accompanied by a simultaneous increased intake of food and water intake. *Hyperthyroidism* frequently is associated with weight loss, increased appetite, a diet high in carbohydrates, and a general increase in food intake. In "apathetic" hyperthyroidism, weight loss and weakness (especially proximal myopathy) may predominate. [11] Traditionally, *hypothyroidism* presents with weight gain; however, it may also present with weight loss when anorexia and apathy are the dominant clinical features. Less common endocrine causes of weight loss include *pheochromocytoma* (catecholamine release), *panhypopituitarism* and *adrenal insufficiency* (lack of cortisol support), and *hyperparathyroidism* (increased metabolism and anorexia).

Gastrointestinal diseases. Mechanisms of weight loss in gastrointestinal disease are often multifactorial, including anorexia, obstruction with vomiting, fear of eating, malabsorption, inflammation, and compression of organs, as in massive splenomegaly. Gastroesophageal reflux disease may present with weight loss secondary to peptic strictures, dysphagia, or a fear of eating. Dysphagia may be related also to achalasia, esophageal or gastric cancer, or a cerebrovascular accident or other neurological condition, such as Parkinson's disease or amyotrophic lateral sclerosis. Benign ulcer disease is a common cause of anorexia and weight loss. Palmer [14] reported that 80% of 650 patients with gastric ulcers lost 10 or more pounds and 55% complained of weight loss. The old adage that patients with gastric ulcers lose weight because eating causes pain and patients with duodenal ulcers gain weight because food soothes the pain is not always true. Peptic ulcers may present also with nausea and vomiting, especially when associated with considerable inflammation. Delayed gastric emptying or gastroparesis may present with weight loss secondary to abdominal fullness, nausea, vomiting, distention, and decreased appetite. Atrophic gastritis and subsequent vitamin B_{12} deficiency can lead to loss of appetite. Constipation can cause anorexia and is frequently identified in the elderly. [15] Diabetic enteropathy, cholelithiasis, cholecystitis, inflammatory bowel disease, hepatitis, end-stage liver disease, pancreatitis, esophageal dysmotility, and malabsorption resulting from celiac sprue or other mucosal abnormalities all must be included in the differential diagnosis of weight loss.

Connective tissue diseases. Patients with scleroderma may have swallowing problems or a more diffuse intestinal dysmotility causing weight loss. Systemic lupus erythematosus and rheumatoid arthritis may present with nausea, anorexia, and malaise, resulting in poor oral intake and weight reduction.

Medications. The side effects of drugs and drug-drug interactions cannot be overemphasized, especially in patients taking multiple medications. The weight loss associated with medications can be secondary to decreased appetite, anorexia, nausea, gastroparesis, or diarrhea. Antiretroviral therapy in acquired immunodeficiency syndrome (AIDS) is a good example of this.

Age-Related Factors By the age of 65, approximately half of all Americans have lost a portion of their teeth and have chewing problems. [16] Absence of teeth, ill-fitting dentures, and pain during eating are predictors of significant involuntary weight loss. [16] Age-related impairment of olfactory and taste sensitivity may lead to decreased food intake. Kamath [17] has reviewed studies that may support a decline in sensitivity to taste with increasing age, although it is difficult to determine the role of the many variables that affect taste. Routine oral hygiene has been shown to improve sensitivity to sweet and salty tastes and increase appetite in some patients. [17] Zinc deficiency is sometimes found in the elderly and can be associated with ageusia. [18] Early satiety in elderly patients has been associated with a fall in the opioid feeding drive and hypersensitivity to cholecystokinin. [19] General medical problems such as arthritis, visual impairment, cardiovascular disease, and dementia make it increasingly difficult for elderly people to shop for and prepare food.

Social Causes Humans tend to consume more calories in social situations. Social isolation may lead to weight loss secondary to decreased food intake. Social isolation may be caused by a lack of transportation, poverty, hearing impairment, or other medical ailments that make people reluctant to enter social situations. Elderly patients may experience a unique social situation that is frequently unrecognized (i.e., not being given food choices appropriate for their ethnic background in their care facility). Furthermore, elderly patients are expected to eat with other patients in a care facility; frequently, this assembly includes demented patients with bizarre eating habits. In such an environment, patients may lose the urge to eat. [8]

Psychiatric and Behavioral Causes *Alcoholism* may be diagnosed at almost any age and become a problem at any point in life. Although alcoholism is frequently associated with depression, they are independent risk factors for weight loss. The diagnosis of alcoholism is often difficult to make, and frequently, a vague complaint such as weight loss may be the only physical sign of the problem. *Depression* can lead to apathy, weight loss, and anorexia, and it frequently presents as a vague complaint without the patient being aware that anything is wrong emotionally. Weight loss as a symptom of depression is more common in the elderly than in the younger population, and depression is the most treatable of the psychiatric disorders of later life. [20] The loss of a loved one may cause depression. The reduced food intake associated with the grieving process results in ketosis, and ketone bodies further suppress the appetite, triggering a vicious cycle. [8] The importance of screening patients for depression, especially elderly patients with weight loss, cannot be overemphasized. Several standard tools are available for quick checks for depression.

Neurological Causes The prevalence of various gastrointestinal symptoms among patients with *Parkinson disease* has been delineated by Edwards and associates. [21] A high frequency of defecatory dysfunction, constipation, dysphagia, and disordered salivation has been described. *Dementia* prevalence increases with age and has been estimated to be 2% to 3% in patients between 65 and 79 years old. [18] Appetite disturbances and apathy clinically appear as cognitive function deteriorates. Patients lose the ability to prepare meals, do the grocery shopping, and eat independently. A recent study in patients with Alzheimer disease actually demonstrated that weight loss precedes mild to moderate dementia, and early weight loss is therefore unlikely to be a consequence of the patient's inability or unwillingness to eat. [22] Weight loss in institutionalized patients with Alzheimer disease is commonly related to a marked decrease in staff time spent feeding the patient, compared to time spent by family members feeding the patient. [8] Weight loss in demented patients is also related to an inability to recognize the need to eat, apraxia of swallowing, picas, and ingestion of nonnutritious substances. [8] The weight loss seen in patients with Alzheimer disease is not related to an elevation in resting energy

requirements. [23]

Diagnosis

Documentation An elaborate workup of weight loss is hardly indicated without adequate documentation of the weight loss. Perception of weight loss may be influenced by the rate of weight change, gender, original body size, and underlying disorders present. [24] In up to 50% of patients who report weight loss, the loss is not corroborated by medical records or the family. [1] The most accurate form of documentation is a previous medical record, but if the record is unavailable, a patient's report of a previous weight or change in clothing size that is confirmed by others is sufficient documentation.
Evaluation A directed, complete history and physical examination are key to early diagnosis, efficient evaluation, and initiation of treatment. In the study by Marton and associates, [1] half the patients studied had a chief complaint that pointed to disease of a specific organ. The history should explore symptoms, past medical history, prior surgeries, and cigarette use; it should quantify alcohol intake and the current and past use of medications, and it should include a thorough review of organ systems. The history should also include a search for psychiatric causes, including alcoholism and depression. A standard testing tool should be employed for detecting depression. Potential social, psychological, and physical factors should be identified. The physical examination should begin with attention to the patient's mood, overall appearance, and affect. A complete physical examination includes inspection of the skin and lymphatics; auscultation of the cardiovascular and pulmonary systems; examination of the joints and bony skeleton, breasts, and abdomen; a genital and pelvic examination; examination of the rectum and prostate; and neurological evaluation with a Mini-Mental Status check. A complete examination encompasses not only auscultation but also palpation. Auscultation for bowel sounds and bruits is incomplete without palpation for masses or hepatosplenomegaly. Diagnostic testing should first be directed at clues or areas of concern found during the history and physical examination. If no clues are unearthed during these examinations, simple diagnostic testing is indicated. Tests that are usually of benefit are listed below, but the cost-effectiveness of this initial screening remains to be established.

1. Complete blood cell count
2. Serum chemistries, including tests of renal and hepatic function and measurement of calcium and albumin
3. Urinalysis
4. Chest x-ray film
5. Thyroid-stimulating hormone assay
6. HIV testing if any risk factors are present
7. Erythrocyte sedimentation rate.

In the absence of localizing symptoms or signs or findings on the laboratory work listed above, routine screening for cancer is indicated, as recommended by the American Cancer Society.

1. Fecal occult blood testing of stools (age 40 or older)
2. Flexible sigmoidoscopy/barium enema or colonoscopy (age 50 or older)
3. Cervical Papanicolaou smear in women
4. Mammography (women past the age of 40 years)
5. Prostate-specific antigen (in men age 50 or older).

If the results of these tests are normal and cancer is still suspected, abdominal and pelvic computed tomography may be warranted.

Treatment and Follow-up

If the results of this initial testing are negative, then a period of careful waiting and watching is in order. In the study of Marton and colleagues, [1] more than 65% of the patients who did well during follow-up had completely normal findings on screening tests. In contradistinction, none of the patients who did poorly had normal findings initially. This waiting period is unlikely to result in an adverse outcome because organic disease is rarely found in patients with normal findings on the history, physical examination, and screening laboratory tests.

Another productive approach is to evaluate the nutritional intake and consider the patient's food preferences and any abnormal attitudes toward eating. Offering favorite foods or snack foods may be sufficient to halt weight loss. Avoidance of special medical diets (salt, fat, or caloric restrictions) may actually be of more benefit to the patient with weight loss than strict compliance with the diet.

Early intervention is the key to a successful outcome. In general, the treatment of weight loss must be directed at treating the underlying disease process. Regardless of the cause, when weight loss is severe and manifestations of malnutrition are seen, nutritional supplementation may be required. Liquid supplements are available that are nutritionally complete. Many patients, however, find these supplements less than palatable.

INTENTIONAL WEIGHT LOSS

Anorexia Nervosa

Historical Perspective The first clinical description of anorexia nervosa appearing in the medical literature was published by Richard Morton, physician to King James II, in his textbook of medicine in 1689. [25] During the next 200 years, additional case reports of anorexia nervosa were recorded. [26] In the early 1900s, Simmonds attempted to ascribe the etiology of anorexia nervosa to pituitary insufficiency, [27] a theory that was later disproved by Sheehan. [26], [27] Major advances in our understanding of anorexia nervosa did not occur until the 1960s, when Dr. Hilde Bruch began extensively studying patients with anorexia nervosa and identified the three common hallmarks of the anorexic patient: a distorted body image, an inability to interpret hunger and satiety, and a paralyzing sense of ineffectiveness. [26], [28] Furthermore, and perhaps more important, she recognized that a true loss of appetite did not occur in anorexia nervosa but rather a preoccupation with food and eating. [26] The revolution in our understanding of anorexia nervosa, begun by Bruch and redefined further by Russell [29] and others, has allowed us to define this disorder clearly, gain insight into its multifactorial etiology, and establish effective treatment.
Epidemiology Anorexia nervosa in Western societies has increased dramatically in the last third of the 20th century. Five well-controlled studies from both Europe and the United States have allowed us to quantify this increase. [29] When the incidence of anorexia nervosa was examined through sequential decades from the 1940s through the 1980s in the same population, it was found in Sweden to be increased fivefold, in Scotland fourfold, in Switzerland threefold, and, in two reports from the United States, twofold and fourfold. [29] Increased incidence rates for anorexia nervosa are now also being reported from many other countries. Rates in Japan are equal to or greater than those in the United States, and increased rates have also been reported from China, Spain, Argentina, and Fiji. [30] When the incidence rates are normalized and specific at-risk populations of girls and women between 16 to 25 years of age are examined, incidences range from 30 per 100,000 to as high as 156 per 100,000, making anorexia nervosa the third most common illness in female adolescents and young adults, exceeded only by obesity and asthma. [31] Because of the chronicity of anorexia nervosa, the prevalence rates are several-fold higher than the incidence rates for any specific population. The most commonly quoted prevalence rates in the United States for anorexia nervosa are from 0.5% to 1%. [32] When more broadly defined, the lifetime prevalence rates for anorexia nervosa have been reported to be as high as 3.7%. [30] Similar prevalence rates have been reported from England and Western Europe. [31] The incidence of anorexia nervosa in males is 5% to 10% that in females. The dramatic increase in eating disorders is thought to represent only the tip of the iceberg. Consistent with the current trends of health consciousness in the United States and to a lesser extent in Europe, dieting behaviors among adolescent girls and young women have profoundly increased. The incidence and prevalence of severe dieting behaviors that fail to meet the specific criteria for anorexia nervosa are reported as between 5% and 10% of young females. [31], [33] Paralleling this rise has been a concomitant increase in body image dissatisfaction. In one U.S. study, half of all underweight adolescent girls wanted to lose weight, and 80% claimed that they were unhappy with their present weight. [34] Overall, one half to two thirds of adolescent girls and young women perceived themselves as too fat, although only 15% were documented to be overweight. [34] In a recent study from the Centers for Disease Control and Prevention, almost 50% of adolescent girls were involved with dieting, whereas only 15% of boys were similarly concerned. [32] Forty percent of these patients felt very negatively about their body image, with the greatest displeasure being focused on their hips, waist, and thighs, a consistent finding in patients with eating disorders. [32] Although most early studies reported that anorexia nervosa occurs primarily in white, middle- and upper-class females, more recent studies have documented that anorexia nervosa is present in all ethnic groups and at all socioeconomic levels. [31], [33], [35] In general, eating disorders are more prevalent in Native Americans, equally prevalent in Hispanics and whites, and less common in blacks and Asians. [30] Anorexia nervosa is especially prominent in persons engaging in appearance-related sports and occupations, such as acting, ballet dancing, modeling, and gymnastics. The risk for the development of anorexia nervosa is greatest between the ages of 15 and 25 years, although

extension into age groups as young as 9 or 10 years is being reported more frequently. Numerous risk factors for the development of anorexia nervosa have been identified. In addition to age, gender, and the strong influence of Western culture, factors include the onset of dieting behavior, excessive exercise, the presence of a physical illness that results in initial weight loss, and the presence of characteristic personality features, such as low self-esteem, obsessive-compulsive and avoidant personality traits, body image dissatisfaction, and body image distortion. [31] In a small percentage of patients, especially those who present under 14 years of age, anorexia nervosa may develop in association with a streptococcal infection. [36] Genetic factors are also prominent; the incidence of eating disorders is increased in the first-degree relatives of patients with anorexia nervosa and in monozygotic twins. [31], [34] The incidence of anorexia nervosa in second-generation immigrants from underdeveloped countries is increased to rates similar to those in the new geographic location, a finding that highlights the importance of cultural factors. [31]

Etiology Although the etiology and pathogenesis of anorexia nervosa are unknown, a certain commonality exists in all the theories about the factors responsible for the development of anorexia nervosa. A succession of factors are thought to be involved: predisposing factors (individual, familial, and sociocultural), precipitating factors (stressors, diet, illness, and weight loss), and perpetuating factors (cognitive reinforcement and effects of starvation). [37] Although no single theory has yet been accepted, all theories propose that antecedent events and variables predispose the susceptible adolescent or young adult to pursue the goal of weight loss. Both positive and negative reinforcements allow the disorder to progress. Conflicts, stresses, and failure result in low self-esteem and dissatisfaction, and the perfectionistic tendencies of these individuals then funnel the need to control some aspect of their life toward dieting and weight loss (thinness being equated with success). An ever-encompassing spiral of weight loss, fear of weight gain, intensified dieting, body image dissatisfaction, and the effects of starvation lead to an uncontrollable progressive weight loss with an increasing feeling of success and control.

Physical Evaluation It is difficult for the patient in whom anorexia nervosa is developing to hide her disease. The rather typical appearance of marked starvation and cachexia, along with noted muscle wasting, a decrease in subcutaneous tissue, and a prepubescent body habitus, are easily identified. Vital signs frequently demonstrate hypothermia, with body temperatures 1° to 2°F below normal, bradycardia with a resting pulse rate as low as 40/min, and hypotension with blood pressures as low as 90/60 mm Hg. Moderate to marked acrocyanosis is almost uniformly present. Skin and hair changes are seen, including a yellow discoloration of the skin secondary to carotenemia, thinning of the scalp hair, and the development of lanugo hair, particularly over the face, upper arms, and back. The skin may also be dry, pale, and atrophic. Deep tendon reflexes are decreased on neurological examination. Despite the cachectic appearance, individuals with anorexia nervosa often appear energetic, although on rare occasions profound degrees of lethargy are present. Lethargy occurring in the individual with anorexia nervosa is of concern and may be the harbinger of early organ failure. It is uncommon for the individual with anorexia nervosa to present to the physician complaining of the physical changes that have resulted from starvation. Rather, the patient with anorexia nervosa will present with complaints that include menstrual irregularity, depression, lethargy, or repeated sports injuries. Additionally, complaints may include weakness, palpitations, chest pain, abdominal pain, or frequent headaches.

Laboratory Evaluation Despite the profound starvation and emaciation, most serum laboratory and chemistry values remain normal. Rarely do serum laboratory studies reflect the level of starvation present. The most common electrolyte abnormalities include hypokalemia, hyponatremia, and a mild metabolic alkalosis. [38] Classically, the individual with anorexia nervosa demonstrates what has been termed the *sick euthyroid* state, with low levels of triiodothyronine (T_3), thyroxine (T_4), and thyroid-stimulating hormone (TSH). This pattern is easily differentiated from hypothyroidism, in which the TSH levels are markedly increased. An additional hallmark laboratory finding in patients with anorexia nervosa is a low sedimentation rate, often recorded as either 0 or 1. This feature allows easy differentiation of anorexia nervosa from other prominent inflammatory processes that may result in significant weight loss. The laboratory and radiologic abnormalities commonly seen in patients with anorexia nervosa are listed in Table 35-4.

Hypokalemia, hyponatremia, metabolic alkalosis
Low thyroid tests, low T_3, T_4, TSH
Low erythrocyte sedimentation rate
Mild leukopenia, relative lymphocytosis
Hypercholesterolemia
Mild increase in hepatic aminotransferases
Mild increase in creatinine
Elevated cortisol
Microcardia
Widened sulci, enlarged ventricles
Decreased pituitary size
Hypoglycemia
Carotenemia
Hypomagnesemia
Anemia, thrombocytopenia
Low phosphorus
Mild increase in serum proteins
Low alkaline phosphatase
Decreased FSH, LH, and prolactin
Electrocardiographic changes: decreased P-wave amplitude, prolongation of PR interval, ST-T wave changes, junctional rhythm
Decreased zinc levels
Metabolic acidosis

FSH, follicle-stimulating hormone; LH, luteinizing hormone; T_3, triiodothyronine; T_4, thyroxine; TSH, thyroid stimulating hormone.

TABLE 35-4 Laboratory and Radiologic Abnormalities in Anorexia Nervosa

Medical Complications The extensive array of medical complications resulting from anorexia nervosa is listed in Table 35-5. These conditions are generally attributable to progressive starvation and emaciation. The most important ones are discussed below.

TABLE 35-5 Medical Complications of Anorexia Nervosa

After suicide, cardiac arrhythmias are the most common cause of death in patients with anorexia nervosa. [34], [38] Arrhythmias occurring in the face of profound bradycardia are most worrisome and carry a significant risk for tachyarrhythmias and sudden death. [34] Additionally, significant prolongation of the QT interval is thought to be an ominous sign predictive of a significant risk for sudden death. [38] Starvation causes both acute and long-term effects on bone mineralization and development. Poor bone growth, reduced bone turnover, and osteoporosis occur to some degree in all patients and may become severe. [38] The bone density measurements of 50% of patients with anorexia nervosa are two standard deviations below the mean. [39] Osteoporosis that develops after puberty is reversible. [38] Severe malnutrition and osteoporosis in early adolescence, however, may lead to a stunting of linear growth, particularly when associated with primary amenorrhea. [40]

Menstruation and reproductive function are significantly affected by anorexia nervosa. The pulsatile release of luteinizing hormone is diminished, pituitary gland output in response to gonadotropin-releasing hormone stimulation is reduced, feedback to estrogen is lost, and multifollicular changes occur within the ovaries. [38] Reproductive function is also affected; 10% of a large sample of anorexic women demonstrated infertility problems. [38] In this same cohort, the rate of infant prematurity was increased twofold, and perinatal mortality was increased sixfold. [38] Structural changes within the brain are common in patients with anorexia nervosa and are thought to be secondary to the profound effects of starvation. [41] Computed tomography and magnetic resonance imaging of the brain have demonstrated widening of the sulci and an increase in ventricular size. [41] Following weight restoration, white matter and cerebrospinal fluid volume slowly return to normal. Gray matter volume deficits may persist for years, may not fully return to normal, and may be associated with persistent deficits in neuropsychological parameters. [30]

Diagnostic Criteria Table 35-6 summarizes the revised diagnostic criteria for anorexia nervosa as listed in the *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition (DSM-IV). [42]

1. Refusal to maintain body weight over a minimally normal weight for age and height (e.g., weight loss leading to a maintenance of body weight <85% of that expected; or failure to make expected weight gain during a period of growth leading to body weight <85% of that expected).
2. Intense fear of gaining weight or becoming fat, even though underweight.
3. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
4. In postmenarcheal females, amenorrhea—that is, the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone [e.g., estrogen] administration.)

Restricting type: During the current episode of anorexia nervosa, the person has not regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Binge-eating/purging type: During the currentepisodes of anorexia nervosa, the person has regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

From ref. 42.

TABLE 35-6 Diagnostic Criteria—Anorexia Nervosa

Treatment Because of the complexity and interweaving of the psychological, nutritional, and medical problems associated with anorexia nervosa, treatment must be structured to incorporate all three of these areas. Reversal of the significant starvation that has preceded treatment is the most important goal of initial therapy. Feedings are reestablished by increasing the caloric intake to approximately 200 to 250 calories above the caloric intake at the time of presentation. The caloric intake is then sequentially increased by 250 to 300 calories every 4 to 5 days to achieve a steady weight gain of approximately 1.5 kg/wk for the hospitalized patient and 0.75 to 1.0 kg/wk for the outpatient. Meals must be supervised closely and patients supplemented with liquid enteral products for food items not consumed. A slow, steady weight gain to 100% of ideal body weight for individuals younger than 16 years and to 90% to 100% of ideal body weight for individuals older than 16 years is set as the goal. Ideal body weight determinations are obtained from the Centers for Disease Control or National Center for Health Statistics standard growth charts for pediatric patients younger than 16 years and from one of the standard height and weight tables, such as the 1983 Metropolitan height and weight tables, for older adolescents and young adults. The nutritionist must play a prominent role not only in supervising meals, but also in addressing and resolving the patient's unusual thoughts regarding food, eliminating food rituals and fears, and removing the misconceptions about fat and calories that have often developed. Involvement by the nutritionist in overcoming the patient's body image distortion and dissatisfaction is extremely important. Because of the hypermetabolic phase of early refeeding, during which time a portion of the calories ingested is expended as heat, the nutritionist may also be called on to assist the anorexic patient in condensing calories. Daily intakes may at times reach 4000 to 5000 calories to maintain weight gain. Medical treatment primarily focuses on nutritional rehabilitation in conjunction with the dietitian. In the first several days of treatment, any electrolyte abnormalities present must be corrected. Hypokalemia is particularly common in patients with anorexia who are purging by vomiting or using laxatives. Potassium supplementation may be required if potassium levels are below 3 mEq/L. Constipation is managed primarily with the use of psyllium and milk of magnesia; stimulant cathartics should be avoided. Gastric fullness and gastric bloating are frequent and generally resolve with 3 to 4 weeks of refeeding, but if severe, a promotility agent may be required. Most other changes associated with starvation self-correct with slow refeeding and do not require significant medical management. Hospitalization may be required if the patient presents initially with a body weight at or below 70% to 75% of the ideal weight, or if hemodynamic compromise, significant electrocardiographic abnormalities, dehydration, electrolyte abnormalities, profound weakness, mental confusion, or failure to progress with intensive outpatient management is noted. Only rarely are enteral tube feedings or hyperalimentation necessary. Regardless of the refeeding approach, extreme caution must be taken to avoid a too rapid or aggressive replenishment of calories, especially in severely underweight patients. This can precipitate the refeeding syndrome, caused by the rapid depletion of already low levels of phosphorus, and result in severe fluid retention, cardiac arrhythmias, congestive heart failure, muscle weakness, delirium, seizures, or death. [43] The psychotherapeutic and psychopharmacological treatment for both anorexia nervosa and bulimia nervosa is discussed at the end of the chapter.

Prognosis: Mortality and Morbidity Morbidity and mortality from anorexia nervosa remain significant. Earlier mortality rates in the 5% to 10% range have now been demonstrated to represent an early mortality of 5% and a late mortality that may be as high as 13% to 20%. [34] Suicide remains the No. 1 cause of death, followed by cardiac arrhythmias, infections, gastrointestinal complications, and emaciation. [38] In a longitudinal study, rates of death were 10 times and rates of suicide 58 times those expected after 11 years. [44] Morbidity rates are estimated to be 25%, with morbidity reflecting the multiple organ system dysfunctions associated with starvation. [45] The most common of these include osteoporosis, renal insufficiency, and infections. [38] Studies are beginning to appear on the long-term prognosis for patients with anorexia nervosa. Rates for full recovery are widely variable, ranging from 32% to 71% after 20 years. [34] Based on a large review of studies with follow-up for at least 4 years after initial treatment, about 44% of patients had outcomes rated as good, 28% variable, and 24% poor; 5% died. [30] Psychiatric comorbidities are also beginning to be recognized. Follow-up studies of adolescents have demonstrated that 30% continue to have problems with affective disorders and 43% with anxiety disorders. [34] Other common persisting comorbid illnesses include obsessive-compulsive disorder, avoidant personality disorder, and substance abuse. [30]

Bulimia Nervosa

Historical Perspective Although reports of engorgement and induced vomiting have been recorded since ancient times, the development of bulimia nervosa is of relatively recent origin. The first clinical description of bulimia nervosa was provided by Gerald Russell in 1979 [46] and was further defined in the *Diagnostic and Statistical Manual of Mental Disorders,* 3rd edition (DSM-III) in 1980. The term *bulimia,* however, was first used by Travisa in 1398 to mean "immoderate appetite." [47] Gradually, the term became associated with gluttonous overeating and induced vomiting and was included as a disorder in a text by Janet based on his classical work on neurosis in 1903. [47], [48] The psychiatric disorder of bulimia nervosa, however, should be distinguished from the gluttony and induced vomiting (bulimia) that were part of the social rituals of earlier times, not a maladaptive behavior used to control calorie consumption and promote weight loss. The key central issues of bulimia nervosa, including loss of control, low self-esteem, and guilt, are not apparent in these early descriptions.

Epidemiology Like that of anorexia nervosa, the incidence of bulimia nervosa has increased dramatically during the last 20 years. This is a disorder that occurs primarily in adolescents and young adult women, with a male-to-female ratio between 1:10 and 1:20, similar to that for anorexia nervosa. The overall incidence of bulimia nervosa is higher than that of anorexia nervosa and is estimated to range from 2% to 5% for female high school and college students. [49] Some series have reported incidences as high as 20%. [49] Prevalence rates for bulimia nervosa range from 1% to 10% in most studies. [32], [34], [50] The incidence of individuals demonstrating some but not all of the symptoms of bulimia nervosa suggests that 17% to 19% of women of college age engage in these behaviors. [49]

Etiology The pathogenesis of bulimia nervosa, like anorexia nervosa, is multifactorial, encompassing familial, developmental, social, cultural, physiological, and genetic factors. There is a strong association of bulimia with affective disorders (depression and dysthymia), and a strong family history of affective disorders in bulimic patients (as high as 50% in first-degree relatives) has been noted. [51], [52] Additionally, alcoholism and drug addiction are prevalent, with alcoholism being reported in 50% to 60% of first- and second-degree family members. [53] Families of patients in whom bulimia nervosa develops are described as having high levels of conflict with unstructured and ambivalent lines of authority, highly achievement oriented, and lacking expressivity. [54] Affective instability and low self-esteem are the hallmark personality features of the individual with bulimia nervosa. [54] As in anorexia nervosa, comorbid psychiatric illnesses such as depression or dysthymia (50%–75%), substance abuse (30%–37%), personality disorders, especially borderline personality disorder and avoidant personality disorder (42%–75%), and bipolar disorder (4%–6%), are frequently present. [30] Initially, a high index of sexual abuse was reported to be a precipitating factor, but more recent studies have shown that the incidence of sexual abuse in patients with bulimia nervosa is no higher than that in adolescents presenting with other psychiatric disorders. [55]

Sociocultural factors are quite prominent precipitating features in bulimia nervosa, as in anorexia nervosa. Bulimic individuals are also in pursuit of thinness. They equate thinness with success and control, and this is compounded by an equally strong societal view of obesity as a stigma. Unlike the individual with anorexia nervosa, in whom dieting leads to malnutrition, decreasing mental function, decreasing self-esteem, and the subsequent need to further intensify dieting, the individual with bulimia nervosa exhibits a divergent pattern. The poorly self-controlled and impulsive individual in whom bulimia nervosa develops cannot override the strong urge of hunger, loses control and binges on food, feels a loss of control resulting from this behavior, and further intensifies dieting. When dieting becomes unsuccessful, purging behavior ensues. Although initially purging is followed by a sense of relief, the bulimic individual begins to loathe the loss of self-control resulting from the purging behaviors and attempts to intensify dieting. A positive reinforcing loop is thus established, resulting in repetitive cycles of binging and purging. Characteristically, the binge episode lasts for 1 to 2 hours, during which a large number of calories are ingested, with the average intake estimated to be 4000 calories. [34]

Physical Evaluation Most bulimic individuals are of normal weight, and suspecting or establishing the diagnosis based on a routine physical examination is difficult. Bulimic individuals remain quite secretive about their behaviors, concealing them until their difficulties with loss of control lead to a desire to confront it. Unlike the individual with anorexia nervosa, the bulimic individual perceives her difficulties as problematic and will often seek help or assistance, particularly when the disorder progresses to the point that most of her daily thoughts and actions are controlled by the process. Before this happens, the bulimic individual may seek medical attention for one of the associated signs or symptoms of the disorder, including fluid retention (with a request for diuretics), abdominal fullness, frequent headaches, chest pain, constipation, hematemesis, and dental problems. On physical examination, three distinct abnormalities may be recognized that are pathognomonic for bulimia nervosa. These include calluses or scarring over the dorsum of the hand or fingers used to induce vomiting (Russell sign), hypertrophy of the salivary glands (sialoadenitis), and erosion of the dental enamel (perimolysis) (see Chapter 50). Up to 70% of bulimic individuals will be noted to have dental caries, and an even greater percentage will demonstrate perimolysis on careful examination, [56] particularly involving the lingual and occlusal surfaces. A chronic sore throat is frequently reported, and on physical examination the posterior pharyngeal areas are often erythematous.

Laboratory Evaluation On laboratory testing, the bulimic individual often demonstrates electrolyte abnormalities, most commonly hypokalemia, hyponatremia, and

hypochloremic alkalosis. [57] Profound electrolyte abnormalities with potassium levels below 3.0 mEq/L can be seen with laxative or diuretic abuse. Chronic dehydration is also frequently present. The laboratory and radiologic abnormalities commonly seen in patients with bulimia nervosa are listed in Table 35-7.

Hypokalemia, hyponatremia, hypochloremic alkalosis
Chronic dehydration
Metabolic acidosis
Elevated cortisol
Increased prolactin levels
Low magnesium levels
Hypoglycemia
Azotemia

TABLE 35-7 Laboratory and Radiologic Abnormalities in Bulimia Nervosa

Medical Complications Although the weight of most bulimic patients remains normal, the yo-yo dieting behavior associated with binging and purging is generally accompanied by a state of semistarvation. This results in a constellation of side effects and common medical complications quite similar to those seen in anorexia nervosa (Table 35-8). In addition to the medical complications in bulimia nervosa that result from starvation, the purging behaviors cause gastrointestinal side effects, including abdominal and epigastric pain, hematemesis, persistent sore throat, and constipation. Electrolyte abnormalities are frequently seen with laxative abuse and may be quite prominent. The number of laxatives taken varies from three or four per day to 150 per day. The long-term use of stimulant cathartics may ultimately result in a cathartic colon, with the patient requiring extensive medical and possibly surgical management.

[illegible]

TABLE 35-8 Medical Complications of Bulimia Nervosa

Electrocardiographic abnormalities are common in patients with bulimia nervosa. Particularly worrisome are those occurring in association with profound hypokalemia, which can result in arrhythmias and sudden death. Cardiac arrhythmias are the leading cause of death in bulimia nervosa. [34]

Diagnostic Criteria Table 35-9 details the revised diagnostic criteria for bulimia nervosa listed in DSM-IV. [42] Two subtypes of bulimia nervosa have now been described to help clarify the diagnosis in those patients who have mixed features of both anorexia and bulimia.

1. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following: (1) eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat in a similar period of time and under similar circumstances; and (2) a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
2. Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting, misuse of laxatives, diuretics, enemas, or other medications, fasting, or excessive exercise.
3. These behaviors both occur, on average, at least twice a week for 3 months.
4. Self-evaluation is unduly influenced by body shape and weight.
5. The disturbance does not occur exclusively during episodes of anorexia nervosa.
Purging type: During the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.
Nonpurging type: During the current episode of bulimia nervosa, the person has engaged in other inappropriate compensatory behaviors, such as fasting or excessive exercise.

From ref. 42.

TABLE 35-9 Diagnostic Criteria—Bulimia Nervosa

Treatment Most of the medical complications resulting from bulimia nervosa will slowly resolve once the purging behaviors have been controlled, and they do not require significant medical management. If electrolyte abnormalities are severe, and particularly if potassium levels are below 3.0 mEq/L, potassium supplementation will be required during the first few days of treatment. A dental consultation should be obtained for most of the individuals who have used vomiting as a means of purging. The most troublesome medical complication is the development of pseudo-Bartter syndrome, which can follow the abrupt discontinuation of diet pills or laxatives in patients who have significantly abused these substances. [58] Chronic laxative and diuretic abuse leads to chronic dehydration, activating the renin-angiotensin-aldosterone system and resulting in hyperaldosteronism. Significant fluid retention and peripheral edema can develop within 2 to 7 days after these drugs have been discontinued. Diuretic therapy is frequently required for the treatment of severe edema, with slow tapering of the diuretics over 4 to 12 weeks, while aldosterone levels normalize. Potassium supplementation is frequently required in conjunction with diuretic administration. The nutritional rehabilitation of the patient with bulimia nervosa focuses on the need to stop the purging behaviors, dispel the myths and inaccurate notions that have developed regarding food, calories, and fat, and overcome body image distortion.

Prognosis: Morbidity and Mortality The mortality rates for patients with bulimia nervosa within 2 to 5 years after diagnosis continue to remain at 5%. [34] Between 50% and 60% of individuals will demonstrate recovery over this same period of time, with a relapse rate between 30% and 50%. [34] In an extensive review of several follow-up studies by Woodside, [34] 2 years after treatment, 20% to 25% of individuals were well, 10% to 15% had minor recurrent difficulties, 15% had major recurrent difficulties, 15% were chronically ill, and 20% to 25% had fully relapsed. In one large study, 6 years after successful treatment, 60% of patients demonstrated a good, 29% an intermediate, and 10% a poor outcome, and 1% had died. [30] The most prominent factor associated with failure to remain well was concomitant alcohol or drug use. [34]

PSYCHOTHERAPY AND PSYCHOTROPIC MEDICATIONS FOR ANOREXIA NERVOSA AND BULIMIA NERVOSA

Successful treatment of anorexia nervosa and bulimia nervosa must address core issues such as distorted beliefs about weight and eating, distorted body image, fear of weight gain, perfectionist self-criticism, interpersonal mistrust, a sense of ineffectiveness, and poor self-regulation. Before intervening, the treatment team should evaluate the importance of these issues to the individual patient. Other issues often include deficits in assertiveness, poor impulse control, fears of the demands of maturity, and poor conflict management skills. A comprehensive evaluation also examines family factors that may contribute to eating disordered behavior, such as emotional overinvolvement, poor role boundaries within the family, lack of conflict resolution, and age-inappropriate intrusiveness.

The initial assessment also should determine whether the patient's symptoms warrant inpatient or some other intensive therapy rather than outpatient care. The presence of additional significant psychopathology decreases the patient's chances for successful completion of low-intensity protocols. Of particular concern is the coexistence of major depression, alcoholism or other substance use disorders, or personality disorders involving poor impulse control, self-injurious behaviors, or extreme distortions in interpersonal relationships. Overt psychotic symptoms, severe dissociative reactions, or symptoms that include assaultive behavior often must receive first priority in treatment planning. A careful psychodiagnostic interview combined with appropriate psychological testing is particularly valuable at this stage.

Hospital-based programs for eating disorders typically are used for those patients with the most severe symptoms or with the complications described above. For anorexic patients below 70% to 75% of their ideal body weight, outpatient programs are not usually feasible, and even partial hospital programs may not offer the intensity of treatment necessary to ensure initial compliance and progress. Clearly, those anorexic patients who are medically compromised or require tube feeding are not appropriate candidates for outpatient care. In the authors' experience, younger patients with a more recent onset tend to show more signs of medical instability at higher weights than do older patients whose condition is more chronic. Because these younger patients also have the greatest opportunity to recover from such potential long-range problems as osteoporosis, we advocate more aggressive treatment with hospitalization at somewhat higher weights. Among both anorexic and bulimic patients, failure to achieve appropriate eating patterns and weight on an outpatient basis should be regarded as a reason to move the patient to more intensive care, such as partial hospital, residential, or inpatient treatment. The presence of suicidal tendencies, substance abuse/dependency, or other significant psychological symptoms in addition to the eating disorder also warrants a higher level of care.

Psychopharmacology

The use of psychotropic medication to treat eating disorders continues to be a very active field. Unfortunately, studies have failed to demonstrate the effectiveness of any psychotropic medication for treating anorexia nervosa. In clinical experience, some patients with anorexia respond to drug therapy; however, this usually reflects the selection of a psychoactive agent targeted at psychopathology other than the anorexia. In brief, psychotropic medication should be used with anorexic patients only when the target of the intervention is some concurrent symptom. The most significant caveat in this area is that severely underweight patients can display other symptoms, particularly depression, anhedonia, and lethargy, simply as a result of their starvation. The general consensus is that treating such depressive symptoms when they are a consequence of starvation is not appropriate clinical management.

In contrast to the results with anorexia, numerous controlled studies have shown effectiveness for the use of antidepressants in decreasing bulimic symptoms. Patients treated with imipramine, [59] desipramine, [60] and fluoxetine, [61] among others, have shown a decreased frequency of binging, purging, and a variety of other measures of bulimic behavior. The effectiveness is often related to the dose, and some studies have shown that moderately long trials of the medication are more effective than brief treatments. Potential problems with using this approach exclusively in treating bulimia include patient noncompliance and the fragility of the effect after medication is discontinued. The results of studies in which earlier classes of antidepressants were used suggest that a smaller percentage of patients recover receiving medication alone compared with psychotherapy. [59]

Family Therapy

Family therapists have applied a variety of methods to the treatment of eating disorders. Structural family therapy [62] and systemic [63] and behavioral methods [64] have been demonstrated to be effective in patients with eating disorders. However, no studies have isolated specific factors that would lead to the selection of family therapy for a particular patient. When the initial assessment identifies specific skill deficits within the family, methods developed to intervene with these deficits are applied. In presenting recommendations for family therapy, it is important that the family members understand that the recommendation is being made so that they may participate in the patient's recovery—not because the treatment team believes that the family caused the eating disorder. Much resistance and fear are generated when the family members perceive that they are viewed as the villains of the piece rather than as potential heroes.

A significant concern is that only one study has compared the effectiveness of family with another form of treatment (i.e., individual psychotherapy for the treatment of anorexia and bulimia). [65] Family therapy was found to be differentially beneficial for patients with anorexia who were younger than 18 years of age and whose disorder had been present for less than 3 years. Older patients with anorexia did significantly better with individual therapy. Patients with bulimia did not show differential effects and did not show much improvement with either therapy method used in this study. In the absence of larger and more complete studies, this finding at least signals the need to use family therapy in a circumspect manner in dealings with adult patients. It does not speak to the use of marital therapy.

Cognitive-Behavioral Therapy

The most comprehensively documented psychotherapy for bulimia is cognitive-behavioral therapy. Treatment may be delivered in either group or individual formats. The purpose of this form of therapy is to alter behavioral patterns, distorted beliefs, and dysfunctional self-perceptions that promote eating disordered behavior. The therapist helps the patient test and invalidate existing assumptions and thoughts about weight and body size. Ultimately, the patient learns to challenge mistaken beliefs and attitudes about herself. Fairburn [66] has demonstrated that this approach can produce success rates as high as 70% in the outpatient treatment of bulimia. These rates appear durable for up to 2 years of follow-up. Similar strong results have been reported for the group treatment of bulimia by Mitchell and colleagues. [59] Cognitive-behavioral therapy has been shown to be superior to behavior therapy as well as placebo. In studies assessing the effectiveness of cognitive-behavioral therapy compared to antidepressant medication alone and the combination of antidepressants and cognitive-behavioral therapy, the cognitive-behavioral therapy is usually, [59] but not always, [60] superior to antidepressants alone and is equal to the combination treatment. [59] With anorexia, the evidence is less powerful, but it remains persuasive enough that cognitive-behavioral therapy should be considered the gold standard of treatment for this disorder.

Interpersonal Therapy

Interpersonal therapy was originally developed as a treatment for depression and has been applied successfully in this area. [67] It has demonstrated effectiveness that cannot be statistically differentiated from that of cognitive-behavioral therapy. [68] The care with which these studies were conducted and the clarity of the results suggest that interpersonal therapy be given serious consideration in the treatment of bulimia, even though more research must be conducted. In interpersonal therapy, the focus is not on weight or body image issues per se. Rather, the therapist helps the patient evaluate interpersonal skills, conflicts with significant people, difficulty in role transitions, and loss. The emphasis is on solving interpersonal problems and patterns of relating to others rather than on changing thoughts. At this time, no research-based criteria are available for recommending interpersonal therapy versus cognitive-behavioral therapy for a particular patient.

We recognize that many other psychotherapeutic approaches have been applied to the treatment of eating disorders. This review has been selective, emphasizing those treatments that are most commonly used in the field or whose effectiveness is supported by clear data. The most significant role for the health care provider in supporting patients during their recovery from an eating disorder is to dispel pessimism regarding treatment. Although old methods of treatment produced discouragingly low rates of recovery, modern treatment studies indicate that eating disorders are very treatable and that many people can expect improvement or recovery.

CHAPTER 36

Judith Korner, Samuel Klein, and Louis J. Aronne

APPROACH TO THE PATIENT WITH OBESITY

Obesity is an overabundance of adipose tissue that arises from an excess of energy intake compared to expenditure. Obesity is not simply the result of gluttony and a lack of willpower. Rather, each individual inherits a set of genes that control appetite and metabolism, and a genetic tendency to gain weight that may be exacerbated by environmental conditions such as food availability, level of physical activity and individual psychology and culture.

Obesity is defined in terms of body mass index (BMI), which provides an index of the relationship between weight and height. The BMI is calculated as weight (in kilograms) divided by height (in square meters), or as weight (in pounds) times 703 divided by height (in square inches). The primary classification of overweight and obesity relates to the BMI and the risk for mortality (Table 36-1). [1] The prevalence of obesity in adults in the United States without coexisting morbidity increased from 12% in 1991 to 17.9% in 1998. Gastroenterologists are in a unique position to manage this disease because of the multiple gastrointestinal conditions associated with increased body weight. This chapter reviews the molecular mechanisms that regulate food intake and body weight, and the comorbidities, in particular gastrointestinal complications, associated with excess body weight. The clinical approach to the patient with obesity is also outlined.

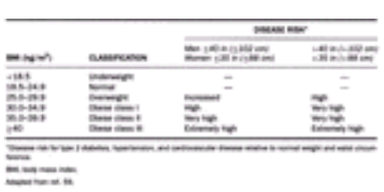

TABLE 36-1 Classification of Weight by BMI, Waist Circumference, and Associated Disease Risk*

MOLECULAR CIRCUITRY OF BODY WEIGHT REGULATION

Multiple factors determine how much we eat and how much we weigh. Weight gain occurs when dietary energy intake is not in balance with daily energy expenditure, and obesity represents an interplay between diet, physical activity, environment, age, and genetics. The estimated heritability of the BMI is between 50% and 90%—that is, the susceptibility to obesity is determined largely by genetic factors, but the expression of these genes is influenced by our environment. In today's modernized societies, the access to large quantities of high-calorie, high-fat foods and the decreased demand for physical activity are responsible for the marked increase in the prevalence of obesity. [2]

The discovery of leptin and other genes responsible for obesity in rodents has made a considerable impact on our understanding of body weight regulation and may lead to exciting advances in the treatment of human obesity. Leptin (derived from the Greek *leptos,* meaning "thin") is a hormone produced by fat cells that circulates at levels proportional to body fat content. Leptin crosses the blood-brain barrier to bind to its receptor in the hypothalamus, thereby activating signals that inhibit food intake and increase energy expenditure. When leptin is given to leptin-deficient mice, obesity and metabolic abnormalities such as hyperglycemia, hyperinsulinemia, and hypercortisolemia are reversed. [3] However, the initial hypothesis that human obesity results from a deficiency of leptin has not been upheld. In fact, most obese humans have high circulating levels of leptin, and only a few individuals with severe obesity have been identified with either a congenital leptin deficiency or a mutation in the leptin receptor gene. [4] In early clinical trials, high doses of subcutaneously administered leptin, often associated with reactions at the injection site, had only a modest effect in reducing body weight. [5] Therefore, it appears that obese persons are "leptin resistant," and if a defect in the leptin pathway exists in human obesity, it is probably a post-receptor defect in the subsequent leptin signaling pathway.

Leptin is also present in the gastric mucosa of humans within secretory granules of endocrine and chief cells. [6] Release of leptin into the systemic circulation and into gastric juice is stimulated by intravenous infusions of pentagastrin or secretin. Leptin receptor is also present in gastric epithelium. These findings raise the possibility that leptin produced in the stomach plays a paracrine, endocrine, and/or exocrine function in energy homeostasis.

Leptin is known to affect the gene expression of other neurohormones involved in energy balance (Fig. 36-1). [7] Neuropeptide Y (NPY) stimulates food intake and decreases energy expenditure. The expression of messenger RNA for NPY is inhibited by leptin. Conversely, leptin stimulates the gene expression of peptides that have opposite characteristics. a-Melanocyte-stimulating hormone (a-MSH), a peptide derived from proopiomelanocortin (POMC), and cocaine- and amphetamine-regulated transcript (CART) are hypothalamic peptides that are positively regulated by leptin and produce anorexia.

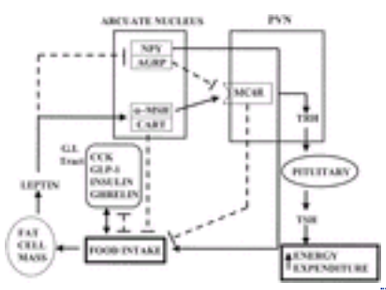

FIGURE 36-1. Interaction of leptin and hypothalamic neuropeptides in controlling energy homeostasis. Food intake increases fat cell mass, which results in an

elevation of circulating leptin levels. Leptin stimulates the synthesis of cocaine- and amphetamine-regulated transcript (*CART*) and the production of a-melanocyte-stimulating hormone (*a-MSH*) in the arcuate nucleus of the hypothalamus, which decreases food intake via melanocortin-4 receptor (*MC4R*) signaling in the paraventricular nucleus (*PVN*). Activation of MC4R also increases energy expenditure via signaling through thyrotropin-releasing hormone (*TRH*) and thyrotropin (*TSH*). Leptin inhibits the production of agouti-related protein (*AGRP*), which allows for more effective signaling of a-MSH at MC4R. Leptin also inhibits the synthesis of neuropeptide Y (*NPY*). Thus, the result of increased leptin levels is stimulation of anorectic (CART and a-MSH) and inhibition of anabolic (AGRP and NPY) signaling pathways to decrease food intake and increase energy expenditure. Gastrointestinal peptides also modulate food intake through peripheral and central pathways. (*Arrows*, stimulatory; *dashed lines*, inhibitory.) *CCK*, cholecystokinin; *GLP-1*, glucagon-like peptide-1.

The melanocortin system, in particular, is under intensive investigation because of strong evidence in both rodents and humans of its control of energy homeostasis. [2] There are five different receptors for a-MSH, two of which, melanocortin-3 receptor (MC3R) and melanocortin-4 receptor (MC4R), are primarily expressed in the brain. Some of the metabolic effects resulting from the stimulation of MC4R are decreased food intake, stimulation of thyrotropin-releasing hormone (TRH), and an increase in energy expenditure. Mutations in MC4R are found in approximately 1% to 5% of patients with a BMI above 40. In addition, rare mutations have been reported in the genes for POMC and the enzyme that processes the POMC protein to a-MSH that are associated with severe childhood obesity. Further evidence for the importance of the melanocortin pathway stems from the identification of agouti-related protein (AGRP). AGRP is a hypothalamic neuropeptide that stimulates food intake in the rat through antagonism of the interaction of a-MSH at MC4R (see Fig. 36-1); expression of the AGRP gene is suppressed by leptin.

Gastrointestinal tissues also mediate important communication to the brain about energy intake through neural signaling and endocrine pathways. Cholecystokinin (CCK), which is released in response to dietary fat, enhances nutrient absorption by slowing gastric emptying and stimulating gallbladder contraction, and inhibits food intake during a meal via the afferent vagal system. [8] Glucagon-like peptide-1 (GLP-1) inhibits gastrointestinal motility, hunger, and food intake. [9] Ghrelin is a peptide found in the hypothalamus and stomach. [10] Intracerebroventricular injection of ghrelin stimulates feeding in the rat and increases body weight through stimulation of NPY and AGRP neurons. Apolipoprotein A-IV is a glycoprotein synthesized by the human intestine in response to fat absorption. [11] Apo A-IV causes central inhibition of food intake and is likely to be involved in the short-term and possibly long-term regulation of food intake. The role of these peptides in the regulation of body weight in humans is under intense study and has important implications for the design of therapeutic agents for obesity.

COMORBIDITIES OF OBESITY

Gastrointestinal Dysfunction

Most large epidemiologic studies have found that symptoms of gastroesophageal reflux disease (GERD) are more common in obese than in lean persons. In a prospective study of 1224 patients referred for upper gastrointestinal endoscopy, reflux esophagitis was found in 16% of the patients and hiatus hernia in 20%. [12] A coexisting hiatus hernia was found in 68% of the patients with reflux esophagitis. Overweight was most pronounced in those with mild to moderate esophagitis, whereas in patients with severe esophagitis, the body weight was normal. These results support the view that adiposity is associated with both sliding hiatus hernia and reflux esophagitis, and that hiatus hernia may play a role in the development of GERD. In contrast, a study of morbidly obese subjects found no significant correlation between body weight, BMI, or waist-hip circumference and reflux. [13]

Although increased intra-abdominal pressure induced by excessive abdominal girth may predispose obese persons to reflux, we are unaware of any randomized controlled trials that have evaluated whether weight loss decreases reflux symptoms. In one study, conducted in lean persons, diet-induced weight loss correlated directly with a decrease in reflux symptoms. [14] However, alterations in diet, rather than a decrease in body weight, may have been responsible for the beneficial effects because even a modest weight loss of 2 to 3 kg was associated with a marked improvement in the symptom score. In studies of patients with class I [15] or class III [16] obesity who had symptoms of GERD, diet-induced weight loss did not relieve symptoms or improve 24-hour esophageal pH values. In contrast, the gastric bypass procedure has consistently been shown to decrease GERD symptoms. [17], [18] In fact, GERD symptoms often resolve immediately after surgery before significant weight loss occurs, suggesting that the elimination of acid or bile reflux, rather than a decrease in weight, is responsible for the beneficial effect. Although some studies have found that vertical banded gastroplasty and gastric banding, which increase resistance to flow through the proximal pouch, do not alter the lower esophageal sphincter pressure or increase episodes of reflux, [19] severe gastroesophageal reflux can occur after vertical banded gastroplasty. [20]

Studies of the relationship between gastric emptying and obesity have yielded conflicting results. Gastric emptying has been reported as accelerated, delayed, or unchanged in the obese. [21] Rapid gastric emptying may result in decreased satiety signals from the intestine and may be a contributing factor in the pathogenesis of obesity.

Gallbladder Disease

Obesity, particularly in women, is an important risk factor for gallbladder disease. [22] Data from the Nurses Health Study demonstrated that the risk for symptomatic gallstones increases linearly with the BMI. Obese women (BMI >30 kg/m [2]) had a twofold and extremely obese women (BMI >45 kg/m [2]) a sevenfold excess risk for symptomatic gallstones in comparison with lean women. [23] The risk for gallstones also increases during weight loss because of increased bile cholesterol supersaturation, enhanced cholesterol crystal nucleation, and decreased gallbladder contractility. The incidence of new gallstones is approximately 30% in obese patients who experience rapid weight loss after treatment with a very-low-calorie diet (<600 kcal/d) or gastric surgery. [24], [25] and [26] Ursodeoxycholic acid therapy at a dose of 600 mg/d provides maximal gallstone prevention. Prophylactic therapy should be considered for patients who are expected to achieve rapid weight loss exceeding 1.5 kg or 1.5% of body weight per week.

Pancreatitis

It is not known whether obese patients are at increased risk for gallstone pancreatitis. However, most studies have found that overweight and obese patients are at higher risk for the development of local complications and severe pancreatitis. [27], [28] Obesity also increases the risk for respiratory insufficiency and mortality. It is possible that excess fat deposited in the peripancreatic and retroperitoneal spaces predisposes obese patients to peripancreatic fat necrosis and subsequent local and systemic complications.

Liver Disease

Obesity is associated with a spectrum of liver abnormalities that can be classified by alterations in liver histology (macrovesicular steatosis, steatohepatitis, fibrosis, and cirrhosis) and are now known collectively as *nonalcoholic fatty liver disease (NAFLD)*. [29] Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are the liver enzymes most commonly elevated in obese patients, but enzyme levels usually do not exceed two times the upper limit of normal and often do not correlate with the severity of the histological abnormalities. Dieting itself often causes a transient increase in serum transaminase concentrations and a decrease in serum alkaline phosphatase concentration during early weight loss. In a histological analysis of liver biopsy specimens from overweight and obese patients who had abnormal liver biochemistries but no overt findings of liver disease or evidence of acquired, autoimmune, or genetic liver disease, 20% of the patients had septal fibrosis alone and 10% had septal fibrosis and “silent” cirrhosis. [30] In a review of the data from a series of studies, 40% to 100% of the patients with nonalcoholic steatohepatitis were obese. [31] Data from autopsy studies, investigations of obese patients undergoing obesity surgery, and cross-sectional analyses of liver biopsy samples suggest that steatosis occurs in about 75%, steatohepatitis in about 20%, and cirrhosis in about 2% of obese patients. [32], [33] and [34]

The pathogenesis and natural history of NAFLD are not well understood. Most patients are asymptomatic, but some may have fatigue, malaise, and vague abdominal discomfort. Hepatomegaly has been reported in up to three fourths of patients with NAFLD. In contrast to the ratio of AST to ALT in patients who have alcohol-induced steatohepatitis, this ratio is usually less than 1 in patients who have NAFLD. In studies that followed patients for up to 7 years, liver disease continued to progress in about 40% of patients, and cirrhosis developed in about 10%. In most patients with simple steatosis, the clinical course was benign, whereas in those with steatohepatitis, fibrosis, and cirrhosis, clinical sequelae of severe liver disease were more likely to develop. Furthermore, obesity increased the risk for fibrosis and cirrhosis in patients with alcoholic liver disease [35] and hepatitis C. [36]

Although weight loss is often recommended as therapy for obese patients with NAFLD, it is not known whether weight loss affects long-term outcome and reduces the risk for progressive disease. A gradual loss of 10% or more of body weight can correct abnormal liver chemistries and decrease liver size, fat content, and features of

steatohepatitis. However, rapid weight loss after gastric surgery, very-low-calorie diets, or fasting decreases the hepatic fat content but can induce hepatic inflammation and exacerbate steatohepatitis. The use of metformin has been shown to reverse fatty liver disease in insulin-resistant obese mice, but this potential therapeutic approach has not been evaluated in humans. [37]

Colon Cancer

Overweight and obesity are associated with an increased risk for esophageal, gallbladder, and colorectal cancers. [38] Men whose BMI is above the fourth quintile have an odds ratio of 1.96 for the development of colon cancer, and women with a BMI above the fourth quintile have an odds ratio of 1.54. [39] The effect of the BMI is strongest for distal cancers and in patients with a family history of colorectal cancer.

Dyslipidemia and Cardiovascular Disease

Obesity is an independent risk factor for cardiovascular disease, including coronary heart disease, congestive heart failure, stroke, and peripheral vascular disease. Increased body weight and abdominal obesity predispose individuals to elevated levels of total cholesterol, low-density lipoprotein (LDL) cholesterol, triglycerides, apolipoprotein B (a marker for small, dense LDL), insulin, and plasminogen activator-1 and to low levels of high-density lipoprotein (HDL) cholesterol. [40] The cluster of hypercholesterolemia, hypertriglyceridemia, hyperuricemia, impaired glucose tolerance, insulin resistance, diabetes, and hypertension in various combinations is known as the *metabolic syndrome* or *syndrome X* and is commonly associated with abdominal fat accumulation. Most studies have found that weight loss decreases serum triglyceride, total cholesterol, and LDL cholesterol concentrations and increases the serum HDL cholesterol concentration. [41] At 2 years, a sustained weight loss of 5% is sufficient to maintain the reduction in serum triglyceride concentrations, whereas serum total and LDL cholesterol levels revert toward baseline if at least a 10% weight loss is not maintained. [42]

Data from the Third National Health and Nutrition Examination Survey (NHANES III) demonstrated that the age-adjusted prevalence of hypertension is more than twofold higher in obese men and women (42% and 38% prevalence rates, respectively) than in lean men and women (~15% prevalence rate in both men an women). Weight loss results in a reduction of systolic and diastolic blood pressure; however, a study of patients after gastric surgery has raised questions about the duration of this effect. [43]

Type 2 Diabetes Mellitus

Body mass index, abdominal fat distribution, and weight gain are important risk factors for type 2 diabetes mellitus. Data from NHANES III showed that the prevalence of diabetes increases from 2% in those with a BMI between 25 and 29.9 kg/m ^{2} to 13% in those with a BMI of 35 kg/m ^{2} or higher. The Nurses Health Study found that the risk of diabetes begins to increase even in women of “normal” weight when the BMI exceeds 22 kg/m ^{2}. Weight loss of 5% improves glycemic control in most obese diabetic patients. In addition, sustained weight loss is effective in preventing the development of new cases of diabetes in obese persons.

HISTORY AND PHYSICAL EXAMINATION

The initial evaluation of an obese patient starting a weight loss regimen includes a history, physical examination, and laboratory studies. A history of eating disorders or purging is a relative contraindication to treatment, and referral to a specialist in these areas is appropriate. The patient’s current level of physical activity and understanding of nutrition should be assessed. Diseases associated with weight gain, such as polycystic ovarian disease, hypothyroidism, and Cushing syndrome, should be ruled out or treated. In addition to the gastrointestinal complications of obesity, the physician should search for other complications, such as hypertension, type 2 diabetes, hyperlipidemia, coronary heart disease, osteoarthritis of the lower extremities, gout, and certain cancers. Depression, and the drugs used to treat depression, may cause weight gain. The physician should be aware of the symptoms and signs of sleep apnea: loud snoring, brief awakenings, sleeping in the sitting position, daytime fatigue, morning headaches, or polycythemia on the laboratory evaluation. If signs of sleep apnea are present, the patient should be referred to a pulmonologist or sleep specialist. Assessment of the patient should include a calculation of the BMI. The distribution of adipose tissue is an important consideration in addition to the BMI. An abdominal distribution of adipose tissue is characterized by an increase in waist circumference, which is measured by placing a measuring tape in a horizontal plane at the level of the iliac crest without compressing the skin. A waist circumference greater than 35 inches (88 cm) in women and 40 inches (102 cm) in men is considered an independent risk factor for type 2 diabetes and cardiovascular disease (see Table 36-1).

TREATMENT

The primary target of treatment should be those individuals at medical risk because of their weight (Table 36-2). A realistic treatment goal is usually a loss of 5% to 10% of the initial body weight over 6 to 12 months followed by long-term maintenance of the reduced weight. Most cardiovascular risk factors are decreased even at this modest level of weight reduction [1]; however, patients with cholelithiasis and osteoporosis must be warned that these conditions may be aggravated by weight loss. A summary of the steps in evaluating and treating the overweight and obese patient is presented in Table 36-3. *The Practical Guide. Identification, Evaluation, and Treatment of Overweight and Obesity in Adults* [44] is a useful source that details the appropriate management of the overweight and obese patient.

TABLE 36-2 Treatment Options

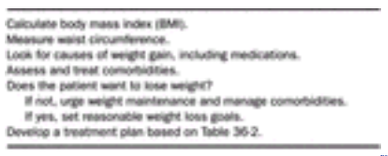

TABLE 36-3 Steps in Evaluating and Treating the Overweight and Obese Patient

Lifestyle Modifications

Calorie-Restricted Diets To induce weight loss, a calorie deficit must be achieved. General guidelines for healthful eating, such as a reduction in fat, sugar, and alcohol intake, should be emphasized. Balanced diets should contain a minimum of 1000 to 1200 kcal/d and provide adequate amounts of all essential nutrients. A diet that is individually planned to create a deficit of 500 kcal/d should produce a weight loss of about 1 lb weekly. The step I diet, consisting of approximately 55% carbohydrate, 15% protein, 30% fat (8%–10% saturated fatty acids, <300 mg of cholesterol per day), and 2.4 g of sodium daily, will also decrease other risk factors, such as high blood cholesterol and hypertension. Water intake should be at least six to eight 8-oz glasses per day. Supplementation with a multivitamin can be considered. A calcium intake of 1000 to 1500 mg/d is particularly important for individuals at risk for osteoporosis. Calories derived from fat are easier to consume in excess because they are “denser” (9 cal/g versus 4 cal/g for protein and carbohydrate) and easily hidden in foods, and they increase food palatability. In general, energy consumed as fat causes less satiety than energy consumed as carbohydrate. Fat-modified foods lower the total fat intake but are an aid to weight loss only if they are also low in calories. Studies suggest that because individuals tend to consume a constant weight of food, a diet low in energy density is likely to lead to a reduction in energy intake. [45] A diet low in energy density is usually low in fat and high in water content, complex carbohydrates, and fiber. Fruits, vegetables, and grain products are foods low in energy density. However, foods high in energy density are not always high in fat content. For example, dry foods such as fat-free pretzels or crackers are high in energy density. The glycemic index of a food, defined as the area under the glucose response curve after consumption of 50 g of

carbohydrate from a test food divided by the area under the curve after consumption of 50 g of carbohydrate from a control food such as white bread or glucose, has been proposed as an important factor in regulating energy intake. [46] Starchy foods such as refined grain products and potatoes generally have a high glycemic index, whereas vegetables, legumes, and some fruits generally have a low glycemic index. In one study, subjects given a diet with a low glycemic index in the morning consumed less food later in the day in comparison with subjects given a diet with a high glycemic index. [47] Although the glycemic index requires further study before it is universally accepted by nutrition professionals, in our opinion, it does play a role in individual dietary prescription.

Exercise Physical activity is a key component of any long-term weight maintenance program. A moderate amount of physical activity uses approximately 150 calories of energy per day. Some examples of moderate activity include walking 2 miles, pushing a stroller 11/2 miles in 30 minutes, bicycling 5 miles in 30 minutes, and swimming laps for 20 minutes. [44] Patients who are physically limited by obesity or arthritis may start with water exercises, bedside stretching, or seated activities. In general, patients should build up to at least a 30- to 45-minute exercise regimen, daily if possible, and the exercise should be of the greatest intensity that is safe for their own level of fitness.

Behavior Therapy

The goal of behavior therapy is to overcome barriers to compliance with a regimen of diet and physical activity. Behavior therapy may consist of self-monitoring, stimulus control, reinforcement, and stress management. *Self-monitoring* includes recording dietary intake (food choices, amounts, times), exercise, and changes in body weight. *Stimulus control* helps the patient to identify and change cues associated with eating too much and exercising too little. *Reinforcement* encourages the attainment of goals that are difficult to achieve by providing rewards other than food when goals are reached. *Stress management* helps the patient cope with stressful events by developing outlets other than eating for reducing stress. Evaluating setbacks and determining how to do better next time can break the chain of negative thinking and self-punishment when lapses occur.

Medications that May Cause Weight Gain and Alternatives

Many commonly prescribed medications are known to cause weight gain as a side effect (Table 36-4). When antiobesity medications are being considered, attention should be paid to the use of such medications and the possibility of switching the patient to others that may induce weight loss. Metformin is often the best first-line drug in the obese diabetic patient because it may induce weight loss and improve the body composition and lipid profile. Acarbose and miglitol, which are a-glucosidase inhibitors, may also induce weight loss. Most mood stabilizers and antidepressants, particularly the tricyclics, cause weight gain, although bupropion may induce weight loss. An anticonvulsant, topiramate, has been shown to induce weight loss, in contrast to the weight gain often associated with other agents, and case reports have appeared of its being used to mitigate the weight gain associated with the new antipsychotic agents, such as olanzipine.

Antidepressants, lithium
Neuroleptics
Insulin, sulfonylureas, thiazolidinediones
Antiepileptics
Antihistamines
Corticosteroids
Hormonal contraceptives
Progestational steroids
β Adrenergic blockers
Phenothiazines

Adapted from ref. 59.

TABLE 36-4 Drugs that May Promote Weight Gain

Pharmacotherapy

The National Heart, Lung, and Blood Institute supports the use of pharmacotherapy for patients who have not achieved weight loss and maintenance goals by means of initial therapy with lifestyle modification (see Table 36-2). Two agents are currently approved by the U.S. Food and Drug Administration for long-term use, sibutramine and orlistat (Table 36-5).

DRUG	DOSE	ACTION
Sibutramine	• 5, 10, 15 mg • 10 mg orally once a day to start • May be increased to 15 mg or decreased to 5 mg	• Inhibits norepinephrine, dopamine, and serotonin reuptake • Reduces appetite and increases thermogenesis
Orlistat	• 120 mg orally with meals	• Inhibits intestinal lipases • Decreases fat absorption

From ref. 44.

TABLE 36-5 Characteristics of Pharmacotherapies Approved for Long-Term Use in the Treatment of Obesity

Sibutramine Sibutramine has been shown to achieve and maintain weight loss for as long as 2 years. [48] The therapeutic effect of sibutramine is based on inhibition of the reuptake of norepinephrine, serotonin, and dopamine and activation of the respective neurotransmitter receptors, which results in decreased food intake. [49] In addition, sibutramine may attenuate the decrease in resting metabolic rate that accompanies caloric restriction and weight loss. [50], [51] In a 1-year placebo-controlled trial, 65% of the patients who received 15 mg of sibutramine daily lost more than 5% of their body weight, versus 29% of the patients who took placebo, and 39% lost more than 10% of their body weight, versus 8% who achieved the same mean weight loss in the placebo-treated group. [52] Patients who lose at least 4 lb in the first 4 weeks of treatment are more likely to achieve a weight loss of at least 5% within 6 months. [53] The most common adverse effects reported in clinical studies of sibutramine have been headache, dry mouth, constipation, and insomnia. [52], [53] and [54] Small mean increases in both diastolic and systolic blood pressure (2 mm Hg at doses of 10 and 15 mg) and pulse rate (3 to 6 beats/min) are associated with sibutramine treatment and occur most frequently during the first 8 weeks of treatment. Routine clinical monitoring of vital signs is therefore recommended.

Orlistat Orlistat binds to gastric, pancreatic, and carboxyl ester lipases in the gastrointestinal tract and blocks the action of these lipases on dietary triglycerides and vitamin esters. The inhibition of fat digestion decreases micelle formation and the absorption of long-chain fatty acids, cholesterol, and certain fat-soluble vitamins. The percentage of malabsorbed fat is directly related to the drug dose in a curvilinear fashion. At a dose of 360 mg/d (120 mg three times daily with meals), approximately 30% of ingested triglyceride is excreted in stool, which is near the maximum plateau value. [55], [56] Several prospective randomized controlled trials have evaluated the efficacy of orlistat therapy in initiating and maintaining weight loss. [43] In one study, after 2 years, 57.1% of orlistat-treated patients maintained a loss of more than 5% of body weight, compared with 37.4% of placebo-treated patients. [55] The most common side effects of orlistat are related to its action on gastrointestinal lipases: abdominal pain, fecal urgency, liquid stools, flatulence with discharge, oily spotting, and incontinence. Long-term treatment with orlistat can affect the homeostasis of certain fat-soluble vitamins. During 1- and 2-year clinical trials of orlistat, vitamin concentrations, usually of vitamins D and E and ß-carotene, fell below normal limits in approximately 5% more orlistat- than placebo-treated subjects. These abnormalities resolved rapidly with vitamin supplementation. It is recommended that all patients who are treated with orlistat be given a daily multivitamin supplement that is taken at a time when orlistat is not being ingested. Orlistat can have medically significant effects on the absorption of lipophilic medications if both drugs are taken simultaneously. Concomitant use of orlistat in a patient taking cyclosporine or warfarin requires careful monitoring of the appropriate parameters. A theoretical concern is that long-term orlistat therapy may increase the risk for specific gastrointestinal diseases, such as gallstones and colon cancer. However, an increased incidence of these diseases has not been observed in subjects who have completed 1- and 2-year clinical trials.

Drugs Approved for Short-Term Use Noradrenergic agents, such as phentermine and diethylpropion, have been shown to be better than placebo in relatively small-scale, short-term studies. No large-scale, long-term studies of the effects of these compounds on weight loss, their health benefits, or their side effects have been performed, although they have been available for more than 30 years. Therefore, if these drugs are used for longer than 3 months, the patient should be informed that such use is “off label” and has not been studied.

Over-the-Counter Products A myriad of products are available and are marketed as “nutritional supplements.” Some, like chromium picolinate, chitosan, L-carnitine, and hydroxycitric acid, have no proven efficacy to recommend their use. Others, like the combination of ephedrine and caffeine often seen in “fat-burning products,” have been shown to be effective but are not safe for unsupervised use because of the risk for tachycardia and hypertension.

Surgery for Weight Management

Obesity surgery should be considered for patients with a BMI above 40 or with a BMI between 35 and 40 if they have failed other methods of treatment and serious obesity-related complications are present. [1], [57] The overall mortality rate for bariatric surgery is approximately 1% but may be higher in individuals with comorbidities. Operative complications such as wound dehiscence, anastomotic leak, stomal stenosis, and thrombophlebitis occur in about 10% of patients. [56] Gastroplasty, also known as *stomach stapling,* involves constructing a 15- to 30-mL pouch along the lesser curvature of the stomach. A Silastic ring or band of polypropylene is used to restrict the outlet size. A modification of this procedure involves the use of an adjustable band that wraps around the proximal stomach to create a small pouch. The outlet of the pouch can be adjusted percutaneously by injecting saline solution into a reservoir, which inflates the band and restricts the size of the outlet. Patients who undergo these procedures feel full after eating very small amounts of food and may vomit if they continue to eat. In general, 70% of patients maintain a loss of 20% or more of total body weight during 5-year follow-up. Complications of laparoscopic gastric banding include stomal stenosis, staple line disruption, increased gastroesophageal reflux, band slippage, esophageal dilatation, erosion of the band into the stomach, infection, and leaks leading to band deflation.

The gastric bypass procedure, also known as *Roux-en-Y gastric bypass,* is the most commonly performed procedure. It involves constructing a small proximal gastric pouch that empties into a segment of jejunum brought up to the gastric pouch as a Roux-en-Y limb. Increasing the length of the limb from 75 to 150 cm increases weight loss but also long-term side effects and nutrient malabsorption. More weight is lost with the gastric bypass procedure than with gastroplasty. Complications of the gastric bypass procedure include stomal stenosis, marginal ulcers, staple line disruption, dilation of the bypassed stomach, internal hernias, dumping syndrome, and malabsorption of nutrients. [43] Supplemental calcium to prevent osteoporosis and a multivitamin containing vitamin B_{12} and folate are recommended daily. Iron supplementation, occasionally requiring intravenous administration because of malabsorption, may be necessary for menstruating women. Magnesium and zinc supplements are required in some individuals. Although technically challenging, laparoscopic gastric bypass surgery is now being performed. Stenosis of the gastric outlet, requiring dilation, and leaks are more common than after the open procedure, but postoperative recuperation and the incidence of abdominal hernia are reduced.

Partial biliopancreatic bypass with duodenal switch is occasionally performed in the most obese patients. This procedure allows the consumption of normal amounts of food and is more effective than the gastric bypass procedure, producing up to 75% weight loss, but it is associated with a greater number of malabsorptive and gastrointestinal side effects.

CONCLUSION

Obesity is a common chronic disorder associated with multiple gastrointestinal comorbidities. Current nonsurgical treatments for obesity produce mean losses of 5% to 10% of body weight, enough to relieve many of these comorbidities. Diet, exercise, and behavior therapy form the cornerstone of treatment for obesity. In certain individuals, the addition of pharmacotherapy or surgery is indicated if a more conservative approach has failed.

CHAPTER 37

William L. Hasler

APPROACH TO THE PATIENT WITH NAUSEA AND VOMITING

Nausea and vomiting are nonspecific symptomatic responses to a variety of conditions. *Nausea* is the subjective sensation of an impending urge to vomit, usually perceived in the throat or epigastrium. *Vomiting* is the forceful ejection of upper gut contents from the mouth. Although usually preceded by nausea, vomiting may occur without nausea. *Retching* may precede vomiting but involves no discharge of gastric contents from the mouth.

Nausea and vomiting should be distinguished from other symptoms. *Regurgitation* is the effortless return of gut contents into the mouth without nausea or somatic muscle contractions. *Rumination* (*merycism*) is regurgitation with rechewing and reswallowing of food, often multiple times after a meal. *Anorexia* is a loss of appetite, which may or may not be associated with nausea. *Early satiety* is a sensation of gastric fullness before meal completion. Nausea may be part of the general complaint of *indigestion,* which includes discomfort, heartburn, anorexia, and bloating.

SOCIOECONOMIC IMPACT

Nausea and vomiting have significant a socioeconomic impact on patients' lives. Most patients with nausea resulting from acute enteric illness restrict their activities. [1] Pregnant women with first-trimester nausea and vomiting report increased fatigue, sleep disturbances, and irritability, which impair family and social interactions. [2], [3] and [4] Nausea and vomiting after cancer chemotherapy and in the postoperative period reduce the time spent on leisure activities and recreation, household tasks, and socializing and increase the level of hardship to family members. [5], [6] and [7] Chemotherapy-evoked nausea restricts functioning more than the associated vomiting. [5] When queried, 32% of patients scheduled for general anesthesia said they would pay extra money out of pocket to avoid postoperative nausea and vomiting. [8]

Patients, employers, and the health care industry incur significant expenses as a consequence of nausea and vomiting. Acute enteric infection reportedly increased medical expenses by $1.25 billion and cost $21.8 billion in lost productivity in the United States in 1980. [9] Two British studies estimated that 8.5 million working days per year are lost because of nausea of pregnancy, and that severely affected women miss a mean of 62 hours of work while pregnant. [10], [11] Nausea and vomiting after chemotherapy decrease employee productivity and increase the health care costs of prolonged hospitalization and home nursing time. [12] Postoperative nausea and vomiting cost outpatient surgical centers a mean of $415 per patient. [13] Another British study calculated that nausea and vomiting after surgery prevent the performance of 96 to 576 surgical procedures per year per center as a consequence of increased recovery room stays and extra nursing effort. [14] In anorectal surgery, recovery room costs are lower with local anesthesia plus intravenous sedation than with general anesthesia because of a reduced incidence of postoperative nausea and vomiting. [15]

Despite the pronounced socioeconomic effects of these sometimes disabling symptoms, available evidence suggests that the impact of current therapies on health-related and monetary consequences of nausea and vomiting is inadequate. In a survey of 1413 outpatients receiving chemotherapy, the routine use of potent serotonin receptor antagonists produced a downward trend in the frequency of vomiting. [16] However, the average duration of posttreatment nausea increased significantly. A second study of 600 patients receiving chemotherapy also reported increases in nausea despite the widespread use of newer antiemetic agents, emphasizing the need for ongoing research into novel agents to treat severe nausea and vomiting. [17]

PATHOPHYSIOLOGY

Vomiting results from a coordinated interaction of neural, humoral, somatic muscular, and gastrointestinal myoelectric and muscular phenomena. What is known about the pathways mediating vomiting comes from studies involving the ablation of neural structures in experimental animals. The mechanisms that result in nausea are less well understood. Whereas vomiting may be generated in decerebrate animals, nausea requires the activation of selected cerebral cortical sites.

Activation of the Emetic Response

Vomiting may be initiated by stimuli acting on structures in the central nervous system and peripherally (Fig. 37-1). The area postrema on the dorsal surface of the medulla at the caudal aspect of the fourth ventricle is believed to represent the "chemoreceptor trigger zone" and is responsive to a broad range of neurochemical activators. [18] Other central nervous system and peripheral afferent sites mediate emesis after other stimuli.

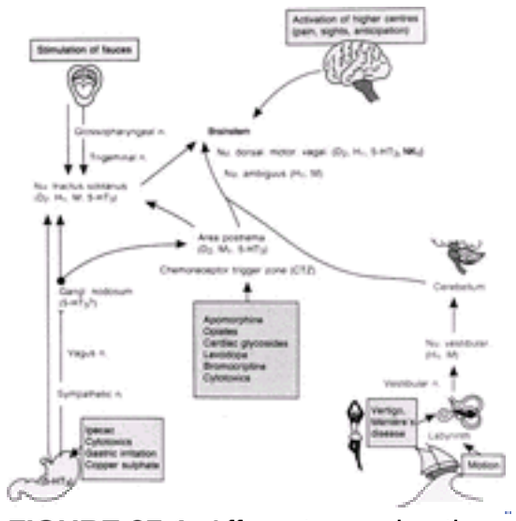

FIGURE 37-1. Afferent neural pathways and receptor populations involved in vomiting, as determined by experimental animal studies. A series of brainstem structures coordinates vomiting after activation of cortical, oral, vestibular, or peripheral afferents of the chemoreceptor trigger zone (area postrema). (Adapted from Mitchelson F. Pharmacological agents affecting emesis. A review [part I]. Drugs 1992;43:295.)

Area Postrema as a Receptor of Neurochemical Emetic Stimuli Because of its location and lack of a tight blood-brain barrier, the area postrema is an interface to receive input from the brain and peripheral nerves and to sample chemical activators in the bloodstream and cerebrospinal fluid. [19] Several observations confirm the role of the area postrema as the site of action for many stimuli. The dopamine receptor agonist apomorphine evokes vomiting when administered systemically or directly to the area postrema, whereas ablation of the structure prevents apomorphine-induced emesis. [18] Drugs (digoxin, opiates, nicotine, ergot alkaloids, some cancer chemotherapies), metabolic disorders (uremia, diabetic ketoacidosis, hypoxemia, hypercalcemia), radiation therapy, and bacterial toxins induce vomiting by area postrema activation. [20], [21] Neurotransmitters localized to the area postrema include dopamine, serotonin, norepinephrine, enkephalins, ?-aminobutyric acid, and substance P. Receptor subtypes characterized in the structure include dopamine D_2, muscarinic M_1, histaminergic H_1, serotoninergic 5-HT_3, and vasopressinergic subtypes.

Other Central Neural Activators of Emesis The central nervous system is the source of emesis in certain settings. Cerebral pathways mediate vomiting from noxious odors, visual stimulation, somatic pain, and unpleasant tastes. [21] Brainstem vestibular nuclei activate emesis in motion sickness, Ménière disease, and labyrinthine tumors or infections via area postrema–independent pathways. [22] Muscarinic M_1 and histaminergic H_1 pathways play important roles in motion sickness. [23] Motion stimuli increase hypothalamic and brainstem histamine levels, and irrigation of the ear with cold or hot water evokes hypothalamic histamine release. [23], [24] It is postulated that motion stimuli activate H [1] receptors in the brain and brainstem that directly coordinate the somatic and gastrointestinal events of emesis. [23] Anticholinergic agents binding to neural M_1 receptors may prevent motion sickness by enhancing habituation responses to motion stimuli. [23]

Peripheral Afferent Neural Activation of Emesis Gastric irritants such as copper sulfate, salicylate, *Staphylococcus* enterotoxin, and antral distention activate afferent nerves projecting from the stomach. [25], [26] and [27] Nongastric intraperitoneal stimuli that evoke emesis include distention of the colon, small intestine, and bile ducts, peritoneal inflammation, and mesenteric vascular occlusion. Stimuli also may originate from the pharynx and heart. These observations explain emesis induced by peritonitis, mesenteric ischemia, and myocardial infarction. Vomiting induced by hypertonic saline solution or intragastric copper sulfate is mediated by the activation of gastroduodenal mucosal afferent fibers, whereas vomiting with gastric distention involves the activation of smooth muscle afferent fibers. [27], [28] Emetic responses to many peripheral stimuli are mediated by vagal pathways. Vagotomy prevents emesis after intragastric copper sulfate and reduces vomiting provoked by the chemotherapeutic agent cisplatinum and by abdominal irradiation. [25], [29], [30] and [31] Splanchnic afferent pathways may modulate emesis after selected peripheral stimuli. [32] Furthermore, there is evidence of plasticity in peripheral afferent neural pathways that activate emesis. [33] In cats, the threshold for vomiting induced by a selective 5-HT_3 receptor agonist is increased by acute vagotomy plus splanchnicectomy. [33] However, if vagotomy is performed 14 to 51 days after splanchnicectomy, the thresholds for induction of emesis are reduced, indicating the recruitment of new neural pathways. Most afferent vagal fibers project to the brainstem nucleus tractus solitarius, although some fibers project to the area postrema or to the dorsal vagal motor nucleus. [34] The nucleus tractus solitarius is believed to initiate the cascade of events associated with emesis. [35] Ablation studies demonstrate that many peripheral stimuli act independently of the area postrema. [18] Serotoninergic pathways play pivotal roles in mediating the effects of many peripheral stimuli. Serotonin synthesized by enterochromaffin cells or myenteric neurons is believed to act on 5-HT_3 receptors on vagal afferent fibers and in the area postrema and nucleus tractus solitarius. [36] 5-HT_3 antagonists reduce the vomiting evoked by cisplatinum and copper sulfate, indicating the importance of 5-HT_3 receptors in mediating vomiting evoked by peripheral stimulation. [36] In some species, activation of the 5-HT_4 subtype may be more important for the emetic response to peripheral stimulation. [37]

Central Neural Coordination of the Act of Vomiting

Multiple brainstem sites mediate the act of vomiting in response to emetic stimuli from the activator sites described above. Immunohistochemical studies show increased expression of c-fos protein in the area postrema, the nucleus tractus solitarius, the dorsal vagal and phrenic nuclei, the medullary nuclei involved in control of respiration, the hypothalamus, and the amygdala after emetic stimulation. [38] The nucleus tractus solitarius receives projections from the area postrema, abdominal vagus, and labyrinths and has been postulated to serve as a common focus for initiating the vagus-dependent gastrointestinal motor and myoelectric aspects of emesis. [34], [35]

The nucleus tractus solitarius also projects to the Botzinger complex in the region of the medullary retrofacial nucleus, which regulates respiration; the nucleus ambiguus, which supplies the laryngeal and pharyngeal musculature; and the trigeminal, facial, and hypoglossal nuclei, which serve the facial and tongue muscles. [39] Neurons of the medullary reticular formation interact with the nucleus ambiguus, the dorsal motor nucleus of the vagus, and the respiratory nuclei. [40] Ablation of the reticular formation prevents emesis in dogs, confirming the importance of this structure. [41] Evidence has shown that nonrespiratory neurons in the reticular area drive respiratory premotor neurons in the ventral respiratory group. [42] During retching, firing rates in pre–Botzinger complex inspiratory neurons nearly disappear, establishing the interrelation of respiratory and nonrespiratory pathways. [43] These findings are consistent with the postulate that output from the medullary reticular formation with modulatory output from the nucleus tractus solitarius coordinates neuronal firing in each of these nuclei to regulate the somatic muscular components of emesis. [44] Once activated, these brainstem structures provide stimulation to the diaphragm via cervical spinal pathways and to the external musculature via the thoracolumbar spinal nerves. The nucleus tractus solitarius also sends ascending projections into the hypothalamus and limbic regions, suggesting activation of cerebral regions regulating the behavioral aspects of emesis. [45]

Investigations also suggest a prominent role for brainstem tachykinin NK_1 pathways in mediating emesis. The most prevalent tachykinin, substance P, induces vomiting when injected into the brainstem. [46] Peripheral administration of NK_1 antagonists block emetic responses and prevent the retching burst firing patterns in brainstem neurons in response to emetic stimulation. [47], [48], [49] and [50] Furthermore, injections of selective NK_1 receptor antagonists into the area postrema, medial solitary nucleus, and dorsal vagal complex also prevent vomiting. [51], [52] and [53] Other transmitters likely modulate the emetic response. The nucleus tractus solitarius and vagal nuclei are rich in catecholamines, enkephalins, somatostatin, vasopressin, and thyrotropin-releasing hormone. Furthermore, selective serotonin 5-HT_{1A} receptor agonists block vomiting evoked by motion sickness, nicotine, cisplatinum, and copper sulfate, suggesting a wide ranging role for 5-HT_{1A} receptors in the emetic response. [54]

Peripheral Responses to the Initiation of Vomiting

Somatic Muscular Events Associated with Vomiting Emesis results from a stereotypical series of somatic muscle actions. During retching, inspiratory thoracic, diaphragmatic, and abdominal muscles contract concurrently against a closed glottis. [55] The resulting high positive intra-abdominal pressure forces gastric contents into the esophagus and herniates the gastric cardia into the thorax. [56] A high negative intrathoracic pressure prevents expulsion of lumenal contents into the mouth, even though the upper esophageal sphincter may relax during retching. [57] In contrast to the pressures during retching, both the intra-abdominal and intrathoracic pressures are positive during vomiting because of a lack of diaphragmatic contraction in the crural region that permits transmission of the high positive abdominal pressure into the thorax. [58] Synchronous contractions of the inspiratory and expiratory muscles contribute to the reversal of intrathoracic pressure during expulsion. During emesis, the high positive intrathoracic pressure represents the force for expulsion of lumenal contents into the mouth. [56] Oral propulsion of the vomitus is

facilitated by movement of the hyoid bone and larynx up and forward. [59] Glottic closure prevents pulmonary aspiration of gut contents. Elevation of the soft palate prevents passage of the vomitus into the nasal cavities. Before emesis, the patient may hyperventilate. However, with vomiting, ventilation is suppressed except for small inspirations between expulsions. [60]

Gastrointestinal Myoelectric and Motor Events Associated with Nausea and Vomiting Gastrointestinal motility is regulated by oscillatory electrical activity, known as the *slow wave,* that controls the maximal frequency and direction of contractions. [61] In the stomach, a pacemaker in the gastric body generates slow waves at 3 cycles per minute (cpm) that propagate to the pylorus. Small intestinal slow waves originate in the proximal duodenum at 11 to 12 cpm. [62] Patients with nausea from pregnancy, gastroparesis, functional dyspepsia, or motion sickness exhibit abnormalities of gastric slow wave frequency, including accelerated (tachygastria) or decelerated (bradygastria) cycling. [63], [64], [65], [66] and [67] Gastric dysrhythmias may result from single ectopic pacemaker sites that overdrive the rest of the stomach, or from several foci with uncoupling of electrical propagation. [68] The causal relationship between gastric dysrhythmias and nausea is unproven. In some conditions, slow wave rhythm is disturbed before or simultaneously with the first report of symptoms, suggesting a possible pathogenic role. [66], [67], [69], [70] However, other stimuli that produce nausea do not disrupt the normal slow wave, indicating that dysrhythmias are not necessary to experience nausea. Motor phenomena that occur before retching include relaxation of the lower esophageal sphincter and proximal stomach, and contraction of the cricopharyngeus and cervical esophagus. [71] With vomiting, gut myoelectric and motor events are more pronounced. Before emesis, intestinal slow waves are abolished and followed by bursts of electrical spikes that propagate orally. [72] A retroperistaltic contractile complex (retrograde giant contraction) begins in the mid small intestine and propagates into the stomach, causing enterogastric reflux. [73] Investigations involving autotransplantation of intestinal segments indicates that these motor phenomena are controlled by extrinsic innervation. [74] After the retrograde giant contraction has passed, phasic intestinal contractions persist for several minutes and are followed by motor quiescence. [73] Subsequent pyloric closure, antral contraction, and lower esophageal sphincter relaxation facilitate expulsion of the intragastric contents. Retroperistaltic contractions of the cervical esophageal body and pharynx also have been described. [59], [71] Blockade of these motor events with atropine or vagotomy does not prevent emesis, indicating they are not strictly needed for vomiting to occur; rather, they enhance the evacuation of lumenal contents. [73], [75] The neuronal pathways that mediate the gut motor events associated with emesis are incompletely characterized. The ability of atropine to block retrograde contractions indicates a role for vagal cholinergic innervation. [73] Centrally, a role for NK_1 receptor mediation was suggested by a study in rats in which injection of substance P into the dorsal vagal motor nucleus produced gastric relaxation that was attenuated by vagotomy or by pretreatment with an NK_1 receptor antagonist. [76]

Endocrine and Autonomic Responses to the Initiation of Nausea and Vomiting Levels of circulating hormones and neurotransmitters are altered with nausea and vomiting. Vasopressin levels increase during motion sickness and electrical vagal stimulation and after apomorphine and cisplatinum administration. [77], [78] and [79] Intravenous vasopressin at supraphysiological doses evokes nausea in humans, suggesting the hormone may contribute to symptom production, whereas in monkeys, vasopressin V_1 antagonists prevent motion-induced emesis. [80], [81] However, the ability of apomorphine to produce vomiting in patients with central diabetes insipidus suggests that vasopressin is not critical for the induction of emesis. [82] Levels of other transmitters, such as epinephrine, ß-endorphin, growth hormone, cortisol, adrenocorticotropic hormone, and prolactin, change during nausea and vomiting; however, their pathogenic importance is uncertain. [83] Autonomic neural disturbances result from the proximity of brainstem nuclei mediating vomiting to those controlling respiratory, vasomotor, cardiac, and salivary activity. With nausea, pallor, diaphoresis, hypersalivation, defecation, tachycardia, or hypotension may be noted. Elevated parasympathetic vagal activity, as measured by increased beat-to-beat heart rate variability, has been observed in women with ovarian cancer experiencing nausea after chemotherapy. [84] Bradycardia and blood pressure variation may occur with retching or vomiting.

Investigation of the Pathophysiology of Nausea

Because of a lack of a suitable animal model, the neural structures that mediate the sensation of nausea are poorly understood. It has been postulated that nausea results from lesser activation of the same pathways that produce emesis. Some investigators consider measurable changes in autonomic function or hormone release to correlate with the experience of nausea in animal models. [85] However, most of these phenomena persist in decerebrate animals incapable of perceiving gastrointestinal sensations. Food avoidance has been proposed as a measure of nausea, but the validity of this model is unconfirmed. [86] Several investigations provide insight into cerebral cortical regions stimulated during nausea in human models. Activation of the inferior frontal gyrus in proportion to the degree of nausea has been demonstrated by magnetic source imaging in healthy human volunteers exposed to vestibular stimulation or apomorphine. [87] This finding is consistent with observations of electroencephalographic changes in temporofrontal regions during motion sickness. [88]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of nausea and vomiting is extensive and includes a broad range of pathological and physiological conditions affecting the gut, peritoneal cavity, central nervous system, and endocrine and metabolic functions (Table 37-1).

TABLE 37-1 Differential Diagnosis of Nausea and Vomiting

Medications

Drug reactions are among the most common causes of nausea and vomiting and usually present soon after the initiation of therapy. Emetogenic drugs may exert their effects by actions on distinct anatomic sites within the central and peripheral nervous systems. Medications that act on the area postrema include antiparkinsonian agents (e.g., L-dopa, bromocriptine), nicotine, digoxin, and opiate analgesics. [20] Nonsteroidal antiinflammatory drugs and erythromycin activate peripheral afferent pathways, most likely vagal. [89] Other medications that cause nausea and vomiting include cardiac antiarrhythmics, antihypertensives, diuretics, oral antidiabetics, oral contraceptives, and gastrointestinal medications such as sulfasalazine.

The most extensively studied medications that evoke emesis are the cancer chemotherapeutic agents. Risk factors for chemotherapy-induced nausea include a low level of social functioning, prechemotherapy nausea, female sex, and the administration of highly emetogenic chemotherapy. [90] Emesis from chemotherapy may be acute, delayed, or anticipatory. Potent agents that induce acute vomiting within hours of administration include cisplatinum, nitrogen mustard, and dacarbazine, all of which increase plasma serotonin levels or the urinary excretion of 5-hydroxyindoleacetic acid (5-HIAA), a serotonin metabolite. [91], [92] In contrast, less emetogenic agents, such as cyclophosphamide, evoke little rise in plasma serotonin or urinary 5-HIAA. [91] Cisplatinum raises ileal tissue serotonin levels and increases the number of serotonin-immunoreactive cells in animal models. [92] Cisplatinum-evoked emesis is reduced by vagotomy, suggesting mediation by peripheral afferent pathways. [30] However, the inability of the peripherally active 5-HT_3 receptor antagonist zatosetron-QUAT to block cisplatinum-induced emesis when given intravenously, coupled with a significant antiemetic effect when administered within the intracerebral ventricles, indicates a central neural component to vomiting evoked by cisplatinum. [93]

In contrast to acute chemotherapy-evoked emesis, delayed and anticipatory vomiting are mediated by serotonin-independent pathways. Delayed emesis after

cisplatinum is not associated with urinary 5-HIAA excretion and is poorly controlled by 5-HT $_3$ receptor antagonist treatment. [91], [94] In dogs, 5-HT $_4$ receptors may mediate the delayed phase of chemotherapy-induced emesis. [95] In another study, increased norepinephrine production was noted during the delayed phase after cisplatinum, suggesting the participation of other neuroendocrine mediators. [96] Anticipatory nausea and vomiting occur in 25% of patients by the fourth course of cancer chemotherapy, more often in younger patients. [97] The development of anticipatory symptoms is dependent on anxiety and coping mechanisms. [97], [98] Patient expectations strongly predict the onset of anticipatory nausea but not anticipatory vomiting. [99] Anticipatory emesis is poorly controlled by antiemetic medications and is best managed by relaxation therapy, systematic desensitization techniques, and anxiolytic medications such as benzodiazepines.

Infectious and Toxic Causes

Infectious illness produces nausea and vomiting, usually of acute onset. Acute enteric illness occurs most often in children younger than 3 years of age but exhibits a second peak incidence in the third decade of life. [1] It occurs at a rate of 1.2 infections per person per year, commonly in the autumn and winter. Viral gastroenteritis may be caused by rotaviruses, reoviruses, adenoviruses, and the Hawaii, Snow Mountain, and Norwalk agents. [100], [101], [102], [103] and [104] Bacterial infection with *Staphylococcus aureus, Salmonella, Bacillus cereus,* and *Clostridium perfringens* also produces nausea and vomiting, in many cases via toxins that act on the area postrema. [105], [106] and [107] The enterotoxin elaborated by *S aureus* has been characterized and is distinct from enterotoxins A through E and the toxic shock syndrome toxin 1. [108] Nausea in immunocompromised patients may result from gastrointestinal infection with cytomegalovirus or herpes simplex virus. [109], [110] Nongastrointestinal infections that produce nausea include otitis media, meningitis, and hepatitis.

Disorders of the Gut and Peritoneal Cavity

Gut and peritoneal disorders represent prevalent causes of nausea and vomiting. Gastric or small intestinal obstruction produces prominent nausea that may be relieved by vomiting. Gastric obstruction often is intermittent, whereas small intestinal obstruction usually is acute and associated with abdominal pain. Superior mesenteric artery syndrome is a rare condition in which the duodenum is compressed by the overlying superior mesenteric artery as it arises from the aorta, causing anatomic obstruction. [111] This syndrome is seen in patients who have had profound weight loss, recent surgery, or prolonged bed rest. Other rare mechanical causes of nausea and vomiting include subacute gastric volvulus and antral webs. [112], [113]

Motility disorders such as gastroparesis and chronic intestinal pseudoobstruction produce nausea secondary to an inability to clear retained food. Gastroparesis is caused by systemic diseases including diabetes mellitus, scleroderma, systemic lupus erythematosus, polymyositis-dermatomyositis, and amyloidosis. [114], [115] Diabetic gastroparesis commonly results from long-standing poor glycemic control but is not necessarily associated with a poor prognosis. [116], [117] Animal models suggest that gastric stasis occurring secondary to diabetes may be a consequence of loss or damage to the interstitial cells of Cajal, which regulate the pacemaker activity of the stomach. [118] Delayed gastric emptying of solids is demonstrable in two thirds of scleroderma patients with abnormal esophageal motility. [119] Gastroparesis develops in fewer than 5% of patients who undergo vagotomy and gastric drainage. [120] In patients with the acquired immunodeficiency syndrome, human immunodeficiency virus infection may contribute to delays in gastric emptying. [121] Pancreatic adenocarcinoma produces gastroparesis by unknown mechanisms. [122] Gastric ischemia is a rare cause of gastroparesis, especially in women. The median arcuate ligament syndrome produces gastroparesis by compression of the celiac axis. [123] Chronic intestinal pseudoobstruction may be hereditary or result from systemic diseases similar to those that produce gastroparesis. Paraneoplastic intestinal pseudoobstruction is reported with some malignancies, most commonly small cell carcinoma of the lung. [124]

Nearly one third of patients with gastroparesis exhibit no underlying systemic disease to explain their symptoms. Some cases of idiopathic gastroparesis are preceded by prodromal symptoms such as diarrhea, fever, headache, or myalgias, consistent with a viral etiology. The agent responsible is rarely identified; however, one report in children detected rotavirus in 8 of 11 cases. [125] In general, postviral gastroparesis confers a better prognosis than nonviral idiopathic disease, with a shorter duration of illness, less severe symptoms, and a better quality of life. [125], [126] Women with idiopathic gastroparesis often report prior physical or sexual abuse, similar to observations in patients with irritable bowel syndrome. [127] Many patients with gastroparesis exhibit disruption of slow wave rhythmicity, suggesting that pacemaker abnormalities may induce some of the motor findings and symptoms in these individuals. [65]

Nausea and vomiting may be prominent in patients with functional (nonulcer) dyspepsia, especially of the dysmotility subtype. Although many patients with functional dyspepsia exhibit abnormalities of gastric motor or myoelectric function, these abnormalities correlate poorly with symptoms and may not be pathogenic in such cases. [128] Nausea also may be a consequence of gastroesophageal reflux; however, many affected individuals also exhibit delayed gastric emptying, providing another cause for their symptoms. [129]

Abdominal disorders not involving the gut lumen may produce nausea and vomiting. Inflammatory conditions such as pancreatitis, appendicitis, and cholecystitis activate afferent pathways from the peritoneum. Biliary colic in the absence of inflammation produces nausea by activating afferents through distention of the biliary tree. Fulminant hepatic failure results in nausea, presumably because of the retention of unknown emetic toxins and increased intracranial pressure.

Central Nervous System Causes

Many emetic stimuli produce symptoms by action on the cerebrum or brainstem. Increased intracranial pressure from malignancy, infarction, hemorrhage, infection, or congenital causes may produce emesis with or without associated nausea. Studies in canine models demonstrate maximal induction of emesis at an intracranial pressure of 80 mm Hg. [130] Emotional responses to unpleasant smells, tastes, or memories may induce vomiting. Psychogenic vomiting most commonly presents in young women, often with a history of psychiatric illness or social difficulties. [131] Other psychiatric conditions associated with nausea include anxiety disorders, depression, anorexia nervosa, and bulimia nervosa.

Labyrinthine disorders such as labyrinthitis, tumors, and Ménière disease produce nausea and vomiting, often with vertigo. Motion sickness is evoked by repetitive movements that activate the vestibular nuclei and is associated with extensive autonomic activation that produces pallor, diaphoresis, and salivation. [132] Space sickness, experienced by most astronauts in zero gravity, is related to motion sickness but may not exhibit the associated autonomic phenomena. [133]

Endocrine and Metabolic Causes

Endocrine and metabolic causes of nausea include uremia, diabetic ketoacidosis, hyper- and hypoparathyroidism, hyperthyroidism, and Addison disease. It has been postulated that uremia, diabetic ketoacidosis, and hypercalcemia activate the area postrema; however, thyroid and parathyroid disease also disrupt normal gastrointestinal motor activity. [20]

First-trimester pregnancy is the most common endocrine cause of emesis, occurring in 50% to 70% of pregnant women. On average, symptoms begin 39 days after the last menses, peak in the ninth gestational week, and last 35 to 45 days. [11], [134] Although nausea of pregnancy is commonly referred to as *morning sickness,* only 1.8% of women report symptoms restricted to the morning, whereas 80% experience symptoms lasting all day. [134] Nausea of pregnancy is more common in women who are primigravidas, younger, less educated, housewives, and overweight. [135] The positive relationship between nausea of pregnancy and preconception body mass is postulated to serve a beneficial role by suppressing maternal tissue synthesis and partitioning nutrients in favor of the fetus. [136] In general, first-trimester nausea is not deleterious to either the fetus or mother. Rather, it has been associated with reduced incidences of miscarriage, congenital heart defects, and fetal demise. [137], [138] However, in less developed regions where malnutrition is prevalent, nausea and vomiting may have nutritional consequences in the later stages of pregnancy that increase the risk for poor pregnancy outcomes. [139] Furthermore, women with more severe or prolonged symptoms may deliver infants with reduced birth weights. [140] Hyperemesis gravidarum, a condition of intractable vomiting complicating 1% to 5% of pregnancies, may produce dangerous fluid and electrolyte abnormalities. The cause of nausea of pregnancy is unknown but is believed to be hormonally related. Although symptoms parallel levels of ß-human chorionic gonadotropin, no clear pathogenic role has been discerned for this hormone. [141] Intolerance of oral contraceptives is strongly associated with nausea of pregnancy, suggesting potential roles for estrogen and progesterone. [142] One recent investigation has reported an association between elevated maternal serum prostaglandin E $_2$ levels and nausea of pregnancy. [143] Acute fatty liver of pregnancy, a condition distinct from first-trimester nausea, produces severe third-trimester vomiting and can be complicated by liver failure, disseminated intravascular coagulation, and fetal or maternal death. [144]

Radiation-Induced Vomiting

Radiation therapy for malignancy produces emesis by effects on both the structure and function of the gut. The incidence of nausea and vomiting is dependent on the region that is irradiated, being as high as 80% when the upper abdomen is included in the radiation field. [145] Involvement of serotoninergic pathways is indicated by the ability of 5-HT $_3$ receptor antagonists to reduce nausea and vomiting evoked acutely by abdominal radiation therapy.

Postoperative Nausea and Vomiting

Nausea and vomiting complicate 17% to 37% of surgical operations, more commonly in women. [146], [147] Postoperative nausea and vomiting occur more frequently after general anesthesia than with regional nerve blocks and correlate with the duration of surgery. The condition occurs more often after abdominal and orthopedic surgery than with laparoscopic or other extra-abdominal operations and is exacerbated by concurrent use of opiate agents.

Cyclic Vomiting

Cyclic vomiting syndrome is characterized by discrete episodes of intractable emesis with intervening asymptomatic periods. The mean age at onset is 5 years, and the condition affects both sexes equally. Affected children typically have eight or nine attacks per year with a mean duration of 1 to 3 days. [148], [149] Two thirds of children miss more than 10 days of school per year. [149] There are strong associations of cyclic vomiting with migraine headaches, motion sickness, gastroesophageal reflux, psychological symptoms, atopy, and prior forceps delivery. [149] Attacks may be precipitated by stress or infections. Cyclic vomiting syndrome also has been observed in adults, who infrequently report the onset of symptoms during menstrual periods or pregnancy or after ingesting a large meal. [150]

The etiology of cyclic vomiting is unknown and is likely multifactorial. Affected children are at increased risk for the development of migraine headaches as they enter adolescence, and there often is a strong family history of migraines. [151], [152] Children with migraine-associated cyclic vomiting syndrome report milder emetic episodes, more abdominal pain, more headache with photophobia, and increased psychological stress. [152] Other proposed causes of cyclic vomiting syndrome in subsets of patients include food allergy and mitochondrial fatty acid oxidation disorders, such as short- and medium-chain acyl-CoA dehydrogenase deficiency and late-onset glutaric acidemia type II. [153], [154]

Miscellaneous Conditions

Posterior myocardial infarction produces nausea via diaphragmatic irritation. Nausea may occur in congestive heart failure from passive congestion of the liver and gut. Excess ethanol intake induces vomiting by local action on the gut and by action on the brainstem. Acute graft versus host disease is the dominant cause of nausea and vomiting in bone marrow transplant recipients, most commonly occurring within the initial months after the transplant. [110] Jamaican vomiting sickness occurs after the ingestion of unripe akee fruit. [155] Excess vitamin intake as well as extended fasting or starvation also may cause nausea.

HISTORY AND PHYSICAL EXAMINATION

Historical Features

A detailed history provides useful diagnostic information about the cause of unexplained nausea and emesis. Acute vomiting (1–2 days) most often results from infection, a medication or toxin, or the accumulation of endogenous toxins, as in uremia or diabetic ketoacidosis. Chronic vomiting (>1 week) usually results from long-standing medical or psychiatric conditions.

Timing of Nausea and Vomiting The timing of symptoms provides clues to the underlying disease. Vomiting soon after a meal occurs with gastric obstruction from ulcer disease or malignancy. Psychogenic vomiting also occurs soon after eating, but most patients control the act of emesis until a convenient receptacle is available. Patients with gastroparesis may report nausea within 5 minutes after eating; however, most have symptoms more than 1 hour after a meal. Nausea and vomiting from inflammatory conditions such as cholecystitis and pancreatitis may present in the first postprandial hour. In some cases of esophagitis or ulcer disease, nausea may abate with eating. Vomiting early in the morning may be reported in first-trimester pregnancy, uremia, and chronic alcoholism.
Character of the Vomitus The characteristics of the vomitus can assist in the diagnosis. The return of undigested food suggests achalasia or a Zenker diverticulum. Vomiting of partly digested food hours or days after ingestion suggests gastric obstruction or gastroparesis. Bile in the vomitus excludes obstruction proximal to the ampulla of Vater, whereas blood or coffee-ground material suggests a process with mucosal damage, such as an ulcer or malignancy. However, retching and vomiting can induce hematemesis from Mallory-Weiss tears across the gastroesophageal junction. Voluminous clear acidic vomitus suggests gastric hypersecretion from Zollinger-Ellison syndrome. Feculent emesis occurs in distal intestinal or colonic obstruction, intestinal bacterial overgrowth, and gastrocolic fistulae. Odorless emesis may be noted with gastric achlorhydria.
Symptoms Associated with Nausea and Vomiting Abdominal pain is noted with ulcer disease, intestinal obstruction, and inflammatory disorders such as cholecystitis and pancreatitis. Vomiting may relieve nausea and pain in ulcer disease and intestinal obstruction but has no effect in inflammatory conditions. Diarrhea, fever, or myalgias are suggestive of enteric infection. Weight loss and malnutrition occur with chronic illness, but psychogenic vomiting rarely produces weight loss. Central nervous system lesions or meningitis are suggested by headaches, visual changes, altered mentation, and neck stiffness. In these disorders, emesis may be effortless, there may be no nausea, or emesis may be projectile. Labyrinthine diseases present with tinnitus or vertigo. Chest pain, dysphagia, or jaundice suggests pregnancy or cardiac disease, esophageal disease, or hepatobiliary disease, respectively. Associated symptoms also indicate the severity of the underlying condition and help to direct treatment. Prolonged vomiting may produce significant fluid and electrolyte loss that may be manifested as postural lightheadedness, rapid heart rate, and mouth dryness.
Complications of Nausea and Vomiting Gastrointestinal hemorrhage may result from retching-induced mucosal tears across the gastroesophageal junction, known as *Mallory-Weiss tears*. A more severe complication, Boerhaave syndrome, occurs when retching or vomiting produces complete esophageal rupture with subsequent mediastinitis or peritonitis. In patients with impaired consciousness, emesis may be complicated by pulmonary aspiration of acidic material leading to severe chemical pneumonitis.

Physical Examination Findings

The physical examination assists in the diagnosis and management of nausea and vomiting. Fever suggests infection or inflammation. Tachycardia or orthostatic hypotension indicates dehydration, which is supported by finding a loss of skin turgor or dry mucous membranes. Skin examination may show sclerodactyly in scleroderma or jaundice in hepatobiliary disease. Oral examination may reveal loss of dental enamel, common in bulimia. Adenopathy raises the possibility of a neoplasm. Hepatomegaly also is found in malignancy as well as in benign hepatic disease. An absence of bowel sounds signifies ileus, whereas high-pitched hyperactive bowel sounds with a distended abdomen are consistent with intestinal obstruction. A succession splash on side-to-side movement is found in gastric obstruction or gastroparesis. If abdominal tenderness or guarding is found, an inflammatory or infectious process such as an ulcer, cholecystitis, pancreatitis, or peritonitis is considered. Gross or occult fecal blood on rectal examination should prompt evaluation for an ulcer or neoplasm. On neurological examination, focal signs, papilledema, and impaired mentation suggest a central nervous system process, whereas nuchal rigidity is consistent with meningitis. Asterixis is present in metabolic diseases such as uremia and hepatic failure. Patients with gut motility disturbances may exhibit peripheral or autonomic neuropathy.

LABORATORY STUDIES AND DIAGNOSTIC TESTING

A thorough history and examination provide the information necessary to diagnose and treat most patients with nausea and vomiting. However, some patients require blood studies, structural evaluations, or assessment of gut function for diagnosis and management.

Laboratory Testing

Laboratory tests are ordered based on the findings of the history and physical examination. With long-standing symptoms or dehydration, the serum electrolytes can show hypokalemia or an elevated blood urea nitrogen relative to the creatinine level. Metabolic alkalosis may result from a loss of hydrogen ions in the acidic vomitus and contraction of the extracellular space from dehydration. A complete blood cell count can rule out anemia from inflammation or blood loss, leukocytosis from an inflammatory source, or leukopenia from a viral infection. Chronic blood loss also may be suggested by low serum levels of iron and iron saturation of transferrin.

Hypoalbuminemia is seen in some chronic diseases and in conditions with gut protein loss. Amylase, lipase, and liver chemistries are obtained for suspected pancreatic or hepatobiliary disease. Endocrine and metabolic causes can be assessed through serum pregnancy testing, thyroid function testing, and measuring the levels of blood urea nitrogen, creatinine, glucose, ketones, calcium, and plasma cortisol. Specific serologic markers can be obtained for presumed collagen-vascular diseases such as lupus, whereas results of tests for antineuronal nuclear antibodies are positive with paraneoplastic intestinal pseudoobstruction (usually from small cell lung carcinoma). [124] Meningitis is confirmed by lumbar puncture.

Structural Evaluation

Structural investigation may be needed to exclude organic disease as a cause of emesis. Flat and upright abdominal radiographs are obtained as a screening examination. Small intestinal air-fluid levels with an absence of colonic air suggests intestinal obstruction, whereas diffuse lumenal distention with absent bowel sounds is consistent with ileus or chronic pseudo-obstruction. Subdiaphragmatic free air indicates visceral perforation. Suspected small intestinal obstruction may be further evaluated, documented, and characterized by dedicated small intestinal contrast radiography. Water contrast agents such as Gastrografin provide reasonable degrees of accuracy in the exclusion of obstructions that require operative intervention. [156] However, barium provides superior anatomic characterization of partial obstruction. If symptoms are intermittent and the index of suspicion for intermittent obstruction is high, enteroclysis may provide a more detailed assessment of small intestinal lumenal processes. [157] With this technique, the proximal intestine is intubated under fluoroscopic guidance and barium and methylcellulose are perfused to provide a double contrast image. If colonic obstruction is a consideration, colonoscopy or barium enema radiography should be performed before small intestinal contrast studies. Upper gastrointestinal endoscopy or contrast radiography may be performed in cases of suspected ulcer disease or outlet narrowing. Endoscopy affords the advantage of providing biopsy capability of abnormal mucosa. Endoscopy also may suggest gastroparesis, demonstrating retained food in the absence of outlet obstruction. For suspected pancreaticobiliary disease, ultrasonography or computed tomography (CT) may be useful. Biliary scintigraphy may provide findings suggesting acute cholecystitis. CT or magnetic resonance imaging (MRI) of the head is indicated if the presentation suggests a central nervous system cause. If bowel ischemia is a consideration, mesenteric angiography or MRI of the mesenteric flow may be diagnostic.

Studies of Gastrointestinal Motor and Myoelectric Activity

When lumenal obstruction has been excluded, functional causes of nausea such as gastroparesis and pseudoobstruction are entertained. The clinician may elect to treat empirically with a medication designed to stimulate gut motility. Alternatively, testing of gut motor and myoelectric activity can be performed to characterize the functional defects.

Quantification of Gastric Emptying Gastroparesis is diagnosed by demonstrating delayed gastric emptying of an ingested meal. Scintigraphic measures of the emptying rates of liquid (e.g., ^{111}In-DTPA [diethylenetriamine pentaacetic acid] in water) or solid (e.g., ^{99m}Tc-sulfur colloid in eggs) radionuclides are the most commonly employed tests of gastric emptying (Fig. 37-2). [158] Under normal conditions, liquids empty with a half-time of between 8 and 28 minutes. Emptying of solids exhibits an initial lag phase, in which little label is passed into the intestine, followed by a linear emptying phase with evacuation of 40% to 80% of the tracer from the stomach at 2 hours. Some clinicians have proposed extending scintigraphic testing to include the 4 hours after eating to enhance the diagnostic accuracy of the test. [159] Solid phase emptying is affected earlier and to a greater extent than liquid emptying in gastroparesis; thus, solid phase scans are more sensitive for diagnosis.

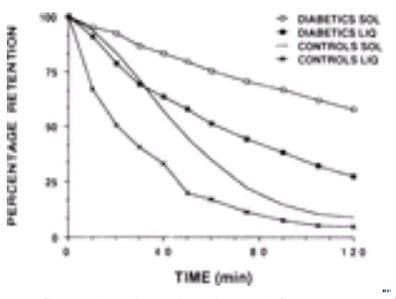

FIGURE 37-2. Gastric-emptying profiles of solids and liquids in diabetics with gastroparesis are delayed in comparison with those of healthy volunteers. (From Urbain JL, Vantrappen G, Janssens J, et al. Intravenous erythromycin dramatically accelerates gastric emptying in gastroparesis diabeticorum and normals and abolishes the emptying discrimination between solids and liquids. J Nucl Med 1990;31:1490.)

Other means of quantifying gastric emptying are under investigation. Investigations measuring gastric dimensions with ultrasound have reported highly reproducible results and demonstrable abnormalities in patients with known gastroparesis. [160], [161] However, ultrasound is less reliable for assessing the emptying of solid meals, so that the test is less useful in patients with mild gastroparesis. MRI can assess emptying of both liquid and solid phases of a meal; however, its cost precludes its widespread use at this time. [162], [163] and [164] Single photon emission computed tomography (SPECT) has been used to measure volumes in the proximal and distal stomach after eating. [165] In addition to determining emptying, this technique offers the potential to assess defects in gastric fundic relaxation. A promising new technology to quantify gastric emptying is ^{13}C breath testing, which involves ingestion of a nonradioactive ligand bound to a digestible nutrient and offers the potential for use in populations in whom scintigraphy is relatively contraindicated (e.g., children and pregnant women). With this technique, ^{13}C-octanoate, ^{13}C-acetate, or ^{13}C-*Spirulina platensis* ingested with a solid meal is delivered into the upper intestine at a rate dependent on the rate of gastric emptying. [166], [167] Digestion and absorption of the ingested compound liberate ^{13}C-carbon dioxide, which diffuses across the intestinal mucosa and is expired in the breath. Results of breath testing correlate reasonably well with those of gastric scintigraphy, although falsely abnormal results are possible in malabsorptive or pulmonary disease. [167], [168] and [169] Some studies suggest that optimal measurements of emptying rates by breath testing may require 6 to 8 hours, thus impairing the clinical utility of the technique. [166], [169]
Gastrointestinal Manometry When scintigraphy provides an incomplete diagnosis of the cause of nausea, gastrointestinal manometry can be performed. Because of the discomfort involved and the personnel required, this test is performed only in specialized centers. Under fasting conditions, the stomach and small intestine exhibit a pattern known as the migrating motor complex (MMC), which consists of three phases that are repeated every 90 to 120 minutes. [170] The most propulsive phase, phase III, clears undigested debris from the upper gut. Absence of gastric phase III, found in some cases of gastroparesis, predisposes to bezoar formation. Loss of intestinal phase III may lead to bacterial overgrowth. The postprandial period exhibits irregular, continuous contractions. [171] The absence of this fed pattern in the stomach correlates with delayed solid phase gastric emptying. [172] In addition to defining gastric dysmotility, manometry can characterize small intestinal disturbances (Table 37-2). In intestinal pseudoobstruction, barium radiography may show intestinal dilatation and delayed transit. Small intestinal manometry provides more specific information regarding the neuropathic or myopathic nature of the condition. Pseudo-obstruction resulting from enteric nerve dysfunction, as in the familial visceral neuropathies or early scleroderma, produces intense, uncoordinated bursts of motor activity with loss of normal MMC and fed motor activity. [173] Smooth muscle dysfunction, as in the familial visceral myopathies or late scleroderma, produces very low amplitude contractions. [174] Intermittent bursts of phasic contractions separated by periods of motor quiescence, a pattern known as the *minute rhythm,* have been observed in patients with small intestinal obstruction, although similar patterns are seen in neuropathic pseudoobstruction and irritable bowel syndrome. [175] Finally, the demonstration of brief, simultaneous pressure increases in all recording sites is diagnostic of rumination syndrome and eliminates the need for further investigation. [176]

MANOMETRIC FINDING	CHARACTERISTICS	DISEASES
Intestinal bursts	Irregular phasic contractions of normal amplitude; failure to develop normal fasting or fed patterns	Visceral neuropathies Scleroderma (early) Amyloidosis (early) Paraneoplastic pseudoobstruction Chagas disease Brainstem lesion Neurofibromatosis
Intestinal hypomotility	Reduced-amplitude phasic contractions	Visceral myopathies Scleroderma (late) Amyloidosis (late) Polymyositis-myositis Muscular dystrophy Myotonic dystrophy
Minute rhythm	Intermittent phasic bursts separated by periods of motor quiescence	Mechanical obstruction Neuropathic pseudoobstruction
Simultaneous contractions	High-amplitude contractions seen simultaneously in all gastric and small intestinal channels	Rumination syndrome

TABLE 37-2 Manometric Findings in Small Intestinal Dysmotility Syndromes

There are limitations to gastrointestinal manometry. Abnormal motor patterns are observed occasionally in healthy individuals. A small number of normal people do not exhibit MMC activity during a 4- to 6-hour fasting recording period, or because of technical reasons, they do not exhibit a fed motor pattern. [177] Consequently, some investigators recommend monitoring intestinal motility for 24 hours in ambulatory fashion to compensate for physiological variability in MMC periodicity. [178] When the diagnosis of neuropathic or myopathic pseudo-obstruction is entertained, a full-thickness intestinal biopsy specimen obtained surgically may be required to document degeneration of nerve or muscle layers. Nevertheless, in selected clinical settings, manometry provides important information. Proposed indications for manometric testing include evaluation of unexplained nausea and vomiting, characterization of the neuropathic or myopathic nature of a dysmotility syndrome, and demonstration of whether dysmotility in a patient with constipation or gastroesophageal reflux is generalized. [179] Additionally, in children, the absence of phase III activity predicts the inability to tolerate enteral nutrition and suggests consideration of parenteral feedings. [180] Finally, and perhaps most importantly, the documentation of normal motility is inconsistent with intestinal pseudoobstruction and suggests that the diagnostic evaluation should be redirected to other etiologies. [181]

Electrogastrography Gastric myoelectric disturbances are diagnosed in referral centers by electrogastrography (EGG), a technique by which slow waves are measured with cutaneous electrodes overlying the stomach. Gastric electrical rhythms are recorded for 1 to 2 hours under fasting and fed conditions, during which unwanted signals from the heart, diaphragm, and intestines are filtered out. Recordings in healthy individuals exhibit a uniform 3-cpm rhythm that increases in amplitude after eating. In nauseated patients, symptoms may relate to abnormally rapid (tachygastria) or slow (bradygastria) EGG rhythms or to an absence of the postprandial signal increase (Fig. 37-3). Some investigators correlate the absence of the fed amplitude increase with delayed gastric emptying of solids. [182] However, other studies suggest that EGG and gastric scintigraphy define different patient populations and are complementary in evaluating the patient with unexplained nausea. [183] One group has observed that nauseated diabetics with EGG abnormalities experience more severe symptoms than those with normal EGG patterns, suggesting that dysrhythmic activity may be a marker of more advanced functional impairment of the stomach. [184] The performance of EGG is associated with pitfalls, including movement artifacts and noise, which can interfere with accurate interpretation. [185] Proposed indications for EGG include evaluation of unexplained nausea and vomiting, noninvasive testing to predict gastroparesis, and exclusion of generalized gastrointestinal dysfunction in patients with constipation or gastroesophageal reflux. [179] EGG has been shown to be of value in predicting the development of postoperative retching and nausea in children undergoing fundoplication for gastroesophageal reflux. [186]

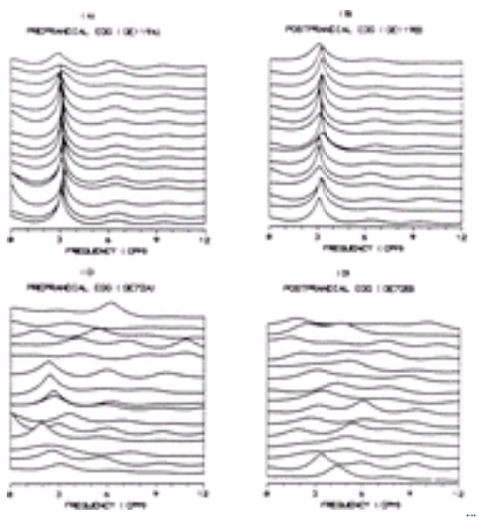

FIGURE 37-3. Frequency spectra of electrogastrographic recordings from an individual with normal gastric emptying and a patient with delayed gastric emptying. Under fasting conditions, the rhythm is regular at 3 cycles per minute (cpm) in the individual with normal emptying (**A**), whereas the patient with delayed emptying exhibits dysrhythmic activity with no dominant frequency (**C**). After eating, the person with normal emptying continues to show 3-cpm activity with increased signal amplitude (**B**), whereas the patient with delayed emptying shows a chaotic slow wave rhythm (**D**). (From Chen JD, Lin Z, Pan J, McCallum RW. Abnormal gastric myoelectrical activity and delayed gastric emptying in patients with symptoms suggestive of gastroparesis. Dig Dis Sci 1996;41:1538).

Approach to Functional Testing of Gastrointestinal Motor and Myoelectric Activity There currently is a lack of consensus regarding the clinical utility of measurements of gastric emptying, gastroduodenal manometry, and EGG in the investigation of nausea and vomiting because of a dearth of well-controlled outcome investigations. In the only large retrospective evaluation of the clinical applicability of gastric-emptying measurement, gastric scintigraphy was found not to influence clinical decision making or alter treatment options. [187] However, the investigation included many patients who were referred for symptoms other than nausea and vomiting, such as postoperative dumping syndrome. Diagnostic findings of intestinal manometry altered treatment recommendations in approximately 20% of patients in one study; however, many individuals were referred for evaluation of lower gastrointestinal symptoms. [188] In a more recent investigation, a diagnosis obtained on gastroduodenal manometry led to new therapy in 13% of cases, a new diagnosis in 15%, and referral to another specialist in 8%. [189] A positive clinical impact was observed in only 29% of patients. To date, there are no publications reporting an impact of EGG on adult patient outcome. Therefore, performance of functional testing in the majority of patients with unexplained nausea and vomiting is based on the ordering practices of each individual physician and on the “need to know” a specific diagnosis. Better-defined guidelines for the rational use of these studies await carefully controlled investigation.

PRINCIPLES OF MANAGEMENT

The care of the patient with nausea and vomiting involves assessment of the etiology and the severity of the condition, with prompt initiation of therapy to prevent complications.

Indications for Hospitalization

The first decision in managing the patient with vomiting is to determine if intravenous resuscitation is needed. Poor skin turgor or orthostatic pulse or blood pressure changes indicate that more than 10% of body fluids have been lost, mandating intravenous infusion of saline solution (0.45% or 0.9%). Potassium supplements may be started for hypokalemia if urine output is adequate. Intravenous fluids can be given in the emergency department or outpatient clinic if the patient is expected to resume adequate oral intake at home. If the prospects for oral replenishment are uncertain, hospitalization should be considered. Patients with mechanical obstruction or ileus may benefit from nasogastric suction. The threshold for hospitalization is lowered for diabetics, patients with concurrent diarrhea, persons with other chronic debilitating disease, and the very young or old, as these patients become rapidly dehydrated.

Dietary and Nonmedicinal Considerations

If the patient can return home, dietary advice should be given. Because liquids empty more rapidly from the stomach than solids, a predominantly liquid diet is recommended. [158] Frequent small meals are prescribed because large volumes may worsen symptoms. Lipids are potent inhibitors of gastric emptying, so that foods

rich in fats should be avoided. [190] Studies suggest that diets preferentially high in protein content may benefit patients with nausea of pregnancy and motion sickness. [191] In patients with gastroparesis, reducing indigestible dietary fiber is recommended to prevent organization of the residue into a bezoar. [192] Finally, medications that inhibit motor function should be discontinued if possible.

Aggressive control of blood glucose is advocated for nauseated patients with long-standing diabetes mellitus. Although the Diabetes Control and Complications Trial documented the beneficial effects of tight glycemic control on objective parameters of peripheral nerve function, the utility of intensive insulin therapy in reducing symptomatic manifestations of gastroparesis in diabetic patients is unknown. [193] Nonetheless, because acute hyperglycemia has profound disruptive effects on gastric motor and myoelectric activity, it is reasonable to strive for near-euglycemic plasma levels. [194]

Medical Therapy for Nausea and Vomiting

Medical or surgical treatment of nausea and vomiting should be directed at the underlying disease process whenever possible. Nevertheless, many patients benefit from the initiation of medications designed to suppress emesis and correct aberrant gastrointestinal function.

Antiemetic Medications Antiemetic drugs acting on central nervous system muscarinic, cholinergic, histaminergic, dopaminergic, or serotoninergic receptors reduce symptoms in many cases (Table 37-3). The use of these agents should be tailored to the underlying emetic stimulus. Antihistamines such as meclizine and dimenhydrinate are useful for vomiting associated with labyrinthine disorders, such as motion sickness or labyrinthitis. [195] They also are effective in treating nausea associated with uremia and the postoperative state. Antihistamines are safe, although sedation and dryness of the mouth may limit their use in some settings. Newer, less sedating antihistamines such as astemizole have limited antiemetic activity. [196]

TABLE 37-3 Characteristics of Antiemetic Medications

Drugs such as scopolamine that antagonize muscarinic receptors in vestibular pathways also are effective in motion sickness when given orally or transdermally. [197] Side effects of antimuscarinic agents, such as dryness of the mouth and eyes, sedation, impaired concentration, headaches, constipation, and urinary retention, limit their usefulness in some individuals. Dopamine receptor antagonists, including phenothiazines (prochlorperazine, chlorpromazine) and butyrophenones (droperidol, haloperidol), are the most commonly prescribed antiemetics. These agents act on area postrema dopamine D_2 receptors and are effective in treating emesis resulting from gastroenteritis, medications, abdominal irradiation, surgery, and toxins as well as some chemotherapeutic agents. [198] Antidopaminergic agents produce many central nervous system side effects, including drowsiness, insomnia, anxiety, mood changes, confusion, dystonic reactions, parkinsonian symptoms, and irreversible tardive dyskinesia. Through effects on the pituitary, antidopaminergics may induce hyperprolactinemia, leading to breast engorgement, galactorrhea, and sexual dysfunction. Other rare side effects include blood dyscrasias and jaundice. Many antidopaminergics have effects on other receptor subtypes and provoke antihistaminic and antimuscarinic side effects as well. Serotonin 5-HT_3 receptor antagonists are now the most widely used agents in the prophylaxis of chemotherapy-induced emesis; however, they frequently are given in other conditions that produce nausea and vomiting. In patients with persistent unexplained nausea and vomiting, 5-HT_3 receptor antagonists may produce small reductions in symptoms. [199] Patients with nausea secondary to human immunodeficiency syndrome also experience some benefit from this class of drug, as may individuals with bulimia nervosa. [200], [201] Side effects from the 5-HT_3 antagonists include constipation, headaches, and rare elevations in liver chemistries.

Prokinetic Agents for Gastroparesis and Intestinal Dysmotility Gut motility disorders may respond to drugs that stimulate gastric emptying and intestinal transit (Table 37-4). These agents are often given before meals to reduce postprandial gastric stasis, with a dose given at bedtime to effect gut clearance of undigested residue during sleep.

MEDICATION	MECHANISM OF ACTION	COMMON SIDE EFFECTS
Commonly Used Agents for Gastroparesis		
Metoclopramide	5-HT_4 receptor facilitation of acetylcholine release from enteric nerves Dopamine receptor antagonism 5-HT_3 receptor antagonism (weak)	Sedation Anxiety Mood disturbances Sleep disruption Dystonic reactions Tardive dyskinesia Galactorrhea Sexual dysfunction
Erythromycin	Motilin receptor agonist	Abdominal pain Nausea and vomiting Diarrhea
Agents of Limited Prescription in Gastroparesis		
Cisapride	5-HT_4 receptor facilitation of acetylcholine release from enteric nerves Direct smooth muscle stimulant 5-HT_3 receptor antagonist (weak)	Cardiac arrhythmias Abdominal cramps Diarrhea
Domperidone	Peripheral dopamine receptor antagonist	Galactorrhea/gynecomastia Sexual dysfunction
Bethanechol	Muscarinic receptor agonist	Abdominal pain Salivation Nausea Diaphoresis
Agents for Small Intestinal Dysmotility		
Octreotide	Somatostatin receptor analog	Diarrhea Altered glycemic control (diabetics) Gallstones Thyroid disease
Leuprolide	Gonadotropin-releasing hormone analog	Amenorrhea Osteoporosis

TABLE 37-4 Prokinetic Medications for Gastrointestinal Dysmotility Syndromes

Metoclopramide is a substituted benzamide that acts via serotonin (5-HT_4) receptor facilitation of gastric cholinergic transmission and via dopamine (D_2) receptor antagonism in the stomach and brainstem. [202], [203] The prokinetic properties of metoclopramide are limited to the proximal gut; thus, the drug is useful for gastroparesis but not small intestinal or colonic dysmotility. Metoclopramide possesses antiemetic activity as well as motor stimulatory action, providing additional symptom control. Because of central antidopaminergic side effects, such as agitation, drowsiness, dystonias, and irreversible tardive dyskinesia, metoclopramide is poorly tolerated in up to 20% of patients. Hyperprolactinemia as a consequence of dopamine antagonism in the pituitary may cause impotence, galactorrhea, and amenorrhea. Selected macrolide antibiotics exhibit potent prokinetic effects in the upper gut. Erythromycin induces antroduodenal contractions and promotes gastric emptying through action on receptors for the hormone motilin, the physiological regulator of the MMC. The abilities of atropine and vagal cooling to block the effects of erythromycin indicate that vagal cholinergic pathways participate in its prokinetic effects. [204], [205] and [206] Some patients with gastroparesis and pseudoobstruction respond to erythromycin, but this agent has a narrow dose range of efficacy, which limits its utility. Low doses have no effect, whereas high doses induce abdominal pain, nausea, and diarrhea through the induction of intense motor spasms. [207], [208] and [209] Studies of investigational erythromycin analogs without antimicrobial effects show similar motor excitatory effects. [210], [211] and [212] Clarithromycin also stimulates gastroduodenal motility in healthy humans, suggesting potential for treating gastroparesis. [213] Domperidone, a benzimidazole derivative not presently available in the United States, is a dopamine D_2 receptor antagonist with prokinetic efficacy in gastroparesis comparable to that of metoclopramide. [214] Furthermore, the drug produces significant improvements in quality of life in affected patients. [215], [216] The drug crosses only into central nervous system regions with porous blood-brain barriers, such as the area postrema, and thus exhibits a side effect profile superior to that of metoclopramide. [217], [218] Because of its lack of central toxicity, domperidone is ideal for treating gastrointestinal symptoms in patients with Parkinson disease, who often must take dopaminergic drugs to control their somatic motor symptoms. [219] Although dystonic reactions are not observed with domperidone, hyperprolactinemia is still a problem because of the incomplete blood-brain barrier of the anterior pituitary. Other prokinetic agents have been largely abandoned because of unacceptable side effect profiles. Cisapride, a benzamide derivative acting on 5-HT_4 receptors to facilitate myenteric acetylcholine release, demonstrated clinical benefits in patients with gastroparesis and intestinal pseudoobstruction. [203], [220], [221] However, numerous deaths were attributed to cisapride, mainly because of induction of cardiac arrhythmias, including torsade de pointes. [222], [223] As a consequence, the drug was withdrawn from the market in 2000 except for selected low-risk patients. Bethanechol, a muscarinic receptor agonist with direct smooth muscle excitatory effects, is a potent stimulant of gut phasic contractions, but much of this motor activity is not propagative, and therefore the drug is a poor prokinetic. [224] Furthermore, side effects, including abdominal cramps, salivation, diaphoresis, and nausea, are prominent; thus, bethanechol is rarely used to manage gut motility disorders. Direct comparisons between the different prokinetic agents have not been made except in rare instances. A metaanalysis of published placebo-controlled clinical trials of metoclopramide, erythromycin, domperidone, and cisapride suggested

that erythromycin is most potent at stimulating gastric emptying, whereas domperidone and erythromycin are most effective at reducing symptoms. [225] Many patients with gastroparesis become refractory to standard prokinetic therapy and represent clinical challenges. In these individuals, combination treatment with two prokinetic drugs may provide superior relief. [226] Furthermore, drug administration by alternate routes may enhance their efficacy. Metoclopramide exhibits significant potency when administered subcutaneously. [227] Intranasal metoclopramide reduces vomiting after moderately emetogenic chemotherapy, suggesting that this experimental formulation may have future utility as well. [228] Agents with selective prokinetic effects on the small intestine may have some utility in certain patients with intestinal pseudo-obstruction. The somatostatin analog octreotide induces propagative small intestinal motor patterns in patients with pseudo-obstruction secondary to scleroderma and, when given over 3 weeks, reduces nausea, vomiting, abdominal discomfort, and objective measures of intestinal bacterial overgrowth. [229] Investigations indicate that octreotide may produce prolonged symptomatic improvement (>6 months) in some patients with pseudo-obstruction. [230] The gonadotropin-releasing hormone analog leuprolide evokes propagative gastric and small intestinal complexes in subsets of patients with intestinal dysmotility and may reduce nausea, bloating, and defecation disturbances in these individuals. [109], [231] Because leuprolide produces amenorrhea and may lead to osteoporosis, recommending this drug for an upper gut motility disorder should be judiciously considered.

Treatment of Emesis Resulting from Cancer Chemotherapy and Radiation Therapy Extensive investigation has focused on antiemetic regimens to prevent or treat nausea and vomiting complicating cancer chemotherapy. Most programs include multiple medications that act on distinct receptor sites. [232] For highly emetogenic agents such as cisplatinum, prophylactic regimens usually include 5-HT $_3$ receptor antagonists such as ondansetron and granisetron. [30], [93], [233] In contrast, 5-HT $_3$ receptor antagonists are less effective for delayed emesis after chemotherapy or with less emetogenic chemotherapeutic agents. [91], [233] Metoclopramide in high doses is useful for the prophylaxis of chemotherapy-induced emesis, possibly stemming from weak 5-HT $_3$ receptor antagonism. [234] Other antidopaminergic agents such as prochlorperazine and domperidone are used with efficacy with some forms of chemotherapy. Corticosteroids exhibit potent antiemetic effects against chemotherapy via unknown mechanisms. [235] In contrast to the 5-HT $_3$ receptor antagonists, the corticosteroids may provide the greatest benefit in reducing delayed chemotherapy-induced emesis. [236], [237] Intravenous benzodiazepines such as lorazepam are included in antiemetic regimens because they produce sedation and reduce anticipatory nausea. [238] Cannabinoids such as tetrahydrocannabinol and nabilone have efficacy in chemotherapy-induced emesis prophylaxis comparable to or slightly better than that of antidopaminergics; however, these drugs produce severe side effects such as somnolence, ataxia, syncope, seizures, and hallucinations, which are prominent in the elderly. [239], [240] Two thirds of the respondents to a recent survey of practicing oncologists indicated they would prescribe marijuana less than once monthly if it were rescheduled, in large part because of concerns about its toxicity. [241] The mechanisms of the antiemetic effects of cannabinoids are unknown, although tetrahydrocannabinol reduces prostaglandin synthesis and stimulates the endogenous production of endorphins. [242] Radiation therapy, both to abdominal and extraabdominal sites, may induce profound nausea and vomiting. As with chemotherapy-induced symptoms, 5-HT $_3$ receptor antagonists exhibit efficacy superior to that of metoclopramide in radiotherapy-evoked emesis. [243], [244] Similar to their actions with chemotherapy, the 5-HT $_3$ receptor antagonists produce better control of radiation-induced vomiting than of nausea. [243]

Therapy of Postoperative Nausea and Vomiting Several antiemetic regimens have been proposed to prevent or control postoperative nausea and vomiting. In several studies, the dopamine receptor antagonist droperidol and the 5-HT $_3$ receptor antagonists have shown efficacy in preventing postoperative symptoms. [245], [246] and [247] Furthermore, the combination of these agents appears to be superior to either drug alone. [245], [246] Other drug classes shown to reduce postoperative nausea and vomiting include the corticosteroids and the a $_2$-adrenoceptor agonist clonidine. [248], [249] and [250]

Miscellaneous Antiemetic Therapies Other medications have been shown in small, often uncontrolled trials to be efficacious in selected emetic disorders. Tricyclic antidepressants are used for nausea associated with depression. Recently, tricyclics have been found to be effective in patients with functional nausea and vomiting as well as in adults with cyclic vomiting syndrome. [150], [251] Emesis in children with cyclic vomiting often is relieved by antimigraine therapies such as sumatriptan. [152], [252] Patients with nausea resulting from opiate withdrawal can respond to opiate antagonists such as naloxone. The a-adrenoceptor agonist clonidine has been reported to benefit some patients with gastroparesis. [253] A new class of drugs that act as antagonists on tachykinin NK $_1$ receptors shows promise in treating both nausea and vomiting resulting from a broad range of conditions. NK $_1$ antagonists were initially used to control chemotherapy-induced emesis; in contrast to the 5-HT $_3$ receptor antagonists, they relieved delayed emesis and nausea as well as acute emesis. [254], [255] and [256] Subsequently, efficacy for NK $_1$ receptor antagonists was demonstrated in postoperative nausea and vomiting as well as motion sickness. [257], [258] and [259] Selected alternative and traditional nonmedicinal therapies have been promoted for treating nausea and vomiting. Ginger has been advocated for patients with postoperative nausea, motion sickness, nausea of pregnancy, and chemotherapy-induced nausea. [260] Vitamin B $_6$ (pyridoxine) also may be of benefit in some women with nausea of pregnancy. [261] Acupuncture, acupressure, and acustimulation have been suggested for nausea of pregnancy, postoperative nausea, motion sickness, and chemotherapy-induced emesis. [262], [263], [264], [265] and [266] Transcutaneous electrical nerve stimulation and electrical stimulation of the vestibular system have been shown to reduce chemotherapy-induced nausea and postoperative nausea, respectively. [267], [268] Finally, hypnosis has been proposed for the prevention of anticipatory nausea in chemotherapy patients. [269]

Surgical and Endoscopic Management of Nausea and Vomiting

For nausea and vomiting that are refractory to dietary measures and medications, the treatment options are limited. In diabetic gastroparesis, intermittent enteral feedings through a jejunostomy tube can reduce symptoms, decrease the number of hospitalizations, and improve the nutritional status. [270] Some patients benefit from the additional placement of a gastrostomy to vent trapped gas and secretions from the stomach. [271] Anecdotal reports suggest that pyloric injection of botulinum toxin may relieve symptoms in patients with diabetic gastroparesis, presumably by reducing associated pylorospasm. [272] In patients with intestinal pseudoobstruction in whom enteral feedings exacerbate symptoms, home intravenous hyperalimentation provides essential nutrition. In patients with pseudoobstruction, decompression stomata also may reduce symptoms when prokinetic drugs are ineffective. [273]

Reports suggest that some gastroparesis patients may derive benefit from electrical stimulation of the stomach. Gastric pacing at a rate of 3 cpm via electrodes implanted in the gastric serosa accelerates gastric emptying and reduces symptoms in patients with diabetic or idiopathic gastroparesis. [274] The U.S. Food and Drug Administration has approved a gastric neurostimulator as a humanitarian device for patients with diabetic or idiopathic gastroparesis. This device, which delivers low-energy electrical pulses at a rate of 12 cpm, improves gastric emptying only modestly; however, uncontrolled trials have reported 80% reductions in nausea and vomiting. [275], [276] Future electrical stimulators may offer the capability of delivering current sequentially at several sites in the stomach, providing greater coordinated propagation of the depolarizing stimulus. [277]

Surgical resections generally are of limited value in patients with refractory emesis. The main exception is gastroparesis resulting from prior vagotomy and gastric drainage surgery. In these patients, completion gastrectomy relieves symptoms, presumably by eliminating gastric retention. [278], [279] and [280] However, poor outcomes have been described in this setting for individuals with severe nausea who require parenteral nutrition and who retain solid food in the stomach. [281] Although gastric drainage procedures and resections generally do not provide symptom relief in patients with idiopathic gastroparesis or gastroparesis secondary to systemic disease, case reports have documented the effectiveness of total gastrectomy in selected patients with severe refractory gastroparesis. [282]

CHAPTER 38

Pankaj Jay Pasricha

APPROACH TO THE PATIENT WITH ABDOMINAL PAIN

> We look away from each pain, in the waiting sadness, Hoping it will pass away. Yet they form our winter's Bower, darkly filling our senses with green, one Of our internal seasons, but not merely season, But place, dwelling, defense, foundation, home.
>
> –Rainier Maria Rilke, *The Duino Elegies*

Pain is a paradox, as reminded by the haunting words of the Austro-German poet Rilke. When acute, it serves to warn the organism about potentially noxious agents in the environment; when chronic, it can so dominate the clinical picture that it can no longer be regarded as a sentinel sensation subservient to an underlying disease but instead assumes the characteristics of a disease state by itself. Further, it is also unique among sensations in that it can evoke, and to some extent be invoked, by complex alterations in the psychosocial state of human beings. An understanding of the underlying complex biologic, psychological, and social factors is therefore critical to a rational and satisfactory approach to the patient with pain.

NEUROBIOLOGY OF PAIN

Anatomic Pathways

Peripheral Pathways Normally, visceral pain begins with the stimulation of the peripheral nerve endings (located in the serosal, muscular, and mucosal layers of the gut) of a special class of spinal sensory neurons (nociceptors) whose cell bodies lie in the dorsal root ganglion (Fig. 38-1). After leaving the viscus they innervate, these nerve fibers run with the sympathetic fibers (as mesenteric nerves) and pass through, without interruption, one of several prevertebral autonomic plexuses associated with the corresponding visceral artery (e.g., celiac, hepatic, superior mesenteric). Thereafter, the nociceptor fibers travel within the regional splanchnic nerve until they reach the paravertebral sympathetic chain. Here they finally part company with the sympathetic nerves, taking the white rami communicans to the spinal nerve and thereafter to their eventual termination in the dorsal horn of the spinal cord. Although nociceptive fibers, like other extrinsic afferent nerves, run together with the sympathetic nerves for a greater part of their length, they are not considered part of the sympathetic nervous system. The sympathetic system does not therefore convey pain, but it may participate in the sensitization of nociceptor peripheral terminals under certain conditions. [1] Similarly, most of the sensory information carried by the parasympathetic vagal pathways is physiological; however, observations suggest that these nerves may also serve a modulatory role in nociception as well as in the autonomic, behavioral, and emotional response to it. [2], [3]

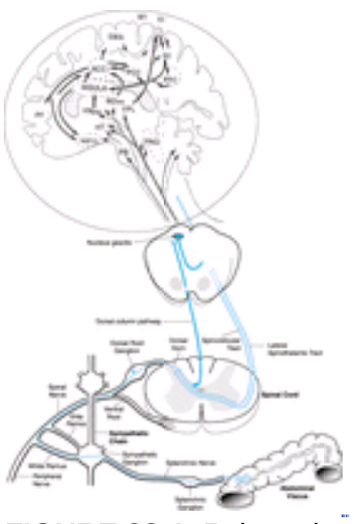

FIGURE 38-1. Pain pathways. (**Bottom**) Classic neuronal pathways, such as the spinothalamic and spinoreticular tract, mediating abdominal visceral pain sensation leave the dorsal horn, cross the midline, and ascend to higher centers. In the postsynaptic dorsal column pathway, nociceptive information from visceral organs is relayed to cells near the central canal. These postsynaptic dorsal horn cells send their axons in the midline of the dorsal column to synapse in the nucleus gracilis. The pathway then crosses the midline in the lower brainstem to ascend to the ventral posterolateral nucleus of the thalamus. (**Inset**) Schematic of ascending pathways, subcortical structures, and cerebral cortical structures involved in processing pain. *ACC,* anterior cingulate cortex; *AMYG,* amygdala; *HT,* hypothalamus; *MDvc,* ventrocaudal part of the medial dorsal nucleus; *PAG,* periaqueductal gray; *PB,* parabrachial nucleus of the dorsolateral pons; *PCC,* posterior cingulate cortex; *PF,* prefrontal cortex; *PPC,* posterior parietal complex; *S-1* and *S-2,* first and second somatosensory cortical areas; *SMA,* supplementary motor area; *VMpo,* ventromedial part of the posterior nuclear complex; *VPL,* ventroposterior lateral nucleus. (*Inset* from ref. [10].)

Spinal Connections After entering the spinal cord, afferent fibers make contact with neurons in the gray matter, which is conventionally described in terms of topographic regions or laminae. Whereas somatic nociceptor afferents mainly synapse in laminae I and II at their corresponding ipsilateral segmental level, visceral nociceptive afferents are more widely distributed, synapsing not only at more than one segmental level above and below the level of entry (up to six spinal segments), but also in several laminae at the same level, ipsilaterally and contralaterally. [4]

Ascending Pathways According to conventional teaching, spinal gray matter neurons mediating abdominal visceral pain cross the midline to the contralateral side and then travel cephalad within monosynaptic ascending pathways in the ventrolateral quadrant of the spinal cord (e.g., the spinothalamic, spinoreticular, spinobrachial, spinomesencephalic, and other tracts), to synapse within several thalamic and reticular formation nuclei of the pons and medulla [5] (see Fig. 38-1). However, findings also suggest that a prominent, and perhaps predominant, component of visceral pain may be relayed in the postsynaptic dorsal column (PSDC) of the spinal cord [6] (see Fig. 38-1). This pathway arises from spinal neurons adjacent to the central canal (lamina X) and ascends in the midline ipsilaterally. The PSDC pathway is polysynaptic in that there is at least one more relay station (the gracile nucleus for neurons originating in sacral spinal levels and in the cuneate and gracile nuclei for thoracic-level neurons) before it reaches a higher center. Neurons from these nuclei, in turn, project to the contralateral ventral posterior lateral

nucleus in the thalamus. Evidence for the functional importance of this pathway is derived from physiological studies as well as from patients with intractable pelvic cancer pain in whom a limited midline myelotomy to interrupt the PSDC resulted in complete or near-complete relief. [7], [8]

Supraspinal Structures and Circuits Involved in Pain Ascending pathways from the spinal cord relay pain to the thalamus and other subcortical organs and then to higher centers. From a functional perspective, these circuits can be viewed as either "sensory-discriminative" or "affective-cognitive." [9], [10] The former is responsible for precisely characterizing the noxious stimuli according to their location and nature. The latter is responsible for early autonomic and emotional responses accompanying pain including arousal, fear, and escape. Subsequently, it also invokes many important aspects of the clinical pain experience such as mood, attention, memory, and ability to cope and tolerate, as well as the characteristic feeling of "unpleasantness" and emotions about the long-term consequences of pain (e.g., "suffering"). Sensory-discriminative function appears to be served by laminae II and other regions in the neck of the dorsal horn and the ventroposterolateral and ventroposteromedial nuclei of the thalamus with projections to the somatosensory cortex. The affective-cognitive component of pain involves the superficial lamina I neurons, parabrachial region of the pons with projections to the ventroposterior inferior and the posterior division of the ventromedial thalamic nuclei, the central nucleus of the amygdala, the ventromedial hypothalamus, the insula, and the anterior cingulate cortex (ACC). Other structures are also involved in the maintenance of these circuits. One of these, the posterior parietal cortex, integrates visual and other sensory cues with nociceptive inputs from the somatosensory cortex and relays this information to the ACC. Another, the insular cortex, is concerned with monitoring the overall threat to the body and determines the destructive significance of pain. The insular cortex is also closely connected with the ACC, which, in turn, receives connections from the prefrontal cortex. Pain unpleasantness, if sustained, eventually engages areas in the prefrontal cortex, which appears to be the region mainly responsible for reflection on future implications of pain and planning and prioritizing the responses to pain as well as determining the secondary pain affect. The ACC therefore appears to occupy a critical position, integrating information about the immediate environmental threat from the parietal cortex with the emotional and behavioral response plans originating in the prefrontal cortex and, subsequently, directing attention and response priorities. In addition to those described previously, several other pathways also carry nociceptive information from the spinal cord to various regions in the brainstem. [11] Some of these regions, such as the reticular formation, may be involved in general arousal and motivational functions. Others, such as the parabrachial nucleus of the pons and the periaqueductal gray, are also well connected to the affective-cognitive circuits described earlier and together modulate the cognitive, emotional, behavioral, and autonomic responses to pain and the "unpleasantness" of the sensation. It is apparent therefore that a pain center as such does not exist in the brain. Instead, it may be more useful to view pain being perceived by a complex neural network (the *neuromatrix*), [12] with two components, one providing fine sensory information about the sensation and the other producing the emotional, cognitive, and behavioral response. This concept helps us to understand why chronic pain is such a complex phenomenon that can so profoundly affect an individual's sense of well being as well as to explain how a variety of physical and emotional stressors can affect the perception of pain.

Descending Pathways The functional connections between the spinal cord and higher centers run both ways (Fig. 38-2). Most of the descending pathways are inhibitory and may serve to provide negative feedback to strong painful input; however, excitatory connections also exist. One of the most important centers involved in descending modulation of nociception is the periaqueductal gray (see earlier), which connects caudally to the spinal cord by the nucleus raphe magnum and raphe spinal pathways. It also receives descending projections from several of the other structures involved in the affective-cognitive aspects of pain including the limbic system and hypothalamic regions and thus may assist in coordinating a "dampening" response. Other centers participating in descending inhibition include pontine nuclei such as the locus ceruleus and subceruleus. [5]

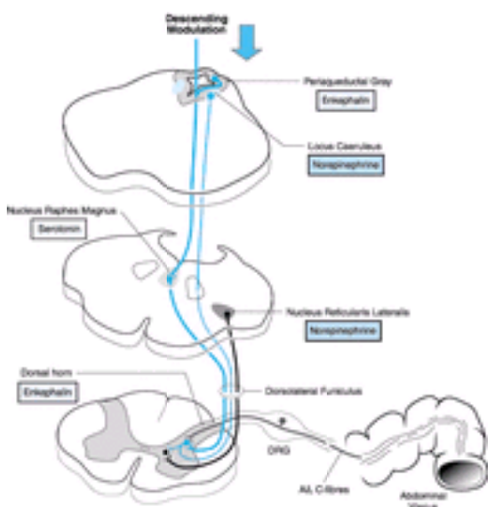

FIGURE 38-2. Descending pathways involved in modulation of nociception and their principal neuromediators (see text for details). (Adapted from Russo CM, Brose WG. Chronic pain. Annu Rev Med 1998;49:123.)

Cellular, Molecular, and Neurochemical Substrate of Pain

Nociceptive sensory neurons consist of slow unmyelinated C fibers and fast myelinated Ad fibers belonging to the primary afferent nociceptor [13] (Fig. 38-3). Both Ad and C fibers are polymodal and respond to both mechanical and thermal stimuli, with C fibers also responding to noxious chemical stimuli such as acid and capsaicin, the pungent component in hot chili peppers. Most visceral C-type nociceptors contain neuropeptides such as substance P (SP) and calcitonin gene–related peptide (CGRP) and are dependent on trophic support by nerve growth factor (NGF). [14]

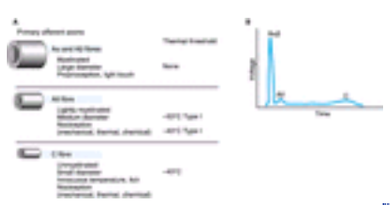

FIGURE 38-3. Different nociceptors detect different types of pain. (**A**) Peripheral nerves include small-diameter (Ad) and medium- to large-diameter (Aa,ß) myelinated afferent fibers, as well as small-diameter unmyelinated afferent fibers (C). (**B**) The fact that conduction velocity is directly related to fiber diameter is highlighted in the compound action potential recording from a peripheral nerve. Most nociceptors are either Ad or C fibers and have different conduction velocities (6–25 and approximately 1.0 m s^{-1}, respectively). (Adapted from ref. [13].)

The nociceptor has to perform three key tasks: transduction of noxious stimulus to an electrical signal, conduction of that electrical signal from the peripheral to the central end of the nociceptor, and, finally, encoding and relaying that signal to second-order neurons in the form of synaptically transmitted chemicals (Fig. 38-4). Signal transduction presents a unique challenge for nociceptors because, unlike other sensory stimuli (e.g., light), noxious stimuli can take one of a variety of diverse forms including heat, pressure, and chemical injury. In general, nociceptors convert noxious stimuli to an electrical response through specialized receptors. Some of these receptors are "promiscuous" in that they are capable of responding to more than one type of noxious stimulation. The best example of this is the receptor for capsaicin, vanilloid receptor 1 (VR $_1$). [13], [15] This receptor is expressed by nociceptive primary afferents, and it responds to and appears to integrate several noxious stimuli produced during tissue injury, including heat, local tissue acidosis, and several pro-algesic metabolites. Activation of the receptor results in a cationic, calcium-preferring current that leads to depolarization of the membrane. Acid and heat are both thought to function as endogenous ligands of this receptor, and evidence also points to a potential role for other biologically active compounds such as anandamide and related lipid metabolites. Further, other pro-algesic agents such as bradykinin or ATP, while independently capable of stimulating nociceptors, may also potentiate VR $_1$ responsiveness by lowering the threshold for activation to the range of normally nonpainful thermal stimuli (i.e., normal body temperature). This diverse portfolio of responses has led the current view of VR $_1$ as a "molecular integrator" of several chemical and physical stimuli that elicit pain.

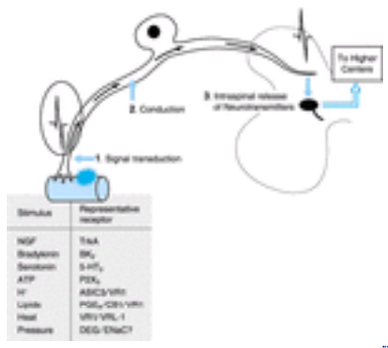

FIGURE 38-4. The primary nociceptor and its functions. Sensation from the peripheral organ is carried by fibers whose origin is in cell bodies within the dorsal root ganglia. The central projections of these neurons, in turn, relay information to second-order neurons in the spinal cord that transmit this information upward to the brainstem and higher centers by distinct pathways. This diagram illustrates the three basic components of pain signaling at the level of the first-order neuron in the nociceptive pathway. A painful stimulus is translated into electrical activity, which is conducted centrally and eventually results in release of neurotransmitters at the central synapses, with stimulation of second-order neurons. (Table data from ref. [13].)

In contrast to thermal and chemical receptors, little is known about the receptors capable of transducing mechanical stimuli. In addition to specific receptors responsive to physiological mechanical stimuli (e.g., the degenerin ion channel family), [13], [16] pressure changes in tissue may be signaled by the release of chemicals such as ATP, which then interact with chemical receptors such as the P2Y and P2X receptors. [17]

Thermal, mechanical, or chemical stimuli, acting through specific receptors, induce a change in the membrane potential of the nociceptor terminal called a *receptor* or *generator* potential. When this exceeds the threshold for activation, an action potential is triggered. Activation thresholds are under a variety of influences including the ionic concentration of the environment, as well as the activity of several intrinsic membrane currents (K^+, Na^+, Ca^{2+}). Attention has been focused on sensory neuronal voltage-gated Na^+ currents (VGSCs), particularly on the tetrodotoxin (TTX)-resistant channels, SNS (PN-3) and SNS2 (NaN), that are expressed predominantly in small sensory neurons. [18] TTX-resistant channels recover from inactivation more rapidly, and their presence is associated with the ability to fire long trains of action potentials and hence contributes to an increased excitability.

Once generated, action potentials are conducted centripetally to the spinal terminals of the nociceptors, where they initiate neurotransmitter (principally glutamate, SP, and CGRP) and thereby relay nociceptive information to second-order neurons. The early response to relatively mild stimuli is transmitted by glutamate acting on the a-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) and kainate ligand-gated ion channels. [19] If the stimulus is sustained or intense enough, it causes release of SP, which acts on the NK_1 receptor [20] to produce a correspondingly more intense postsynaptic response, an effect that, in turn, is boosted by another glutamate receptor, the *N*-methyl-D-aspartate (NMDA) receptor. CGRP, which is coexpressed with SP, also plays a role in nociceptive transmission, with effects that are less well understood. [21] Finally, other glutamate receptors such as the metabotropic (mGluR) receptors are also brought into play at higher levels of noxious stimulation and appear to play a critical role in central sensitization, along with the NK_1 and NMDA receptors (see later).

In addition to the “classic” neurotransmitters described earlier, several others may also be involved in spinal nociceptive processes. These include excitatory neuropeptides such as neurokinin A and brain-derived neurotrophic factor (BDNF), possibly inhibitory ones such as somatostatin and galanin, vasoactive intestinal polypeptide (VIP), and nitric oxide. [22], [23] and [24] Finally, many receptors that act at the peripheral ends of nociceptors (e.g., VR_1, P2X, and prostaglandin E_2 receptors), are also expressed receptors on the central ends, suggesting a role for their ligands in spinal modulation of nociception. [13]

The dorsal horn cannot be considered a simple way station, but rather a critical point where peripheral signals may be enhanced or attenuated by caudally directed neural connections from higher centers (see Fig. 38-2) before they are relayed cranially. Descending inhibitory neurons counteract the excitation from the periphery, mainly by the release of glycine and ?-aminobutyric acid (GABA). $GABA_B$ receptors act mainly presynaptically, whereas $GABA_A$ receptors, like glycine receptors, modulate dorsal horn neurons postsynaptically. [23] Although serotonin (5-HT) is also thought to be an important participant in descending inhibition, its effects are not straightforward, because of the multiplicity of receptors, some of them with conflicting actions on nociception. $5\text{-HT}_{1B/D}$ receptors probably mediate selective inhibition of nociceptive neurons, whereas other receptors have either mixed (5-HT_{2C}) or excitatory effects (5-HT_3). [23] A closely related inhibitory system involves norepinephrine, whose effects on nociception are largely mediated by a $_2$-adrenergic presynaptic receptors. [23] The spinal cord also contains high concentrations of opioid receptors (μ,d,?, in order of abundance), with the majority presynaptic in location, that is, on primary afferents. [22] Opioid activation of these receptors leads to a hyperpolarization of the neurons and inhibition of the release of excitatory neurotransmitters such as SP and glutamate. In this context, cholecystokinin (CCK) appears to share an intimate and complex relationship with opioids. CCK, acting through the CCK-B receptor, effectively antagonizes the analgesic effects of opioids. [25] Other mediators found in the dorsal horn with potentially antinociceptive effects include acetylcholine, adenosine, nociceptin, and a variety of others whose roles yet to be fully understood. [26]

Thus, the dorsal horn is the site of a complex interaction between a variety of neurotransmitters and their receptors derived from or located on afferent fibers, intrinsic dorsal horn neurons, or descending (modulatory) fibers. This interaction determines the nature and intensity of the signal that travels up the ascending pain pathway to higher centers.

PAIN AND SENSITIZATION

Most pain, if lasting more than a few minutes, occurs on a background of a potentiated or “sensitized” nociceptive system. [19] This is an extremely important concept to understand because it can help to explain many commonly encountered clinical situations. The stimuli that cause pain also produce tissue injury or inflammation; this, in turn, results in the local accumulation of several factors that amplify the activity of peripheral nociceptors as well activate previously dormant neurons (“silent nociceptors”). Tissue injury may also produce *phenotypic switching,* a phenomenon in which normally nonnociceptive fibers (e.g., Aß) display changes in neurotransmitter content and central innervation pattern that allow them also to participate in pain signaling. [27] Together, these phenomena are termed *peripheral sensitization* and lead to an “afferent barrage” that eventually produces central sensitization or an increase in the responsiveness of dorsal horn neurons. [28] The gain of the entire system is therefore reset upward, with the result that noxious stimuli now elicit a pain response that is much greater when compared with the normal state, a phenomenon termed *hyperalgesia.* A further characteristic of the sensitized state is called *allodynia,* a phenomenon in which innocuous or physiological stimuli are perceived as painful. These manifestations of sensitization are graphically illustrated in Figure 38-5. As an example, one can therefore postulate that patients with painful chronic pancreatitis exhibit pancreatic neuronal sensitization and may experience mechanical allodynia: pain in response to physiological changes in intraductal pressure, which would otherwise have not been perceived. Similarly, subsequent minor flares of inflammation in such patients could also cause the associated pain to be felt as severe, rather than mild (hyperalgesia).

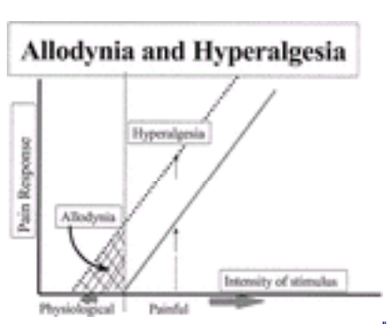

FIGURE 38-5. Basic concepts of pain sensitization, as illustrated in a theoretical stimulus-response curve. The *solid line* on the **right** represents a hypothetical control

population, whereas the *broken one* on the **left** represents the response in a sensitized population (e.g., patients with pancreatitis). The *broken vertical line* represents the threshold for painful stimulation in the control population. The sensitized population experiences pain in response to stimulation that is in the nonpainful (physiological range) for the control population, a phenomenon known as allodynia (*shaded area*). Hyperalgesia refers to a response to painful stimulation that is greater than the control population (*arrows*).

Pain sensitization results from both early posttranslational changes as well as later transcription-dependent changes in effector genes; these occur in both nociceptors and dorsal horn neurons. These changes can be initiated by a variety of factors in inflamed tissue including ions (K^+, H^+), amines (5-HT, histamine), kinins (bradykinin), prostanoids (prostaglandin E_2), purines (ATP), cytokines (tumor necrosis factor, interleukin-1 or 6), nitric oxide, and caloric activity (heat). [29] In the short-term, several of these agents, acting through specific receptors or cellular messengers, initiate a chain of events that lead to an increase in the phosphorylated state of critical ion channels, such as the nociceptor-specific TTX-resistant sodium channel SNS, thus enhancing excitability (Fig. 38-6). These early sensitization events are sustained and are further amplified by transcriptional up-regulation of several of the foregoing channel proteins hours to days later after the onset of tissue injury or inflammation. [19] This process is exemplified by the effects of NGF, whose levels are increased in variety of inflammatory states including chronic pancreatitis. [30] Increased tissue levels of NGF result in increased expression of various genes important for nociception (see Fig. 38-6), thus amplifying and perpetuating the sensitized state. [31] Similar paradigms of sensitization can be used to illustrate the processes underlying central sensitization, including early posttranslational and late, transcriptional events [19] (Fig. 38-7).

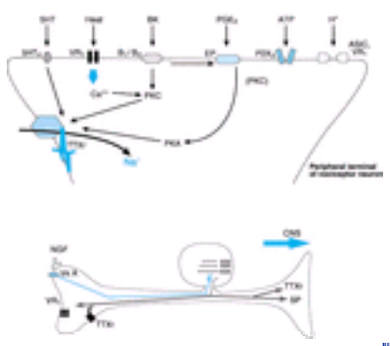

FIGURE 38-6. (**Top**) Peripheral sensitization: early events. Various biologic mediators comprising the inflammatory “soup” interact with specific receptors expressed on the peripheral ends of sensory neurons. Some of these (e.g., noxious heat) can activate neurons directly, whereas the majority can acutely sensitize the neuron, that is, make it more excitable by changes in intracellular calcium and phosphorylation states that result in greater activation of critical ion channels such as the tetrodotoxin-resistant sodium channel (TTXr). *ASIC,* acid sensing ion channel; *BK,* bradykinin; *5 HT,* 5-hydroxytryptamine; *PGE2,* prostaglandin E_2; *PKA,* protein kinase A; *PKC,* protein kinase C; *VR1,* vanilloid receptor 1. (**Bottom**) Model for “late” sensitization of sensory neurons. Neurotrophins such as nerve growth factor (NGF) are released in response to inflammation and cause up-regulation of genes critical for nociception such as ion channels such as VR1, TTXr (expressed in the periphery) and neurotransmitters such as brain-derived neurotrophic factor (BDNF) and substance P (SP) released centrally. (From Woolf CJ, Costigan M. Transcriptional and posttranslational plasticity and the generation of inflammatory pain. Proc Natl Acad Sci U S A 1999;96:7723.)

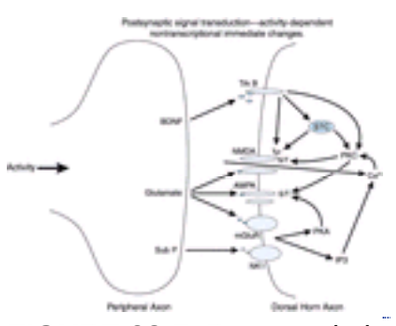

FIGURE 38-7. Posttranslational changes within dorsal horn neurons after release of transmitters from C fiber central terminals. These transmitters/neuromodulators act on receptors and ion channels in the dorsal horn to activate protein kinases that phosphorylate membrane-bound NMDA and AMPA receptors and alter their functional properties, increasing membrane excitability and thereby eliciting central sensitization. (From Woolf CJ, Costigan M. Transcriptional and posttranslational plasticity and the generation of inflammatory pain. Proc Natl Acad Sci U S A 1999;96:7723.)

Sensitization, Visceral Hyperalgesia, and “Functional” Pain Syndromes

The concepts discussed earlier provide a biologic basis for the perpetuation of the pain state in inflammatory visceral conditions such as pancreatitis and may also be valid in conditions such as irritable bowel syndrome (IBS) or other functional pain syndromes such as nonulcer dyspepsia. [24], [32] Patients with IBS experience pain at distention pressures or volumes that produce, at best, normal internal sensation in healthy volunteers (allodynia); they also experience more severe discomfort at noxious distention pressures or volumes (hyperalgesia). [24] Experimental evidence suggests that both inflammatory and motor events could theoretically set in motion a cascade of events leading to sensitization in this condition. Thus, mucosal inflammation accompanying gastrointestinal infections can produce visceral hyperalgesia by both peripheral sensitization and central hyperexcitability. [33] Motor events in the gut, if prolonged and abnormally excessive, may also result in a state of sensitization: repeated distention of the colon in humans (to 60 mm Hg) has been shown to increase the area of pain referral in the short term. [34] Further, significant numbers of patients develop IBS-like symptoms after a bout of acute infectious gastroenteritis. [35] According to one theory, the lack of overt inflammation or disruption of tissue architecture in patients with IBS is explained by the fact that the initiating event was transient but left persistent changes in its wake that resulted in peripheral and central hyperalgesia. In such a sensitized state, even normal contractile events could be perceived as painful (i.e., allodynia). Host factors and genetic susceptibility may determine which patients eventually develop the clinical syndrome.

Although there is reasonable evidence to suggest nociceptive sensitization in these syndromes, the relative contributions of central and peripheral factors remain known. A very active area of research includes functional imagines studies of the brain in response to noxious visceral stimulation. Although the implications of these findings remain to be fully understood, these studies are important in showing objective evidence of altered processing of noxious information in patients with functional bowel pain. [35]

NOCICEPTION, SUFFERING, AND ILLNESS BEHAVIOR: THE BIOPSYCHOSOCIAL CONTINUUM OF THE PAIN EXPERIENCE

It is important to understand that *nociception,* the detection of tissue damage by specialized transducers attached to C and Ad fibers, is not synonymous with pain, and increased afferent signaling to the central nervous system by itself is not necessarily enough to make a patient with chronic pain seek medical attention. Nociception can lead to pain *perception,* but this can also occur in the absence of nociception resulting from damage to the peripheral or central nervous system. Pain perception, in turn, can cause *suffering* (a combination of anxiety, fear, stress, uncertainty, and loss of loved objects). [36] *Illness behavior,* another important concept, reflects how pain is acted on by an individual person and results from a complex mixture of physiological (e.g., pain intensity/severity or associated features), psychological (e.g., mental state, stress, mood, coping style, prior memories or experiences with pain), and social (e.g., concurrent negative life events, attitudes and behavior of family and friends, perceived benefits such as avoidance of unpleasant duties) factors. [37] The biologic basis of these processed can be partially explained within the known framework of the nociceptive process described earlier. Thus, the well-known exacerbation of pain in patients with stressful life events may result from changes in central descending modulatory systems and perhaps as well by alterations in sympathetic discharge locally. [24]

It is important therefore to understand that the patient with chronic pain represents a dysregulation or dysfunction of a system that is, in effect, a continuum of

biopsychosocial factors (Fig. 38-8). In a given patient, the primary disturbance may disproportionately affect one component of the spectrum, and it is the wise physician's task to identify this without losing sight of the whole.

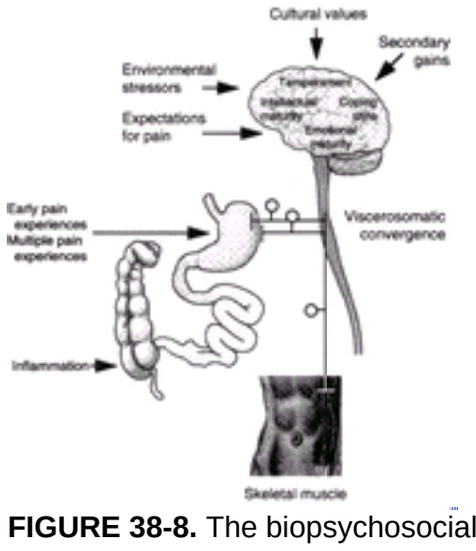

FIGURE 38-8. The biopsychosocial model of chronic abdominal pain. In this illustration, inflammation in the colon is shown as initiating pain and sensitization, providing nociceptive input to the central nervous system. Thereafter, psychological, developmental, and social/environmental factors alter the "experience" of pain. (From Hyams JS, Hyman, PE. Recurrent abdominal pain and the biopsychosocial model of medical practice. J Pediatr 1998;133:473.)

CLINICALLY IMPORTANT PHYSIOLOGICAL CHARACTERISTICS OF ABDOMINAL PAIN

Abdominal pain in the abdominal region can arise from the internal organs and their immediate peritoneal lining (visceral pain) or from the parietal peritoneum or the muscular and other layers of the abdominal wall (somatic pain). At the onset at least, visceral pain has certain distinct characteristics, reflecting the peculiar nature of visceral innervation. [28] First, it is not evoked equally from all organs (solid ones are less sensitive than hollow organs, and capsular or serosal coverings are more sensitive than the organs themselves), because not all structures receive equal nociceptive innervation. Second, visceral afferents are relatively few (as compared with somatic structures) and diverge extensively in the central nervous system, with the result that the pain tends to be poorly localized. Third, acute visceral pain is often accompanied by autonomic disturbances such as changes in blood pressure and heart rate, pallor and sweating, and visceral motor phenomena such as vomiting and diarrhea. In addition, intense emotional responses and anxiety can occur. Finally, and perhaps most importantly from a physician's perspective, most clinically significant forms of visceral pain are referred to somatic areas, a phenomenon that is discussed next in greater detail.

A patient with "pure" visceral pain is seldom seen by the physician, because this phase usually lasts only a few hours. When it begins, it is felt in the midline in the epigastric, periumbilical, or hypogastric regions, reflecting the ontogenic origin of the involved organ from the foregut, midgut, or hindgut, respectively (Fig. 38-9). Even observant patients may find it difficult to describe as a real pain, and they may perceive it as a deep and dull discomfort instead. This phase of pain is typically limited, and if the underlying insult persists, referred pain sets in later. Referred pain is perceived in overlying or remote superficial somatic structures such as skin or abdominal wall muscle, with the site varying according to the involved visceral organ. Referred pain is more helpful in determining the site of the underlying disorder than the original pure visceral pain, which tends to be perceived in the midline regardless of the organ involved (see Fig. 38-9). Further, referred pain is sharper and assumes several of the characteristics of pain of somatic origin.

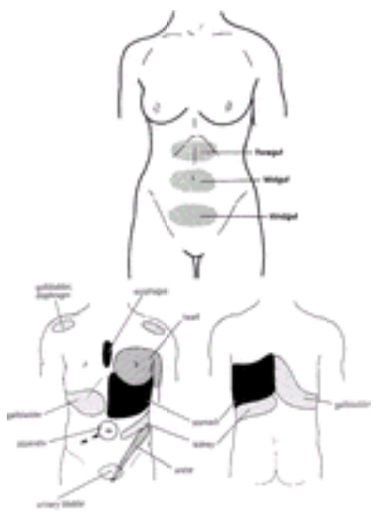

FIGURE 38-9. True visceral and referred pain patterns. (**Top**) Approximate levels of the abdomen where "true" visceral pain is felt, according to its source. (From Mulholland MW. Approach to the patient with abdominal pain. In: Yamada T, ed. Textbook of gastroenterology, 3rd ed. Philadelphia: JB Lippincott, 1999:826.) (**Bottom**) Important skin areas for referral of visceral pain. (From Snell RS. Clinical anatomy for medical students, 6th ed. Philadelphia: Lippincott Williams & Wilkins, 2000.)

Referred pain can occur without hyperalgesia of the somatic structure (simple irradiation) or can be accompanied by sensitization of these structures with resulting hyperalgesia. [38] The physiological basis of referred pain is incompletely understood, and no one theory is completely satisfactory. Nevertheless, familiarity with these theories is important to understand the clinical implications of these phenomena (Fig. 38-10).

FIGURE 38-10. Theories of referred pain from a visceral organ, using skeletal muscle as the site of referral. (**Left**) The convergence-facilitation theory states that painful visceral insults produce an "irritable focus" in the corresponding spinal cord segment, thus facilitating or amplifying signals from somatic structures whose nerves converge on the same spinal neurons. According to this theory, therefore, the referred hyperalgesia is mainly central. (**Right**) The reflex-arc theory states that viscerocutaneous or visceromuscular reflexes traveling through the spinal cord induce neurogenic changes in the muscle or skin that result in a local painful state. According to this theory, referred hyperalgesia can be viewed as peripheral. (From ref. [38].)

CAUSES AND CLASSIFICATION OF ABDOMINAL PAIN

Gastrointestinal viscera are relatively insensitive to stimuli such as light touch, pinching, cutting, and even burning, compared with cutaneous and other somatic structures. [39] Instead, typical painful visceral stimuli include changes in length-pressure relationships within hollow organs (contractions and/or distentions), stretching of capsules, ligaments, or mesenteric attachments, inflammation with local production of sensitizing chemical and biologic agents, and ischemia, particularly when it affects visceral musculature. An appealing approach to the classification of pain, used widely in the somatic literature, is based on putative neurophysiological mechanisms. According to this, pain can be either *nociceptive* or *neuropathic;* [40] the former is the result of persistent stimulation of peripheral nociceptors by local injury and/or inflammation), whereas the latter is independent of nociceptor stimulation, implying changes in the pain pathways (either peripheral or central) that result in persistent but aberrant signaling. The pain of some acute gastrointestinal conditions such as pancreatitis or cholecystitis can be considered to be predominantly nociceptive. Somatic neuropathic pain syndromes include poststroke pain (central) or diabetic neuropathy (peripheral); whether there is a visceral counterpart remains unknown. The chronicity of pain is also important: acute pain serves a useful biologic function warning the organism of impending injury, whereas pain that persists beyond the expected course of an injury to heal appears to have outlived its utility and can result in significant secondary morbidity in the form of physical, emotional, or socioeconomic stresses on the patient, family, and society. [40] These issues can often so dominate the overall clinical picture that the pain is often dismissed by physicians as “psychogenic,” “functional,” “not organic,” or, worse still, “malingering.” In fact, most patients with chronic abdominal pain are not malingerers or hypochondriacs; however, their “psychosocial burden” can be overwhelming. The challenge for clinicians is to recognize and address this without losing track of the fundamental nature of the problem.

CLINICAL ASSESSMENT OF ABDOMINAL PAIN

History

A carefully taken history often holds the key to an accurate diagnosis of abdominal pain. Several critical features need to be elicited.

Site The phenomenon of referred pain (see earlier) renders it difficult to make a diagnosis of visceral pain by site alone. Nevertheless, such an approach is commonly used with most clinicians dividing the abdomen into four quadrants (Table 38-1). These general, if crude, inferences have been supported by studies using balloon insufflation in various organs in conscious patients. [39], [41] There is considerable overlap between the pain from various organs such as the bile ducts and the proximal small intestine. Further caution is warranted when dealing with patients with chronic painful conditions (including IBS) who often have distorted patterns of pain rendering when compared with healthy volunteers. [34]

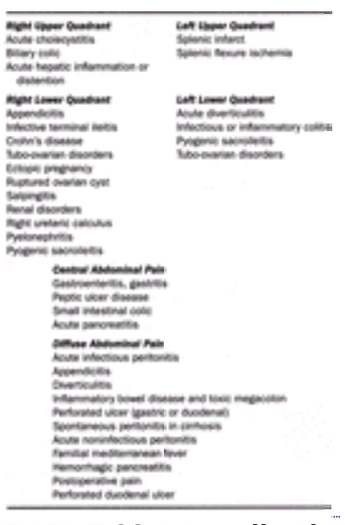

TABLE 38-1 Localization of Common Causes of Acute Abdominal Pain

Temporal Characteristics Among the most important of these characteristics are the nature of onset and the pattern of variation with time (intermittency and periodicity). Immediate pain is suggestive of an acute obstruction of a hollow viscus (e.g., bile duct obstruction by a stone), perforation (e.g., free perforation of a duodenal ulcer), or a catastrophic ischemic condition such as acute mesenteric ischemia. The more common situation is a relatively gradual onset of pain; the transition from a “glowing ember” to a “raging flame” may take hours or days, depending on the underlying condition and is typical of inflammatory conditions such as appendicitis, diverticulitis, pancreatitis, and cholecystitis. Abrupt cessation of pain can occasionally occur spontaneously and should suggest the relief of an obstructed organ (e.g., stone passage or resolution of a volvulus). In many cases, however, the pain is intermittent in that it wanes for varying intervals of time, only to wax to its original intensity subsequently. Such pain is typical of colic, usually intestinal in origin. Biliary pain, although traditionally also labeled as colic, shows less variability than commonly thought. *Periodicity* refers to a long duration (weeks to months) of pain-free intervals. Such periodicity is seldom regular (unless pain is pelvic and related to the menstrual cycle) and used to be characteristic of conditions such as peptic ulcer disease (in the days before effective therapy was available). Other examples include patients with recurrent urinary stones, patients with IBS (in which the pain often varies with periods of psychosocial stress and associated disturbances in bowel function), and a long list of less common conditions (Table 38-2).

TABLE 38-2 Some Causes of Intermittent Abdominal Pain

Character and Intensity of Pain These attributes are influenced by the social and educational background of the patient as well as past personal experience. This may account for the fact that rating the severity or describing the nature of the pain seldom helps in distinguishing the cause of the pain. For example, the pain associated with peptic ulcer disease has been described by such apparently contradictory terms as aching, gnawing, sharp, burning, tearing, and squeezing. Furthermore, patients often ascribe different meanings to common descriptors. As an example, many patients often associate colic with any diarrheal illness. From a medical perspective, however, the pain of colic refers to a characteristic wavelike buildup in intensity culminating in severe pain often associated with other symptoms such a sweating, nausea, and dizziness. [42] The pain of colic is the result of visceral obstruction and peristaltic contractions associated with increased intralumenal pressure and generally is similar in character regardless of the organ involved (Table 38-3).

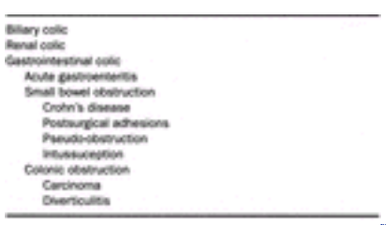

TABLE 38-3 Common Causes of Colicky Abdominal Pain

Relieving and Aggravating Factors A relationship between fluctuations in pain and physiological gastrointestinal activity suggests a link to a hollow viscus (rather

than musculoskeletal causes) and may point toward a specific diagnosis. Thus, pain with swallowing (*odynophagia*) almost invariably points to an esophageal lesion. The pain of duodenal ulcer tends to improve with food or antacid use, whereas gastric ulcer pain may be worsened by food intake. The specific nature of the food that either relieves or aggravates pain is seldom of diagnostic value, contrary to popular belief. Thus, the relationship between fatty foods and biliary pain or between spicy foods and peptic ulcer pain is dubious at best. [43] Relief after vomiting suggests a pyloric or proximal small bowel lesion. Colonic pain or distress may be relieved by a bowel movement, particularly in patients with IBS. Conversely, anorectal conditions such as proctitis or fissures may be aggravated by bowel movements. Retroperitoneal processes, including pancreatitis, tend to be somewhat relieved by maneuvers that increase the volume of this space (sitting up and bending forward). Visceral pain by itself often induces restlessness in the patient, but when parietal or somatic structures become involved, aggravation by motion, coughing, or straining is characteristically noted. Most inflammatory conditions of visceral organs are associated with varying degrees of systemic reaction including anorexia, malaise, and, perhaps, fever.

Physical Examination

The patient with acute abdominal pain is best dealt with as an emergency, possibly surgical in nature (see Chapter 40). In patients with more chronic pain, vital signs are less likely to be disturbed. Systemic examination may provide useful clues to the diagnosis such as purpural rashes, pallor, jaundice, edema, and other obvious signs of a more generalized disorder (Table 38-4).

PHYSICAL FINDING	RELATED CONDITION
Jaundice	Choledocholithiasis
	Gallstone pancreatitis
	Liver congestion or inflammation
Purpural or retinal cytoid bodies	Autoimmune process
Distended abdomen	Bowel obstruction
	Ascites
Palpable mass	Hernia
	Neoplasm
Focal neurological finding	Nerve root compression
	Vertebral body fracture
Anal fissure	Crohn's disease
Dark red "port-wine" urine	Acute intermittent porphyria
Occult blood in stool	Bowel inflammation
	Peptic ulcer disease
	Gastrointestinal cancer
Positive Carnett test	Abdominal wall hernia
	Cutaneous nerve entrapment
	Myofascial pain syndromes
	Rectus sheath hematoma
	Rib tip syndrome

Note: From Zackowski SW. Chronic recurrent abdominal pain. Emer Med Clin North Am 1998;16:877.

TABLE 38-4 Clues to the Etiology of Abdominal Pain on Clinical Examination

Subsequently, a careful examination of the abdomen is made. It begins with inspection: note is made of surgical scars and abdominal distention. This is followed by palpation, which should be performed with warm hands and should begin away from the area of maximal tenderness. This will often identify localized masses, free peritoneal fluid such as ascites, or areas of tenderness. It can also determine whether there is localized or diffuse peritoneal inflammation. Eliciting rebound tenderness, a staple of medical school teaching, is generally to be discouraged because not only may it be unreliable, [44] but also, because of its painful nature, it may compromise the patient's further cooperation. Auscultation of the abdomen may help in ascertaining the general state of the bowels (it is seldom helpful to auscultate all four quadrants). Peritonitis is associated with hypoactive or absent bowel sounds; hyperactive sounds may be heard in patients with infectious gastroenteritis. Infrequent, prolonged rushes of high-pitched or "tinkling" peristalsis are often heard over the distended loops of bowel seen with intestinal obstruction.

Rectal examination in male patients and pelvic examination in female patients may occasionally reveal signs of local peritonitis in the area. The presence of occult blood in the stools may provide a clue to an intralumenal lesion such as peptic ulcer.

When no obvious clinical or laboratory clues to a specific disease process are seen, the Carnett test may help to determine whether chronic intermittent abdominal pain arises from the abdominal wall or has an intra-abdominal origin. [45], [46] If a tender spot is identified, the patient is asked to raise his or her head, thus tensing the abdominal musculature. If there is greater tenderness on repeat palpation, the Carnett test is positive and suggests a cause in the abdominal wall (Table 38-5). Conversely, diminished tenderness may suggest an intra-abdominal process.

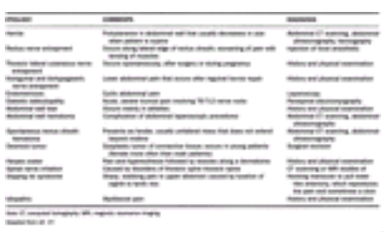

TABLE 38-5 Etiology of Abdominal Wall Pain

Differential Diagnosis

The differential diagnosis of "abdominal pain" is immense. Familiarity with common gastrointestinal diseases and their natural history is a prerequisite for an accurate approach to the patient, and clinical suspicion should form the basis for further testing. These diseases are dealt with in their entirety in other chapters; nevertheless, it is important to point out certain specific clues to such conditions.

Gastroduodenal Pain Gastric pain is usually felt in the midepigastric region but can also be perceived in the left upper quadrant and occasionally in the chest. [39] Peptic ulcers are one cause of *dyspepsia,* which is syndrome of epigastric pain, discomfort often accompanied by bloating, and early satiety, as well as other symptoms. Many conditions can cause a similar clinical picture including disorders of the pancreas or biliary tree, gastric malignant disease, gastroesophageal reflux, and use of several medications including antibiotics. When no underlying cause is found, the term *nonulcer* or *functional dyspepsia* is used. This is dealt with extensively in Chapter 30.

Biliary Pain Biliary pain, whether arising from the gallbladder or the bile duct, is felt as a dull sensation in the midline (epigastrium) initially; with the development of inflammation or if the pain continues, it is often referred to the right upper quadrant and occasionally to the right infrascapular region. Acute obstruction of the biliary tree is almost always painful, although not necessarily "colicky" in the true sense. A gradual dilation of the bile duct, as from a distal ampullary or pancreatic cancer, may remain painless throughout its course.

Pancreatic Pain Pancreatic pain usually either results from inflammation (acute or chronic) or is caused by a neoplasm. The pain is typically felt as severe and deep in the midline, and it is often associated with referred pain in the left upper quadrant. It can also radiate to the back, reflecting the proximity of the pancreas to the underlying vertebral column. Further, peripancreatic inflammation can often track to different locations in the abdomen, causing pain in remote sites, including the lower abdomen or chest.

Liver Pain Liver pain results from acute stretching or distortion of the liver (Glisson capsule), which can be caused by inflammation, vascular engorgement, or rapidly expanding lesions under the surface. [39] Deep parenchymal lesions of the liver, including tumors, are typically painless, as are chronic processes such as simple fatty liver or chronic viral hepatitis.

Splenic Pain Splenic lesions cause pain only when the capsule is stretched. The usual causes of splenomegaly (hematologic disorders and malignant diseases, portal hypertension) develop slowly and are usually painless. More acute causes including trauma can, however, result in pain that is felt in the left upper quadrant.

Small Bowel Pain Small bowel pain can result from nonobstructing lesions such as inflammation, ulcers, or neoplasms. It is aggravated by food intake and is typically felt as a dull periumbilical or other midline discomfort; occasionally, it can be felt in either flank or in the back. [39] A more dramatic form of small bowel pain is intestinal colic, which reflects intense muscular activity usually proximal to an obstruction but also seen in patients with acute gastrointestinal infections. Ischemia, acute or chronic, can also cause small bowel pain, including the rare but classic “abdominal angina” seen with chronic obstructing vascular lesions of the intestine, resulting in avoidance of eating because of the aggravation of pain.

Large Bowel, Rectal, and Pelvic Pain The large bowel has dual nociceptive innervation. Pain afferents, through the hypogastric nerves, run with sympathetic nerves to the spinal cord at T10-L2; in addition, they course with parasympathetic pelvic nerves to spinal cord S2-S4. [39] Inflammatory or neoplastic lesions of the colon can cause pain, which can be similar to small bowel pain, particularly if it arises in proximal segments. Pain in the distal colon is felt in the lower abdomen, reflecting its anatomic origin. Again, unless referred pain sets in or the parietal peritoneum is involved, the pain is felt as dull and in the midline. Despite the origin of the word, colic is usually not a typical manifestation of obstructing lesions of the colon, because this organ is relatively fixed and is capable of dilating significantly. However, inflammatory or infectious lesions of the colon can give rise to what is often described by patients as “spasms”, which typically are associated with and are usually relieved (at least temporarily) by bowel movements. *Rectal lesions* can also cause the symptom of *tenesmus,* a term that signifies frequent and painful desire to evacuate the bowel that is often not successful or leaves the patient with a feeling of incomplete evacuation. In this regard, it is analogous to the urinary symptom of strangury. It usually signifies proctitis (idiopathic or infectious) but can also be caused by rectal cancers or occasionally thrombosed hemorrhoids. Another peculiar and incompletely understood rectal syndrome is that of *proctalgia fugax,* which is a transient, but often recurrent and usually severe ache in the rectal region that typically wakes the patient up at night. Pain arising in the lower abdomen may also arise in the pelvic organs; such pain is often difficult to distinguish from colonic pain unless it is accompanied by disturbances in menstruation or by dyspareunia (painful coitus). However, in many instances no obvious cause is found, and such patients present as much of a dilemma to gynecologists as they do to gastroenterologists.

Abdominal Wall Pain Pain arising primarily in the abdominal wall can result from a heterogeneous and poorly defined group of conditions whose description remains largely anecdotal (see Table 38-5). [47] The diagnosis is suggested when the pain is superficial, when it is localized to a small area that is usually significantly tender, when it is associated with dysesthesia in the involved region, and when Carnett’s sign (see earlier) is positive. If there is an obvious scar from previous surgery or injury, a diagnosis of entrapment neuropathy (with or without a “neuroma”) is often entertained. In the absence of a scar, the pain is postulated to arise from “myofascial trigger points” thought to represent abdominal cutaneous nerve entrapment resulting from a fibrous ring in the rectus muscle. [48] Other causes of such pain include epigastric hernias that typically occur in patients lifting heavy weights, possibly resulting in a tear in the linea alba in the midline. These hernias are associated with the protrusion of peritoneal fat (epiplocele) or abdominal wall fascia but rarely become large enough to permit entry of a hollow viscus. Although they have been associated with considerable pain, their prevalence and contribution to chronic abdominal wall syndromes are unclear. Spigelian hernias, between the external and internal oblique muscles, can also produce similar pain, but this is at the level of the arcuate line. “Trigger” point injection with local anesthetics is popularly regarded as a useful method to distinguish abdominal wall pain from that of visceral origin. [49] However, this can be misleading if the referred component of a visceral pain has dominated the clinical picture. Such a phenomenon may also account for some of the observed inaccuracy in the predictive value of the abdominal wall tenderness test. [50]

Rare and Obscure Causes of Abdominal Pain Rare causes of abdominal pain [51] (Table 38-6) include disorders that primarily affect visceral nerves rather than the organs themselves, such as acute intermittent porphyria, chronic poisoning with lead or arsenic, or diabetic radiculopathy. Women taking oral contraceptives may experience mysterious attacks of abdominal pain that can sometimes be related to mesenteric venous thrombosis.

TABLE 38-6 Rare or Obscure Causes of Abdominal Pain

Diagnostic Workup

Even though acute abdominal pain is traditionally equated with a surgical diagnosis, fewer than 5% of adults presenting with acute abdominal pain will require hospital admission, and even fewer will ever need surgery. [52] Indeed, in a substantial proportion of patients with acute abdominal pain, no definite abdominal disorder will be found to account for the symptoms. [53] Similarly, in the absence of obvious clinical or laboratory clues, it is relatively unusual to uncover a new pathophysiological basis for patients with chronic abdominal pain who have previously been seen by other physicians. [54] In the absence of specific indications, further diagnostic tests (e.g., endoscopic retrograde cholangiopancreatography) are rarely helpful in the patient with chronic abdominal pain lasting longer than 6 months. [55] Laparoscopy is often considered in such patients, particularly if a clinical suspicion of “adhesions” exists. However, adhesions are very common in women, even in the absence of prior surgery, [56], [57] and are found in equal proportion in patients complaining of pelvic pain and those with other complaints. [58] Laparoscopy for chronic pain for adhesions or other lesions therefore seldom leads to a specific diagnosis and even less often results in a change in management. [59]

If enough tests are done, there is a considerable statistical probability of uncovering some abnormalities. However, these abnormalities can be minor and of questionable relevance to the patient’s complaints (e.g., minimal changes in the secondary branches of the pancreatic duct). Before acting on these abnormalities, the prudent physician must carefully reevaluate the patient (Table 38-7) and consider the possibility that the patient may have functional bowel syndromes including the functional abdominal pain syndrome (FAPS).

Clinical Issues
Does the patient:
Have pain that has persisted for 3 months or longer?
- Despite appropriate interventions?
- In the absence of progressive diseases?

Have unrealistic expectations of
- Health care provider?
- Treatment offered?

Complain about previous health-care providers?
Have a history of substance abuse?
Display pain behaviors?
- Grimacing
- Rigid or guarded movement

Legal and Occupational Issues
Is litigation pending?
Is the patient receiving disability compensation?
Was the patient employed before the onset of the pain?
Is there a job to which the patient can return?
Does the patient have a history of frequent changes in occupation?

Psychosocial Issues
Do other family members also suffer from chronic pain?
Excessive depression or inappropriate moods present?
Major stressful event before onset of pain exacerbation?
- High levels of marital or family conflict?

History of childhood abuse or other sexual trauma?
Activities given up because of pain?
- Plans for renewed or increased activities if pain is reduced?

TABLE 38-7 Questions to Assess a Patient with Pain: Red Flags for Referral to Specialists in Functional Bowel Disease

FUNCTIONAL ABDOMINAL PAIN SYNDROME

It has become evident that patients whose chronic abdominal pain remains unexplained despite a careful evaluation share enough common features to warrant consideration of a distinct syndrome, the FAPS [60] (Table 38-8). The lack of association with physiological gastrointestinal events such as eating or defecation distinguishes it from other functional disorders such as IBS. FAPS is relatively uncommon, found in only about 2% of respondents, and appears to increase with age;

women account for more than two thirds of the patients. [61] Nevertheless, patients with FAPS are heavy users of medical resources and have high morbidity. [62]

At least 6 months of 1. Continuous or nearly continuous abdominal pain, 2. No or only occasional relationship of pain with physiological events (e.g., eating, defecation, or menses); and 3. Some loss of daily functioning; and 4. The pain is not feigned (e.g., malingering); and 5. Insufficient criteria for other functional gastrointestinal disorders that would explain the abdominal pain.

TABLE 38-8 Diagnostic Criteria for Functional Abdominal Pain Syndrome

Etiology and Pathophysiology

Psychological, social, and cultural factors play a major role in the presentation of these patients. Like those with other more "organic" forms of chronic pain such as pancreatitis or cancer, patients with FAPS frequently suffer from depression, anxiety, sleep disturbances, withdrawal, decreased activity, fatigue, loss of libido, and morbid preoccupation with the chronic pain. [63], [64] and [65] These patients are often functionally impaired at many levels including work, family, and social settings. [66] Unlike patients with other forms of chronic pain, however, many of these patients have experienced abdominal pain in childhood, and they often have relatives with past or present abdominal pain. [66] A history of previous physical or sexual abuse is very frequent, reported in up to one half of these patients in some series. [67] The onset of pain may also be associated with the death of a relative, spouse, or other important figure. [62]

Illness behavior may also be aberrant in these patients. Pain may serve many functions in these patients, including a means of atonement, derailment of success, and a morbid replacement for loss of relationships. Finally, it is possible that because of positive reinforcement, actions that mitigate pain, such as decreasing physical activity or the use of medications, will often continue even after the inciting event (e.g., the acute pain symptom) is resolved. At the same time, other behaviors (e.g., appearing uncomfortable and helpless, not reporting for work) may be reinforced by many of the outcomes that result from the gains the patient may feel he or she is obtaining. These gains may include increased or renewed attention and empathy from within the family structure, avoidance of the stresses associated with work and family responsibilities, and monetary compensation. Thus, in susceptible patients, a set of behaviors becomes established that contributes to the maintenance of chronic pain.

Although our understanding of FAPS is rudimentary at best, it is helpful to view the contribution of these factors in terms of the biopsychosocial paradigm discussed previously in this chapter. In this context, FAPS can be viewed as representing a dysfunction of perception, coping, or response strategies resulting in a patient who has clearly lost a sense of well-being to pain.

Clinical Features

Chronic abdominal pain may occur in bouts lasting from several hours to days or weeks, but even between severe exacerbations, there is residual pain, albeit not as severe or incapacitating. The abdominal pain is often described in vague terms, sometimes through unusual, idiosyncratic, or even bizarre language. [62] The lack of association with physiological events such as eating or defecation and the maintenance of weight also suggest FAPS. Although nocturnal pain is often assumed to be "organic," functional pain may also sometimes awaken patients from their sleep. [68] Pain in locations other than the abdomen is also common in these patients, as are various somatic complaints. [69], [70]

Physical examination provides many pointers to this diagnosis but is not itself conclusive. Suggestive clues include absence of the autonomic activation (e.g., tachycardia, diaphoresis), inconsistent tenderness, discrepancy between tenderness elicited with pressure from the stethoscope and that from the examining hand, clutching of the physician's arm during the examination, and the "closed eyes sign" (characterized by the patient's keeping his or her eyes closed, often with a fixed, beatific smile, during abdominal palpation). [71] Other clues at the time of the interview may provide insight into social impairments contributing to the clinical presentation. These include the constant presence of a spouse or parent who assumes responsibility as a mediator between the physician and the patient, suggesting family "enmeshment" that may be contributing to illness behavior.

Management

A gastrointestinal cause of the symptoms is rarely found through subsequent investigations (including surgical exploration) or follow-up visits in these patients. [70], [72] Yet, many physicians feel compelled to embark on an ever more invasive and expensive series of tests in hope of uncovering the magical but elusive explanation for the patient's symptoms. Such activity ("furor medicus" [73]), in fact, may be counterproductive because it reinforces the patient's conviction that there is something wrong to account for the pain that, if only found, could be successfully corrected. For this and other reasons, pain may become a central feature in the lives of these patients, leading to a "pain career." [62] Often, when a "cause" is discovered, it is not clear whether it is truly the source of the pain, an incidental finding or epiphenomenon, or a consequence of the treatment, often surgical, used in an attempt to treat the original complaint. [74] In most of these cases, the presumed cause of pain will have been diagnosed and treated, only to see the pain remain or a new type of pain to manifest itself elsewhere. Patients with chronic intractable abdominal pain are rarely substantially free of pain after one or more years of follow-up, [62] emphasizing the importance of focusing on adaptation to the pain rather than cure. Given our current state of knowledge about this syndrome, it is unrealistic to talk about a cure for FAPS. Palliation is therefore an appropriate goal, and, in most patients, it is achievable. In general, the therapeutic approach to FAPS is similar to the multifactorial approach to other forms of chronic pain described later, with greater emphasis on the psychosocial dimensions.

TREATMENT OF ABDOMINAL PAIN

Whenever possible, healing of the underlying tissue insult or injury provides the most satisfactory approach to the control of pain. In many patients with pain of suspected gastrointestinal origin, however, the underlying condition may not be reversible or even identifiable. Pain management then often becomes the primary therapeutic issue and requires familiarity with some general principles. In patients with acute pain, once the need for immediate surgical exploration is ruled out, attention is quickly turned toward effective pain relief, typically in the form of potent opiate drugs such as morphine (5 to 10 mg) or the equivalent dose of meperidine. Although analgesics are often withheld in patients with acute abdominal pain for fear of "masking" the diagnosis, this concern has not been validated by any scientific studies and probably dates to the era when high doses of morphine (30 mg or more) were used. [75] If ongoing pain relief is required over a period of several days, narcotics are best administered using patient-controlled devices. Although intermittent use of narcotics (either as needed or at fixed intervals) is commonly practiced, inadequate dosing or frequency can lead to unnecessary patient discomfort.

Patients with chronic abdominal pain present a far greater challenge. The multifactorial and complex nature of chronic pain has made it clear that no single set of drugs, skills, or techniques can address all the issues that affect the quality of life in most patients. Ideally, these different dimensions require a multidisciplinary approach, requiring the help, at various times or in parallel, of pain-management physicians (internists, anesthesiologists, neurologists, or neurosurgeons), clinical psychologists, nurses, and, often, vocational rehabilitation specialists and nutritionists. However, the disadvantage of such an approach, even when available, is that it may lead to fractionated care; this, in turn, can lead to poor compliance on the patient's part when faced with therapeutic aspects that may be initially difficult to accept. Therefore, it is important for the gastrointestinal physician to remain engaged as the patient's gatekeeper; this role also requires a broad understanding of the management of chronic pain. Such knowledge will facilitate appropriate referral to other specialists, promote a more meaningful interaction with them, and maintain a strong and supportive patient-physician relationship, instead of leading to feelings of abandonment and other negative attitudes. A critical factor in the success of this role is the establishment of a relationship with the patient over several visits, [76] while providing reassurance and empathy. A successful outcome, although still difficult, is almost impossible without such a relationship firmly in place. Because many patients may have chronic abdominal pain or functional bowel syndromes, it is very important for the practicing gastroenterologist to understand the interaction between psychosocial factors and disease in producing gastrointestinal symptoms and illness-related behavior. These aspects are discussed in greater detail in Chapter 29.

Pharmacological Management of Chronic Pain

Narcotic Analgesics Gastroenterologists are loath to use traditional nonsteroidal antiinflammatory drugs, for fear of inducing gastrointestinal side effects, as well as the general feeling that they are less effective in the treatment of chronic abdominal pain than in the relief of acute pain. [77] Indeed, when mild pain chronic pain necessitates analgesic use, these drugs are often bypassed in favor of the weak opioids, propoxyphene or codeine. However, neither of these drugs is particularly potent, although their efficacy be enhanced with the addition of acetaminophen. [78] More severe pain requires stronger analgesics such as morphine, methadone, or transdermal fentanyl. Opioids are thought to be more effective in nociceptive pain (see earlier) than in neuropathic pain, which may require considerably higher doses. Meperidine is generally believed to be the drug of choice for patients with pancreatitis because of its lesser tendency to cause sphincter of Oddi spasm; however, this has been shown to be true only at subanalgesic doses. [79], [80] Because meperidine is more likely to produce other side effects, it is seldom used for chronic pain management. Opioid analgesics share a common adverse effect profile in general: constipation, nausea, sedation, respiratory depression, and depression of gastrointestinal motility when used on a long-term basis ("narcotic bowel"). However, the problem most physicians fear is the potential for addiction. Nevertheless, in patients with diseases such as chronic pancreatitis, these drugs can and should be used judiciously, using fairly rigid guidelines or protocols for narcotic use (Table 38-9). Patient selection remains of paramount importance; the use of narcotics in patients with functional bowel pain is hardly ever a good idea.

1. The patient has a clear understanding that opioids are being used for a limited term in the first instance.
2. Only one practitioner takes responsibility for the opioid prescription.
3. Opioid prescription is contingent on certain agreed obligations or goals being met by the patient, such as return to work or alteration of inappropriate behaviors. This could take then form of a written contractual arrangement.
4. Unauthorized demands for emergency injectable opioids will not be tolerated, although some provision can be made for "rescue analgesia" for brief exacerbations of pain.
5. The patient understands that opioid dosage compliance will be checked at various random intervals, which may include drug screens and blood samples.
6. Physicians must be prepared to terminate the arrangement if the goals are not met or if there is evidence of misuse, even though this may lead to a confrontational meeting with the patient.

TABLE 38-9 Guidelines for Narcotic Use in Patients with Chronic Noncancer Pain

Antidepressants Tricyclic antidepressants (TCAs) have a proven track record in the management of chronic functional visceral pain. A metaanalysis of antidepressant treatment for functional gastrointestinal disorders concluded that these agents were quite effective, with an NNT of 3.2 (i.e., three patients needing treatment for one patient to experience symptom improvement) and a relatively large improvement in pain (about 0.9 standard deviations). [81] However, these drugs have not been fully embraced by either gastroenterologists or their patients. The latter often fear being stigmatized as having "mental" problems, a misperception that is perpetuated if a clear rationale for the use of these drugs is not presented by the prescribing physician. Effective analgesic doses of these drugs are significantly lower than those required to treat depression, and there is reasonable evidence to conclude that the beneficial effects of antidepressants on pain occur independently of changes in mood. However, in this regard, diminution of anxiety and restoration of mood and sleep patterns can be considered desirable. Most of these drugs act on the presynaptic pump, inhibiting the uptake of the neurotransmitters (principally serotonin and norepinephrine) and hence increasing their availability in the synaptic cleft. The principal mode of action is believed to result from modulation of central nervous system monoamine neurotransmitter levels, although a peripheral mechanism, possibly involving an opiate-like mechanism, may also contribute. [82] TCAs are well absorbed after oral administration, undergo extensive first-pass hepatic metabolism with long elimination half-lives (measured in days and weeks), and have active metabolites, some of which are also marketed as drugs. In addition to the putative analgesic effects on monoamine uptake, several of the older agents have anticholinergic (muscarinic) and antihistaminic (both H_1 and H_2) properties that contribute to their side-effect profile. Other serious side effects include cardiac conduction problems including a prolonged QT interval and dysrhythmia. Selective serotonin reuptake inhibitors (SSRIs), such as paroxetine, sertraline, and fluoxetine, which are currently the mainstay in the treatment of depression, have fewer side effects and have been advocated particularly for patients with functional constipation because these drugs can increase bowel movements and can even cause diarrhea. However, they have been less well evaluated in the management of pain than TCAs; at the present time, the somatic pain literature suggests that the efficacy of these agents for chronic pain is equivocal at best. [83] Newer antidepressants may hold more promise in this regard. [83] These include the serotonin and norepinephrine reuptake inhibitors such as venlafaxine, which inhibits the uptake of both norepinephrine and serotonin almost equally. Before antidepressants are prescribed, it is important to assess the psychological profile of the patient, because this may be important in determining the choice of therapy. If the patient is depressed, then it may be more appropriate to use full antidepressant doses of a drug that also has analgesic properties. This could be either a TCA with a low side effect profile or perhaps one of the newer agents discussed earlier (not an SSRI). If the patient is already taking an antidepressant, but this does not have proven analgesic activity (e.g., an SSRI), consideration should be given to switch to one that does. If the patient is not depressed, it is critical to spend some time explaining the scientific rationale for the use of antidepressants, with an attempt to separate the analgesic effects clearly from the antidepressant effects. The most appropriate agent to start with in this setting is one of the TCAs. A typical regimen would start with 25 mg of amitriptyline or nortriptyline (an even lower dose such as 10 mg may be considered in the elderly patient). This is given at night and will almost immediately begin helping with disturbed sleep pattern that often accompanies chronic pain. Daytime sedation may occur, but tolerance develops rapidly. Tolerance to the antimuscarinic effects may take longer, and it is important to advise the patients about this. In the absence of significant side effects, the dose of the antidepressant is gradually increased until adequate benefit is achieved or the upper limit of the recommended dose is reached. It is also important to tell the patient that the analgesic effect may take several days to weeks to develop and that, unlike conventional analgesics, the drug is not to be taken on an as-needed basis but on a fixed schedule. A trial of at least 4 to 6 weeks at a stable maximum dose is recommended before the drug is discontinued. If a particular TCA is clearly not found to be effective under these circumstances, one may consider switching to an antidepressant of another class, such as nefazodone, mirtazapine, or venlafaxine.

Other Neuropsychiatric and Miscellaneous Drugs Unlike the antidepressants, the use of neuroleptics (fluphenazine and haloperidol), antiepileptic drugs (phenytoin, carbamazepine, gabapentin, valproic acid, and clonazepam), clonidine (an a_2-adrenergic agonist), baclofen (a $GABA_B$ receptor agonist), and the NMDA receptor antagonists ketamine and dextromethorphan in chronic pain management is controversial, with equivocal evidence of efficacy and the lack of a clear biologic basis. [84], [85], [86], [87] and [88] Although the rationale for the use of these drugs is appealing (see the discussion earlier in this chapter), their use in gastrointestinal pain disorders is limited by gastroenterologists' lack of familiarity with these agents, inadequate or no controlled studies, and the side effects. Finally, mention must be made of the use of benzodiazepines, which are frequently prescribed for patients with chronic pain including insomnia, anxiety, and muscle spasm. Although these drugs are useful in these settings for short-term use, there is a significant risk of dependence on these drugs, and there is little if any evidence that they have any real analgesic effect.

Neural Blockade

Theoretically, interruption of the pain pathways should provide relief of pain that is peripheral in origin. This has led to the development of various techniques, both for diagnostic and therapeutic purposes. [89] However, interruption of the peripheral ends of the nociceptive nerves may not relieve pain if impulses continue to be generated at the proximal end, including the dorsal root ganglia. Further, if interruption of peripheral input is incomplete, altered spinal processing of nonnociceptive fiber input will continue to cause allodynic pain (see earlier). Even if interruption is complete, a component of central sensitization could be present in certain pain states that could result in continuous pain signaling despite the absence of peripheral input. Variability in these biologic factors, combined with inconsistencies in blockade techniques, may explain why, for instance, celiac plexus blocks may work for pain arising from pancreatic cancer but are generally ineffective in patients with chronic pancreatitis (see later).

Despite these limitations, it is clear that neurolytic techniques are valuable for certain subsets of patients, particularly those with cancer; celiac neurolysis may be effective in up to 85% of patients with pancreatic cancer pain and in about 70% of patients with pain from nonpancreatic cancers. [90] By contrast, use of these techniques to relive nonneoplastic pain, such as the pain of chronic pancreatitis, is not routinely recommended because of low efficacy (50% or less) and the short duration of relief (around 2 months) even in those patients who initially respond. [91]

Techniques of neurolysis vary considerably with respect to choice and concentration of agents (e.g., alcohol or phenol), method of injection (guided by plain radiography, fluoroscopy, computed tomography, or ultrasound). Endoscopic ultrasound has been used in patients with pancreatic cancer pain, with results that appear comparable to those of standard percutaneous techniques. [92] There appears to be little basis to favor one particular technique over another, and the choice of procedure should be individualized depending on local expertise and the patient's preference.

Local neural blockade has been used with good effect in some patients with chronic pain secondary to abdominal wall causes. [47], [93] Once a trigger point has been identified by digital examination, a small amount of lidocaine (1%) is injected at site of greatest tenderness elicited by the tip of the needle. Although the response may be short-lived, this can serve as a valuable therapeutic trial. Further, many patients obtain long-lasting relief after one or two injections alone. For patients whose relief is temporary, a 1:1 mixture of lidocaine and steroids (e.g., triamcinolone) can be used. More ablative chemicals (e.g., phenol) are best left to the anesthesiologist to

administer.

CHAPTER 39

William L. Hasler

APPROACH TO THE PATIENT WITH GAS AND BLOATING

NORMAL PHYSIOLOGY

The gastrointestinal tract of a normal human contains less than 200 mL of gas, whereas daily gas expulsion averages 600 to 700 mL. [1] On average, healthy men pass flatus 14 times per day, although as many as 25 daily expulsions are considered normal. Larger flatus volumes are passed after meals, but flatus production persists during sleep at a slower rate. [1] The principal gases in flatus are nitrogen, oxygen, carbon dioxide, hydrogen, and methane, and they show significant inter- and intraindividual variability (Fig. 39-1). [2] Most hydrogen production results from bacterial metabolism of ingested carbohydrates and endogenous glycoproteins from sloughed enterocytes. Methane also is produced in 40% of the population by the bacterial breakdown of carbohydrates. Carbon dioxide in flatus derives from fermentation of carbohydrates, fats, and proteins. Gases produced by colonic bacteria (hydrogen, methane, and carbon dioxide) represent 74% of flatus. Flatus odor correlates with hydrogen sulfide concentrations; other sulfur-containing gases in flatus include methanetriol and dimethylsulfide (see Fig. 39-1). [3] Another prominent metabolic pathway in the colon is the consumption of hydrogen to form acetate from carbon dioxide.

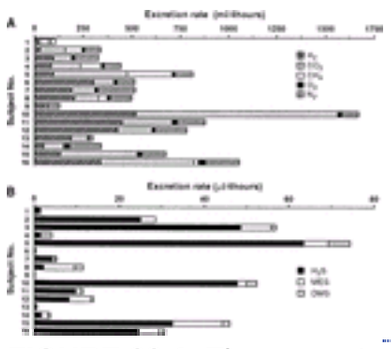

FIGURE 39-1. The amounts of major gases responsible for flatus volume (**A**) and odor (**B**) passed during a 4-hour period are shown for each of 16 healthy individuals. Quantitatively important gases include hydrogen (H_2), carbon dioxide (CO_2), methane (CH_4), oxygen (O_2), and nitrogen (N_2). Prominent sulfur-containing gases include hydrogen sulfide (H_2S), methanetriol (*MES*), and dimethylsulfide (*DMS*). (From ref. [2].)

Several factors modulate gas production by colonic bacteria. Age, gender, and the methane-producing capabilities of a given individual's flora do not significantly affect flatus frequency, although men produce more aromatic flatus than women. [4] Major shifts in the production of methane or a reduction of sulfates occurs spontaneously, indicating the inconstancy of bacterial flora populations. Variability in bacterial hydrogen production reflects changes in methane production or mixing of the stool within the colon. [5] Reductions in hydrogen production develop during daily lactose feeding in patients with lactase deficiency, indicating dietary modulation of the gut flora metabolic pathways. [6]

CLINICAL SYNDROMES

Gas in the gastrointestinal tract is responsible for several clinical phenomena. Eructation, or belching, is the retrograde expulsion of esophageal or gastric gas from the mouth. Involuntary belching after eating is caused by the release of swallowed air after gastric distention and may be exacerbated by foods that reduce lower esophageal sphincter tone. The *Magenblase syndrome* is defined as epigastric fullness and bloating relieved by belching. Manometric studies of eructation show decreases in lower esophageal sphincter tone followed by upper esophageal sphincter relaxation. [7] Flatulence is the volitional or involuntary release of gas from the anus. Manometric studies performed during flatulence demonstrate propagated colon contractions and increased rectal pressure coupled with early anal sphincter relaxation. [8] Bloating is the perception of retained excess gas within the gut lumen. Bloating is experienced monthly by 15.9% of individuals in the United States, whereas 21.8% experience abdominal pain or discomfort. [9] Women are more likely to experience bloating or distention than men (19.2 versus 10.5%). Although some conditions give rise to increased intestinal gas volumes, many patients with bloating exhibit normal amounts of gas within the gastrointestinal tract. [10] Other symptoms experienced by patients with complaints of excess gas include abdominal pain, halitosis, anorexia, early satiety, nausea, loud borborygmi, and constipation.

PATHOGENESIS

Gas and bloating are reported in a number of disorders. These gaseous symptoms may result from excess gas production, abnormal gas transit with generation of retarding motor patterns, and abnormal perception of normal amounts of gas within the gut.

Carbohydrate Maldigestion

Maldigestion and malabsorption of carbohydrates commonly are associated with intestinal gas production. Substances that cause gaseous symptoms include simple and complex carbohydrates and dietary fiber. Unabsorbed carbohydrates are propelled to the colon, where they serve as nutrient substrates for enteric bacteria. Unlike carbohydrate handling by mammalian tissues, bacterial carbohydrate metabolism liberates hydrogen gas and short-chain fatty acids. Flatulence is the initial symptom reported; borborygmi and bloating develop with greater degrees of malabsorption, and abdominal pain and diarrhea develop with the highest levels. Carbohydrate maldigestion and malabsorption may result from loss of enterocyte enzymes in normal intestinal mucosa, inability to transport a poorly absorbed sugar in an otherwise healthy individual, or an organic disorder of the intestinal mucosa, such as celiac disease.

Maldigestion and Malabsorption of Simple Sugars The most common carbohydrate maldigestion syndrome, lactose intolerance, results from insufficient levels of

enterocyte lactase, which hydrolyzes ingested lactose into glucose and galactose. Lactase deficiency is present in 21% of Caucasian Americans but is more prevalent in individuals of African (75%), Hispanic (51%), and Native American (79%) background. [11] Absence of intestinal lactase is rare, so that most individuals can tolerate small amounts of milk products. In individuals who consider themselves severely lactose intolerant, symptoms attributable to lactase deficiency are uncommon unless more than 240 mL of milk is ingested per day. [12] However, in most lactase-deficient individuals, symptoms develop after they ingest 1 L of milk or more. Other simple sugars also may lead to gas and bloating. Furthermore, nonabsorbable sugars such as lactulose accelerate small intestinal transit, further increasing gastrointestinal symptoms. [13] Increased gas production long has been recognized to result from the consumption of fruits or juices. Only 60% of fructose, a sugar in fruits and soft drinks, is absorbed in the normal human intestine. As little as 37.5 g of fructose can produce significant symptoms in some individuals (Fig. 39-2). [14] Sorbitol, a natural substance in fruits and an artificial sweetener in diet foods, is malabsorbed by 43% of Caucasians and 55% of nonwhites. [15] Severe sorbitol intolerance is reported in 32% of non-Caucasians versus 4% of Caucasians. Some subjects are susceptible to as little as 5 g of sorbitol, whereas nearly all develop severe symptoms with 20 g. [16] Consumption of chocolate containing isomalt produces greater increases in breath hydrogen than chocolate with sucrose, and xylitol also is malabsorbed to variable degrees. [17] In fact, 2% to 4% of sucrose is malabsorbed by healthy individuals, although most of this is salvaged in the colon. [18]

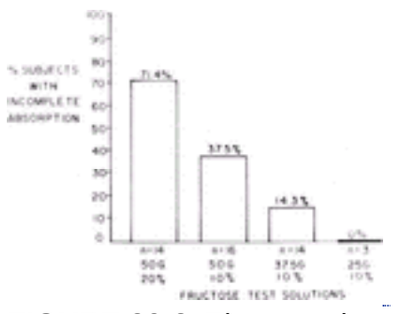

FIGURE 39-2. The prevalence of incomplete fructose absorption as a function of the ingested dose as defined by an increase in breath hydrogen to 20 parts per million or more. (From ref. [14].)

Finally, hereditary syndromes of intolerance of specific sugars are described. Sucrase-isomaltase deficiency is a rare condition presenting with symptoms of carbohydrate malabsorption after sucrose ingestion. Symptoms typically, but not always, begin in infancy. The disorder is inherited in autosomal recessive fashion and results from one of several defects in the sucrase-isomaltase gene. [19]

Maldigestion of Complex Carbohydrates and Fiber Ingested complex carbohydrates also may be poorly assimilated. The average amounts malabsorbed from 100-g meals are 20 g for baked beans, 7 to 10 g for wheat, oats, potatoes, and corn, and 0.9 g for rice (Fig. 39-3). [20] Comparisons of pH and concentrations of lactic and volatile fatty acids in cecal fluid and expelled feces indicate that most unabsorbed starch is metabolized in the colon. Whole grains produce five times more hydrogen than refined flours. There is no evidence that significant adaptation develops with respect to the volumes of gas expelled in persons habitually ingesting a diet rich in beans. Nondigestible oligosaccharides, such as stachyose, raffinose, and verbascose, are abundant in beans and legumes. Flour derived from soy beans low in these oligosaccharides produces less gas than flour derived from standard soybeans. [21]

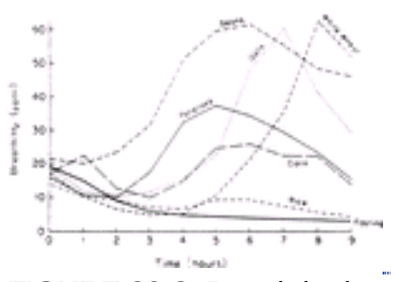

FIGURE 39-3. Breath hydrogen excretion patterns from healthy volunteers after ingestion of different complex carbohydrate-containing foods. Beans, oats, and wheat produce the greatest amount of gas, whereas rice provokes little hydrogen production. (From ref. [20].)

Fiber intake correlates with flatus production in many individuals, although some studies have found no association of gas and bloating with ingestion of psyllium or methylcellulose. [4] In one investigation, fiber-free diets reduced daily gas expulsion from 700 to 200 mL. [1] The intrinsic flora may contribute to bloating after fiber ingestion; individuals who produce low levels of methane experience more symptoms than those who produce high levels of methane. [22] However, incubation of bran with human feces produces only 10% as much hydrogen and carbon dioxide as incubation of lactulose. A clinical correlate of this laboratory finding is a report that fiber supplements increase feelings of bloating but not flatus frequency, whereas lactulose increases both. [23]

Small Intestinal Bacterial Overgrowth

The stomach and small intestine are relatively sterile compared to the colon. Small intestinal bacterial overgrowth complicates several obstructive disorders of the gut, including adhesions, Crohn's disease, radiation enteritis, ulcer disease, and malignancy. Small intestinal diverticula predispose to bacterial overgrowth as a consequence of lumenal stasis, whereas patients with vagotomy acquire intestinal colonization because of hypochlorhydria. The ability of proton pump inhibitors to induce symptomatic bacterial overgrowth is uncertain. Increased small intestinal bacterial counts are prevalent during treatment with omeprazole; however, symptoms commonly are not observed. [24] Patients with functional gut disorders, including intestinal pseudo-obstruction, exhibit overgrowth because of an impairment of gut clearance mechanisms. Such patients frequently show loss of the activity fronts of the migrating motor complex, the fasting pattern responsible for clearing undigested debris from the small intestine. Forty-three percent of cases of diabetic diarrhea are attributed to bacterial overgrowth, mostly from altered motor function. [25] Disorders that increase bacterial delivery to the upper gut, such as cologastric fistulae and coprophagia, may overwhelm normal defenses against infection. Reports suggest that a subset of patients with irritable bowel syndrome may have small intestinal bacterial overgrowth as a cause of symptoms. [26] In some of these individuals, antibiotics relieve gastrointestinal complaints. Finally, bacterial overgrowth is considered in the differential diagnosis of unexplained symptoms in the elderly. Abnormalities of intestinal motor function are believed to underlie development of the condition in older individuals.

Small bowel bacterial overgrowth is defined by the presence of more than 10 [5] colony-forming units per milliliter in intestinal fluid samples. The mean number of bacterial species infesting the upper intestine is 4.6 ± 0.8. The main organisms cultured are *Streptococcus, Escherichia coli, Lactobacillus,* and *Bacteroides*. [27] In addition to producing gas, bloating, diarrhea, abdominal discomfort, and nausea, bacterial overgrowth leads to nutrient malabsorption and weight loss. Other complications include the development of metabolic bone disease and an increased risk for spontaneous bacterial peritonitis in cirrhotic patients. [28]

Dysmotility Syndromes

Conditions that alter gut motor function may produce prominent gas and bloating. Bloating and fullness commonly are reported by individuals with gastroparesis resulting from gastric retention of solids, liquids, and gases. Patients with fat intolerance and rapid gastric emptying also have bloating. [29] Fundoplications for gastroesophageal reflux involve wrapping the gastric fundus around the lower esophagus, thus reducing the ability to belch or vomit. In the early postoperative period, up to 73% of patients experience bloating. [30] Two years later, this gas-bloat syndrome has abated in 71% of individuals. Preoperative delay in gastric emptying is a risk factor for gas-bloat syndrome. Patients with chronic intestinal pseudo-obstruction experience gas and bloating and exhibit small intestinal dilation because of delayed gas transit and small intestinal bacterial overgrowth. Causes of gastroparesis and intestinal pseudo-obstruction include diabetes mellitus, scleroderma, amyloidosis, familial conditions, paraneoplastic syndromes, and endocrine disease. Many cases are idiopathic in nature. Bloating also is reported by patients with chronic constipation.

Acute processes producing adynamic ileus also are associated with prominent gas and bloating. Ileus may involve the entire gut or may be localized, as in acute colonic pseudo-obstruction. Causes of acute ileus include systemic infection or inflammation, the postoperative state, medications, generalized or localized gut hypotension, metabolic disturbances, and cardiovascular disease.

Functional Bowel Disorders

Gas and bloating are prevalent complaints of patients with functional bowel disorders, such as irritable bowel syndrome (IBS) and functional dyspepsia. In one investigation of IBS, bloating was rated the most bothersome symptom by 60% of patients, whereas only 29% considered pain to be most intrusive. [31] Bloating was experienced on 28% of days in another study of IBS, whereas pain was reported on 33% of days. [32] Of the symptoms related by IBS patients, episodes of bloating and pain lasted the longest, on average 5 days. Among different IBS subtypes, patients with constipation-predominant IBS experience greater bloating than those with diarrhea.

The pathophysiology of gas and bloating in the functional bowel disorders is poorly understood. Some have attempted to ascribe these symptoms to anatomic causes. Early publications made reference to a splenic flexure syndrome with air trapping in that region. [33] More recent examinations of digitized computer images of radiographs have identified increases in gas bubbles in patients with functional disorders; however, gas amounts correlate poorly with symptoms. Computed tomography in IBS patients shows increases in lateral abdominal profiles, which have been attributed to changes in gut smooth muscle tone. [34] Others have postulated that the increased distention of IBS results from weak abdominal muscles, recent weight gain, a low position of the diaphragm, or exaggerated lumbar lordosis.

Abnormal fermentation has been proposed as a possible cause of gas and bloating in the functional bowel disorders. Different studies have reported variable responses to dietary exclusion of lactose, sorbitol, and fructose. [35] One study observed a poor correlation of breath hydrogen excretion with pain and bloating in patients with IBS, whereas another noted increased hydrogen production that was responsive to dietary exclusion of certain starches. [36] One group observed increased hydrogen and methane production after lactulose administration in patients with functional dyspepsia and *Helicobacter pylori* infection, suggesting potential pathogenic roles for bacterial populations outside the colon. [37]

Abnormal gastrointestinal motor and sensory functions likely play an important role in the pathogenesis of gas and bloating in IBS. The transit of radioactively labeled bran from the ileum to the colon is faster in IBS patients with bloating than in healthy volunteers. [38] In argon washout studies, patients with functional abdominal pain retain normal amounts of intestinal infused gas. [10] However, more gas refluxes from the small intestine into the stomach, indicating abnormal gas transit. An investigation of distal duodenal gas perfusion reported increased pain in IBS patients without alterations in small intestinal motility, suggesting a primary abnormality of visceral afferent function. [39] More recently, in a study using jejunal perfusion of gases physiologically similar to venous proportions, IBS patients exhibited abnormal gas retention with increases in abdominal distention and symptoms, whereas healthy volunteers tolerated large volumes of gas without retention or symptom development. [40]

Miscellaneous Causes

Most upper gastrointestinal air in healthy individuals accumulates as a result of aerophagia, which can be worsened by gum chewing, smoking, or oral irritation. During aerophagia, negative intrathoracic pressure pulls air into the esophagus across an open upper esophageal sphincter. Patients who have undergone laryngectomy experience gaseous symptoms as a consequence of swallowing air to facilitate esophageal speech. Patients with ulcer disease, gastroesophageal reflux, or biliary colic exhibit aerophagia and chronically belch in an effort to reduce their symptoms. Intestinal obstruction may produce bloating, although other symptoms usually are present. Endocrinopathies such as hypothyroidism may result in gaseousness as part of a broader symptom presentation. Patients with inferior myocardial infarction can experience excess eructation. [41] Finally, medications (anticholinergics, opiates, calcium channel antagonists, antidepressants) produce gas through effects on gut motility.

EVALUATION OF THE PATIENT

History and Physical Examination

Patients with excess gas may report symptoms consistent with functional disease but that also can result from a structural abnormality. Thus, the clinician must search for clues that suggest an organic cause. Relief of symptoms with defecation or flatus is consistent with IBS, as is the absence of symptoms that awaken the patient from deep sleep. In contrast, vomiting, fever, weight loss, nocturnal diarrhea, rectal bleeding, or steatorrhea indicates probable organic disease. Conditions that predispose to small intestinal bacterial overgrowth should be determined by history. The use of medications that delay gut transit should be questioned. Assessment of ethnic background and family history can determine the risk for carbohydrate maldigestion syndromes, such as lactase deficiency. Finally, a history of anxiety or other psychiatric disease raises the possibility of aerophagia or a functional bowel disorder.

A dietary history may correlate symptoms with specific foods. Ingestion of legumes, fruits, unrefined starches, and lactose-containing foodstuffs should be addressed. The clinician should ascertain if soft drinks containing fructose or diet foods and gums containing sorbitol are being consumed. Activities that involve excess swallowing, such as gum chewing, smoking, and chewing tobacco, predispose to aerophagia.

The physical examination findings usually are normal in patients with excess gas, but anxiety, hyperventilation, and air swallowing may be evident as an initial impression. Findings suggestive of organic disease include sclerodactyly with scleroderma, dermatitis herpetiformis in celiac disease, peripheral or autonomic neuropathy with dysmotility syndromes, and cachexia, jaundice, or palpable masses with malignant obstruction. Abdominal inspection may reveal scars from prior fundoplication, vagotomy, or other operations that can cause adhesions. Auscultation assesses for absent bowel sounds with ileus or myopathic dysmotility, high-pitched bowel sounds with intestinal obstruction, or a succussion splash in gastric obstruction or gastroparesis. Abdominal percussion and palpation may reveal tympany and distention in the patient with mechanical obstruction or intestinal dysmotility. The presence of shifting dullness or a fluid wave indicates ascites rather than excess intestinal gas. A rectal examination is performed to exclude occult fecal blood, which would suggest lumenal inflammation or neoplasm.

In general, patients with gas and bloating do not experience serious sequelae of their condition. However, in some patients with complete mechanical intestinal obstruction or toxic megacolon secondary to inflammatory colitis, lumenal perforation may develop and can be life-threatening. Patients with acute colonic pseudo-obstruction are at risk for perforation secondary to thinning of the cecal wall. Rarely, pneumatosis cystoides intestinalis develops in patients with excess hydrogen-producing bacteria in the small intestine. [42] Other complications of organic disease occur rarely and generally are manifestations of the underlying disease rather than of the gas itself. Case reports have appeared of explosions resulting from ignition by tobacco smoking of feculent gas expelled by eructation in patients with gastrointestinal obstruction and bacterial overgrowth. [43] Colonic explosions infrequently have been reported in patients undergoing colonoscopy with mucosal cautery. These rare complications result from inadequate bowel cleaning or the use of mannitol or sorbitol purging solutions, which generate hydrogen and methane to concentrations approaching 30% to 45%. [44]

Laboratory and Structural Testing

Screening laboratory tests assist the clinician in excluding organic disease. The determination of a normal complete blood cell count, electrolyte, glucose, albumin, and total protein levels, and sedimentation rate excludes most inflammatory or neoplastic conditions. In some individuals, a determination of calcium and phosphate levels, parameters of renal and thyroid function, liver chemistries, and fasting morning cortisol levels may be needed. Amylase may be elevated in patients with ischemic gut segments. Patients with diarrhea should collect stools for ova and parasites to rule out giardiasis. Endomysial or tissue transglutaminase antibody levels can be used to screen for celiac disease. [45] If these are positive, the diagnosis is confirmed by intestinal mucosal biopsy. Other serologies of value in selected patients include antinuclear antibodies and scleroderma antibodies to evaluate for possible rheumatologic disease, and antinuclear neuronal antibodies to screen for paraneoplastic visceral neuropathy. [46]

Imaging techniques may be needed to test for disorders that produce mechanical obstruction or functional gas retention. Flat and upright abdominal radiographs may reveal diffuse distention consistent with ileus or pseudo-obstruction, diffuse haziness in ascites, or air-fluid levels in the patient with intestinal obstruction. Distinguishing ileus from obstruction may not be accomplished by plain radiography alone. Contrast enema radiography can detect colonic or distal small intestinal obstruction. Small intestinal contrast radiography can evaluate for partial gastric outlet or small intestinal obstruction. Upper or lower gastrointestinal endoscopy facilitates the identification and biopsy of lesions producing partial blockage. Small bowel barium studies also can crudely quantify intestinal transit and assess motor patterns in patients with possible chronic intestinal pseudo-obstruction. If the index of suspicion for partial obstruction is high, enteroclysis may provide a more detailed assessment of small intestinal lumenal processes. [47] With this technique, the proximal intestine is intubated under fluoroscopic guidance, and barium and

methylcellulose are perfused to provide a double contrast image. Ultrasonography or computed tomography can provide useful information regarding the causes of gaseous distention and exclude processes such as ascites, which may be misinterpreted as abdominal gas.

Functional Testing

When the results of structural testing are unrevealing, tests of gut function may provide insight into the cause of gas and bloating. Techniques are available to quantify gut transit, assess carbohydrate absorption, and measure flatus production.

Tests of Gut Motor Function In suspected gastrointestinal dysmotility, gastric-emptying scanning or gastrointestinal manometry may be considered. Scintigraphic measures of the emptying of liquid (^{111}In-DTPA [diethylenetriamine pentaacetic acid] in water) or solid (^{99m}Tc-sulfur colloid in eggs) radionuclides are the most commonly performed tests of gastric emptying. Scintigraphy also has been used to assess rates of small intestinal or colonic transit. [48] Alternatively, radiopaque marker techniques are easily performed to diagnose slow transit constipation. [49] In chronic intestinal pseudo-obstruction, small intestinal manometry provides information about the neuropathic or myopathic nature of the condition. Pseudo-obstruction resulting from enteric nerve dysfunction, as in the familial visceral neuropathies or early scleroderma, produces intense, uncoordinated bursts of motor activity with loss of normal migrating motor complex (MMC) and fed motor activity. [50] Smooth muscle dysfunction, as in the familial visceral myopathies or late scleroderma, produces low-amplitude contractions. Intermittent bursts separated by periods of motor quiescence, a pattern known as the *minute rhythm,* has been observed in patients with small intestinal obstruction, although similar patterns are seen in neuropathic pseudo-obstruction and IBS. [51] Manometry does not provide precise characterization of the underlying pathology in some cases. Thus, a full-thickness intestinal biopsy specimen obtained surgically may be required to document degeneration of nerve or muscle layers.

Breath Testing Hydrogen breath testing may be used to confirm carbohydrate maldigestion or malabsorption as a cause of gas and bloating. This technique relies on the ability of lumenal bacteria to produce hydrogen during the metabolism of ingested substrates and the inability of human tissue to utilize similar metabolic pathways. Expired breath samples commonly are obtained before and for 2 hours after the ingestion of an aqueous solution of the sugar that is presumed to be malabsorbed or maldigested. Proper breath holding followed by immediate exhalation reduces the variability in hydrogen levels from 28% to 10%. [52] Increases in breath hydrogen by more than 20 parts per million within 120 minutes of lactose ingestion distinguishes biopsy-proven lactase deficiency from lactase sufficiency with a sensitivity of 90%. [53] Hydrogen excretion after lactose ingestion correlates well with ymptoms of carbohydrate maldigestion, whereas lactose tolerance testing with measurement of plasma glucose concentrations shows a poor correlation. [54] Hydrogen measurement may have to be extended to 10 hours if testing for maldigestion of complex carbohydrates such as starch is being performed. Even for lactose, some have proposed extending hydrogen measurements to 5 to 7 hours to increase the sensitivity and specificity of the test. [55] Children with sucrose intolerance may be tested for sucrase-isomaltase deficiency with sucrose hydrogen breath testing. Some patients may be tested for fructose or sorbitol malabsorption with hydrogen breath testing, although normal values for these tests are less well defined. Hydrogen breath testing also has been used to test for small intestinal bacterial overgrowth. Elevations in fasting breath hydrogen or early rises within 30 minutes after substrate ingestion suggest overgrowth. The most commonly used sugar for breath hydrogen testing in suspected bacterial overgrowth is glucose, which provides diagnostic sensitivities and specificities of 60% to 90%. Others have proposed using lactulose or rice as substrates, but one study reported only 17% to 33% sensitivity for detecting bacterial overgrowth by these methods. [56] False-negative results of breath tests occur in patients with few hydrogen-producing bacteria, whereas false-positive results occur with rapid transit of the ingested carbohydrate to the colon. Other centers have relied on ^{14}C- or ^{13}C-labeled substrates, with measurement of breath ^{14}C-carbon dioxide or ^{13}C-carbon dioxide, although special facilities are necessary for these analyses. A comparison of glucose hydrogen breath testing and ^{14}C-xylose breath testing noted superior sensitivity for the hydrogen measurements in the detection of bacterial overgrowth. [57] When the diagnosis is in doubt, the gold standard remains quantitative culture of duodenal or jejunal secretions. [58] Bacterial counts above 10 ^{5} colony-forming units per milliliter are diagnostic of bacterial overgrowth. Finally, hydrogen breath testing has been used to quantify orocecal transit in suspected chronic intestinal pseudo-obstruction. Unabsorbed substrates such as lactulose are used for this purpose. The transit time is measured from ingestion until an increase in breath hydrogen, representing the onset of colonic bacterial metabolism, is observed (Fig. 39-4). This method has significant limitations. It often is difficult to determine when the increase in hydrogen production ensues. Furthermore, lactulose itself accelerates small intestinal transit. [59] Finally, erroneous values are obtained in patients with small intestinal bacterial overgrowth.

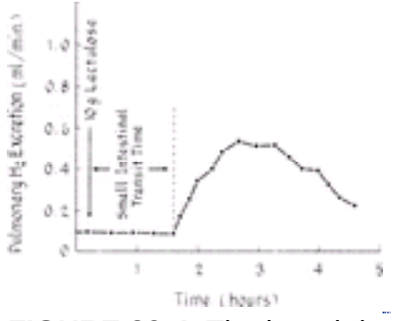

FIGURE 39-4. The breath hydrogen excretion profile for a healthy volunteer after ingestion of 10 g of lactulose. The short intestinal transit time is quantified by the time required to detect an increase in expired hydrogen. (From ref. [13].)

Flatus Analysis In some research institutions, flatus analysis is performed to gain insight into the processes responsible for excess flatulence. Testing consists of counting the number of flatus passages over 24 hours to determine if increased flatulence is present (normal, <20 daily). [60] The expelled gas is then analyzed to determine if it is rich in nitrogen, indicating aerophagia, or gases such as carbon dioxide, hydrogen, and methane, suggesting increased colonic production. Such scrutiny has been used to direct the treatment of patients with severe flatulence. [60]

PRINCIPLES OF MANAGEMENT

The management of the patient with gas and bloating depends on the cause of the symptoms. Structural abnormalities such as mechanical obstruction may require surgery. Patients with excess eructation from gastroesophageal reflux can derive benefit from acid-suppressive medications. For other causes of gaseous symptoms, several recommendations can be made, including dietary modifications and the prescription of nonmedication and medication therapies.

Dietary and Nonmedication Therapy

Dietary measures may reduce gas and bloating in selected patients. Elimination of lactose may produce improvements in individuals with lactase deficiency. Most lactase-deficient persons tolerate small amounts of lactose (0.5–7 g), indicating residual lactase activity. [61] When consumed in yogurt with active cultures, lactose may be better tolerated because of the presence of bacterial ß-galactosidase. Hydrogen production from yogurt is only one third of that from milk. [62] The pasteurization of yogurt reduces its lactase activity, increasing breath hydrogen concentrations by 39%. However, pasteurized yogurt containing up to 20 g of lactose is tolerated by lactase-deficient individuals, suggesting that some of the benefits of yogurt stem from factors other than its enzymatic capabilities. Fermented milk products containing *Lactobacillus acidophilus, Bifidobacterium* species, and *Lactobacillus bulgophilus,* developed to increase lactase levels, reduce bloating in patients with lactose intolerance. [63] Children with sucrase-isomaltase deficiency also benefit from dietary modifications with elimination of sucrose. In some individuals, sucrose can slowly be reintroduced into the diet because the colon possesses some capacity for fermentation of the sugar.

Many IBS patients are postulated to have symptoms resulting from carbohydrate intolerance. The efficacy of lactose restriction in IBS patients with lactase deficiency is unimpressive, with only a subset experiencing symptom benefits. [64] Similarly, 40% of patients experience symptom relief after exclusion of fructose and sorbitol. [35] This value is similar to responses to placebo in controlled trials of IBS; thus, it is uncertain whether the result is clinically significant. Others have proposed the initiation of low-gas diets that exclude many complex carbohydrates. [65] This diet has been reported to reduce flatus frequencies by 50% in some patients (Table 39-1). [66]

VISCEROSENSORY SYMPTOM (N = 443)	INDICATED BY PATIENT, % (No.)	SINGLE MOST BOTHERSOME SYMPTOM, % (No.)
Extra-abdominal symptoms		
Pain behind chest bone	14 (61)	3 (11)
Pressure behind chest bone	11 (52)	3 (13)
Nausea	49 (229)	3 (15)
Bloating symptoms		
Sensation of gas	76 (357)	22 (98)
Sensation of bloating	66 (308)	5 (24)
Sensation of fullness	56 (253)	17 (75)
Bloating with distention of the belly	58 (262)	16 (73)
Incomplete evacuation		
Sensation of fullness in the rectum after a bowel movement	32 (143)	3 (15)
Abdominal pain		
Belly pain	60 (227)	29 (129)

Note: The prevalence of visceral sensory symptoms and the single most bothersome symptom during the past 2 weeks according to the patient are shown.

From ref. 50.

TABLE 39-1 Prevalence of Symptoms in Irritable Bowel Syndrome

In some instances, the foods themselves may be modified to decrease their propensity to produce gas. Soaking cowpeas and yam beans for 12 hours and cooking for 30 minutes eliminates most malabsorbed oligosaccharides, reducing raffinose from between 0.71% and 6.86% to between 0.04% and 0.40%, and stachyose from between 2.38% and 4.14% to between 0.12% and 0.72%. [67] Gamma irradiation to levels used for insect disinfestation (0.25–0.75 kGy) also reduces raffinose in mung beans. [68]

Lifestyle changes and other nonmedication treatments are offered to selected individuals. Many cases of excess eructation stem from aerophagia, which can be controlled by cessation of gum chewing and smoking. The chronic belcher may benefit from observation in a mirror to emphasize the role of air swallowing. Gas-trapping undergarments have been proposed for individuals with excessive malodorous flatus. The best-characterized device consists of an airtight Mylar brief with a charcoal-lined cushion and has been reported to absorb more than 90% of offensive gases (Fig. 39-5). [3]

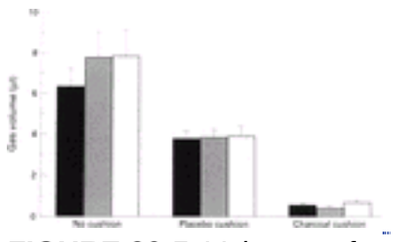

FIGURE 39-5. Volumes of sulfur-containing gases escaping into the surrounding environment when gas was instilled at the anus in the presence of an activated charcoal cushion, a placebo cushion, and no cushion. Values are shown for hydrogen sulfide (*black bars*), methanetriol (*shaded bars*), and dimethylsulfide (*white bars*). (From ref. [3].)

Medication Therapy

A number of medications have been proposed to treat gas and bloating. However, few controlled trials have confirmed their efficacy versus placebo. Thus, many recommendations regarding their utility are based on studies in healthy individuals or are grounded in the anecdotal experience of clinicians who care for these patients.

Enzyme Preparations Enzyme preparations are advocated to facilitate the breakdown of food residues incompletely digested by intrinsic enzymes in patients with gas and bloating. The best-characterized exogenous enzymes are the ß-galactosidase (lactase) preparations used for lactose intolerance. In adults, lactase supplements reduce hydrogen excretion and bloating, cramps, and flatulence after the ingestion of lactose. [69] Similarly, in lactose-intolerant children, lactase tablets reduce hydrogen levels after a lactose challenge from 60 to 7 parts per million, with corresponding reductions in pain, bloating, diarrhea, and flatulence. [70] Small studies have reported differential efficacy of different lactase preparations, but this finding must be confirmed in larger trials. [71] Other enzyme compounds are used to prevent gaseous symptoms. Hydrogen production and bloating and cramping decrease when children with sucrase-isomaltase deficiency are given sacrosidase, a liquid derived from *Saccharomyces cerevisiae* that contains 6000 IU of sucrase activity per milligram of protein. [72] Bacterial a-galactosidase derived from *Aspergillus niger* (Beano) reduces flatulence in healthy volunteers who consume meatless chili rich in oligosaccharides. [73] However, most indigestible fiber does not contain galactose; thus, this agent is less likely to produce benefit in patients with gas from causes other than a legume-rich diet. Encapsulated pancreatic enzymes reduce bloating, gas, and fullness after high-calorie, high-fat meals in healthy individuals without reducing breath hydrogen or methane. [74] However, studies of pancreatic supplements have not been performed in patients with gas and bloating to test if they have broader utility.

Adsorbents and Agents to Decrease Surface Tension Some agents are proposed to reduce distention by a defoaming action or by direct adsorption of excess gas. Simethicone promotes rupture and liquid drainage from thick foam films. One study reported decreases in breath hydrogen in healthy subjects who received simethicone; however, a second study observed no reduction in hydrogen with simethicone in a randomized, double-blinded trial. [75] Simethicone reduced symptoms to a greater degree than cisapride in an investigation of patients with functional dyspepsia. [76] Another study reported superior relief of gas-related abdominal discomfort in patients with diarrhea given the combination of loperamide and simethicone in comparison with either agent alone. [77] Activated charcoal has been used to treat both the volume of gas produced and its odor. Charcoal reduced flatulence and breath hydrogen after the consumption of gas-producing meals in one study. [78] In a second controlled investigation, charcoal decreased bloating, cramps, and hydrogen after lactulose in separate populations in the United States and India. [79] However, another study showed no reductions in hydrogen or flatulence with charcoal after the ingestion of baked beans. Similarly, the effects of activated charcoal on flatus odor are uncertain. In dogs, charcoal reduces fecal hydrogen sulfide production. [80] Ingestion of charcoal in combination with *Yucca schidigera* and zinc acetate reduces the number of flatulence episodes with bad odor by 86%. However, an investigation in humans did not observe any effect of charcoal on sulfur-containing gases responsible for flatus malodor. [81] Bismuth compounds also have been promoted to reduce flatus volume and odor. Tripotassium dicitrate bismuth, bismuth subsalicylate, and bismuth subnitrate inhibit in vitro fermentation of lactose-enriched feces. Studies of flatulent patients observed a reduced fermentation of raffinose with chronic bismuth subsalicylate therapy. Furthermore, fecal homogenates from individuals on bismuth subsalicylate for 3 to 7 days showed impaired hydrogen sulfide release, suggesting a role for this agent in controlling flatus odor. [82]

Antibiotics Antibiotics provide benefit to patients with small intestinal bacterial overgrowth. Elderly patients treated for bacterial overgrowth exhibit increases in weight and body mass index. Several inexpensive antibiotics reduce symptoms of bacterial overgrowth, including tetracycline and metronidazole. In patients with systemic sclerosis, ciprofloxacin produced superior symptom control versus trimethoprim. [83] In a second study, amoxicillin-clavulanic acid and cefoxitin effectively treated more than 90% of strains responsible for small intestinal bacterial overgrowth. [27] A third investigation observed 70% reductions in breath hydrogen after norfloxacin. [84] More recently, researchers have focused on nonabsorbable antibiotics that are bacteriocidal without entering the systemic circulation. In separate studies, rifamaxin produced greater reductions in hydrogen excretion and symptoms than activated charcoal and chlortetracycline. [85] Antibiotics have been proposed as primary therapy for IBS. The importance of endogenous flora in IBS is suggested by the evaluation of a population followed after antibiotic treatment for *H pylori* infection. [86] In persons treated with antibiotics, IBS developed less frequently than in those who did not receive antibiotics. In a poorly controlled follow-up of IBS patients with purported bacterial overgrowth, antibiotics produced symptom relief in 48%. [26] A more recent controlled trial of IBS patients with positive hydrogen breath test results after lactulose observed benefits in 50% of individuals after a 10-day course of neomycin, versus 17% with placebo. [87]

Prokinetic Medications Drugs that stimulate gut propulsion theoretically should benefit patients with gas and bloating secondary to gastrointestinal dysmotility. In addition to reducing nausea and vomiting, metoclopramide decreases fullness and bloating in patients with diabetic gastroparesis. Similarly, the peripheral dopamine receptor antagonist domperidone relieves bloating as well as nausea and heartburn in Parkinson's disease patients with delayed gastric emptying. [88] The recently withdrawn serotonin 5-HT $_4$ receptor agonist cisapride decreases eructation in patients with gastroesophageal reflux. Likewise, some but not all placebo-controlled studies report reduced bloating in functional dyspepsia patients treated with cisapride. In one investigation, this improvement was restricted to patients with normal

rather than delayed gastric emptying. [89] In contrast to its therapeutic efficacy in gastric dysmotility, metoclopramide provides no benefit to patients with postoperative ileus. [90] Other prokinetics may selectively target the small intestine and colon. Cisapride was shown to accelerate orocecal transit and eliminate bacterial colonization in cirrhotic patients with bacterial overgrowth. In studies of IBS patients, cisapride produced no significant reductions in bloating or flatulence, although one investigation reported relief of distention. [91] The somatostatin analog octreotide reduces breath hydrogen after glucose in scleroderma patients with intestinal pseudo-obstruction and bacterial overgrowth. [92] When administered over 20 to 33 weeks, the combination of the motilin receptor agonist erythromycin and octreotide decreased symptoms in patients with chronic intestinal pseudo-obstruction. [93] The 5-HT $_4$ receptor agonist tegaserod accelerates small intestinal and ascending colon transit in patients with constipation-predominant IBS. [94] Investigations with tegaserod in constipated IBS patients report at least temporary reductions in bloating associated with the syndrome. [95]

Probiotics and Alternative Therapies The aim of probiotic therapy is to replace pathogenic colonic organisms with ingested innocuous strains. Probiotics also may have additional mechanisms of action. *Lactobacillus plantarum* increases fecal carboxylic acid and decreases blood fibrinogen levels; the importance of these effects is unknown. [96] *Lactobacillus casei* strain GG reduces bloating, diarrhea, and taste disturbances associated with antibiotic therapy of *H pylori* infection. However, in IBS patients with bloating, *Lactobacillus* GG did not reduce abdominal pain, fecal urgency, or bloating, although it did promote a trend to improved fecal consistency in patients with diarrhea. [97] A second study observed significant reductions in flatulence but not bloating during 4 weeks of treatment with *L plantarum,* which was associated with decreased fecal enterococci in comparison with placebo treatment. [98] Although these reports suggest possible benefits of microbial therapy, probiotics should be considered experimental until larger double-blinded trials are performed to confirm their efficacy. Other alternative therapies have been proposed for gas and bloating. Hypnotherapy reduces bloating and flatulence and improves quality of life in IBS patients and has been described as treatment for intractable eructation. [99] In an open trial, acupuncture relieved bloating and improved general well-being in a small group of patients with IBS. The addition of auricular plaster therapy to acupuncture at the Zusanli point promoted faster recovery of normal peristalsis in patients with postoperative ileus than in a control group. [100]

Surgical Management

Operative therapies for gas and bloating usually are considered only for patients with the most refractory cases of severe organic disease. Percutaneous endoscopic gastrostomy is effective in selected cases of gas-bloat syndrome after fundoplication. [101] Excision of small intestinal diverticula reduced symptoms and vitamin B_{12} malabsorption in a patient with small intestinal bacterial overgrowth. Selected patients with localized intestinal pseudo-obstruction may benefit from resection of the dysfunctional bowel segment. Patients with more extensive intestinal pseudo-obstruction may experience symptom relief after a venting jejunostomy. [102] Similarly, some patients with acute colonic pseudo-obstruction may require surgical or radiographic insertion of a decompressing cecostomy to prevent rupture of the organ. Finally, some individuals with advanced pseudo-obstruction require surgical or radiographic placement of indwelling central venous catheters for home total parenteral nutrition.

CHAPTER 40

Michael W. Mulholland and John F. Sweeney

APPROACH TO THE PATIENT WITH ACUTE ABDOMEN

The term *acute abdomen* describes a syndrome of sudden abdominal pain with accompanying symptoms and signs that focus attention on the abdominal region. It is clinically useful to limit discussion to cases in which the pain has been present for less than 24 hours. Associated symptoms such as nausea, vomiting, constipation, diarrhea, anorexia, abdominal distention, and fever are often present and sometimes confuse the overall clinical picture. Although operative therapy is not required for all cases of acute abdomen, unwarranted operative delay can have serious, potentially fatal consequences. Successful management of affected patients is based on the following: a careful initial assessment, incorporating history taking and physical examination; delineation of clinical priorities; and concurrent resuscitation, diagnosis, and therapy. The most common causes of the acute abdomen are listed in Table 40-1 and Table 40-2.

Gastrointestinal	
Appendicitis	
Perforated peptic ulcer	
Intestinal obstruction	
Intestinal perforation	
Intestinal ischemia	
Colonic diverticulitis	
Meckel diverticulitis	
Inflammatory bowel disease	
Pancreatic, Biliary, Hepatic, and Splenic	
Acute pancreatitis	
Acute cholecystitis	
Hepatic abscess	
Ruptured or hemorrhagic hepatic tumor	
Acute hepatitis	
Acute cholangitis	
Splenic rupture	
Urologic	
Ureteral stone	
Pyelonephritis	
Retroperitoneal	
Aortic aneurysm	
Retroperitoneal hemorrhage	
Gynecologic

TABLE 40-2 Extra-abdominal Causes of Acute Abdomen

NEUROANATOMY OF ABDOMINAL PAIN

Nerve fibers that mediate painful visceral stimuli have cell bodies in dorsal root ganglia. Processes of first-order sensory neurons pass through spinal nerves to white rami communicantes and then to sympathetic ganglia, which parallel the spinal cord. Nerve processes then travel from sympathetic ganglia through the splanchnic nerves to reach intra-abdominal splanchnic ganglia. The splanchnic ganglia are concentrations of nervous tissue surrounding the origins of the celiac, superior mesenteric, and inferior mesenteric arteries. Sensory nerve fibers traverse splanchnic ganglia without synapse and accompany blood vessels to reach their target organs. Second-order neurons transmit afferent impulses centrally through the lateral spinothalamic tract on the side opposite to the dorsal root containing the nerve cell body. Neurons in the lateral spinothalamic tract project to the thalamus, where they synapse with tertiary neurons mediating sensory and discriminatory aspects of pain. Tertiary neurons project to the somatosensory cortex. Some secondary neurons in the lateral spinothalamic tract synapse in the brainstem with neurons

projecting to the limbic system. Almost all nerve fibers that transmit painful sensations travel in association with sympathetic nerves. As a result, although 80% to 90% of vagal fibers are afferent, interruption of parasympathetic innervation by vagotomy does not block abdominal pain.

During normal embryological development, abdominal organs receive bilateral sympathetic innervation, with input to each organ originating from several adjacent spinal levels. As a result, visceral pain is sensed as a midline, poorly localized sensation. The location of the pain is determined by the developmental origin of the affected organ (Fig. 40-1). Visceral pain originating from organs derived from the foregut is sensed in the epigastrium. Foregut structures include the stomach, liver, biliary system, pancreas, spleen, and duodenum. Pain from midgut structures usually is experienced in a periumbilical distribution, whereas organs derived from the hindgut project painful sensations to the hypogastrium and lower midline. The embryonic midgut develops into the jejunum, ileum, appendix, and colon to the level of the midtransverse colon. Hindgut structures include the distal transverse, splenic flexure, descending, and sigmoid portions of the colon.

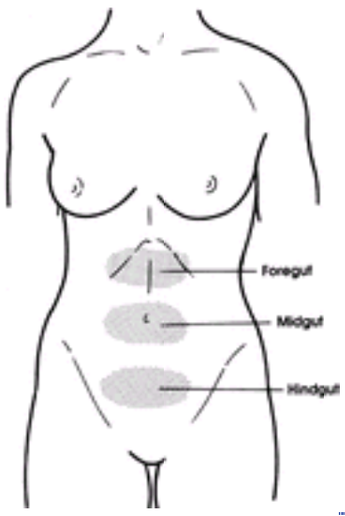

FIGURE 40-1. Distribution of visceral pain perception based on embryological origin of diseased organ.

Neuronal pathways that conduct visceral abdominal pain are composed of slowly conducting C-type fibers. Nociceptive fibers may be stimulated by distention, forceful muscular contraction, mesenteric traction or torsion, or certain noxious chemicals. In hollow organs, such as the small intestine, sensory fibers are found within the muscular wall. In solid organs, such as the liver, nociceptive fibers are limited to the capsule of the organ. For this reason, mass lesions of the liver parenchyma usually do not cause pain until increasing size causes stretching of the Glisson capsule or traction on the organ.

The peritoneum provides a continuous layer over the inner surface of the abdominal wall, reflecting onto the intraperitoneal viscera. Although visceral and parietal peritoneal surfaces have a common mesenchymal derivation, their patterns of innervation are entirely different. The visceral peritoneum is supplied by C-type nociceptive fibers, which transmit painful visceral sensations as outlined earlier. The parietal peritoneum is supplied by rapidly conducting A-type nerve fibers. A-type nerve fibers have small receptive fields and produce sharp, well-localized, highly discriminated sensations. The parietal peritoneum is somatically innervated in a unilateral dermatomal distribution. Somatic peritoneal nerves transmit painful impulses in response to changes in temperature or pH and in response to pressure or incision. Somatic pain caused by stimulation of the parietal peritoneum usually is perceived as intense and constant.

Physiological properties of the peritoneum, including particulate and microbial absorption and circulation of intraperitoneal fluid, may affect perception of noxious stimuli. The peritoneal cavity is the largest extravascular space in the body, with an estimated surface area of 1.7 m^2 in adults. Although the entire peritoneal surface can participate in water and low-molecular-weight solute exchange, removal of particulate matter occurs only along the undersurface of the diaphragm. In this area, specialized lymphatic vessels are present beneath the mesothelial layer covering the diaphragmatic surface. Large pores, or *lacunae,* serve as channels for passage of peritoneal particulate matter up to 10 µm into the lymphatic circulation. Negative intrathoracic pressure during inspiration draws fluid into the lymphatic channels; valves in thoracic lymphatic channels prevent reflux during expiration.

The removal of fluid by means of diaphragmatic lymphatics causes movement of fluid within the peritoneal cavity. Experimentally, injection of contrast material into the right iliac fossa is followed by accumulation of contrast in the right paracolic region, in both subhepatic spaces, and in the pelvis. [1] The patterns of intraperitoneal circulation correspond to movement of contaminated material after rupture of an abdominal viscus and to subsequent abscess formation. Because the parietal peritoneum is sensitive to chemical irritants, movement of fluid may cause pain to be sensed in an area distinct from the site of the disorder. As an example, perforated duodenal ulcer may cause pain in the right lower quadrant as a result of movement of gastric contents along the right paracolic gutter.

A distinctive feature of visceral abdominal discomfort is its association with pain perceived at an extra-abdominal site unrelated to the injured organ. This phenomenon, called *referred pain,* is associated with intra-abdominal or retroperitoneal pathology and usually is described as a dull ache near the body surface. In general, referred pain is sensed in a cutaneous area that has its somatic innervation derived from the same spinal segments that supply visceral afferents to the diseased organ. Patterns of referred pain are often stereotypical enough to be diagnostically useful. Gallbladder inflammation frequently is associated with pain referred to the right scapula. Subdiaphragmatic inflammation causes pain referred to the area supplied by cervical dermatomes 3, 4, or 5. Pain from pancreatic disease may be sensed in the posterior midline in the region of the first lumbar vertebra (Fig. 40-2).

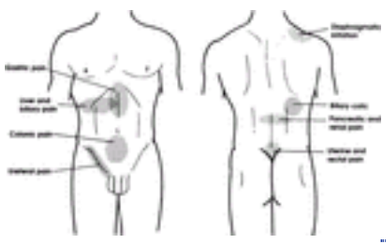

FIGURE 40-2. Common patterns of referred pain in patients with acute abdominal processes. (From Mulholland MW, Debas HT. Approach to the patient with acute abdomen. In: Kelley WN, ed. Textbook of internal medicine, 3rd ed. Philadelphia: Lippincott–Raven, 1997:620.)

ASSOCIATED GASTROINTESTINAL SYMPTOMS

Visceral abdominal pain is distressing, yet difficult for patients to describe. As a result, patients and physicians may focus on associated gastrointestinal symptoms that almost invariably accompany acute visceral pain.

Anorexia accompanies almost all acute abdominal processes but is not specific to any pathological process. Anorexia is usually present in cases of acute appendicitis, and its absence should place that diagnosis in question. Anorexia is also common in the initial phases of acute cholecystitis. The symptom is found less frequently with urologic or gynecologic causes of acute abdominal pain.

Emesis occurs as a result of reflex stimulation of the medullary vomiting center in the initial phases of acute abdominal processes. Reflex vomiting is not progressive and does not relieve unpleasant symptoms. In contrast, vomiting resulting from mechanical intestinal obstruction is recurrent and progressive. Vomiting caused by intestinal obstruction may cause intravascular volume depletion and prerenal azotemia. Bacterial proliferation proximal to the obstruction causes the vomitus to

become feculent.

Abdominal distention associated with acute abdominal pain usually signifies accumulation of swallowed gas in the bowel as a result of mechanical obstruction or ileus. Fluid secreted into the bowel lumen proximal to a mechanical obstruction also may contribute to abdominal distention. Mechanical obstruction may be associated with hyperactive or high-pitched bowel sounds, but the auscultatory finding of diminished bowel sounds is not a reliable sign differentiating ileus from mechanical obstruction. A truly silent abdomen in the presence of distention and tenderness is an ominous sign of bowel necrosis and peritonitis.

Constipation may be a sign of previous health habits (e.g., diet), a disease process (e.g., diverticulitis), or the development of a complication (e.g., perforation). The cessation of intestinal movements or flatus coinciding with the development of acute abdominal pain is more properly referred to as *obstipation.* Obstipation is associated with both mechanical obstruction and functional ileus.

Watery diarrhea associated with acute abdominal pain suggests acute gastroenteritis or infectious colitis. Bloody diarrhea in the context of the acute abdomen may be associated with exacerbation of chronic inflammatory bowel disease, with mesenteric ischemia, or occasionally with mesenteric venous thrombosis.

HISTORY

Treatment for patients with acute abdominal processes differs fundamentally from care delivered to patients with long-term complaints. The potential for pathological processes to be rapidly progressive, and for serious adverse consequences to result from therapeutic delay, places a time constraint on diagnosis and treatment. An accurate diagnosis should lead promptly to specific therapy. A complete and accurate history and physical examination are the most important requirements for success.

The treating physician first should focus on the nature and timing of the abdominal pain. The pattern of onset and the progression of pain provide valuable clues to cause. The pain associated with perforation of a duodenal ulcer or rupture of an abdominal aortic aneurysm is incapacitating, begins suddenly, and quickly reaches peak intensity. Because the onset of pain is so dramatic, affected patients may be able to provide detailed information about the time of onset or their activities at that moment. In contrast, pain associated with appendicitis increases over a period of 1 to several hours. Similarly, pain caused by acute cholecystitis increases over hours before reaching a steady intensity. The duration of painful symptoms is equally important. Biliary colic typically lasts for several hours before rapidly resolving, presumably as a result of the offending stone's dislodging from the cystic duct. Pain caused by acute pancreatitis is unrelenting. Initially, patients with mechanical small bowel obstruction may feel remarkably well between episodes of intense and debilitating colic.

Prior symptoms may implicate preexisting disease. A history of epigastric pain relieved by food may indicate prior duodenal ulceration, whereas previous biliary colic is common in patients presenting acutely with cholecystitis or pancreatitis. Previous abdominal operations influence both the occurrence and the manifestations of acute abdominal processes. Adhesions resulting from previous intraperitoneal operation are the most frequent cause of mechanical obstruction of the small intestine. Patients who have undergone hysterectomy, appendectomy, or pelvic colonic resection are at greatest risk of adhesive obstruction.

PHYSICAL EXAMINATION

The physical examination should be conducted in a systematic and unhurried manner. A complete abdominal examination requires unhindered visualization of the area between the nipples and the midthigh, anteriorly and posteriorly. The examination should begin with observation of the patient's expression and behavior. A patient with serious intraperitoneal disease usually has an anxious, pale face. Sweating, dilated pupils, and shallow breathing are common. In the presence of chemical or bacterial contamination of the peritoneum, the patient tends to lie immobile, to minimize movement of inflamed viscera against the parietal peritoneum. Knees may be flexed, the abdomen scaphoid, breathing shallow. Inhaling deeply or coughing aggravates the pain. With ureteral colic or mesenteric ischemia, by contrast, the patient may appear restless, with frequent changes in posture in an attempt to relieve discomfort. During inspection, the location of all surgical scars, masses, external hernias, and stomas should be determined.

Auscultation should precede abdominal palpation. All four quadrants should be auscultated for tone and quantity of bowel sounds and the presence of vascular bruits. Bowel sounds are considered absent only if no tones are heard over a 2-minute period of auscultation.

Next, the abdomen should be palpated. To determine areas of tenderness and the vigor with which palpation may be pursued, it is useful first to ask the patient to demonstrate the point of maximal discomfort. Palpation should begin in the abdominal quadrant farthest from the area of suspected disease. Gentle pressure to elicit tenderness and muscular resistance then ensues. Progressively deeper palpation is attempted to delineate masses. Intentional efforts to reproduce abdominal pain by deep palpation and rapid release of pressure, termed *rebound tenderness,* are not helpful and should not be attempted. Production of rebound tenderness provides no information that is not available through gentle examination, causes the patient to guard voluntarily, and eliminates the possibility of meaningful serial abdominal examinations. The best evidence of a localized inflammatory process is demonstration of *point tenderness,* caused by the movement of parietal peritoneum against the inflamed surface of a diseased viscus. Point tenderness should be sought by palpation in the area of maximal discomfort but also may be elicited by grasping the patient's hips and gently rocking the pelvis; the movement of inflamed peritoneum is presumed to cause pain. The stethoscope also may be used to palpate the abdominal quadrants.

Every patient must undergo a digital rectal examination. If an inflamed appendix lies deep within the pelvis, point tenderness sometimes may be elicited only by palpation through the right rectal wall. Stool should be tested for guaiac positivity. In females, manual and speculum vaginal examinations are required; vaginal secretions should be obtained for Gram stain and culture. All external stomas, wounds, and fistulae should be explored digitally.

CONFOUNDING FACTORS

Female Gender

Virtually all series of surgically treated patients with acute abdominal pain report that diagnostic inaccuracy is greatest in young women. [2] Detailed sexual and menstrual histories are crucial; a pregnancy test is mandatory in every female patient of childbearing age who is evaluated with acute abdominal pain. Gynecologic causes of acute abdominal pain include ectopic pregnancy, ruptured or twisted ovarian cyst, acute salpingitis, and tuboovarian abscess. On pelvic examination, ectopic pregnancy may present as a tender, unilateral, adnexal mass. Inflammatory disease of the fallopian tubes and uterus produces physical findings of local cervical tenderness, bilateral pelvic pain with displacement of the cervix, adnexal mass, or cervical discharge. All secretions from the cervical os should be submitted for aerobic and anaerobic cultures. Fluid within the pouch of Douglas can be aspirated and examined for blood or bacteria. When the distinction between acute appendicitis and salpingitis is difficult, pelvic ultrasound can be diagnostic. [3] The pelvic organs and appendix also may be observed laparoscopically, with laparoscopic appendectomy as a therapeutic option.

Pregnancy

The most common cause of the acute abdomen in pregnancy is acute appendicitis, occurring in 1 of 6000 pregnancies. [4] Diagnosis of acute abdominal pain in pregnancy is complicated because uterine enlargement displaces organs from their normal anatomic positions. For example, the appendix is moved progressively from the right lower quadrant toward the right upper quadrant (Fig. 40-3). As a consequence, point tenderness associated with appendicitis is sensed in a position more cephalad than usual. In addition, the appendix is moved away from the abdominal wall by the uterus, so parietal peritoneal irritation may be absent. Pregnant women should be evaluated as aggressively as nonpregnant patients; although therapy may be more cumbersome in pregnancy, the indications for operation are usually unchanged. Operative delay that permits progression of acute appendicitis to appendiceal perforation often is followed by premature labor. [5] In one study, three fetal deaths (43%) occurred among seven premature deliveries. [4] In the same series, no fetal or maternal mortality was noted in a group managed without appendiceal perforation. The best guarantee for a living, healthy baby is a healthy mother.

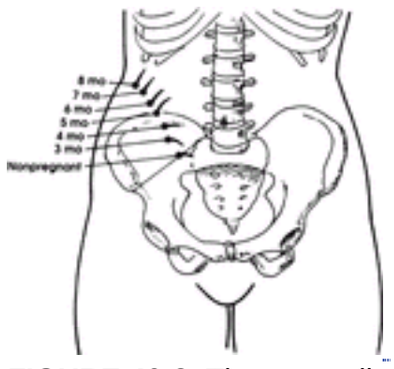

FIGURE 40-3. The appendix is displaced upward and to the right by the uterus during pregnancy. Movement of the appendix during pregnancy may cause the pain of acute appendicitis to be sensed in an atypical position.

Age

The diagnosis of acute abdominal pain is most difficult at the two extremes of age. Communication is limited in infants, and the temporal progression of symptoms may be impossible to elicit. The abdominal wall in infants is not well developed muscularly, and guarding in response to underlying inflammatory processes is diminished. Because fever and leukocytosis are common accompaniments of many childhood illnesses, their diagnostic usefulness is reduced. In contrast, fever and elevated leukocyte counts are much less common in elderly patients, even in the presence of advanced disease. Physical signs of intraperitoneal inflammation likewise are diminished in older patients.

Immunosuppression

Patients who are immunosuppressed may not exhibit appropriate clinical responses to acute intraperitoneal inflammatory processes. Included in this category are patients with the acquired immunodeficiency syndrome, patients receiving long-term corticosteroid therapy, and those undergoing chemotherapy. At special risk are recipients of solid organ transplants. The physical signs of peritonitis (e.g., pain, muscular guarding, rebound) may not be apparent, and fever is often absent. Intraperitoneal infection may progress to septic shock as the first manifestation of disease. Leukocytosis is usually present but decreased; a shift to immature leukocyte forms is apparent. Early use of radiologic evaluation, especially computed tomography (CT), is appropriate.

A syndrome of diffuse abdominal pain, fever, and diarrhea has been reported in patients with severe neutropenia (<100 neutrophils/mL). Patients with acute leukemia or aplastic anemia and those undergoing bone marrow transplantation are at greatest risk. The pathological entity termed *neutropenic colitis* is characterized by diffuse mucosal ulceration, invasive infection with enteric microorganisms, and sepsis. [6] The ascending colon is the intestinal segment most often affected, although the other portions of the colon and the terminal ileum also may demonstrate ulceration. Cecal edema may be demonstrated by CT. Operation is indicated if perforation is suspected, but recovery correlates more closely with rebound of neutrophil counts than with surgical treatment.

Recent Laparotomy

Acute abdominal processes are difficult to evaluate after recent laparotomy. Abdominal pain is universally present but much decreased if laparoscopic techniques were used. Leukocytosis is common in the early postoperative period. Numerous sources for fever exist, including pulmonary atelectasis, urinary infection, phlebitis, and infection in the surgical incision. In evaluating abdominal pain in the postoperative period, it is important to consider the signs and symptoms in relation to the time after operation. Uncomplicated recovery should be accompanied by a steady progression: lessening abdominal pain, resolving biochemical abnormalities, predictable recovery from ileus, and increasing mobility. Failure to achieve this progress warrants investigation. The most common causes of abdominal sepsis after operation relate to inadequacies of surgical technique, such as anastomotic dehiscence. Acute acalculous cholecystitis also may occur in the postoperative setting.

CAUSES OF ACUTE ABDOMEN IN ADULTS

Appendicitis

Acute appendicitis is the most common cause of the acute abdomen in the United States and should be included in the differential diagnosis for every patient presenting with acute abdominal pain. About 250,000 appendectomies are performed in the United States annually, with 2000 deaths resulting from complications of the disease. [7] One in 15 persons develops appendicitis during his or her lifetime.

Appendicitis develops as a result of obstruction of the appendiceal lumen by fecalith or appendiceal calculus or by hyperplasia of submucosal lymphatic tissue. In the initial stages, the pathogenesis of appendicitis resembles that of bowel obstruction. Typically, the first symptom is upper midline or periumbilical pain. Discomfort develops over 1 to several hours and is followed by anorexia, nausea, and vomiting. If the appendiceal lumen remains occluded, inflammatory changes, initially confined to the appendiceal mucosa, become transmural. Contact of the inflamed serosal surface of the appendix with the parietal peritoneum is associated with a change in the pain pattern: a shift to the right lower quadrant. The usual presentation of midline abdominal pain moving to the right lower quadrant is seen less frequently in older patients, in whom diffuse pain and nonlocalized tenderness are more common. Early diagnosis is also more difficult in children, and, as a consequence, perforation and infectious complications are more frequent. [8]

Approximately 2% to 3% of patients with appendicitis have an abdominal mass at initial evaluation. [9] The mass, formed by inflamed omentum and adherent loops of intestine, signifies the development of a phlegmon or an abscess secondary to appendiceal perforation. Perforation also should be suspected if the patient has been symptomatic for more than 24 hours, if the temperature exceeds 38°C, or if the leukocyte count is greater than 15,000 cells/mL.

Abnormal gas patterns on abdominal radiograph, including right lower quadrant ileus or diffuse small bowel air-fluid levels, are present in 62% of patients with uncomplicated appendicitis, in 71% of those with periappendiceal phlegmon, and in 97% of those with gangrenous appendicitis or perforation. [7] An appendicolith is visible on abdominal flat plate in 7%. Pneumoperitoneum is distinctly uncommon, present in less than 1% of cases.

Appendicitis is a clinical diagnosis, supported by carefully selected laboratory and radiologic studies. Patients with compatible historical features and physical examinations do not need additional diagnostic studies, and immediate surgical exploration is appropriate. Ancillary tests are reserved for atypical or equivocal presentations.

Abdominal sonography may be helpful in patients in whom the clinical features of appendicitis are ambiguous. [10] The technique depends on graded compression of the abdomen with the ultrasonographic transducer to displace gas-filled loops of bowel. The appendix is visualized in the shape of a round target with the anechoic lumen surrounded by a hypoechoic and thickened (>2 mm) appendiceal wall. For nonperforated appendicitis, ultrasonography has been reported to have a diagnostic accuracy of 93%, with a negative predictive value of 97%, in selected series. [11], [12] Muscular rigidity accompanying perforated appendicitis prevents adequate abdominal compression and significantly reduces ultrasonographic accuracy. Low diagnostic sensitivity in this group is less important, however, because the need for surgical management is usually clinically obvious. CT scanning is a reliable method for differentiating periappendiceal phlegmon from abscess, and it may be useful in nonoperative management of periappendiceal mass. [13], [14] and [15] CT has a 97% sensitivity and a 91% specificity for acute appendicitis associated with mass. [13] CT may also provide useful information on a broad spectrum of diseases that may mimic appendicitis. [16]

Patients presenting with acute appendicitis not complicated by abdominal mass should undergo emergency appendectomy. The overall perioperative mortality rate among patients with appendicitis is about 0.5%. Although fewer than 0.2% of patients with nonperforated appendicitis die, the mortality rate rises tenfold with the occurrence of perforation. Mortality is clearly related to age, with the highest mortality rates occurring in patients aged more than 50 years. Overall mortality rate is less than 1% for patients less than 50 years of age, 4.5% for those 51 to 70 years of age, and 20% or greater for patients aged 71 to 90 years. [17]

Septic complications occur with increased frequency in the presence of perforation. The wound infection rate is 1.8% when a noninflamed appendix is removed, increasing to 8.5% for inflamed appendices, and 17% with appendiceal perforation. [18] Pelvic abscess occurs in about 15% of patients after resection of a perforated

appendix.

In 10% to 20% of patients explored for presumed appendicitis, a normal appendix is discovered at laparotomy. A literature review of 13,848 cases showed a linear correlation between the rate of appendiceal rupture and diagnostic accuracy. [19] As diagnostic accuracy increases, so does the rate of perforation. If operation is used earlier, diagnostic accuracy decreases, as does the rate of perforation. A negative appendectomy rate of 10% to 15% is widely considered a reasonable compromise. In 30% of cases in which the appendix is not inflamed, a different, specific cause of abdominal pain is identified. Mesenteric lymphadenitis, Meckel diverticulitis, cecal diverticulitis, pelvic inflammatory disease, ectopic pregnancy, and ileitis lead a long list of diseases that can mimic appendicitis.

An appendiceal mass or abscess may be treated by both operative and nonoperative means. [13], [19], [20] Early operative intervention is not favored by most surgeons treating appendiceal abscesses or phlegmons. Initial treatment should include ultrasonographic or CT evaluation, percutaneous drainage of periappendiceal fluid collections, and antibiotics. [21] With resolution of periappendiceal inflammation, elective interval appendectomy is performed. Interval appendectomy is associated with a 0.2% mortality rate and a major complication rate of only 1.2%. [22] Laparoscopic approaches for appendectomy have been developed, adapted to children and adults, and widely disseminated. [23], [24] and [25] The advantages of laparoscopic treatment of appendicitis relative to open appendectomy are not as clear-cut as the advantages of laparoscopy in the treatment of gallstone disease. Laparoscopic appendectomy is associated with a longer operative time, a small reduction in hospital stay, and an earlier return to normal activities. Wound complications are slightly more frequent after laparoscopic appendectomy. Laparoscopic appendectomy is more expensive than open treatment. [26], [27]

Perforated Duodenal Ulcer

Although hospitalization rates for peptic ulceration have declined since 1970, the overall rate of duodenal ulcer perforation has not decreased. Furthermore, the introduction of newer antisecretory drugs has not affected rates of perforation. In two thirds of affected patients, perforation is the first manifestation of duodenal ulcer disease. Whereas the overall rate of peptic ulcer perforation has not decreased, the patient profile has changed, with affected patients being increasingly elderly. Currently, 63% of patients are more than 60 years old, and 44% are older than 70 years. [28], [29] Elderly patients, who more frequently have coexisting medical illnesses, also have higher morbidity and mortality rates.

The patient usually experiences sudden, severe epigastric pain, followed by diffuse abdominal pain. Somatic pain is caused by chemical irritation of the peritoneum by acidic gastric contents. Subphrenic collection of gastric content is associated with right scapular radiation of pain. Respiration worsens symptoms; the patient typically seeks to minimize movement. Physical examination reveals a quiet abdomen with marked muscular rigidity and epigastric tenderness. If perforation has occurred within less than 24 hours, low-grade fever and tachycardia are often present, but hypotension is unusual. Laboratory examinations reveal leukocytosis; mild hyperamylasemia is attributed to resorption of duodenal contents from the peritoneal cavity. Upright abdominal films demonstrate pneumoperitoneum in 80% of cases (Fig. 40-4). If pneumoperitoneum is absent, water-soluble contrast examination may be used to demonstrate perforation.

FIGURE 40-4. Pneumoperitoneum accompanying perforated duodenal ulcer. Upright radiographs from two patients reveal (**A**) minimal pneumoperitoneum (*arrows*) and (**B**) massive pneumoperitoneum.

The empty, acid-secreting human stomach contains 102 to 103 organisms, with lactobacilli and aerobic streptococci predominating. Because the initial bacterial inoculum is low, septic consequences associated with duodenal perforation are closely related to the length of time that elapses before definitive treatment. [30] Peritoneal fluid samples obtained within 6 to 12 hours of perforation are culture positive in fewer than 50% of cases; by 24 hours, more than two thirds are positive. After 24 hours, coliform species predominate.

Nonoperative management of documented duodenal ulcer is justified only in unusual circumstances. Operative treatment of perforated duodenal ulcer has four goals: patient safety, peritoneal debridement, closure of the perforation, and alteration of the ulcer diathesis so the risk of recurrent ulceration is minimized. Risk factors that predict operative mortality include serious concurrent medical illness, preoperative shock, and long-standing perforation (i.e., longer than 48 hours). [31] If these factors are absent, definitive ulcer operations may be performed with predictably low mortality and acceptable morbidity. In the presence of one or more risk factors, simple omental patch closure is an expedient and safer alternative to definitive ulcer surgery. [32] The long-term prognosis for patients with perforated acute ulcers is similar to that for patients with perforated chronic ulcers at follow-up of 5 to 6 years. [33] Minimally invasive techniques for treatment of duodenal perforation have been developed. [34], [35]

Laparoscopic omental patch closure may be combined with postoperative anti- *Helicobacter* therapy. This treatment plan assumes that secure closure of the perforation can be obtained and that most ulcers are caused by *H pylori.* Initial results are promising. Minimally invasive approaches to perforation are likely to become standard practice for the future. [36]

Obstruction of the Small Intestine

Obstruction of the small intestine accounts for about 5% of acute surgical hospitalizations; despite significant advances in anesthetic and surgical techniques, the mortality rate still ranges from 3% to 7%. In the United States, 70% to 80% of cases of small bowel obstruction result from postoperative adhesions. In one fourth of cases, adhesive obstruction is preceded by a gynecologic operation, and in another fourth, obstruction follows total or segmental colectomy. After adhesions, in decreasing order of incidence, primary or metastatic carcinoma, external hernias, regional enteritis, and internal hernias are causes of small bowel obstruction. Less common conditions include previous abdominal or pelvic radiation, intussusception, endometriosis, volvulus, and congenital abnormalities.

Intestinal colic is the cardinal symptom of obstruction of the small intestine. Initially, periods of crampy pain centered in the midabdomen may be interspersed with relatively pain-free intervals. If intestinal distention is unrelieved, pain becomes unrelenting. Vomiting is progressive. Bacterial overgrowth in the obstructed segment causes the nature of the vomitus to change with time, becoming feculent. Complete small intestine obstruction is associated with obstipation, although gas and stool distal to the point of obstruction may continue to pass for a short interval after initial symptoms.

The most important diagnostic consideration with these patients is to differentiate partial from complete obstruction. Evaluation begins with plain abdominal radiographs. Complete obstruction is characterized by dilated loops of small intestine with air-fluid levels and no visible gas within the colon (Fig. 40-5). Patients with partial obstruction usually show clear evidence of gas in the colon above the peritoneal reflection in addition to dilated loops of small intestine.

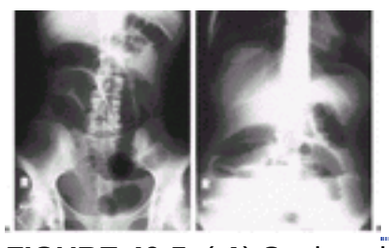

FIGURE 40-5. (**A**) Supine abdominal radiograph of a patient with small bowel obstruction demonstrates dilated loops of small intestine. (**B**) Upright radiograph of

same patient demonstrates air-fluid levels in obstructed segments of the small intestine.

If the diagnosis of complete small intestinal obstruction is unequivocal, additional radiologic studies to demonstrate the site of obstruction or the nature of the obstructive process are neither appropriate nor necessary in most patients. Barium contrast radiography is useful to clarify the diagnosis in patients with atypical symptoms or nondiagnostic plain abdominal films, to differentiate paralytic ileus from mechanical obstruction, and to evaluate selected subsets of patients in whom nonoperative management would be desirable. [37] The last group includes patients with multiple laparotomies for adhesive obstruction, those suffering obstruction in the immediate postoperative period, patients with known intraperitoneal carcinomatosis, patients who have undergone extensive abdominal radiation therapy, and those with Crohn's disease. CT is rapidly displacing traditional contrast radiography in evaluation of small bowel obstruction. [38] CT scanning reveals a point of transition between dilated bowel proximal to the obstruction and collapsed distal bowel. Associated findings, such as tumor masses or hernia defects, may be visualized and may provide additional diagnostic information not available by contrast radiography.

If initial diagnostic studies indicate partial small intestine obstruction, nonoperative management consisting of nasogastric decompression and intravenous hydration is appropriate. Seventy-five percent of patients treated in this manner have clinical and radiographic improvement within 24 hours. An additional 15% respond within 48 hours. Failure to achieve clinical improvement by 48 hours is an indication for operative treatment. There is no evidence that long intestinal tubes are more effective than standard nasogastric tubes in achieving intestinal decompression.

In contrast to partial obstruction, complete small intestine obstruction is an indication for emergency laparotomy because of the risk associated with the development of intestinal strangulation. [39] The presence of intestinal necrosis triples operative mortality rates and increases the incidence of serious postoperative complications fivefold to tenfold. In patients with complete obstruction of the small intestine, preoperative diagnosis of strangulation cannot be made or excluded by any currently available radiologic test, clinical parameter, or combination of parameters or by experienced clinical judgment. In one prospective evaluation, preoperative clinical indices and judgments of senior attending surgeons were assessed in 51 consecutive patients about to undergo laparotomy for complete small bowel obstruction. [40] The signs usually considered diagnostic—continuous abdominal pain, fever, peritoneal irritation, leukocytosis, and acidosis—were not sensitive, specific, or predictive for strangulation. Senior surgeons, aware of all preoperative data, correctly predicted strangulation in only 10 of 21 affected patients (48% sensitivity). Nonoperative treatment of complete small intestine obstruction entails a calculated risk (30%) of delayed definitive treatment of intestinal ischemia. [40]

Resuscitation before operative intervention should focus on the following: correction of hypoxemia caused by respiratory restriction secondary to abdominal distention; replacement of intravascular volume deficits caused by losses through vomiting, bowel wall edema, and extravasation of fluid into the peritoneal cavity; and correction of serum electrolyte abnormalities. Because of intralumenal bacterial overgrowth and the potential for septic complications associated with intestinal obstruction, broad-spectrum antibiotics should be administered preoperatively. Gastric decompression is necessary to lessen the risk of pulmonary aspiration during anesthetic induction.

Patients who have been treated for cancer and who subsequently develop obstruction of the small intestine present a special challenge. [41] It is important to realize that 25% to 40% of such patients do not have recurrent or metastatic cancer as the cause of their obstruction. For these patients, lysis of adhesions or herniorrhaphy provides long-term relief. If localized recurrent or metastatic tumor is the cause of obstruction, significant palliation may be obtained by operative treatment. Advanced metastatic tumor causing small intestine obstruction, exemplified by ovarian carcinomatosis, has a dismal prognosis and may be a contraindication to operative treatment. [42]

As with other causes of acute abdomen, elderly patients affected by small bowel obstruction tend to present with more advanced disease and with fewer laboratory and physical findings. In one report, 35% of patients older than 70 years who developed intestinal gangrene had no abnormal physical signs or laboratory parameters. [43] Resultant diagnostic uncertainty in elderly patients is associated with operative delay and a 40% increase in perioperative morbidity.

Minimally invasive approaches have been adapted to the treatment of small intestinal obstruction. [44], [45] Intestinal distention may limit abdominal insufflation in some cases, but laparoscopic enterolysis is associated with more rapid return of bowel activity and shorter hospitalization.

Colonic Diverticulitis

Acute abdominal processes involving the large intestine and emergency surgical procedures used to treat colonic diseases are associated with higher mortality and morbidity rates than are diseases in any other organ system. The treatment of acute diverticulitis illustrates many of these difficulties.

Colonic diverticula are extremely common and are clearly age related in the United States. By the seventh decade, more than 50% of the population can be demonstrated to harbor colonic diverticula. The sigmoid segment is involved in 90% of cases and is the only site of diverticulosis in half. Isolated right colonic or cecal diverticula are present much less frequently, demonstrated in about 2% of examinations. Although diverticulosis is common, symptomatic diverticulitis develops in few patients with colonic diverticula; lifetime risk approximates 5%. [46]

The signs and symptoms associated with acute diverticulitis depend on the colonic segment involved, the degree of pericolonic inflammation, and the development of extracolonic complications. Classically, patients present with left-sided lower abdominal pain, fever, and obstipation. Nausea and vomiting are usually not prominent. Mild abdominal distention is variably present. Leukocytosis is so common that in its absence the diagnosis should be questioned. Physical examination may reveal a palpable, tender mass in the left lower quadrant, but the absence of a mass does not exclude the diagnosis of diverticulitis.

Acute diverticulitis is a clinical diagnosis. Therapy, consisting of parenteral antibiotics and bowel rest, should be initiated empirically if appropriate symptoms exist. In 85% of cases, symptoms abate within 3 days of initiating treatment. [47] After patients become asymptomatic, radiographic or endoscopic evaluation of the colon should be performed to confirm the diagnosis of diverticulitis and to exclude other diseases, specifically colonic adenocarcinoma. If symptoms do not subside promptly, or if a complication of diverticulitis is suspected, additional radiologic evaluation is indicated.

Plain abdominal radiographs, usually obtained in symptomatic patients, do not reveal any abnormality in 70% of cases. Although findings consistent with diverticulitis are demonstrated in approximately 60% of cases by barium enema, complications of diverticulitis can be detected in only 30% to 40%. The most common findings are localized extravasation of contrast material, indicating a contained perforation, or a fixed, narrowed segment of colon. Because of the volume of contrast used and the pressure under which it is infused, barium enema carries a definite risk of exacerbating diverticulitis.

When diverticular complications are suspected, CT has been increasingly used as the initial test. [48], [49] CT has several advantages in this clinical situation: it causes much less discomfort than a barium enema, the risk of perforation is negligible, and extracolonic complications of diverticulitis can be evaluated. Pathological changes of diverticulitis detectable by CT include intramural colonic thickening, mesenteric edema, pericolonic and mesenteric abscesses, phlegmon formation, and pneumoperitoneum. [50] If intravenous contrast is not administered, visualization of contrast material within the bladder is presumptive evidence for colovesical fistula. CT examination has a sensitivity of 65% for uncomplicated disease, with a 90% to 100% sensitivity for detecting diverticulitis complicated by perforation, abscess, or fistula. [49], [51]

The ability of CT to define the complications of acute diverticulitis, such as pericolonic abscess, allows for CT-guided percutaneous needle aspiration and catheter drainage in properly selected patients. [52], [53] The goal of percutaneous drainage of diverticular abscesses is to minimize the need for colostomy formation and to optimize the conditions for resection with primary anastomosis while not compromising patient safety. Patients with generalized peritonitis, pneumoperitoneum, or colonic obstruction secondary to diverticulitis are not candidates for this treatment approach. In addition, small pericolic or intramesenteric abscesses that could be resected en bloc with the sigmoid colon are not appropriately treated with percutaneous drainage.

A 2.5- to 5-mm (8- to 16-French) catheter usually is used. A sinogram should be obtained through the catheter within 48 hours of placement to evaluate abscess cavity size and to demonstrate fistulization to the colon. Catheter injection should be repeated periodically to evaluate progress. CT-guided percutaneous drainage of peridiverticular abscesses is feasible in about 75% of patients. In a selected series of patients, catheter drainage was associated with resolution of sepsis in 89%. [54] Fistulous communication with the colon was demonstrated radiologically in 47% but was feculent in only 16%. In 74% of treated patients, single-stage sigmoid resection with primary anastomosis was performed subsequently without complication.

The presence of pneumoperitoneum, generalized peritonitis, or colonic obstruction associated with diverticular abscess is an indication for emergency operation. Operative goals include resection of the diseased segment of colon and peritoneal debridement. In the presence of active intraperitoneal infection or a mechanically unprepared bowel, resection of the diseased segment, formation of a proximal colostomy, and closure of the rectum (i.e., Hartmann procedure) comprise the safest surgical option. [55] Intestinal continuity is restored 2 to 3 months after resolution of the septic process, often laparoscopically. [56]

Acute Cholecystitis

Impaction of a gallstone in the cystic duct causes biliary colic, characterized by pain in the epigastrium or right upper quadrant of the abdomen. Biliary colic begins gradually before reaching a plateau of steady pain, which typically lasts several hours. Discomfort relents as the stone dislodges. The pain of biliary colic is severe and is frequently accompanied by nausea and vomiting. Symptoms classically are associated with the ingestion of a fat-containing meal, although they may also begin during fasting.

Continued obstruction of the cystic duct initiates an inflammatory response in the gallbladder wall. The presence of obstruction plus inflammation distinguishes acute cholecystitis from simple colic. Because of continuing ductal obstruction, the pain of acute cholecystitis may persist for many hours to days. If the inflammatory process progresses to involve the serosal surface of the gallbladder, adjacent parietal peritoneum is irritated. In this instance, pain becomes more intense and more clearly localized to the right upper quadrant. Movement of an inflamed gallbladder against the parietal peritoneum during breathing may inhibit deep inspiration, producing a positive Murphy sign. Accompanying fever is usually low grade. Most patients with uncomplicated cholecystitis have mild leukocytosis, with leukocyte counts ranging from 12,000 to 16,000 cells/mm [3]. Levels of serum bilirubin, alkaline phosphatase, and amylase may be nonspecifically elevated, usually not more than twice normal.

Although 95% of patients with acute cholecystitis have calculous biliary disease, the demonstration of cholelithiasis in patients with abdominal pain does not confirm the diagnosis of cholecystitis. Asymptomatic gallstones are present in 30% to 40% of persons older than 40 years of age, and only 15% to 35% of patients who have symptoms consistent with cholecystitis are proven to have the disease. Because of the high frequency of symptomless gallstones, additional tests are necessary to support the clinical diagnosis.

Ultrasonography is the preferred initial screening test for acute cholecystitis. Ultrasound has advantages of cost, portability, and ease of performance. In addition to detecting gallstones with 95% sensitivity, the procedure also provides information regarding other organs in the upper abdomen. Secondary findings that support the diagnosis of acute cholecystitis include gallbladder wall thickening, distention of the gallbladder, pericholecystic fluid, and sonographic lucency within the gallbladder wall. [57] Thickening of the gallbladder wall greater than 3 mm predicts acute cholecystitis with more than 90% accuracy, but this finding must be interpreted within the clinical context, because wall thickening has also been reported with portal hypertension, hypoalbuminemia, and ascites, as well as after gallbladder contraction when patients have not fasted.

A sonographic Murphy sign is elicited by placing the ultrasonographic transducer over the gallbladder and applying pressure or asking the patient to inspire deeply. In the presence of gallstones, a positive sonographic Murphy sign predicts acute cholecystitis in 90% of cases.

Cholescintigraphy is based on iminodiacetic compounds that are taken up by hepatocytes and secreted into bile. Technetium 99 labeling permits visualization after intravenous injection. The upper abdomen is imaged for 2 to 3 hours after injection, and delayed images may be obtained up to 24 hours. In normal patients, the liver is imaged first, followed by the gallbladder, common bile duct, and duodenum. If the common bile duct and duodenum are visible but the gallbladder is not, cystic duct obstruction is presumed to be present. If neither the gallbladder nor the common bile duct can be seen, common duct obstruction may be present. Severe hepatocellular disease and hyperbilirubinemia also may produce this pattern.

The gallbladder cannot be seen by cholescintigraphy in half of patients with chronic cholecystitis, even if the cystic duct is not acutely obstructed. False-positive findings also may result from failure to fast, alcoholic liver disease, and long-term parenteral nutrition. Because of these limitations, cholescintigraphy usually is reserved for patients with normal ultrasonography but strong clinical suspicion of acute cholecystitis and for those with gallstones who have no ancillary ultrasonographic findings of cholecystitis. [58]

Optimal management of patients with acute cholecystitis is laparoscopic cholecystectomy, both open operative and laparoscopic approaches are available in properly selected patients. [59], [60], [61] and [62] A detailed discussion of laparoscopic cholecystectomy may be found in Chapter 100 and Chapter 161.

Mesenteric Ischemia

Acute visceral ischemia is a prototypical, common, and frequently misdiagnosed cause of acute abdomen in adults. The four major ischemic syndromes are mesenteric embolism, acute mesenteric thrombosis, low-flow mesenteric ischemia, and iatrogenic mesenteric ischemia. Each syndrome is life-threatening, with mortality rates exceeding 50%. Early recognition, aggressive resuscitation and monitoring, and directed, specific therapy are essential.

Mesenteric embolism accounts for about 50% of cases of acute visceral ischemia. The embolic source is typically cardiac and is derived from mural thrombus associated with atrial fibrillation or myocardial infarction. Embolism to visceral vessels of atheromatous debris from the thoracic aorta is much less common.

Mesenteric embolism is accompanied by sudden severe epigastric and midabdominal pain. Forceful vomiting and evacuation of stool commonly follow the onset of pain. The general physical examination may reveal an irregularly irregular pulse of atrial fibrillation or a cardiac murmur. Early after embolization, physical examination of the abdomen may be entirely unremarkable; a classic presentation is severe abdominal pain out of proportion to physical findings. Abdominal distention, guarding, and absence of bowel sounds are associated with intestinal infarction and imply disease progression.

No laboratory tests are pathognomonic for mesenteric embolism or visceral ischemia. Hemoconcentration, leukocytosis, and acidosis, like definite physical findings, indicate advanced disease. Electrocardiography may confirm cardiac conduction abnormalities suspected on physical examination. Diagnosis depends on emergency diagnostic angiography. Emboli to the superior mesenteric artery (SMA) typically lodge at branch points of the artery distal to its origin. The inferior pancreaticoduodenal artery and the middle colic artery, the first two branches of the proximal SMA, may be spared with the embolus impacted distally (Fig. 40-6). After diagnosis, systemic heparinization is instituted, vigorous resuscitation with central cardiac monitoring is begun, and the patient is taken for emergency operation. Surgical therapy involves isolation of the proximal SMA and extraction of the embolus through a longitudinal arteriotomy. After restoration of flow, an assessment of intestinal viability is performed, and frankly necrotic bowel is resected.

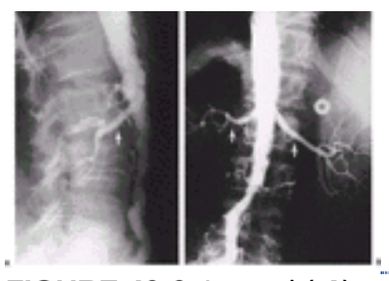

FIGURE 40-6. Lateral (**A**) and anteroposterior (**B**) emergency visceral angiograms demonstrate the absence of celiac and superior mesenteric artery filling in a patient with acute mesenteric thrombosis. Patent renal arteries are indicated by *arrows.*

Mesenteric thrombosis causes acute visceral ischemia after atherosclerotic narrowing of the SMA exceeds a critical level or becomes complete. Although acute thrombosis can occur without antecedent symptoms, a history of postprandial abdominal pain and weight loss, termed *chronic intestinal angina,* may exist. Unlike lesions resulting from mesenteric embolism, those associated with thrombosis tend to occur at the origin of the SMA from the aorta. Acute symptoms, abdominal

physical findings, and laboratory tests are similar to those listed for mesenteric embolism. Diagnosis relies on emergency visceral angiography. Emergency revascularization procedures involve construction of an arterial conduit, usually with an autogenous vein, from the aorta to the vessel distal to the point of obstruction.

Nonocclusive visceral ischemia occurs in low-flow states that cause intestinal vasoconstriction. Shock, decreased cardiac output, dehydration, hypovolemia, and inappropriate use of vasoconstrictive or inotropic agents can cause nonocclusive mesenteric ischemia. Patients typically have a history of recent myocardial infarction, congestive heart failure, or arrhythmias before development of intestinal ischemia. Visceral angiography reveals severe vasoconstriction of mesenteric vessels, which typically have a pruned appearance (Fig. 40-7).

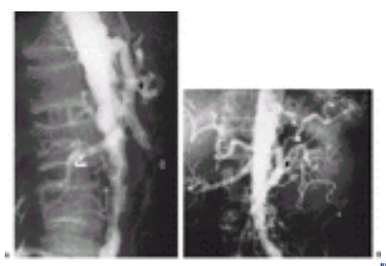

FIGURE 40-7. Lateral (**A**) and anteroposterior (**B**) postoperative angiograms from the patient shown in Figure 40-6 show the prosthetic graft (*black arrow*) supplying the superior mesenteric artery (*open arrow*). The renal artery (*curved arrow*) is similar to that shown in Figure 40-6.

Treatment of nonocclusive mesenteric ischemia requires restoration of intravascular volume and hemodynamic stability, elimination of contributing pharmacological agents, and efforts to relieve mesenteric vasospasm. Papaverine infusion through catheters placed angiographically into the SMA has been reported to reverse vasoconstriction. Peripheral infusion of glucagon (2–4 mg/hour) also has been used for this purpose. Operative therapy is not therapeutic in nonocclusive mesenteric ischemia and is reserved for resection of necrotic bowel.

Iatrogenic mesenteric ischemia occurs most commonly after angiographic procedures or operations on the aorta. Angiography may cause intestinal ischemia by dislodging atheroma from a diseased vessel wall or by vessel dissection or intimal flap formation. Aortic aneurysm resection is the operation most often associated with visceral ischemia because of involvement of the inferior mesenteric artery with the aneurysm. Clinically apparent colonic injury occurs in 1% to 2% of cases. Sigmoid colonic ischemia is heralded by bloody diarrhea; the diagnosis may be confirmed by urgent flexible sigmoidoscopy.

Abdominal Aortic Aneurysm

Acute symptoms caused by abdominal aortic aneurysm are usually a result of expansion or rupture or, less commonly, are secondary to dissection, distal embolism, or thrombosis. Through mechanisms that are not well understood, acute expansion of the aortic wall before rupture is associated with severe pain in the back, flank, or abdomen. Back pain is also typical of small tears, which produce leakage of blood into the retroperitoneum before catastrophic intraperitoneal hemorrhage. About 20% of ruptured abdominal aortic aneurysms present with these prodromal symptoms.

The classic clinical presentation of ruptured abdominal aortic aneurysm is diffuse abdominal pain, hypotension, and pulsatile abdominal mass. Pain may radiate to the back, flank, or groin. Profound shock implies free intraperitoneal leakage of blood. The most frequent diagnostic errors result from failure to palpate an abdominal mass, and the most frequent misdiagnosis is myocardial infarction.

If ruptured abdominal aortic aneurysm is suspected, additional diagnostic tests are not required. Subsequent resuscitation and therapy should take place in an operating room where immediate laparotomy can be performed. The postoperative mortality rate is about 50%. Acute renal failure, colonic ischemia, and lower extremity ischemia are common postoperative complications.

OPERATIVE THERAPY FOR ACUTE ABDOMEN

The treatment of patients with an acute abdomen has changed fundamentally since the 1980s. The proliferation of diagnostic and therapeutic modalities has provided greater flexibility in the treatment of these patients. The therapeutic hierarchy now includes endoscopic interventions, invasive radiologic procedures, and laparoscopy, in addition to supportive medical care and laparotomy. The proper treatment of these patients requires a sophisticated understanding of the power and limitations of each approach, as well an appreciation of the correct sequence for their application. For example, whereas supportive medical therapy is still the mainstay for treatment of acute biliary pancreatitis, endoscopic papillotomy is appropriate for selected subgroups of patients. Similarly, endoscopic detorsion is the accepted initial therapy for acute sigmoid volvulus, with operative treatment reserved as a secondary option. In most cases, peridiverticular abscess may now be treated by CT-guided percutaneous drainage, converting what was formerly an emergency laparotomy into elective colectomy. Laparoscopic cholecystectomy has become standard treatment for acute cholecystitis; conversion to open cholecystectomy is reserved for when the laparoscopic approach is anatomically difficult or unsafe. These approaches are detailed in other chapters of this text and are not discussed further here. Nonetheless, laparotomy is still required in many patients with acute abdominal disease.

After the initial history and physical examination, a basic question must be answered: Is immediate operation necessary? Immediate intervention is required if the suspected pathological process is progressive and potentially fatal. This criterion is met with intraperitoneal hemorrhage, for example, ruptured abdominal aortic aneurysm or ruptured ectopic pregnancy. In these circumstances, laparotomy becomes a method of diagnosis as well as a means of treatment.

If immediate operation is not immediately necessary, the next question becomes: Will operation ultimately be necessary? If initial evaluation reveals pneumoperitoneum, radiologic evaluations to differentiate perforated duodenal ulcer from perforated colonic diverticulum are not required; the processes may be distinguished easily at operation. In fact, the time required for additional diagnostic tests may be detrimental if therapeutic delay permits the disease process to progress. Instead, preoperative efforts should be expended to prepare the patient for anesthesia and operation. If the need for operation is uncertain, additional tests to define precisely the diagnosis are justified. As the processes of diagnosis and resuscitation proceed, a timetable is essential; worsening clinical evaluation mandates earlier surgical intervention.

Preparation for Operative Therapy

After a decision for operative intervention has been made, expeditious efforts to prepare the patient are undertaken. The first priority is assessment of operative risk.

General anesthesia has an associated risk, even without a surgical procedure. Improvements in anesthetic technique and agents have decreased mortality from approximately 1:10,000 in the 1950s to about 1:100,000 or less for healthy patients in 1997. About 50% to 75% of deaths directly attributable to anesthesia are the result of human error and usually are related to improper airway management: unrecognized esophageal intubation, unrecognized extubation, and unrecognized disconnection from the ventilator with resultant inadequate ventilation. The routine use of capnometry and pulse oximetry, in addition to other noninvasive monitors, has reduced significantly the incidence of problems associated with intubation.

Coronary Artery Disease Perioperative cardiac events are the leading cause of death after laparotomy, and much of the preoperative risk assessment is directed toward detecting the presence of ischemic heart disease. Preoperative congestive heart failure, recent myocardial infarction, and unstable angina are significant risk factors for postoperative cardiac complications. Diabetes mellitus, atherosclerotic peripheral vascular disease, and hypertension also confer risk but less than congestive heart failure or unstable angina. For patients with valvular heart disease, perioperative cardiac risk is proportionate to the severity of associated congestive heart failure, pulmonary hypertension, and arrhythmias. Stable angina and advanced age alone do not appear to be significant predictors of perioperative cardiac morbidity. Previous coronary artery bypass surgery appears to lower the risk of adverse postoperative cardiac events. The resting 12-lead electrocardiogram is the best screening test for ischemic heart disease, although the evaluating physician must be aware that resting electrocardiography may not detect all patients with ischemic heart disease and is not sensitive for prior subendocardial myocardial infarction. Whereas stress evaluations may be appropriate for elective surgical procedures, this level of sophistication is not available in emergency cases. A history of prior myocardial infarction should be sought in every case. Studies have

demonstrated that the risk of repeated infarction is related to the time elapsed since the previous myocardial infarction, with the incidence of reinfarction at 6% after 6 months. [63] Reinfarction for patients undergoing emergency noncardiac surgery usually occurs within 48 hours and causes extreme morbidity, with an associated mortality of 20% to 50%. [64] Patients with three-vessel or left main coronary artery occlusion are at increased risk. Intra-abdominal procedures lasting longer than 3 hours are associated with increased rates of reinfarction. Aggressive invasive hemodynamic monitoring and pharmacological intervention can reduce the risk of postoperative reinfarction.

Congestive Heart Failure The presence of congestive heart failure is a strong predictor of postoperative cardiac morbidity, and elective surgical procedures should be deferred if it this condition detected. Patients with ventricular dysfunction are at high risk during emergency laparotomy because they are intolerant of the intravascular fluid shifts associated with inflammatory disease processes and the myocardial depression associated with anesthetic agents. When emergency laparotomy is necessary, aggressive perioperative management should attempt to optimize cardiac output.

Hypertension Hypertension is the most common chronic medical condition in surgical patients. The incidence of intraoperative hypotension and myocardial ischemia is increased for patients with uncontrolled hypertension relative to those with well-controlled hypertension. When operation is elective, hypertension should be treated preoperatively to the patient's normotensive levels, and antihypertensive medications should be continued postoperatively. Hypertensive patients have exaggerated responses to painful stimuli during general anesthesia.

Pulmonary Disease Preexistent pulmonary disease is important in planning anesthetic management during emergency laparotomy. Pulmonary disease may be categorized as acute or chronic and restrictive or obstructive. Restrictive disease, defined by reduction of lung volumes, may be caused by processes that are intrinsic or extrinsic to the lungs. Intrinsic restrictive disorders that are commonly encountered in the context of emergency laparotomy include adult respiratory distress syndrome. Extrinsic causes of restrictive pulmonary disease include obesity and chest wall deformity. Safe management of patients with restrictive pulmonary disease requires recognition and alterations in ventilatory techniques but less preoperative preparation than for obstructive disease. Obstructive disease is characterized by reduced flow rates on pulmonary function tests. Obstructive pulmonary disease can be either chronic (emphysema) or acute (asthma). For most patients, obstructive pulmonary disease has a reversible component; this contribution to obstruction should be treated preoperatively by bronchodilators and therapy to mobilize secretions. Asthmatic patients frequently have reactive airway disease, in which the introduction of the endotracheal tube may induce bronchospasm during anesthetic induction and emergence. Because of the increased risk of postoperative complications, patients with preexisting pulmonary disease should be extubated only when they meet adequate extubation criteria, based on preoperative functional data. Alterations of pulmonary mechanics and resulting postoperative complications are greatest after upper abdominal surgery. Vital capacity and functional residual capacity are reduced, with lowest levels in the first 2 days postoperatively. Therapy with incentive spirometry seeks to restore functional residual capacity to preoperative levels. In patients with pulmonary compromise, the use of epidural narcotics for postoperative pain control is an important advance, allowing earlier extubation for patients with intrathoracic and upper abdominal surgery and earlier restoration of pulmonary function to preoperative levels.

Obesity Obesity represents a major comorbid factor for emergency laparotomy. Morbid obesity is defined as twice ideal body weight. Obese patients exhibit restrictive pulmonary defects as a result of reduced functional residual capacity; this deficit is exacerbated by the supine position necessary for laparotomy. Because of reduced functional residual capacity, obese patients frequently desaturate on anesthetic induction. Obese patients also have increased rates of pulmonary hypertension, right-sided heart failure, and occult coronary artery disease. Gastroesophageal reflux, a result of increased intra-abdominal pressure, increases risk of aspiration on induction of anesthesia. Fatty tissues may cause prolonged effects of lipid-soluble anesthetics.

Preoperative Resuscitation

When diseases that cause intraperitoneal hemorrhage are suspected (e.g., ruptured abdominal aortic aneurysm or ruptured ectopic pregnancy), preoperative resuscitation should be conducted within the operative suite. For these diseases, restoration of intravascular volume requires control of the source of hemorrhage, and laparotomy should proceed immediately. Most other causes of the acute abdomen have an inflammatory or infectious pathogenesis, with potential systemic disturbances in cardiovascular, pulmonary, and renal function. In these instances, preoperative resuscitative efforts must be undertaken before anesthetic induction. No patient should undergo anesthetic induction while he or she is suffering from septic shock. Effective intravascular volume should be restored by infusion of crystalloid solutions. Electrolyte abnormalities, commonly observed with repeated vomiting or small bowel obstruction, should be addressed. Coagulation abnormalities, if present, may require correction by transfusion of plasma factors or platelets. Preoperative administration of intravenous antibiotics is appropriate in almost all cases. Initial antibiotic choice should be dictated by the presumptive diagnosis and anticipated associated organisms. For example, perforation in acute appendicitis is accompanied by intraperitoneal spillage of colonic organisms, including gram-negative species and anaerobes such as *Clostridium perfringens.* Second- or third-generation cephalosporins are appropriate preoperatively. Subsequent antibiotic therapy can be guided by the findings at operation and by intraoperatively obtained peritoneal cultures.

Preoperative and Intraoperative Monitoring

Patients undergoing general anesthesia are routinely monitored by pulse oximetry, exhaled ventilatory capnometry, and electrocardiography. An esophageal or precordial stethoscope and esophageal temperature probe are standard. Stimulating electrodes can be applied to monitor the level of muscular paralysis. A Foley catheter is an atraumatic and inexpensive means to monitor renal perfusion.

Additional, invasive hemodynamic monitoring is appropriate for selected patients undergoing emergency laparotomy. Invasive monitoring is appropriate for patients with significant preexisting cardiopulmonary dysfunction and for those with evidence of preoperative shock or hemodynamic instability. Right or left ventricular dysfunction, pulmonary hypertension, or hemodynamically significant valvular disease are clear indications for insertion of a flow-directed pulmonary artery catheter (Swan-Ganz catheter). The catheter travels through the central venous circulation and the right heart to the pulmonary artery. Right atrial and pulmonary artery pressures can be measured directly. Left atrial pressure is approximated by the wedged pulmonary artery pressure. Thermodilution can be used to measure cardiac output; systemic and pulmonary vascular resistances then can be calculated. In most instances, the decision to insert a pulmonary artery catheter should prompt insertion of a radial artery catheter to provide direct measurement of arterial pressure and access to arterial blood samples.

Diagnostic Laparoscopy for Acute Abdomen

Diagnostic laparoscopy is a safe and accurate tool that can be used to rule out acute intra-abdominal disease, thus avoiding the need for a laparotomy. This technique is especially appealing in critically ill patients, in whom the morbidity and mortality associated with a nontherapeutic laparotomy can be substantial. In many cases, definitive therapy can be also undertaken using minimally invasive techniques. Moreover, if conversion to a formal laparotomy is required, the information obtained from the diagnostic laparoscopy allows the surgeon appropriately to place and minimize the size of a laparotomy incision.

Although diagnostic laparoscopy can be undertaken using local anesthesia and intravenous sedation, as a general rule the procedure should be undertaken in the operating room with the patient under general anesthesia. Patient positioning and manipulation during the procedure, airway control, and immediate conversion to laparotomy are all facilitated by general anesthesia. Patients should be placed in the supine position, with their arms tucked. This allows the surgeon to stand toward the head of the operating table when laparoscopic evaluation or treatment of pelvic structures is being undertaken. An orogastric tube and Foley catheter should be inserted to decompress the stomach and bladder, respectively, minimizing the risk of an injury to either structure during the procedure. Access to the abdomen is obtained by an "open" approach using a small periumbilical incision. The abdomen is then insufflated to 15 mm Hg with carbon dioxide. Once adequate pneumoperitoneum is established, additional trocars for instrumentation can be placed under direct vision as needed. A general inspection in a systematic fashion of all four abdominal quadrants is undertaken using a 30° or 45° laparoscope. Any free fluid that is encountered should be sent for Gram stain and culture. Exposure of upper abdominal structures is assisted by placing the patient in the reverse Trendelenburg position (head-up tilt). Placing the patient in a severe Trendelenburg position, which retracts the small bowel cephalad out of the pelvis, facilitates exposure of pelvic structures. Finally, tilting the operating table laterally from side to side aids with exposing the right and left paracolic gutters of the abdominal cavity. Atraumatic graspers are used to inspect the liver, gallbladder, stomach and duodenum, colon, appendix, and pelvic organs. The small intestine should be inspected from the ileocecal valve to the ligament of Treitz. Opening the gastrocolic ligament allows one to access the pancreas and posterior stomach for inspection.

Performance of Laparotomy

The placement of incision is influenced strongly by the presumed pathological process and by the certainty of diagnosis. Strong suspicion of acute appendicitis dictates exploration by a small transverse incision in the right lower quadrant. The oblique and transversus muscles are separated along the direction of their fibers to expose the peritoneum. Open cholecystectomy usually is performed through a right subcostal incision. In many instances, the precise diagnosis is not known at the time of laparotomy; in these cases, a vertical midline incision may be preferred. A midline laparotomy incision allows access to all four quadrants of the abdomen and permits mobilization of intraperitoneal structures to expose retroperitoneal organs. Midline incisions do not interfere with placement of ostomies or drains.

A careful, systematic abdominal exploration ensues after incision. The intraperitoneal organs are examined sequentially, usually starting in the upper abdomen with the stomach, the first portion of the duodenum, the liver, and the gallbladder. The ligament of Treitz is located to the left of the midline beneath the transverse colon,

and the small bowel is inspected from the jejunum to the ileocecal valve. The transverse and sigmoid segments of the colon can be inspected without additional dissection, as can the anterior surfaces of the ascending and descending colon. The greater omentum and visceral and parietal peritoneal surfaces are easily visualized. A thorough inspection of retroperitoneal organs requires additional dissection. The posterior surface of the stomach and the pancreas may be exposed by dividing the gastrocolic omentum, entering the lesser sac. The posterior surfaces of the ascending or descending colon may be viewed directly only after mobilization from the retroperitoneum.

The peritoneal cavity ordinarily contains a minute amount of free fluid, enough to lubricate the peritoneal surfaces. Increased amounts of fluid may represent inflammatory exudate, ascites, and chylous leakage. Peritoneal fluid should be sampled for bacterial and fungal culture and Gram stain. White blood cell count and differential, determination of fluid amylase and protein content, and cytology may also be performed. Organ masses are noted, and an attempt is made to distinguish inflammatory and neoplastic masses. The omentum and peritoneal surfaces are inspected for mass involvement; intraoperative biopsy usually is performed more easily from these sites. Organ perfusion is assessed clinically, based on color, tissue turgor, and the presence of pulsatile flow in small mesenteric vessels. When these clinical signs are equivocal, intraoperative Doppler ultrasonography and intravenous fluorescein may be used to provide additional information. Lymph node enlargement should be noted and may prompt intraoperative biopsy.

CHAPTER 41

Robert W. Summers

APPROACH TO THE PATIENT WITH ILEUS AND OBSTRUCTION

Ileus is a pathophysiological state of inhibited motility in the gastrointestinal tract that may be temporary (reversible) or permanent. The adjectives *paralytic* and *adynamic* emphasize the activation of inhibitory mechanisms. Motor paralysis and paresis may be better terms than ileus because they describe the physiological malfunction more clearly, but neither enjoys wide use. The term *functional obstruction* is a possible alternative, but it is confusing because “functional” could imply a psychological component to some, as in the functional bowel disorder, and “obstruction” implies an anatomic impediment to flow; neither is intended, however.

Pseudoobstruction is often used in describing a chronic abnormality of function simulating mechanical obstruction but having no anatomic cause. Sudden massive idiopathic dilation of the colon is called *acute colonic pseudoobstruction,* or Ogilvie syndrome in more common use. *Toxic megacolon* is a special sort of ileus in which severe transmural inflammation produces atony of the colonic muscle, and at the same time the mucosal barrier is disrupted, resulting in systemic toxemia.

Obstruction implies blockage of the gut at one or more sites; the adjective *mechanical* emphasizes the anatomic nature of the problem. *Obturation* is a synonym that implies that the process is intralumenal. The obstruction is complete if there is complete inability of intestinal contents to pass through the digestive tract, and it is partial if passage continues but is impaired. Obstruction is described as *simple* if the lumen is occluded at only one location. The term *closed loop obstruction* is used if the lumen is obliterated at two sites. This situation is often accompanied by impairment of the blood supply. If the blood supply is inadequate to maintain the viability of the gut, the term *strangulated obstruction* is used to describe the condition.

PATHOPHYSIOLOGICAL CONSIDERATIONS

The pathophysiology of simple and strangulated obstructions is summarized in Figure 41-1.

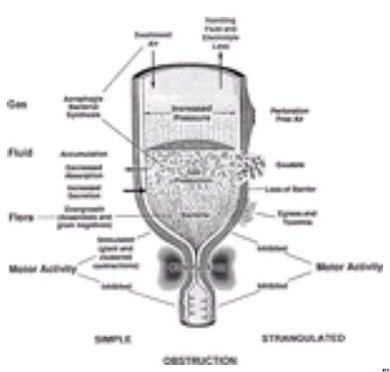

FIGURE 41-1. Pathophysiology of simple (**left**) and strangulated (**right**) obstruction in the small intestine.

Changes in Blood Flow

Strangulated obstruction, a potentially lethal event, impairs blood flow and requires urgent recognition and management. Few investigators have studied the problem in humans because of the invasive methods required to measure blood flow and the critical nature of the condition. The major threat to life in closed loop obstruction is impairment of blood flow in large vessels. The vascular supply can be compromised through external compression of the bowel or its mesentery by adhesions, hernial orifices, tumors, torsion (i.e., volvulus), or intussusception. Except in closed loop obstruction, an increase in intralumenal pressure causes local ischemia only as a late event. Pressures reach only 8 to 10 cm H_2O in simple obstruction and are not high enough to produce transmural ischemia. [1] Total mesenteric blood flow actually increases in experimental simple obstruction, and an increase in muscle blood flow occurs during heightened motor activity because some blood is shunted from mucosa to the muscle. [2]

The mucosa has the greatest metabolic need for blood and is the most sensitive to ischemia. Within minutes after vascular occlusion, damage to the tips of the villi is manifest by sloughing of the epithelial cells. [3] If ischemia continues for 30 to 60 minutes, the villi are almost completely denuded, and only the crypt epithelium is preserved. The major early consequences of these changes are impairment of the basic transport processes, loss of the protective barrier to gut bacteria and their toxic products, and exudation and hemorrhage into the lumen. [4] Failure to recognize and treat strangulated obstruction inevitably leads to infarction, necrosis, and perforation of the bowel wall with peritonitis or sepsis and a mortality rate of 30%.

Ileus can result from arterial blockade caused by mesenteric vasculitis, atherosclerosis, or emboli. The converse is not the case; that is, ileus does not impair large arterial blood flow, and the intralumenal pressures generated with ileus are insufficient to compromise mucosal blood flow.

Changes in Bowel Flora

The clinical picture in ileus and obstruction is affected by the bowel flora. The flora of the stomach, jejunum, and proximal ileum are mainly gram-positive and facultative organisms. Organisms are present in low concentrations (about 10^3–10^4 organisms/mL of fluid). Aerobic lactobacilli, streptococci, staphylococci, and fungi

are normal flora in this region, whereas anaerobes and coliforms are rare and are present in even lower concentrations. [5] The organisms in the colon are drastically different in numbers and kind. About 10^{9} to 10^{12} organisms/g of feces exist in the colon, constituting up to 40% of the fecal dry weight. Most (99%) are non–spore-forming anaerobic rods, including *Bacteroides* species, lactobacilli, and enterobacteria. [6] About 1% are aerobic gram-negative rods, mostly coliforms. Distal ileal flora represents a mixture of upper intestinal and colonic flora. The concentrations are commonly 10^{6} to 10^{7} organisms/mL.

Mechanisms regulating gut flora involve primarily gastric acidity and propulsive motility. Large numbers of bacteria normally are destroyed by the acid milieu in the stomach, but, if the pH is high because of achlorhydria or antisecretory drugs, higher concentrations of organisms are found in the upper intestine. [7] Normal motility clears both nutrients and organisms from the intestine, but if propulsive activity is impaired, stasis and bacterial overgrowth occur. Within a few hours after complete obstruction, the contents of the proximal bowel become malodorous and feculent because of a marked increase in anaerobic organisms, especially *Bacteroides* and gram-negative species. [8]

In partial obstruction (e.g., ileal strictures from Crohn's disease) or impaired motility (e.g., diabetic autonomic neuropathy or scleroderma), intestinal stasis promotes bacterial overgrowth and malabsorption. Excessive lumenal organisms cause mild mucosal injury, excessive gas formation, catabolism of nutrients with formation of short-chain fatty acids, and protein deprivation. Deconjugation of bile acids by bacteria impairs micelle formation and causes steatorrhea. Vitamin B_{12} deficiency develops from bacterial binding of the vitamin B_{12} intrinsic factor complex.

The most serious consequence of increased lumenal bacteria occurs in strangulated obstruction. The ischemia compromises the integrity of the bowel wall's defense barrier. The mucosa is especially susceptible to anoxia and necrosis, which lead to hemorrhage and increased permeability with transudation of toxic, infected intralumenal fluid across the bowel into the peritoneum, regional nodes, and mesenteric circulation. This exudate is particularly lethal if clostridial bacteria and their exotoxins are present in the fluid. Enterotomy without antibiotic coverage leads to a high rate of postoperative wound infection.

Less is known about changes in bowel flora with ileus, but it is likely that qualitative and quantitative changes occur that are similar to those seen with mechanical obstruction. Bacterial overgrowth occurs, with impaired propulsive motility. [9]

Changes in Bowel Contents

Absorption and secretion of fluid and electrolytes take place in both small and large intestines. The duodenum and jejunum accomplish high-capacity absorption, whereas the ileum and colon provide high efficiency. With intestinal obstruction, fluid and electrolytes accumulate proximal to the obstructive site. Isotopic studies of water and electrolyte flux during the first 12 hours after obstruction demonstrate both reduced net absorption and increased secretion of water, sodium, and potassium. [10] As obstruction is prolonged, failure of absorption and enhanced secretion of water and electrolytes increase still further, and net absorption becomes net secretion. Neural reflexes, activated by stretch receptors, induce secretion. Bacterial overgrowth contributes to the enhanced secretion, partly through the metabolism of ingested nutrients, but the exact mechanism is not known. [11] In contrast, absorption of water and electrolytes continues in the obstructed colon, resulting in the conversion of the liquid ileal effluent to a solid fecal mass. Fluid and electrolyte fluxes with ileus have not been studied satisfactorily but probably are not greatly different from normal.

In addition to increased fluid, intestinal gas adds to the abdominal distention and the gas-filled loops routinely observed on plain abdominal radiographs. The origin of the gas is mainly from swallowed air in both ileus and obstruction. Gas does not accumulate to any degree if a cervical esophagostomy is performed in experimental obstruction, and analysis of the gas composition reveals high concentrations of nitrogen from swallowed air. If oral intake continues, bacterial fermentation produces gases (e.g., carbon dioxide, hydrogen, methane) from ingested nutrients, adding to distention.

Bowel distention contributes significantly to the patient's discomfort. Abdominal pain is much more severe in obstruction than it is in ileus. Distention also may compromise respiration, especially in patients with cardiorespiratory problems, through impairment of diaphragmatic motion. Finally, the lumenal sequestration of fluid and electrolytes, loss of absorptive capacity, and vomiting contribute to dehydration and circulatory insufficiency through fluid loss from the extracellular and intravascular compartments.

Changes in Motility

Marked changes in motor activity occur with obstruction of the small intestine or colon (Fig. 41-2). In experimental obstruction of the intestine, the segment distal to the obstruction is inhibited immediately, but contractions increase proximally. [12] Accumulated fluid, gas, and nutrients raise intralumenal pressure and wall tension, stimulating stretch receptors and enhance the peristaltic reflex. The increased motor activity proximally is prevented by atropine and thus is cholinergically mediated. [13] With more prolonged obstruction, periods of quiescent motor activity lasting 1 minute or longer are interspersed with intense regular 10- to 11-minute pressure waves, some of which occur only at one recording site and others of which migrate aborally. Clustered contraction patterns often are seen in the normal fasting state, but they are not normal after a meal. They produce the intermittent colic and borborygmi that patients with obstruction typically experience after eating. [14] These migrating clustered contractions are typical of partial as well as complete obstruction after a meal, but they are not diagnostic because they occur in other conditions, including pseudoobstruction. [15] If the obstruction is allowed to continue, the quiescent periods become progressively longer, and motor activity throughout the bowel is gradually reduced through activation of inhibitory intestinointestinal reflexes.

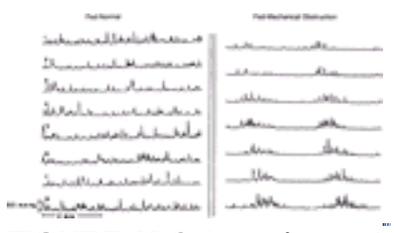

FIGURE 41-2. Irregular contractions normally occur evenly after a meal (**left**). In the obstructed intestine, clusters of contractions occur postprandially at intervals of 1 to 2 minutes, with intervening periods of quiescence (**right**).

In experimental obstruction, almost no contractile activity occurs in the segment of small bowel aborad to the obstruction throughout the period of obstruction. The mechanism of this descending inhibition is not established. It is not caused by an absence of intestinal contents, because contractions do not increase after chyme is infused. [13] It is not reversed by a- or ß-adrenergic antagonists, nor is it overcome by cholinergic agonists. It may be caused by activity of the nonadrenergic, noncholinergic inhibitory (nitric oxide) nerves, but this hypothesis is unproven.

Colonic obstruction also causes changes in motility that occur more slowly as a result of the larger accommodative volume. [16], [17] If the right colon is obstructed, both the segment proximal to the obstruction and the distal colon exhibit reduced contractions. If the left colon is obstructed, however, motor activity increases throughout the large bowel, exhibiting a pattern of clustered contractions similar to that seen in small bowel obstruction.

Mechanisms involved in adynamic ileus may be neurogenic, myogenic, or humoral. They may include either excessive inhibition or deficient excitation. The least understood mechanisms are the reflex mechanisms and muscle failure, whereas most is known about circulating substances because many are easily measurable. Any of the following may reduce or abolish motor activity: blood-borne toxins, drugs, circulating hormones, and abnormalities in mineral balance, acid-base balance, and oxygen supply.

Postoperative ileus has been studied more than some other causes of motor paralysis and may be a prototype for some of the other conditions. Somatic inhibitory reflexes are activated as soon as the parietal peritoneum is entered. After an operation, gastrointestinal motor failure ensues for several days; food and fluids are not tolerated, and no flatus or stool is passed per rectum. Anesthetic agents themselves inhibit motility. [18] Studies of motor activity in animals showed that contractions return first in the small intestine 3 to 6 hours after laparotomy, in the stomach after 24 hours, and in the colon after several days. [19], [20] and [21] Analogous human

studies confirm that the colon is slowest to recover, and activity of the right colon returns several days before that of the sigmoid colon. [22], [23] Because motility patterns do not return entirely to normal as soon as contractions return, normal digestive function is delayed. Postoperative ileus persisting longer than 3 to 4 days suggests that a complication exists. The factors influencing the duration of ileus are varied. Manipulation of the abdominal organs delays return of function longer than does a laparotomy alone. Chemical or physical irritants in the peritoneal cavity, such as bile, blood, or acid, delay recovery even longer. Low-grade sterile peritonitis may stimulate the somatic inhibitory reflexes. Bowel dilation from gas and fluid accumulation activates visceral afferents and an inhibitory reflex arc. [24], [25] Opioid narcotics reduce propulsive motility patterns and augment inhibitory reflexes. If none of these is present, a mechanical obstruction may exist. Abdominal computed tomography and small bowel enteroclysis are the most helpful studies to differentiate between obstruction and motor paresis. [26]

The mediators involved in postoperative ileus are unknown. Adrenergic inhibition has been thought to be the cause, but this concept does not explain why the process lasts several days. Plasma concentrations of catecholamines and norepinephrine turnover are increased temporarily after anesthesia, laparotomy, and intestinal manipulation, [27], [28] and the return of migrating motor complexes is faster if an operative splanchnicectomy is performed. The use of epidural anesthesia, which blocks efferent sympathetic nerves, does not shorten ileus or the time of first passage of gas or feces, however, and the benefits of adrenalectomy, demedullation, or adrenergic antagonists are controversial. [19], [29], [30] These findings suggest that mechanisms other than spinal reflexes play a major role in development and maintenance of postoperative ileus. [31]

Metabolic Consequences and Systemic Effects

One of the first systemic consequences of obstruction or ileus is fluid, electrolyte, and acid-base imbalance. The type of disturbance is largely dependent on the anatomic site of the block. With gastric outlet obstruction, repeated emesis of clear fluid high in hydrochloric acid and potassium chloride leads to metabolic alkalosis with hypokalemia and hypochloremia. With distal duodenal or proximal jejunal obstruction, alkaline biliary and pancreatic secretions are lost, producing metabolic acidosis. The volume of emesis is less with distal intestinal obstruction, but vomiting is less likely to decompress the bowel; therefore, the colicky pain and abdominal distention are more severe. Vomiting and dehydration are uncommon in colonic obstruction, but distention and pain may be intense. If the ileocecal valve is incompetent, colonic obstruction more closely resembles ileal obstruction; if the valve is competent, however, gas accumulates rapidly from both swallowed air and bacterial fermentation. The pressure inside the colon may rise rapidly and cause rupture, most commonly in the cecum. The tensile strength of the cecum is relatively low, and mucosal microcirculation is more tenuous than in the small bowel. By the law of Laplace, tension in the wall is greatest where the radius is the greatest. Emergency decompression of the colon is required if the diameter of the colon rapidly enlarges to greater than 12 cm, because of the risk of perforation.

The same metabolic consequences may occur as a result of ileus, although in most situations ileus is caused by metabolic abnormalities. Vomiting, changes in flora, and alterations in absorption and secretion may produce a clinical situation identical to that seen in simple obstruction. Ischemic complications and sepsis are uncommon, however.

With closed loop obstruction and strangulation, a systemic inflammatory response occurs as a result of the release of a wide range of substances from necrotic bowel. Cyclooxygenase and lipoxygenase metabolites, slow-reacting substance, a variety of kinins, histamine and serotonin, lysosomal enzymes, and free radicals all probably play a role in the fever, leukocytosis, fluid shifts, and shock that may precede or coexist with the developing sepsis. Finally, organ failure and death may ensue with one or more of the following: metabolic encephalopathy, acute renal insufficiency, hepatic failure, high-output shock and myocardial dysfunction, adult respiratory distress syndrome, and disseminated intravascular coagulation.

HISTORY

The clinical findings in ileus and obstruction depend on the anatomic site (Table 41-1). The physician should attempt to determine the anatomic site involved and to ascertain the underlying cause. For management decisions, it is important to know the duration of the process and whether complications such as peritonitis, perforation, sepsis, or strangulation are present. The main symptoms of obstruction are crampy, spasmodic abdominal pain, vomiting, borborygmi, abdominal distention, and obstipation.

TABLE 41-1 Clinical Features of Ileus and Obstruction Dependent on Anatomic Site

Partial obstruction causes intermittent crampy abdominal pain occurring after meals, especially after eating fiber-rich foods. If the patient eats a low-residue diet or avoids eating entirely, symptoms are reduced or avoided. As the obstruction becomes increasingly complete, the pain intensifies. True intestinal colic is dull, crampy, or squeezing, and it occurs in waves of severe pain followed by waning intervals of rest in 1- to 10-minute cycles. Bowel sounds may be so loud that they can be heard by others in the room (i.e., borborygmi). With ileus, pain is much less intense and may be sensed only as a feeling of pressure or fullness. Patients may observe abdominal distention or bloating.

As the obstruction becomes more advanced, nausea, vomiting, and pain are more frequent and more severe. Pain and distention are relieved by vomiting in proximal but not distal obstruction. See Table 41-1 for other site-specific features of obstruction. With complete obstruction and protracted vomiting, dehydration and orthostatic hypotension cause reduced urine output. Patients also develop obstipation and fail to pass flatus. Patients with fecal impaction often have paradoxic diarrhea.

To investigate the underlying causes of obstruction, inquiry should be made about the following: previous operations, which may indicate adhesions; previous episodes of obstruction; bulges on the abdominal wall or in the groin, which may indicate hernias; previous cancers or polyps; abdominal irradiation; inflammatory bowel disease; peptic ulcer; gallstone disease; pancreatitis; foreign body ingestion; and diverticular disease. A psychiatric history (e.g., ingestion of foreign bodies) and a family history of polyps or cancer may provide helpful clues to the underlying diagnosis. Exaggeration of pain during menses suggests endometriosis.

Hypomotility and paralytic ileus most often are caused by the following: metabolic, electrolyte, and acid-base disorders; pharmacological inhibition of motility; or primary or secondary neuropathies or myopathies. Careful family, medication and illicit drug, endocrine, and immunologic histories are important in discovering the underlying cause. The physician should be alert to thyroid and parathyroid disorders, hypokalemia, diabetes mellitus, scleroderma, heavy-metal poisoning, and porphyria.

The development of constant unremitting localized pain, fever, chills, rigors, and a general sudden worsening of the clinical state all suggest ischemia and infarction. Waiting for such signs to develop before acting is poor clinical judgment, however. Strangulation and necrotic bowel may exist with none of these features being present. A high index of suspicion and aggressive management are important practices to adopt if mortality is to be kept low. If the clinical condition changes and any of these systemic symptoms appear, urgent steps must be taken to search for and treat potentially ischemic or necrotic bowel.

PHYSICAL EXAMINATION

In mechanical obstruction, the patient may be doubled over, holding the abdomen and writhing restlessly in bed, frequently changing position, and vomiting or retching. Intervals of relief may occur during which the patient may lie still. With ileus, the pain is less severe in the face of moderate abdominal distention, but it is more steady and unrelenting, and the patient usually lies quietly in bed.

Some physical findings may provide clues to the underlying cause of the obstruction or ileus (Table 41-2).

PHYSICAL SIGNS	DIAGNOSIS
Abdominal scars	Adhesions
Pyoderma gangrenosum, erythema nodosum	Ulcerative colitis, Crohn's disease
Buccal, palmar, plantar pigmentation	Peutz-Jeghers syndrome
Cullen, Grey, Turner sign	Hemorrhagic pancreatitis
Cutaneous atrophy, hyperpigmentation	Chronic pancreatitis, abdominal radiation
Vesicles, bullae, scars, pigmentation	Porphyria
Neurofibromas	Von Recklinghausen disease
Acanthosis nigricans	Gastrointestinal malignant diseases
Butterfly dermatitis	Lupus erythematosus
Atrophy, telangiectasias, variable pigmentation	Scleroderma, dermatomyositis

TABLE 41-2 Cutaneous Findings That Are Clues to the Cause of Obstruction

Carefully palpate the umbilicus, the lower trunk, and both inguinal and femoral areas in every patient with suspected obstruction, to detect external hernias. Incarcerated femoral hernias are especially easy to overlook in the obese patient. Hernias sometimes can be manually reduced, relieving the obstruction and avoiding the hazards of strangulation. Careful palpation is also imperative to detect hepatosplenomegaly, liver masses, or other intra-abdominal masses that suggest malignant neoplasms. Tender lumps may suggest an abscess from Crohn's disease or diverticulitis, an intussusception, or an ischemic incarcerated loop of bowel. Localized tenderness occurs at the lateral margin of the rectus abdominis with a lateral ventral or spigelian hernia. Metastatic nodes in the umbilicus (Sister Mary Joseph nodule) indicate peritoneal carcinomatosis, whereas nodes in the inguinal region may occur with colorectal or other neoplasms. A careful rectal and pelvic examination always should be done to find rectal or vaginal tenderness, as well as masses and fecal or barium impaction. For example, obturator and sciatic hernias are discovered only by rectal examination, and a Blumer shelf indicates metastatic cancer.

Resonant percussion or tympany occurs in both ileus and obstruction because of entrapped intestinal or colonic gas. Shifting dullness or a puddle sign occurs if there is free abdominal fluid and may suggest associated malignant or inflammatory ascites, as in complicated pancreatitis, bowel necrosis, or early tuberculous peritonitis.

Auscultation is important in differentiating obstruction from ileus. With ileus, the abdomen is almost completely silent. Rare low-pitched gurgles or weak tinkles are heard, along with transmitted heart tones and moving water if the patient changes position. In obstruction, bowel sounds become louder, higher pitched, and hyperactive unless the obstruction is prolonged for several days or is complicated by ischemia, necrosis, or peritonitis. These sounds have a musical, tinkling, or metallic quality and occur in clusters or rushes, coinciding with colic. The examiner may need to listen for 10 to 15 minutes to hear abnormal sounds. In recent-onset proximal obstructions, these sounds may occur every 3 to 5 minutes or up to 15 minutes if obstruction is in the distal bowel or is more prolonged or complicated by strangulation.

Repeated examinations are essential because complications may develop with time and may produce changing physical findings. If bowel sounds disappear, or if signs of peritoneal irritation, such as low-pitched rubs, muscle guarding, rigidity, or rebound tenderness, intervene, the bowel is probably ischemic, and rapid intervention is imperative. Patients with fevers, hypotension, rigors, or signs of sepsis develop ominous findings that often signal a life-threatening complication.

DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC STRATEGIES

Causes of Mechanical Obstruction

The causes of mechanical obstruction are varied and may be divided into extrinsic lesions, intrinsic lesions, and intralumenal objects (Table 41-3). In adults, the most common causes of obstruction are adhesions and hernias in the small bowel and cancer in the colon. It may not be possible to diagnose the cause of the obstruction preoperatively, but a careful clinical examination and appropriate studies usually yield a diagnosis and aid in management decisions.

Extrinsic Lesions
Adhesions and congenital bands
Hernias
External hernias
Internal hernias
Diaphragmatic hernias
Pelvic hernias
Volvulus
Gastric
Midgut
Cecal
Sigmoid
Extrinsic masses
Benign or malignant tumors
Abscesses
Aneurysms
Hematomas
Endometriosis
Intrinsic Lesions
Benign and malignant neoplasms
Adenocarcinomas
Lymphomas, lymphosarcomas
Carcinoid tumors
Inflammatory conditions
Tuberculous enteritis, Crohn's disease
Strictures secondary to IKDI, nonsteroidal antiinflammatory drugs, and ischemia
Intrinsic Lesions (continued)
Radiation injury, caustic ingestants
Eosinophilic gastroenteritis, ameboma
Diverticulitis, pelvic inflammatory disease
Intussusception
Congenital defects
Hypertrophic pyloric stenosis, annular pancreas
Intestinal atresia/agenesis
Malrotation/volvulus
Intestinal duplication, mesenteric cysts
Meckel diverticulum
Hirschsprung disease
Hematoma
Abdominal trauma
Thrombocytopenia
Henoch-Schönlein purpura
Intralumenal Objects
Meconium ileus
Barium impaction
Fecal impaction
Gallstone ileus
Gastric bezoars
Foreign bodies

TABLE 41-3 Causes of Mechanical Obstruction

Extrinsic Lesions Extrinsic masses can compress the bowel or mesentery and cause obstruction. Adhesions are the most common cause of small intestine obstruction in adults, but they rarely obstruct the colon. They most commonly occur after gynecologic procedures and operations on the small and large intestine and uncommonly occur after gastric and biliary surgical procedures. Adhesions may occur from a few days to 10 or 20 years after an operation. They may occur without a history of an operation, usually after infection (e.g., peritonitis) or irradiation. Adhesive bands form and contract with time, entrapping a loop of bowel. They often cause a closed loop obstruction, commonly associated with strangulation. Congenital bands may occur in association with malrotation (i.e., Ladd bands) or in the absence of any known cause.

Hernias. Hernias may cause either simple obstruction or closed loop obstruction; strangulation is common in incarcerated hernias (i.e., those that cannot be reduced) because the blood supply is compromised by the hernial ring. External hernias protrude through the abdominal wall, are palpable as tender masses, and are often reducible. Internal hernias are not palpable and usually are identified at the time of operation. Diaphragmatic hernias rarely cause obstruction unless they are paraesophageal. Uncommon pelvic hernias may be palpable but require careful pelvic, rectal, and perineal examination and are most often recognized at operation as the cause of bowel obstruction. Chapter 121 includes a complete discussion of hernias.

Volvulus. A *volvulus* is an abnormal torsion of a segment of bowel, usually colon, producing a closed loop obstruction and occlusion of the blood supply. It involves the sigmoid colon in 70% to 80% of cases and the cecum in 10% to 20% of cases. Typically, the onset of pain is sudden, severe, and followed rapidly by severe abdominal distention. A tender mass may be palpated, and characteristic abdominal plain radiographic findings are often present (Fig. 41-3). Reduction is possible by barium enema or colonoscopy, but the volvulus is likely to recur. Volvulus of the small intestine occurs in newborns but is rare in adults. Volvulus of the stomach often is associated with large defects in the diaphragm, congenital malrotation, or large paraesophageal hernias.

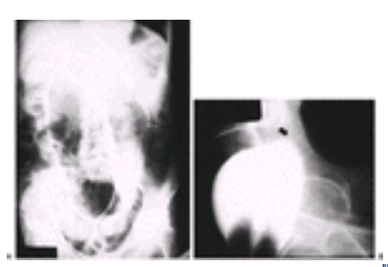

FIGURE 41-3. (**A**) Plain abdominal radiograph shows colonic obstruction secondary to sigmoid volvulus. (**B**) Barium enema reveals a tapered cutoff at the site of the

volvulus (*arrow*).

Intrinsic Lesions

Tumors. Tumors can narrow or obstruct the lumen, or they may be the leading point of an intussusception. Neoplasms causing obstruction may be benign or malignant. If malignant, they may be primary or metastatic, although metastatic tumors usually tether and fix the bowel rather than involve the lumen. Although uncommon, primary malignant tumors of the small bowel are most often carcinoids, lymphomas, or adenocarcinomas. Adenocarcinoma is the most common cause of colonic obstruction.

Inflammatory or ischemic processes. Inflammatory or ischemic processes involving the bowel wall produce strictures, lumenal narrowing, muscle dysfunction, and impaired transit. Blunt trauma to the abdomen can produce intramural hemorrhage and compromise of the lumen. Hematomas also may occur as a result of severe thrombocytopenia or clotting disorders with or without the vascular fragility seen, for example, in Henoch-Schönlein purpura.

Intussusception. Intussusception exists when a leading segment of bowel invaginates into an accepting segment. In older children and adults, an intrinsic bowel lesion, such as a tumor or Meckel diverticulum, usually initiates the process. The inner, advancing invaginated segment is called the *intussuscipiens,* and the outer, accepting invaginating segment is termed the *intussusceptum.* Initially, the inner walls become edematous because of lymphatic obstruction. As the process advances, venous obstruction, infarction, and necrosis follow.

Intralumenal Objects Barium from an upper gastrointestinal series can cause a barium impaction in the colon if it is not evacuated promptly. Excessive extraction of water from the barium occurs if there is prolonged colonic stasis. This is often caused by an underlying motility disorder, such as scleroderma, chronic intestinal obstruction, or colonic pseudoobstruction. [32] Obstructing fecal impaction may result from severe chronic constipation, a variety of drugs, such as narcotics or antipsychotics, an underlying colonic carcinoma, or diverticulitis. Large gallstones occasionally erode through the gallbladder wall into the duodenum or, more rarely, into the colon or stomach. Some of these stones are large enough to obstruct the bowel, most commonly the distal ileum. This condition is misnamed gallstone ileus and may be suspected if dilated loops of bowel proximal to a small bowel obstruction are associated with air in the biliary tree from the cholecystoduodenal fistula. Finally, objects from the stomach may produce intestinal obstruction if they pass into the intestine, such as gastric bezoars, ingested foreign bodies, and iatrogenically introduced bodies.

Causes of Adynamic Ileus

Ileus is never primary, and a search for the etiologic disorder is essential to achieve success in management. Because the clinical picture in ileus can be so similar to that in mechanical obstruction, diagnostic considerations for both disorders must proceed concurrently. Long-standing or complicated mechanical obstruction may even terminate with ileus. The underlying causes of mechanical obstruction are overt, simple, anatomic, and almost always conclusively apparent. Conversely, the underlying mechanisms in acute motor paralysis are occult, complex, and rarely completely understood. Causes of adynamic ileus are outlined in Table 41-4. The conditions associated with ileus often can be defined, but a great deal is yet to be learned before the mechanisms are understood and rational therapy can be applied. Conversely, treatment usually is successful through management of the underlying cause.

Intra-abdominal Causes	Extra-abdominal Causes
Reflex inhibition	Reflex inhibition
Laparotomy	Craniotomy
Abdominal trauma	Rib, spine, or pelvic fractures
Renal transplantation	Myocardial infarction
Inflammatory conditions	Coronary bypass
Perforated viscus or penetrating wounds	Open heart surgery
Bile peritonitis	Pneumonia, pulmonary embolus
Chemical peritonitis	Burns
Intraperitoneal hemorrhage	Black widow spider bites
Toxic megacolon	Drug-induced
Familial Mediterranean fever	Anticholinergic/ganglionic antagonists
Acute pancreatitis	Opiates
Acute cholecystitis	Chemotherapeutic agents
Celiac disease	Tricyclic antidepressants
Inflammatory bowel disease	Phenothiazines
Acute irradiation injury	Metabolic abnormalities
Abdominal irradiation	Septicemia
Infectious processes	Electrolyte imbalance
Bacterial peritonitis	Heavy metal poisoning (lead, mercury)
Appendicitis	Porphyria
Diverticulitis	Uremia
Herpes zoster virus	Diabetic ketoacidosis
Anorectal herpes simplex virus	Sickle cell disease
Ischemic processes	Pulmonary failure
Arterial insufficiency	
Venous thrombosis	
Mesenteric arteritis	
Strangulation obstruction	
Retroperitoneal processes	
Ureteropelvic stones	
Pyelonephritis	
Retroperitoneal hemorrhage	
Pheochromocytoma	
Malignancy (Ogilvie syndrome)	

Note: Adapted from ref. 34.

TABLE 41-4 Causes of Adynamic Ileus and Acute Colonic Pseudo-obstruction

Chronic intestinal pseudoobstruction clinically mimics mechanical obstruction but is not caused by an anatomic blockage. It may result from primary neuropathic or myopathic disorders, which are often familial. It also may develop secondary to a variety of other disorders (see Chapter 73).

The term *acute colonic pseudoobstruction* implies that nonobstructive massive dilation of the colon is temporary and reversible. The condition is commonly called Ogilvie syndrome, although this term is technically incorrect. Ogilvie described chronic dilation in association with invasion and destruction of the celiac axis and semilunar ganglion by retroperitoneal malignant disease. [33] Its underlying causes are multiple and essentially the same as those compiled for ileus (see Table 41-4). [34] Numerous mechanisms must be operative for such a range of associated conditions. Impaired motility or aerophagia each plays an important role, but which comes first and which dominates are uncertain. It is likely that the massive dilation initiates autoinhibitory reflexes that perpetuate the problem.

Toxic megacolon occurs in severe inflammatory bowel disease and in other forms of colitis, including bacillary or amebic dysentery. The exact pathogenesis remains an enigma, but it is likely that transmural inflammation adversely affects the neuromuscular apparatus. Inhibitory drugs, such as anticholinergics, opiates, and antidiarrheals, probably have an important deleterious effect and must be avoided or discontinued.

ASSESSMENT

Biochemical and Hematologic Tests

Laboratory studies have limited usefulness in the diagnosis of mechanical obstruction, but they are critical in its management. Early in the course of obstruction, all blood tests are usually normal. Except for laboratory evidence of infection, inflammation, or tumors, biochemical and hematologic tests only rarely aid in establishing the cause of a mechanical obstruction. In contrast, because of the metabolic abnormalities that commonly produce or are associated with ileus, the laboratory is essential in discovering the underlying cause of ileus and in its management. In milder conditions, measurement of serum electrolytes, blood urea nitrogen, and creatinine is helpful in assessing fluid balance and the presence and severity of dehydration. As vomiting and dehydration persist, hemoconcentration increases, and hemoglobin, hematocrit, and serum albumin levels rise. Leukocytosis is common in infectious and inflammatory disorders. In more severe cases, measurement of arterial blood gases is also necessary to assess acid-base balance. More proximal obstructions cause greater acid-base imbalance, whereas the more distal obstructions cause greater electrolyte disorders. Abnormalities of serum calcium, magnesium, and phosphate may contribute to ileus and, if abnormal, should be corrected.

If the bowel is ischemic or infarcted, a variety of enzymes may leak across the intestine and be released into the circulation. Pancreatic and hepatic enzyme elevations may be encountered, but no laboratory test is a reliable indicator of infarction. In addition, enzyme levels may be elevated because of concurrent primary pancreatic or hepatic disease. Sepsis also may contribute to these abnormalities as well as to elevations in bilirubin and in serum and urine phosphate. Most of the abnormalities manifest late in the course of the disease. [35], [36], [37] and [38] In summary, even though abnormalities in laboratory tests may occur because of intestinal infarction, they are neither sensitive nor specific in this setting. Analysis of ascites can be very helpful in establishing diagnosis or in discovering complications. Analyses should include cell counts, albumin (subtract ascites albumin from simultaneous serum albumin to obtain serum/ascites albumin gradient), total protein, glucose (with simultaneous blood glucose) lactate, amylase, and cultures in blood culture media.

Radiologic Studies

Plain Films If the clinical evaluation suggests either obstruction or ileus, radiographic examination is extremely helpful to confirm the diagnosis, to differentiate ileus

from obstruction, to localize the level of an obstruction, and to contribute to an understanding of the underlying cause. [39], [40] The first studies to be selected include posteroanterior and lateral chest radiographs and upright and supine films of the abdomen without contrast. One study found that a supine abdominal film and an upright frontal chest radiograph identified pertinent abnormalities in 98% of cases and were sufficient for screening. [41] The chest radiograph is important to detect pneumonia or other extra-abdominal processes as a cause of ileus, to evaluate cardiorespiratory status preoperatively, and to discover free air or other subdiaphragmatic abnormalities. If an upright chest film is not physically or technically possible, a cross-table lateral film of the abdomen with the left side down may demonstrate free peritoneal air. It is important to wait 5 to 10 minutes after the patient assumes this position to allow migration of small amounts of air to the paracolic gutter. The abdominal radiographs demonstrate the amount and distribution of gas and fluid in the gastrointestinal tract. The jejunum lies in the left upper and central abdomen, the ileum lies in the right central and lower abdomen, and the colon occupies the flanks and right iliac fossa. Some radiologists recommend a prone abdominal view instead of or in addition to a supine view, because it allows intestinal gas to fill the left colon and rectum, improving the assessment of colonic obstruction. [42] Normally, there is almost no air in the small intestine and only scattered gas bubbles and feces in the colon. In early or incomplete small bowel obstruction, gas and fluid begin to accumulate, causing the lumen to become dilated. Air, fluid, and feces persist in the colon, and without contrast it is difficult to determine the level of obstruction or even to differentiate obstruction from localized ileus. With total lumenal blockage, more gas and fluid accumulate proximal to the level of the obstruction, and the lumen becomes widely dilated (often >3.5 cm in the jejunum). The valvulae conniventes of the small intestine produce markings across the entire lumenal diameter (Fig. 41-4). In the upright or decubitus position, multiple air-fluid levels occur with a stepladder pattern (i.e., different levels in adjacent loops). Distal to a complete obstruction, the bowel, including the colon, empties and collapses within 12 to 24 hours. If air persists in the colon, its diameter is less than that of the small bowel, which is evidence of a partial obstruction.

FIGURE 41-4. Plain abdominal radiograph shows multiple dilated loops of intestine indicating small bowel obstruction caused by adhesions from previous surgery. No gas is present in the colon.

With colonic obstruction, most or all of the air and fluid accumulate in the colon proximal to the obstruction if the ileocecal valve is competent. The haustra cause incomplete indentations in the contour of the wall, producing a scalloped effect. Distal to the obstruction, the colon and rectum become free of gas and feces. If the ileocecal valve is incompetent or absent, gas and fluid are seen throughout both the proximal colon and the small bowel. Except in proximal colonic obstruction, the diameter of the transverse colon is greater than that of the small bowel. Early in the course of strangulation, no features clearly distinguish the radiologic findings from those of simple obstruction. If strangulation is far advanced, the necrotic bowel loses its mucosal contour and becomes splayed by edema, exhibiting a thumbprinted appearance. Air may be seen in the bowel wall (i.e., pneumatosis), in branches of the portal venous system, or free within the peritoneal cavity, signifying perforation. In ileus, gas and fluid accumulate differently throughout the gastrointestinal tract (Fig. 41-5). Loops of mildly distended bowel may develop proximal or adjacent to the site of an acute inflammatory process such as appendicitis or pancreatitis. These loops are involved by localized ileus and are called *sentinel loops.* If peritonitis coexists with ileus, the bowel wall becomes thickened, and the properitoneal fat line becomes obscured. If ascites is present, it produces a hazy, ground-glass density throughout the abdomen. In acute colonic pseudoobstruction, the entire colon becomes dilated, but the cecal diameter is usually the greatest.

FIGURE 41-5. The small intestine is dilated and distended with gas; a small amount of gas is also present in the colon. These findings suggest ileus, caused in this case by jejunal ischemic necrosis.

In the differentiation of ileus from obstruction, the degree of intestinal distention, the amount of intralumenal fluid and gas, and the distribution pattern of air-fluid levels in the upright or decubitus position are important features to compare. Obstruction usually causes more fluid and gas accumulation than ileus, and air-fluid levels tend to be longer and more pronounced. Intestinal gas accumulates in both conditions, but in ileus more gas is in the colon than the small bowel. The pattern is reversed in small bowel obstruction. A stepladder appearance can occur in either obstruction or ileus. If multiple air-fluid levels appear in a string-of-beads pattern, however, a high-grade partial or complete obstruction of the small bowel is likely. This obstruction is caused by small air bubbles trapped in the superior recesses of splayed-out valvulae conniventes in an upright or decubitus position while the dilated loop is filled with large amounts of fluid. Supine films, conversely, may show little or no gas in the small intestine. If the diagnosis is inconclusive, sequential films often help to define it.

Contrast Studies The differentiation of ileus from mechanical obstruction is not always possible with plain abdominal films, and the presence or absence of obstruction can be determined only by using contrast media. Barium provides better contrast and detail than water-soluble media and therefore is usually the agent of choice. If there is a question of bowel viability or perforation, however, barium should be avoided because it would create an intense inflammatory reaction if leaked into the peritoneal cavity. Contrast studies can usually differentiate complete obstruction from partial obstruction and from paralytic ileus and can aid in the selection of therapy. Small bowel enteroclysis should be the method of choice to detect early or subtle structural disorders and most accurately to document normal status. Some authors recommend abandoning the conventional small bowel follow-through method. [43] When enteroclysis is not available, the follow-through can be improved by adding the peroral pneumocolon or gas-enhanced double-contrast study. One study used a 6-hour radiograph after oral Gastrografin (diatrizoate and iodine) to provide information in clinically equivocal intestinal obstruction. When the contrast agent was in the colon in 6 hours, almost 90% of the patients could be managed nonoperatively. [44] If there is any doubt about the site of obstruction, barium should not be given orally until colonic obstruction is excluded by barium enema or colonoscopy. When orally administered barium accumulates proximal to a colonic obstruction, water continues to be extracted from colonic contents, and the barium becomes inspissated and impacted. It can be removed only at the time of operation, which is hazardous because of potential spillage. It is acceptable to give small amounts of barium orally or by intubation in small bowel obstruction after colonic obstruction is excluded. Net secretion in the small bowel keeps the barium in a liquid suspension, and if necessary it can be removed through an intralumenal tube. In small bowel obstruction, barium provides superior definition to water-soluble media, which are hyperosmolar and become diluted by secretion and mixing with intestinal contents, thus reducing contrast and definition. Barium also should be used for retrograde studies unless there is a possibility of perforation. A nonionic contrast agent, such as Amipaque (metrizamide), is isotonic with blood. Therefore, it is the contrast agent of choice whenever a water-soluble agent is needed; however, high cost usually limits its clinical application to neonates and young children.

Other Imaging Procedures Angiography is sometimes useful in diagnosing abdominal tumors, but other modalities have generally replaced this method. It is still useful in suspected mesenteric ischemia and infarction. Ultrasonography has a limited role in both obstruction and ileus because the gas-blocking from dilated loops of bowel prevents imaging beyond the tissue-gas interface. Computed tomography may be very helpful in establishing the diagnosis and in locating the obstruction

anatomically if other imaging studies are inconclusive. Establishing the diagnosis with certainty preoperatively is not always necessary or even desirable if a needed operation is delayed by waiting for the test.

Other Studies

The role of esophagogastroduodenoscopy in ileus and obstruction is limited, as is enteroscopy. Benign ulcers, strictures, and carcinomas are the most commonly encountered lesions. However, the placement of stents can be useful in palliation of pancreatic cancer that partially obstructs the duodenum. Similarly, colonoscopy can be of value in the diagnosis and management of sigmoid volvulus, obstructing cancers, and inflammatory strictures (see section “ Nonoperative Therapy”).

Endoscopic procedures play a limited role in diagnosis of small and large intestinal obstruction but may be more important in therapy. Brushings and biopsies can provide definitive histological diagnosis to plan treatment. However, endoscopy is increasingly used to decompress and devolvulize the stomach and colon or to relieve obstruction through the use of expandable metallic stents.

An abdominal paracentesis should be done if fluid is present and the cause of obstruction or ileus is not clear. The presence of blood, bile, amylase, proteins, leukocytes, bacteria, or malignant cells is helpful in making therapeutic decisions.

THERAPEUTIC CONSIDERATIONS

Therapeutic Strategy

Decision making in acute obstruction requires repetitive, careful patient observations, well-informed clinical judgment, and close communication with a skilled surgeon. After the initial evaluation and establishment of the presence of obstruction or ileus, fluid, electrolyte, and acid-base resuscitation should begin. Adjustments in the composition and rate of administration are made as soon as the relevant laboratory tests become available. Decompression of the distended bowel is instituted at the same time by nasogastric aspiration. The next decision to be made is whether to use urgent operative therapy, expectant operative therapy, or nonoperative therapy.

Acute complete bowel obstruction is a surgical emergency. The objective of treatment is to relieve the mechanical impediment to propulsion, and operative therapy is most often the means to that end. Ileus is managed by treating the underlying cause, and operative therapy should be avoided entirely unless some other intra-abdominal catastrophe requires laparotomy.

Replacement of Fluids

Correction of fluid, electrolyte, and acid-base imbalances must be guided by the level and duration of obstruction and measurements of the hematocrit; of serum sodium, potassium, chloride, bicarbonate (HCO_3^-), blood urea nitrogen, and creatinine; and of arterial blood gases and pH. Bedside estimates of dehydration are inaccurate, although orthostatic hypotension and tachycardia support the need to begin therapy. If severe hypovolemia exists, restoration of intravascular fluid volume should be monitored by measurements of urinary output, central venous pressure, and arterial blood pressure. If heart failure, chronic obstructive pulmonary disease, or renal failure is a concurrent problem, a Swan-Ganz catheter should be used to monitor the function of the left ventricle.

Fluid replacement should be based on estimates of previous deficits, daily maintenance requirements, and current losses. Mild to moderately severe dehydration may vary from 4% to 8% of total body weight. Half of this deficit should be given during the first 24 hours and half during the second 24 hours. Maintenance requirements average 1500 to 2000 mL in an afebrile 70-kg person with normal renal function. Continued losses through vomiting or nasogastric suction can be measured to allow calculation of total fluid replacement and caloric loss. A balanced salt solution, such as lactated Ringer solution, should be used to correct the deficit.

In patients with metabolic alkalosis from gastric outlet obstruction, fluid replacement should begin with isotonic sodium chloride. As soon as adequate urine output is assured, potassium chloride should be given because renal potassium loss is great in gastric outlet obstruction. The potassium loss can be measured in a 24-hour urine sample. Hydrochloric acid can be given intravenously, but it is rarely needed. In metabolic acidosis, 2 mmol/L $NaHCO_3$ or one sixth molar sodium lactate should be given. Large amounts of sodium HCO_3^- ($Na\,HCO_3^-$) given as ampules of 44.6 mmol/L may produce intracellular volume depletion. If correction of acidosis with $NaHCO_3$ is too rapid, cerebrospinal fluid pH may fall rapidly and worsen neurological symptoms. Overcorrection of arterial pH above 7.4 shifts the hemoglobin dissociation curve to the left and reduces delivery of oxygen to the tissue by increasing the affinity of hemoglobin for oxygen. Slower restoration of pH to 7.4 may be desirable; if there is no liver dysfunction, sodium lactate may be preferred over $NaHCO_3$. Net HCO_3 deficit resulting from gastrointestinal loss may be roughly calculated from plasma HCO_3 concentration (plasma [HCO_3^-]) as follows: 24 mEq/L - plasma HCO_3^- × 0.6 body weight (kg). $NaHCO_3$ should be given if the arterial pH is less than 7.1. One half of the calculated deficit should be given to raise the plasma HCO_3^- to 16 mEq/L after 12 to 24 hours. If nothing is allowed by mouth for several days, some provision must be made for nutrition.

Decompression of the Bowel

There is value in reducing gaseous distention. It is distressing for the patient, causing pain and respiratory embarrassment. Distention induces secretion, causes nausea and vomiting, and may result in aspiration, particularly during induction of anesthesia. Nasogastric suction is appropriate in both obstruction and ileus, but the use of long indwelling intestinal tubes, such as the Cantor tube or Miller-Abbott tube, is controversial and is not recommended routinely. [45] The long tubes are difficult and sometimes impossible to pass without endoscopic guidance. [46] The balloons may expand to dangerous volumes during passage, may predispose to intussusception, or produce intestinal obstruction themselves, and they are probably no more effective in reducing distention than a nasogastric tube. They may be tried if strangulation is unlikely, if nasogastric suction is ineffective, or if long-term nonoperative therapy is planned. Experience is accumulating with temporary endoscopic decompression of colonic obstruction. A flatus tube can be passed over an endoscopically directed guidewire through a distal pinhole lumen. [47] Alternatively, the obstruction can be relieved using a through-the-scope balloon-dilating catheter or a laser or an expandable metallic stent. [48, 49]

Principles of Surgical Treatment

As a general rule, acute complete mechanical obstruction of the small intestine should be relieved as soon as preoperative resuscitation is adequate and nasogastric decompression is established. In the presence of complete obstruction, strangulation cannot be excluded by clinical criteria, and delay in operation may be fatal. [50] These reasons led to a valid clinical dictum, “don’t let the sun set on a small bowel obstruction.” The reason for urgency is mostly that the mortality associated with ischemic bowel complicating obstruction is high, and this problem can be detected with certainty only at operation. An operation provides the ultimate procedure to detect strangulation and to accomplish definitive treatment. Antibiotics almost always are given prophylactically because an enterotomy in an unprepared bowel has a high incidence of wound infection, and sepsis is a frequent complication whenever blood flow is compromised. Coverage must be provided for anaerobes and gram-negative organisms. Laparoscopic management of small bowel obstruction is possible in about 60% of patients. Its use allows quicker recovery, early discharge, and cost savings. [51]

When strangulation is encountered from any cause, the grossly necrotic bowel is resected, and the viability of the adjacent bowel must be assessed. This is difficult if not impossible to do on the basis of gross observation of the tissue. Two important new intraoperative aids to improve accuracy are Doppler ultrasonography and fluorescein dye injection. After restoration of mesenteric circulation, a handheld Doppler probe sends and receives sound waves to assess blood flow. [52] The technique is easy to perform and determines viability accurately, as confirmed by a second-look operation. [53] Intravenous fluorescein can be quantitatively detected in the bowel through the use of a perfusion fluorometer. This method is also highly accurate and useful in determining viability, especially in longer segments. [54, 55] Nonperfused segments are resected, followed by an end-to-end anastomosis. Primary neoplasms of the small intestine are rare but require adequate resection with lymph node dissection if the lesion is malignant. Metastatic tumors are better bypassed than resected.

In partial small bowel obstruction, immediate operative therapy is not usually necessary, and antibiotics are of no proven benefit. There is time to establish the severity and underlying cause with relevant diagnostic tests. If the patient continues to pass stool and flatus and if air persists in the colon, strangulation is unlikely, and expectant therapy is usually appropriate. If any worrisome signs should arise, such as fever, rebound tenderness, leukocytosis, or unexplained hyperamylasemia, laparotomy is indicated. If an external hernia can be found, gentle attempts should be made to reduce it, with avoidance of excessive force and watching for evidence

of infarction or perforation after successful reduction.

Immediate operation is also usually not indicated if the patient has a history of multiple previous episodes of bowel obstruction, multiple abdominal operations with extensive adhesions, extensive abdominal radiation therapy, bacterial peritonitis, Crohn's disease, or carcinomatosis with widespread metastases. In these situations, strangulation is less likely the result of fixation of the bowel. Operative procedures in this setting are exceedingly difficult because of dense adhesions that increase the risk of inadvertent enterotomies, with possible wound contamination, infection, and postoperative intestinal fistulae. In patients who have been treated surgically for abdominal malignant disease, obstruction should be considered to be a result of adhesions and should be managed operatively. If metastatic lesions are known to exist, obstructive episodes usually are managed nonoperatively. [56] If nonoperative therapy is chosen and decompression does not produce marked clinical improvement and resolution of bowel distention in 24 to 48 hours, successful nonoperative therapy is unlikely, and surgical intervention is indicated. [45], [57] If distention resolves, the patient may be managed by follow-up; if signs of bowel infarction appear at any time, however, abdominal exploration is urgently indicated. The value of immediate operation compared with tube decompression and close observation for 48 hours in the treatment of small bowel obstruction remains controversial. The mortality in patients with ischemic bowel is about 30%, and the high risks of this potential complication combined with the difficulty in prompt detection argue for early operative therapy in most settings.

Colonic obstruction usually develops over several days, but it almost always requires surgery. The principles of correcting dehydration and electrolyte balance, decompressing the bowel, and administering antibiotics before colonic surgery always apply. Nasogastric suction may or may not be effective in reducing the distention. Resuscitation reduces operative risk, and emergency surgery is not necessary unless there is peritonitis, perforation, or respiratory embarrassment from excessive distention.

The two most common obstructing colonic lesions are cancer and diverticulitis. The two may be difficult or impossible to differentiate on clinical or radiologic grounds, and they may coexist. If there is any doubt about the diagnosis of diverticular disease after radiologic or endoscopic studies, a resection should be done. Sometimes the cancer is apparent only after careful histological examination. If the problem presents as an acute obstruction, proper bowel cleansing is often not possible. A two-stage operation consisting of resection and diversion, followed by reanastomosis at a later date, has been the standard practice because primary anastomoses had a high rate of anastomotic leaks, wound contamination, and abscess formation. [58] However, resection and primary anastomosis are increasingly used unless the patient is severely ill or has peritonitis from perforation or infarction. Postoperative infections are reduced by intraoperative irrigation of the bowel. [59], [60] and [61] The management problems with diverticular disease are similar to those with cancer. If perforation and abscess are present, the diseased bowel often is resected, and the proximal segment is temporarily diverted. [62]

Nonoperative Therapy

Nonoperative therapy may be helpful in certain benign and malignant disease processes. Endoscopy can be useful not only for the diagnosis of ileus or obstruction but also for definitive therapy. Graded pneumatic balloon catheters can accomplish brusque dilation of obstructing lesions. This approach has been especially helpful in Crohn's disease. [63], [64] and [65] Radial cuts can be made in narrow, short strictures and membranes. Frequently, volvulus of the sigmoid colon and, less often, of the cecum can be reduced by aspirating the gas with a colonoscopically placed tube. Another technique that may be tried in sequence is to exert gentle hydrostatic pressure with a barium enema or other rectally introduced contrast medium. The risk of perforation or necrosis cannot be ignored when either of these procedures is used. If these procedures are successful, frequent examinations should continue for several days to watch for signs of infarction. Recurrence with both cecal and sigmoid volvulus usually requires elective repair. Resection rather than fixation is indicated if there is evidence of ischemia, and some surgeons recommend it in all cases. [66] Adhesions or radiation-induced strictures are uncommon causes of obstruction in the colon. Endoscopic treatment with hydrostatic or pneumatic balloons sometimes can relieve the obstruction, thus obviating the need for emergency surgery in some cases, although recurrences demand definitive surgical therapy. [67]

Snares, heater probes, bipolar cautery devices, and lasers can be used to heat and remove or coagulate obstructing tumors. The necrotic tissue sloughs and provides a larger opening in the lumen. Relief of obstruction resulting from colon cancer is increasingly achieved with self-expandable stent endoprostheses. A stent may be inserted under direct colonoscopic observation and fluoroscopic control as an adjunct to operative preparation in patients with obstructing cancers. Temporary relief of obstruction permits preoperative mechanical and antibiotic preparation, allowing for a one-stage procedure instead of a temporary colostomy. Such an approach is increasingly successful and can provide significant cost savings by avoiding a second surgical procedure. Unfortunately, most patients presenting with obstruction already have advanced disease, but stents also may provide long-term palliation. The procedure may be complicated by perforation or stent displacement. Stent placement also is being investigated for management of neoileal stenosis resulting from recurrent Crohn's disease after an end-to-end anastomosis. [68], [69] Palliative relief of obstruction sometimes can be accomplished in inoperable colon cancer through the use of laser coagulation. [49], [70], [71] However, the yttrium-aluminum-garnet laser, balloon dilation, and chemical sclerosis techniques are falling out of favor because their use has a high rate of complications. [72] The laser partially vaporizes and coagulates the tumor; the necrotic tissue sloughs, and the lumen is restored. Although perforation is a risk, this procedure may be preferable to surgical therapy in elderly patients with other serious medical problems. In some patients with advanced cancer, intestinal obstruction may not be amenable to operative therapy because of high morbidity, mortality, or complication rates or unresectability. Obstructive symptoms often can be controlled pharmacologically, but in a few cases, mostly in patients with proximal obstruction, endoscopic or surgical venting gastrostomy or jejunostomy can provide relief of nausea, vomiting, and colic. Anticholinergic, antispasmodic, and antisecretory drugs, such as hyoscine sulfate, can be effective in relieving colicky pain and the frequency and volume of emesis, but they may cause agitation or other side effects, especially in elderly patients. Octreotide 0.3 mg daily reduced nausea and vomiting more than hyoscine butylbromide 60 mg and may be helpful in refractory cases. [73] Antiemetic agents such as haloperidol can be helpful in reducing nausea and vomiting; they can be given subcutaneously by a pump for extended periods, whereas this is not possible with most phenothiazines. Morphine is probably the most effective analgesic drug if pain is a major factor.

The therapy for ileus is directed primarily toward treatment of the underlying or associated disease. Sometimes the underlying cause is not apparent, and the ileus resolves spontaneously with supportive care. Resolution of the associated condition is accompanied by return of intestinal or colonic motor activity. Drugs inhibitory to motility should be withdrawn if possible. In most cases, however, a thorough search for the underlying cause is the key to successful management. The simple step of patient positioning is critically important. When the patient lies supine, the gas stays in the anterior-located transverse colon, but it quickly moves to the left colon when the patient lies on the right side. The gas moves to the rectosigmoid when the patient becomes supine and into the rectum when the patient is prone or in the knee-chest position.

In the postoperative period, temporary ileus is expected; if it persists for more than a few days, the routine causes of ileus should be evaluated, beginning by correction of metabolic abnormalities and withdrawal of any drugs that inhibit motility, especially narcotics. If evidence of impaired propulsion appears after the ileus has resolved and the patient has begun oral intake, a new mechanical obstruction must be suspected, and proper steps must be initiated to document and treat the problem. Obstructions from early adhesions tend to be fibrinous and rarely compromise the vascular supply. Most patients respond to conservative therapy and do not require a second operation. [74], [75]

In acute colonic pseudoobstruction, fluid and electrolyte imbalances must be corrected; nothing is allowed by mouth, and nasogastric suction is instituted. The patient must be examined frequently to assess abdominal girth, tenderness, and signs of peritoneal irritation or sepsis. As in intestinal ileus, treatment must be directed toward any underlying cause, such as sepsis, and inhibitory drugs should be withdrawn. Gentle enemas may aid in evacuation of the distal bowel, and plain abdominal radiographs should be obtained regularly to determine changes in colonic diameter. If the condition can be anticipated or recognized early, it is likely that massive dilation can be prevented with supportive care. Although 12 cm is often stated as the upper limit of colonic diameter for which medical management can be continued, a rapidly expanding colonic diameter is stronger evidence of impending perforation and a more important indicator of risk than a single numeric value. Furthermore, the risk of perforation appears to correlate better with the duration of dilation than with the diameter. [76] If there is any question whether a mechanical obstruction is present, a contrast enema or colonoscopy is mandatory before resorting to drug therapy. If an ominous degree of dilation appears, some method of rapid decompression must be instituted because perforation, massive peritoneal soilage, and fatal sepsis may result. A surgical cecostomy has been the standard therapy and rarely may be indicated if all other measures fail. Colonoscopic deflation has been recommended enthusiastically, with a reported success rate of 75% to 100%. [77], [78] The use of limited air and carbon dioxide insufflation and a large-bore aspiration catheter dragged alongside the colonoscope with a snare may facilitate the procedure. If the procedure is to be of long-term benefit, the decompression catheter should be left for continuous aspiration. Colonoscopy has its own inherent risk of perforation, especially in a poorly prepared colon, and the recurrence rate approaches 50%. The latest approach involves the slow intravenous infusion of a cholinergic agonist. Neostigmine is given slowly over 3 to 5 minutes with mandatory cardiovascular monitoring; at a dose of 2.5 mg in 100 mL saline. Decompression by passage of flatus occurs in 3 to 30 minutes in greater than 90% of cases. [79], [80] and [81] Acute colonic pseudoobstruction may not be as hazardous as previously thought, and dilation usually resolves spontaneously with conservative positioning and nonendoscopic and nonsurgical treatment (86%). [82] Present information supports initial conservative therapy of acute colonic pseudoobstruction, but careful clinical monitoring continues to be mandatory because perforation remains a disastrous complication. If the problem is unresponsive or worsens, pharmacological therapy should be tried. Colonoscopic deflation should be the next step, followed

by operative cecostomy in the event of failure.

CHAPTER 42

Don W. Powell

APPROACH TO THE PATIENT WITH DIARRHEA

GENERAL EPIDEMIOLOGY

Diarrheal diseases affect developed nations quite differently than they do developing nations. In developed nations, diarrheal disorders are primarily of economic significance. Total costs (direct plus indirect) in the United States were estimated as more than $4 billion (year 2000 dollars) for acute diarrheas and $2 billion for chronic diarrhea plus inflammatory bowel disease (IBD). [1] Other investigators have estimated the cost of all food-borne illnesses in the 1980s as more than $28 billion per year. [2] Although diarrheal diseases are a minor cause of death in industrialized nations, they are among the leading causes of death and morbidity in developing countries. Since the early 1980s, global death rates from diarrheal diseases, mostly affecting infants and small children, have decreased from 5 to 10 million per year to 3 to 4 million. [3], [4]

Diarrhea related to acquired immunodeficiency syndrome (AIDS) is covered elsewhere (see Chapter 124), as are the details of infectious diarrhea (see Chapter 74, Chapter 75, and Chapter 88) and many specialized forms of diarrhea (see Chapter 56, Chapter 76, Chapter 77, Chapter 78 and Chapter 79, Chapter 83, Chapter 85, Chapter 86, Chapter 95, and Chapter 125, Chapter 126, Chapter 127, Chapter 128, Chapter 129 and Chapter 130).

GENERAL DEFINITION

Normal stooling frequency ranges from three times a week to three times a day. [5], [6] Diarrhea was defined by Doctors Roux and Ryle in 1924 as “the too rapid evacuation of too fluid stools.” [7] A decrease in stool consistency or fluidity and stools that cause urgency or abdominal discomfort are more likely to be termed *diarrhea* by patients than increases in frequency alone. [5], [8] The physician or clinical investigator often chooses to define diarrhea as a physical sign (24-hour excretion weight or volume) rather than a symptom. Healthy children and adults have daily stool weights of less than 200 g, [9] and infants have a daily stool weight of less than 10 g/kg. [10] Even though stool consistency probably best defines diarrhea, it cannot be easily measured. Thus, stool weights in excess of 200 g/24 h may be the most easily obtainable, objective definition of diarrhea. This definition may cause misdiagnosis in 20% of patients with loose stools of less than this weight. [8] Twenty-seven percent of both men and women report one loose stool in the previous month. [11] Because stool composition varies from 60% to 85% water, [8], [12], [13] this definition implies that diarrhea is a disease of intestinal water and electrolyte transport.

A stool pattern of increased frequency, with either no change in consistency or a 24-hour stool output of less than 200 g, often accompanies motility disorders (irritable bowel syndrome [IBS]) or anorectal disease (proctitis). Some term this *pseudodiarrhea. Incontinence* (which is not necessarily diarrhea) is defined as the involuntary release of rectal contents. It is a relatively common (2%–10% of the population) and increases with age. It is reported to occur in 50% of nursing home patients. [14], [15] and [16] Incontinence is more common if stool is liquid, and it is present more often in the setting of abnormal neuromuscular function (abnormalities of afferent sensation or efferent motor function) or pelvic problems (trauma to or disease of the sphincter or pelvic muscles). [14], [16] Thus, it is more common in elderly patients, in persons in poor health, and in postpartum women.

Aside from water content, the factors governing normal stool weight and consistency are not completely understood. *Consistency* is best defined as the ratio of fecal water to the water-holding capacity of insoluble solids. [8] Fiber content and bacterial mass, which make up one half of the dry weight of stool, are probably the major components of these fecal solids. [17] Increasing fiber (wheat bran) ingestion from 10 to 26 g/d increases average stool weight from 100 to 149 g/d and increases average stool frequency from less than once to twice per day. [9] The weight of women’s stool is less than that of men by one half, reflecting differences in dietary fiber intake or hormonal factors. [9] There is some controversy whether the ovarian cycles do [9] or do not [18] influence stool weight and consistency. Both exercise [19] and stress [20] increase stool weight, presumably by decreasing jejunal or colonic fluid and electrolyte absorption. Even personality factors correlate with stool weight. [6] Finally, intralumenal bile acid content may influence stool weight, because the ingestion of cholestyramine [21] or aluminum hydroxide, [22] potent bile acid-binding substances, induces constipation. As described later, abnormal stool weight (>200–300 g/24 h) is almost always the result of a failure of intestinal solute and fluid absorption or actual solute and fluid secretion.

PATHOPHYSIOLOGY OF DIARRHEA

Abnormal Motor Function

In the early 20th century, diarrhea was thought to be caused primarily by increased gastrointestinal motility. Although gastrointestinal motility plays a role in diarrhea (see Chapter 11, Chapter 73, and Chapter 86), most of the diarrheal conditions that have been studied have shown alterations of both intestinal fluid and electrolyte transport and the induction of propagative forms of intestinal motility. What is less clear is whether there is diarrhea caused specifically and only by abnormal motility, a condition termed *diarrhée motrice.* The diarrhea caused by autonomic dysfunction in patients with hexosaminidase B deficiency (Sandhoff disease) may be such a type of diarrhea. [23] Perhaps the “pseudodiarrhea” of anorectal disease and the rapid small intestine transit of IBS are other examples of motility-induced diarrhea. Most clinicians, however, would agree with the concept of the diarrhea spiral shown in Figure 42-1.

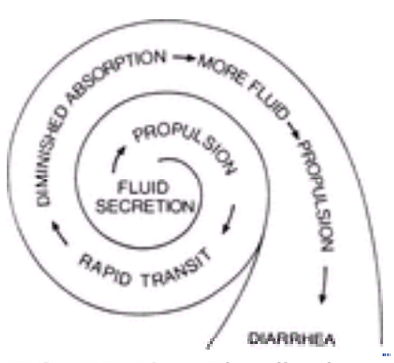

FIGURE 42-1. The diarrhea spiral. An increase in the amount of intralumenal fluid resulting from abnormalities in intestinal fluid and electrolyte transport initiate propulsive activity both by reflex and as a result of the same pathophysiological processes that disturbed epithelial function. Rapid transit follows with decreased contact time and perhaps also with diminished surface area. This causes diminished absorption, more intralumenal fluid, more propulsion, and finally diarrhea. (From Read NW. Diarrhée motrice. Clin Gastroenterol 1986;15:657.)

Abnormal Fluid and Electrolyte Transport

Decreased Absorption As shown in Table 42-1, entering the duodenum each 24 hours is 8 to 10 L of fluid containing 800 mmol sodium (Na^+), 700 mmol chloride (Cl^-), and 100 mmol potassium (K^+). Two liters of this duodenal load is derived from the diet; the remainder comes from secretions of the salivary glands, stomach, liver, pancreas, and the duodenum itself. The small intestine normally absorbs all but 1.5 L of this fluid, and this is the volume characteristically presented to the colon. The colon, in turn, absorbs all but approximately 100 mL of this fluid, which contains approximately 3, 8, and 2 mmol of Na^+, K^+, and Cl^-, respectively. Although the maximum absorptive capacity of the small intestine remains undefined, the capacity of the normal adult human colon is 4 to 5 L/24 h. [24] Theoretically, diarrhea can result from decreased absorption by either the small intestine or the colon. If either deranged epithelial transport mechanisms or the presence of nonabsorbable solutes in the intestinal lumen reduce the absorptive capacity of the small intestine by 50%, the daily volume of fluid then presented to the normal colon (approximately 5 L) would exceed its absorptive capacity. A stool excretion of up to 1000 mL would result, which, by definition, is diarrhea. Alternatively, if the colon is deranged so it cannot absorb even the 1.5 L normally presented to it by the small intestine, then diarrhea (stool volume >200 mL/24 h) would result.

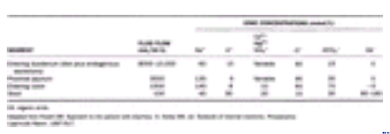

TABLE 42-1 Organ Physiology of Human Intestinal Water and Solute Transport

Increased Secretion In the decade after 1965, scientists rediscovered and documented the ability of the intestine to secrete as well as to absorb fluid and electrolytes, and the result was an entirely new concept: intestinal secretion as a pathophysiological mechanism of diarrhea. The subsequent discoveries that neurotransmitters, hormones, bacterial enterotoxins, inflammatory mediators, and cathartics all stimulated intestinal Cl^- and water secretion through changes in intracellular cyclic adenosine monophosphate, cyclic guanosine monophosphate, or ionized calcium (Ca^{2+}) further developed this concept (see Chapter 14). Although initially it was thought that bacterial enterotoxins cause secretion only by a direct effect on enterocyte receptors, 50% or more of the intestinal secretion initiated by bacterial enterotoxins in vivo comes about from stimulation of receptors on enterochromaffin cells that release hormones that activate the enteric nervous system, secondarily stimulating the enterocyte. [25], [26] Furthermore, inflammatory mediators (adenosine, histamine, serotonin [5-HT], hydrogen peroxide, platelet-activating factor, leukotrienes, and prostaglandins) released from immune cells (mucosal mast cells and resident phagocytes such as eosinophils, macrophages, and neutrophils) and mesenchymal cells (myofibroblasts, endothelium, and smooth muscle) in the lamina propria and submucosa are also capable of

initiating intestinal secretion. [27], [28] These mediators may directly stimulate the enterocyte and may also activate the enteric nervous system. Studies of intestinal electrolyte and water transport have demonstrated that the intracellular messengers also inhibit electrically neutral NaCl absorption, in addition to stimulating electrogenic Cl^- and bicarbonate (HCO_3^-) secretion by enterocytes of the small intestine and colon. Because the direction of net fluid movement is in response to the net direction of solute movement, a submaximal secretory stimulus gives the appearance of an inhibition of absorption rather than stimulated secretion.

Normal Intestinal Physiology

There are two general categories of diarrheal pathophysiology—malabsorption and secretion—also referred to as osmotic and secretory diarrheas, respectively. To understand this concept, it is necessary to consider how a normal intestine alters intralumenal ionic concentrations and osmolality and, subsequently, how these parameters are perturbed by secretory agonists or by the presence of nonabsorbable (osmotic) solutes.

The fasting intestinal flow rate in healthy humans averages approximately 2.5 mL/min in the upper jejunum and 0.4 to 0.9 mL/min across the ileocecal valve. [24] After meals, flow rates depend on the rate of gastric emptying, the rates of pancreatic and biliary secretion, and the osmolality of the ingested meal. Rates may approximate 20 to 50 mL/min in the upper jejunum and 5 to 10 mL/min across the ileocecal valve. Regardless of whether a subject ingests a hypotonic meal, such as a steak with an osmolality of 230 mOsm/kg H_2O, or a hypertonic meal, such as milk and a doughnut with an osmolality of 630 mOsm/kg H_2O, the very permeable duodenum allows the movement of water and electrolytes into or out of the lumen, rendering the meal approximately isotonic by the time it reaches the proximal jejunum (Fig. 42-2). At this point, the electrolyte content is essentially that of plasma (Fig. 42-3). Furthermore, the volume of this meal is augmented by gastric, pancreatic, biliary, and duodenal secretions such that the 313-mL milk and doughnut meal expands to 1200 mL and the 645-mL steak meal approaches 2000 mL by the time it reaches distal duodenum or proximal jejunum. However, the high-carbohydrate hypertonic meal is handled differently from the high-protein hypotonic meal. The rapid digestion of starches and lactose into sugars presents a large osmotic load to the proximal small bowel, and considerable amounts of fluid must passively enter to equilibrate the osmolality. After ingesting this meal, it may be at the midjejunum before efficient absorption of the fluid and electrolytes begins. In contrast, after ingesting the hypotonic steak meal, absorption begins virtually in the duodenum (see Fig. 42-2). In either case, as the chyme moves toward the colon, the electrolyte concentrations in the lumenal fluid remain approximately those of plasma, except for Cl^-, which is reduced to concentrations of 60 to 70 mM, and HCO_3^-, which is increased to a similar concentration, as the result of the Cl^- and HCO_3^- transport mechanisms residing in the small intestine (see Fig. 42-3).

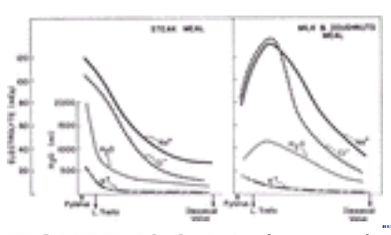

FIGURE 42-2. Intralumenal volumes and electrolyte content in the human small intestine after a hypotonic (steak) meal and a hypertonic (milk and doughnut) meal. (From ref. [12] and Fordtran JS, Locklear TW. Ionic constituents and osmolality of gastric and small intestinal fluids after eating. Am J Dig Dis 1966;11:503.)

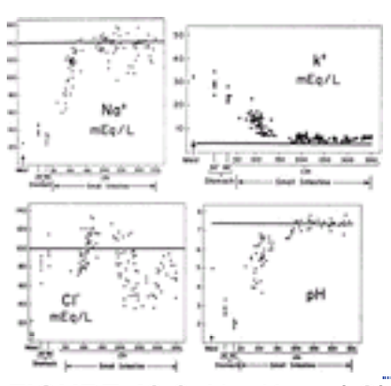

FIGURE 42-3. Na, K, and Cl concentrations and pH values in human gastric and small intestine fluid after a steak meal. The horizontal line in each figure indicates normal plasma concentrations or pH. (From ref. [12].)

In the colon, the amiloride-sensitive Na^+ transport mechanism of the colonocyte and the low epithelial permeability allow this segment to extract Na^+ and fluid very efficiently from the contents. In fact, the crypts of the distal colon may act like suction devices to extract fluid from the stool efficiently, thus forming solid feces. [29] As a result, the Na^+ content of stool decreases to approximately 30 to 40 mM, and poorly absorbed divalent cations such as magnesium (Mg^{2+}) and Ca^{2+} are concentrated to values of 5 to 100 mM, depending on diet (see Table 42-1). K^+ values increase from 5 to 10 mM in the small bowel to 75 to 90 mM in stool as the result of both the lumen negative electrical potential difference, which favors the movement of cations from blood to lumen, and the active K^+ secretory mechanisms present in the colon. [30] The anion concentrations in the intestinal lumen change drastically in the colon. Bacterial degradation of carbohydrate (i.e., unabsorbed starches, sugars, and fiber) creates short-chain fatty acids that attain concentrations of 80 to 180 mM. [31], [32] At colonic pH, these are present as organic anions, mainly acetate, propionate, and butyrate. Depending on the concentrations and quantities of organic anions created, stool pH may decrease to 4 or lower. Even though colonic bacteria degrade carbohydrates and increase the concentration of organic anions and therefore the number of osmotically active particles, the osmolality of stool, if measured as soon as it is passed, is approximately that of plasma, 280 to 310 mOsm. [31], [32], [33] and [34] If stool osmolality is measured hours to days after passage, even if it has been stored in deep freeze, the osmolality may increase to greater than 350 mOsm because of continued bacterial degradation of stool carbohydrate in the collecting container.

Pathophysiology of Osmotic Diarrheas

Contrast the events just described with what transpires after a lactase-deficient subject ingests a lactose test meal, [35] or a physiologically normal subject ingests a nonabsorbable solute such as polyethylene glycol (PEG) or Mg^{2+}. [33] Although the same dilution of the meal occurs in the duodenum (Fig. 42-4), the lactase-deficient subject is unable to reabsorb the fluid because the unabsorbable molecule lactose is not metabolized to absorbable glucose and galactose. Similarly, the osmotic activity of ingested PEG, which is nonabsorbable, or poorly absorbable Mg^{2+} causes fluid entry into the small bowel, rendering the intralumenal solutions isosmotic with plasma. Intralumenal Na^+ concentrations drop to less than 80 mM, and the permeable jejunum cannot absorb Na^+ against such a steep lumen-to-plasma gradient. What happens to the chyme when it reaches the colon depends on the nature of the unabsorbed solute. If the solute is nonmetabolizable (i.e., PEG or Mg^{2+}), some Na^+ and water may be absorbed by the colon, which can concentrate Na^+ from lumenal concentrations of less than 30 mM, but it cannot absorb all the excess stool water. In fact, there is a linear relationship between the ingested osmotic load of PEG and stool water output (stool weight). If the unabsorbed solute is a carbohydrate (i.e., lactulose or lactose) that can be metabolized by colonic bacteria, it effects stool weight differently. The disaccharide is metabolized to short-chain fatty acids (organic anions) that obligate retention of inorganic cations, significantly increasing the number of osmotically active particles in the colon. This increases the solute load, promoting the movement of more fluid into the colon. Although some of the organic anions and fluid are absorbed as they traverse the colon, the unabsorbed carbohydrate, the organic anions with their obligate cations, and fluid are excreted in the stool. [33]

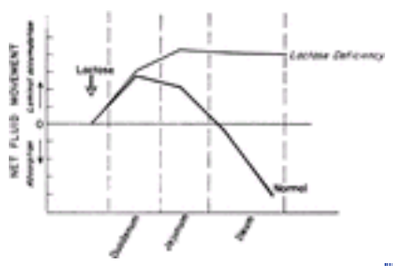

FIGURE 42-4. Changes in fluid absorption and secretion in the small intestine of normal and lactase-deficient subjects after a lactose meal of 50 g/m ^{2} body surface area in 400 mL of distilled water. (From Binder HJ, Bayless TM, Whiting DS. Pathophysiology of diarrhea. Unit VIIB. In: The undergraduate teaching project in gastroenterology liver disease. Timonium, MD: American Gastroenterological Association, 1979; data from ref. [35].)

With ingestion of either unabsorbable solute (i.e., Mg^{2+} or PEG) [33] or unabsorbed carbohydrate (i.e., lactulose [33] or, in some persons, lactose [35]), a considerable amount of the osmolality of stool results from the nonabsorbed solute, so there is a significant difference, or gap, between stool osmolality and the sum of the electrolytes in the stool (see section " Stool Weight, Response to Fast, and Stool Osmotic Gap").

The osmotic solutes causing osmotic diarrheas can be derived from either exogenous (ingested) or endogenous sources and may result from congenital or acquired malabsorptive disease. The causes are listed in Table 42-2 and are discussed in more detail in later sections.

Exogenous
Laxatives
Polyethylene glycol/saline (Golytely), $Mg(OH)_2$ (Milk of Magnesia), $MgSO_4$ (Epsom salts), Na_2SO_4 (Glauber or Carlsbad salt), Na_2PO_4 (neutral phosphate), lactulose
Antacids
Those containing MgO or $Mg(OH)_2$
Dietetic foods, candy or chewing gum, and elixirs containing sorbitol, mannitol or xylitol
Acarbose (α-glucosidase inhibitor)
Olestra, orlistat (lipase inhibitor)
Miscellaneous drugs
Long-term ingestion of colchicine, cholestyramine, neomycin, paraaminosalicylic acid, biguanides, methyldopa
Endogenous
Congenital
Specific malabsorptive diseases
Disaccharidase deficiencies (lactase, sucrase-isomaltase, trehalase)
Glucose-galactose or fructose malabsorption
Generalized malabsorptive diseases
Abetalipoproteinemia and hypobetalipoproteinemia
Congenital lymphangiectasia
Enterokinase deficiency
Pancreatic insufficiency (cystic fibrosis or Schwachman syndrome)
Acquired
Specific malabsorptive diseases
Postenteritis disaccharidase deficiency
Generalized malabsorptive diseases
Pancreatic insufficiency (alcohol), bacterial overgrowth, celiac sprue, rotavirus enteritis, parasitic diseases (giardiasis, coccidiosis), metabolic diseases (thyrotoxicosis, adrenal insufficiency), inflammatory disease (eosinophilic enteritis, mastocytosis), protein-calorie malnutrition, short-bowel syndrome, jejunoileal bypass

TABLE 42-2 Classification of Osmotic or Malabsorptive Diarrhea

Pathophysiology of Secretory Diarrheas

In secretory diarrheas, particularly in the fasting state, the major solutes in the lumen are Na^{+}, K^{+}, Cl^{-}, and HCO_3^{-}. It is the failure to absorb these electrolytes, their active secretion, or both that determines the amount of fluid entering or leaving the colon. In secretory diarrheas, therefore, the stool osmolality will be very close to twice the concentrations of stool Na^{+} plus K^{+}.

As is the case with osmotic causes of diarrhea, the stimuli causing secretory diarrhea may be of exogenous origin or they may be endogenous (Table 42-3). Endogenous substances such as dihydroxy bile acids [36] and dietary long-chain fatty acids may cause secretory diarrhea, [37], [38] particularly if they have been hydroxylated by intestinal microflora. [39] The important concept here is that there are "malabsorbed" endogenous detergents that may lend an element of secretory diarrhea to otherwise malabsorptive diseases. The detergent stool softener dioctyl sodium sulfosuccinate [40] and the cathartic ricinoleic acid (castor oil) [41] are examples of exogenous long-chain fatty acids that stimulate colonic secretion.

Exogenous
Laxatives
Phenolphthalein, anthraquinones, bisacodyl, oxyphenisatin, senna, aloe, ricinoleic acid (castor oil), dioctyl sodium sulfosuccinate
Medications
Diuretics (furosemide, theophilline): asthma medication (theophylline); thyroid preparations; methionine
Cholinergic drugs; glaucoma eye drops and bladder stimulants (acetylcholine analogs or mimetics); myasthenia gravis medication (cholinesterase inhibitors); cardiac drugs (quinidine and quinine); gout medication (colchicine); prokinetic drugs (metoclopramide); antihypertensives (ACE inhibitors); H_2 blockers (ranitidine); antidepressants (selective serotonin reuptake inhibitors); antineoplastics; chenodeoxycholic acid
Prostaglandins (misoprostol); 5-aminosalicylic acid (sulfasalazopyrin); gold (may also cause colitis); NSAIDs
Toxins
Metals (arsenic); plant (mushroom, e.g., Amanita phalloides); organophosphates (insecticides and nerve poisons); seafood toxins (ciguatera, scombroid poisoning, paralytic, diarrhetic, or neurotoxic shellfish poisoning); coffee, tea, or cola (caffeine and other methylxanthines); ethanol; monosodium glutamate
Bacterial toxin
Staphylococcus aureus, Clostridium perfringens and C botulinum, Bacillus cereus
Gut allergy without histologic change
Endogenous
Congenital
Microvillus inclusion disease
Congenital chloridorrhea (absence of Cl^{-}/HCO_3^{-} exchanger)
Congenital Na diarrhea (absence of Na^{+}/H^{+} exchanger)
Congenital enterocyte heparan sulphate deficiency
Bacterial enterotoxins
Vibrio cholerae, toxigenic Escherichia coli (LT and ST), Campylobacter jejuni, Yersinia enterocolitica, Klebsiella pneumoniae, Clostridium difficile, Staphylococcus aureus (toxic shock syndrome)
Endogenous laxatives
Dihydroxy bile acids and long-chain fatty acids, especially hydroxylated ones
Hormone-producing tumors
Pancreatic cholera syndrome and ganglioneuromas (VIP); medullary carcinoma of thyroid (calcitonin and prostaglandins); mastocytoses (histamine); villous adenoma (secretagogue unknown, ? prostaglandins)
(LT, heat-labile toxin; ST, heat-stable toxin; VIP, vasoactive intestinal polypeptide.)

TABLE 42-3 Classification of Secretory (Deranged Electrolyte Transport) Diarrhea

Pathophysiology of Inflammatory Diarrheas

Some diarrheas are characterized by enterocyte damage and death, with minimal to severe inflammation, in which both malabsorption and secretion occur. As described in Chapter 14, the paradigm of neuroimmunophysiology allows us to postulate how the adherent and invasive microorganisms of infectious diarrhea, as well as idiopathic inflammatory diarrheas such as IBD, cause diarrhea. [26], [27] and [28] After initial colonization, adherence, or epithelial invasion by microorganisms, or the initiated inflammation of IBD, there is a release of various cytokines such as interleukin-1 (IL-1), tumor necrosis factor-a (TNF-a), and chemokines such as IL-8 from the epithelium and subepithelial myofibroblasts (Fig. 42-5). IL-8 is a potent chemotactic molecule that activates resident phagocytes and recruits new phagocytes to the lamina propria. If the chemotactic substance released by the epithelium (IL-8) or by lumenal microorganisms (chemotactic peptides) is also sufficiently concentrated in the lumen of the bowel, neutrophils may cross the epithelium to form a crypt abscess. [42] Release of mediators such as prostaglandins, leukotrienes, platelet-activating factor, and hydrogen peroxide from phagocytes induces intestinal secretion by acting on the enterocyte and also by activating enteric nerves. [25], [26], [43], [44] and [45]

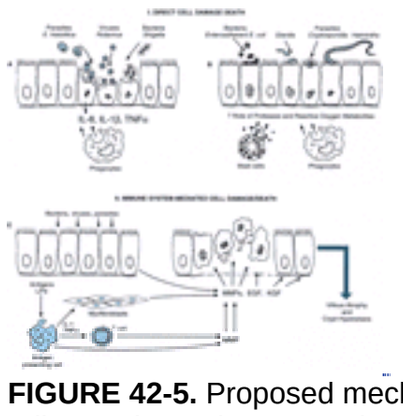

FIGURE 42-5. Proposed mechanism of enterocyte damage and death. Direct damage as a result of (**A**) enterocyte penetration and (**B**) secretion of toxic products by adherent bacteria or parasites. There may be a role for immune cell products in the damage also (see **C**). Indirect (immune system-mediated) damage or death as a result of (**C**) activation of macrophages and dendritic cells (antigen-presenting cells), T-lymphocytes, and myofibroblasts. These cells secrete matrix metalloproteinases (*MMPs*), epidermal growth factor (*EGF*), and keratinocyte growth factor (*KGF*), which remodel the tissue, resulting in villous atrophy and crypt hyperplasia.

There are three general mechanisms of inflammatory diarrhea. Most are accompanied by enterocyte brush border damage and some by enterocyte cell death with ulceration. [45]

1. Lumenal or invading microorganisms or parasites may directly damage or kill enterocytes [46] (see Fig. 42-5 *A*).
2. If the infecting microorganism is complex, such as a nematode, then intestinal anaphylaxis will play an important role in the diarrhea (see Fig. 42-5 *B*). Infection with complex worms causes mild inflammatory enteritis, but it is accompanied by the development of IgE and IgG antibodies against the worm. With continued infection or reinfection, the antibodies cross-link IgE or IgG receptors on the mast cells, resulting in the explosive release of mast cell inflammatory mediators such as histamine, adenosine, prostaglandins, and leukotrienes. This pathophysiological response in the gut is not unlike that experienced in the upper airway in allergic rhinitis or asthma, in which there is an initial anaphylactic response followed by inflammation. The resulting intestinal secretion washes out, [45] and the muscle contraction physically expels the nematode from the intestine. [47]
3. Immunologic mechanisms may cause enterocyte damage and death by products released from polymorphic neural leukocytes, epithelial macrophages, and T-lymphocytes.

In all these situations, epithelial cells, macrophages, and subepithelial myofibroblasts may release matrix metalloproteinases that attack the basement membrane and interstitial matrix molecules. [48], [49], [50] and [51] The result is exfoliation of the epithelium and subsequent remodeling of the matrix with the development of villous atrophy and crypt hyperplasia in the small intestine [48] and an attenuated surface but hyperplastic irregular regenerative crypts in the colon. [52] The culmination of these events may be the presence of damaged or immature cells on rudimentary or nonexistent villi of the small intestine and on the surface of the colon. These immature absorptive cells have poor disaccharidase and peptide hydrolase activity, reduced or absent Na^+-coupled sugar or amino acid transport mechanisms, and reduced or absent NaCl absorptive transporters. Conversely, the crypt cells and the new, immature villus or surface cells maintain their ability to secrete Cl^- (and perhaps HCO_3^-). At the same time, the release of inflammatory mediators from the inflammatory cells of the lamina propria stimulates secretion from the hyperplastic crypt and immature villus or surface cells. Immune-mediated vascular damage may cause protein to leak from capillaries. If severe ulceration has occurred, exudation from capillaries and lymphatics may contribute to the diarrhea. After damage, epithelial restitution and proliferation begin secondary to release of prostaglandins and growth factors, such as transforming growth factor, hepatocyte growth factor, keratinocyte growth factor, epidermal growth factor, and fibroblast growth factor, from the epithelial cells, immune cells, and myofibroblasts. [50], [51], [53] These processes repair the epithelial surface. Repeated bouts of inflammation may lead to fibrosis rather than repair. [54] Lymphocyte and neutrophil activation also release IL-1 and tumor necrosis factor-a in the blood, and their action on the brain accounts for some of the systemic effects of severe inflammation (fever, malaise, anorexia, and obtundation). These cytokines also activate corticotropin-releasing factor in the brain that stimulates the pituitary-adrenal axis and initiates the glucocorticoid stress response.

There are four general categories of inflammatory diarrhea: infection, hypersensitivity, cytostatic (anticancer) agents, and idiopathic (possibly autoimmune) diseases (Table 42-4).

With Minimal to Moderate Inflammation
Infections
Bacteria (enteroadherent or enteropathogenic *Escherichia coli*)
Viruses (rotavirus and Norwalk agent, human immunodeficiency virus)
Parasites (*Giardia*, *Cryptosporidium*, *Isospora*, *Cyclospora*, *Ascaris*, *Trichinella*)
Mixed organism (tropical sprue, bacterial overgrowth)
Cytostatic (anticancer) agents
Chemotherapy (mucositis)
Radiation therapy (acute or chronic radiation enteritis, radiation sickness)
Hypersensitivity
Nematode infestation, food allergy
Idiopathic or autoimmune
Microscopic (lymphocytic) and collagenous colitis, Canada-Cronkhite syndrome, graft versus host disease
Medications
Nonsteroidal antiinflammatory drugs; simvastatin; ticlopidine; cimetidine; lansoprazole; gold (Auroitin); cyclosporine
With Moderate to Severe Inflammation With or Without Ulceration
Infections
Destruction of enterocytes (*Shigella*, enteroinvasive *E coli*, *Entamoeba histolytica*, hookworm)
Penetration of mucosa (*Salmonella*, *Campylobacter jejuni*, *Yersinia enterocolitica*, *Mycobacterium avium* complex, Whipple disease)
Hypersensitivity
Celiac sprue, milk or soybean protein hypersensitivity, eosinophilic gastroenteritis, nematode infestation
Drug-induced colitis (gold, methyldopa)
Idiopathic or autoimmune disorders
Ulcerative colitis or proctitis, Crohn's disease, lymphoma

TABLE 42-4 Classification of Inflammatory Diarrheas

ACUTE DIARRHEAS: DEFINITION

Acute diarrheas are defined as those of less than 2 to 3 weeks' duration and, at most, 6 to 8 weeks' duration. Although they have many causes, the most common acute diarrheas are those caused by infectious agents and drugs or chemicals.

ACUTE INFECTIOUS DIARRHEAS

Epidemiology

Developing Versus Developed Countries The most important epidemiologic factor for the diagnosis and management of acute infectious diarrhea is whether the diarrhea is occurring in developing countries or in developed countries. [1], [2], [3] and [4] In 1995, acute infectious diarrhea caused more than 3 million deaths worldwide. This mortality occurred in children younger than 5 years of age in developing nations, where two thirds of the world's population live in extreme poverty, and in areas of rapid urbanization, crowded substandard housing with inadequate sewage disposal and inadequate water supplies, insufficient food with lack of refrigeration, poor education (particularly in regard to personal hygiene), and a fundamental lack of access to health care. [2] In addition to socio-economic status and hygienic practices, in developing countries there is a relationship between diarrhea incidence and ambient air temperature, [55] which may explain the higher incidence of diarrhea in tropical emerging nations. Deaths occur in developed nations as well. The incidence of infant diarrheal deaths in the United States decreased by 75% from 1968 to 1991, [56] but diarrhea was still the principal cause of death for more than 500 children each year. [2], [56] Twenty to 40 of these deaths resulted from rotavirus infection. [57] Reported diarrheal death rates in the United States are probably underestimated, but they may be as high as 5000/year from food-borne infections alone. [58] The death

rate for children and young adults in the United States is 2 to 3/100,000 persons and is approximately 15/100,000 persons for persons more than 74 years old. [59], [60] Thus, even though there are far more episodes of diarrhea in children compared with adults, the elderly are truly the age group at risk for death from diarrheal diseases in this country. In developing countries, children have 100 to 1500 episodes per 100 child-years, and approximately 10% of the episodes result in dehydration requiring therapy. [2] In the United States, children have an average of two to three episodes per year. In the total population of the United States, food-borne illness alone accounts for 76 million episodes of diarrhea and 325,000 hospital admissions per year. [58] With improvement in sanitation and education in the United States, rates of parasitic diarrheas have declined, but, in the 1990s, in those diseases with person-to-person transmission (e.g., rotavirus) or food- or water-borne transmission (e.g., *Salmonella* or *Campylobacter* organisms), the incidences doubled. [61] Preliminary data from the United States Centers for Disease Control and Prevention (CDC) indicate that the rates of *Salmonella, Shigella, Listeria, Escherichia coli,* and *Yersinia* infections (but not *Vibrio* infection) have declined by 20% to 30%, most likely as the result of increased attention to food safety.

Sporadic Diarrhea Most infectious diarrheas are acquired by fecal-oral transmission, which can occur by way of water, food, or person-to-person contact. Although microorganisms can be spread by any of these vehicles, certain classical relations exist between vehicle and disease (Table 42-5). Water systems may be contaminated by human waste as the result of poor sewage systems or by animal feces from farm run-off material. Diarrheal disease results if the water is not properly purified. Beef, pork, or poultry may be the source of infection if it is poorly cooked. More commonly, infection comes from contamination of food-preparing surfaces by organisms present on these meats; the organisms then are spread to uncooked foods, such as salads, that are prepared on these same surfaces. Transmission also comes from minute inoculation of certain foods that is followed by bacterial proliferation because the food is either poorly refrigerated or inadequately heated before serving. This commonly occurs at picnics, banquets, or restaurants. Person-to-person transmission can occur through aerosolization (rotavirus), through contamination of hands (*Clostridium difficile*), or through contamination of fomites. [62], [63] Spread also comes from sexual activity, particularly oral-genital or oral-anal contact.

TABLE 42-5 Epidemiologic Clues to Infectious Diarrhea

Patients with infectious diarrhea complain of nausea, vomiting, and abdominal pain and have watery, malabsorptive diarrhea or dysentery (bloody diarrhea and fever) (see Chapter 74, Chapter 75, and Chapter 88). Both large and small bowel infections can present with any combination of these signs and symptoms, but certain patterns tend to occur characteristically (Table 42-6). Certain enteric infections are accompanied by systemic symptoms that may be clues to their diagnosis or account for delayed, often severe, complications [64], [65], [66], [67], [68], [69], [70], [71], [72], [73] and [74] (Table 42-7). Conversely, patients with systemic diseases (see Table 42-6) may have diarrhea as a significant component of the illness, either because the gastrointestinal mucosa is the portal of entry, as in hepatitis, listeriosis, and legionellosis, or because of the systemic release of inflammatory mediators, such as the interleukins or bradykinin, that cause intestional secretion.

TABLE 42-6 Correlations Between Pathophysiology and Symptoms of Infectious Diarrhea

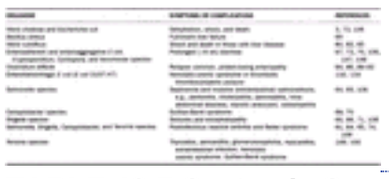

TABLE 42-7 Systemic Symptoms and Complications of Enteric Infections

Food- and Water-Borne Diarrheas Estimates of the incidence of food-borne illness in the United States range from 6 to 81 million cases per year [58], and the World Health Organization (WHO) believes the incidence to be 300 times more frequent than suggested by reported cases. Emerging food-borne diseases over the past several decades include the enteritides serotype of *Salmonella* and *Campylobacter jejuni.* Deaths from *E coli* O157:H7 and *Cyclospora* infections in the United States, United Kingdom, and Japan, as well as the deaths related to bovine spongiform encephalology (mad cow disease) in the United Kingdom, have produced a crisis in public confidence regarding government-regulated food safety. [75], [76] Various factors relating to the industrialization of food consumption and eating habits are responsible for the surge in food-borne illness. [2], [76] Food poisoning occurs not only from invasive organisms but also from toxin producers (see Table 42-5). The infectious food poisonings can occur with ingestion of either fin fish or shellfish. [77], [78], [79], [80] and [81] Fish can become contaminated in their own environment (especially the filter-feeding bivalve molluscs such as muscles, clams, oysters, and scallops), or fish can be contaminated by food handlers. [80] The infectious organisms contaminating seafood include invasive organisms such as hepatitis virus, Norwalk virus, *Salmonella, Shigella, Campylobacter,* and *Plesiomonas,* and watery diarrhea–producing organisms such as *Aeromonas, Clostridium botulinum,* and *Vibrio cholerae*. [80] Organisms that are specific for seafood are the noncholera vibrios, such as *V parahemolyticus,* which causes either watery or bloody diarrhea, and *V vulnificus,* which causes watery diarrhea, but also fatal septicemia especially in those with liver disease. [82], [83] Food poisoning also occurs with chemicals such as monosodium glutamate, heavy metals or insecticides, and natural toxins found in mushrooms or seafood. [77], [78], [79] and [80] Ciguatera, diarrhetic, paralytic, neurotoxic, amnestic, and pfiesteria fish poisonings are all caused by dinoflagellates ingested by fish or shellfish. [77], [78], [79], [80] and [81] Puffer fish poisoning is caused by a toxin (tetrodotoxin) contained only in this fish, and scombroid poisoning comes from the breakdown of flesh in certain fish with the release of histamine.

High-Risk Groups

Antibiotic-Associated Diarrheas Diarrhea may occur in up to 20% of patients receiving broad-spectrum antibiotics, but only a portion (30%–50%) of these diarrheas are the result of *C difficile* infection (pseudomembranous colitis) (Table 42-8). [84], [85], [86] and [87] *C difficile*–negative diarrhea has been ascribed to antibiotic-induced abnormalities in colonic carbohydrate fermentation, with resulting decreased short-chain acid production, [87] to overgrowth of fungi (*Candida* species), [88] or to overgrowth of other, unidentified microorganisms. Non– *C difficile* diarrhea is usually mild and self-limited and clears either spontaneously or in response to cholestyramine therapy. *C difficile* colitis, however, can cause severe diarrhea that has significant morbidity and mortality and may present with a relapsing course after seemingly successful therapy with metronidazole or vancomycin. [89], [90], [91], [92] and [93] Antibiotic-associated diarrhea can follow treatment with any antibiotic, although broad-spectrum antibiotics such as clindamycin and third-generation cephalosporins are particularly problematic. [85], [86], [94] The disease can be nosocomial and is increasing in frequency. The incidence of *C difficile* and other antibiotic-associated diarrheas may be reduced by the concomitant administration of probiotics. [93] Relapses of *C difficile* colitis not responding to repeated courses and tapering regimens of antibiotics [89] may respond to long-term cholestyramine therapy, [90] intravenous immunoglobulin infusion, [92] or administration of normal, donated stool through the colonoscope. [91]

TABLE 42-8 High-Risk Groups for Infectious Diarrhea

Traveler's Diarrhea Not only are North American travelers to developing countries at high risk of acute infectious diarrhea, but so are travelers on airplanes and cruise ships, where errors in food preparation can lead to common-source epidemics. [80] Bacterial agents account for 85% of traveler's diarrhea, with enterotoxigenic *E coli* (ETEC), *Shigella, Campylobacter, Aeromonas, Plesiomonas, Salmonella* and noncholera vibrios leading the list. [95], [96] Prevention through education or chemoprophylaxis (doxycycline, trimethoprim-sulfamethoxazole, or fluoroquinolones) and both fluid replacement and antibiotic treatments are discussed in more detail in Chapter 56.

Sexually Transmitted Diarrheas Men who have sex with men and prostitutes are apt to develop infectious diarrhea through the oral-fecal route. "Gay bowel syndrome" is discussed in Chapter 88, and AIDS diarrhea is covered in detail in Chapter 124.

Day-Care Diarrhea Diarrhea is extremely prevalent in the more than 6 million children in the United States attending day care, and it usually involves those organisms that colonize at a low inoculum dose (e.g., *Shigella, Giardia, Cryptosporidium*) or those that are spread easily (e.g., rotavirus, astrovirus, adenovirus). [63], [97] However, almost any organism can be isolated in outbreaks of day-care diarrhea. The mechanism of transmission in day-care centers is person-to-person contact by way of fecal contamination of hands and fomites (e.g., toys, surfaces in diaper changing areas, bathroom tap, and flush handles). The secondary attack rate from day-care diarrhea ranges between 10% and 20%, representing an important source of infection for parents and siblings as well. [63], [98]

Diagnosis of Acute Infectious Diarrheas

Differential Diagnosis An algorithm for the evaluation of acute infectious diarrheas is given in Figure 42-6. This approach relies heavily on consideration of the epidemiology of acute infectious diarrhea as described earlier and on ruling out other causes of acute watery or bloody diarrhea. [99]

FIGURE 42-6. Algorithm for the diagnostic approach to acute diarrhea. (Adapted from Aranda-Michel J and Giannella R. Acute diarrhea: a practical review. Am J Med 1999;106:670.)

The differential diagnosis of acute watery diarrhea includes the food toxins, drugs, and medications listed in Table 42-2 and Table 42-3. Although these drugs are the most common culprits, any medication can cause diarrhea. In children, acute appendicitis may be misdiagnosed as "acute gastroenteritis," thus delaying surgery. [100] The differential diagnosis of acute bloody diarrhea in adults includes infectious causes, superior mesenteric arterial or venous thrombosis or ischemic colitis (see Chapter 131), IBD (see Chapter 83), and drug-induced colitis (see Chapter 85). Although the patient's age and the presence of manifestations of atherosclerosis may suggest mesenteric vascular insufficiency or ischemic colitis, older people also may have more severe clinical manifestations with invasive infectious agents. Radiographically, enterohemorrhagic *E coli* infection can mimic ischemic colitis, with submucosal hemorrhage presenting as thumbprinting on the flat plate of the abdomen. Ulcerative proctitis or colitis and Crohn's disease can present with an acute course that suggests infectious enterocolitis, or vice versa. Although the colonoscopic and radiographic appearance of the various invasive enteritides can mimic IBD with aphthous-like ulcers, segmental colitis, or pancolitis, colonic biopsy will yield histological hallmarks that differentiate IBD from infectious diarrheas. *C difficile* infection may have the classic pseudomembranous enterocolitis appearance by radiography or endoscopy, but on occasion the pseudomembrane is not present, particularly in pancytopenic patients undergoing cancer chemotherapy, and then the disease looks more like IBD. On rare occasions, the opposite mistake is made, and blood-filled macrophages in the stool of a patient with ulcerative colitis are mistaken for blood-filled trophozoites of amebiasis, or chronic ischemic colitis masquerades as pseudomembranous colitis. To complicate matters further, the colonic mucosa inflamed with ulcerative colitis appears to be more susceptible to colonization by pathogenic enteric bacteria. *Salmonella, Campylobacter,* or *C difficile* infection may accompany IBD and may confuse the diagnosis and treatment. Drugs that may induce colitis indistinguishable from ulcerative colitis include gold (administered for rheumatoid arthritis) and methyldopa (for hypertension).

Laboratory Diagnosis of Infectious Diarrheas The cost of making the diagnosis of infectious diarrhea and of delivering specific (antibiotic) therapy is high, especially for a disease that is common and is usually mild and self-limited. Because fewer than 10% of stool specimens are positive for pathogens, [99], [101] the cost of a single positive stool culture is quite high (more than $1000), if stools are cultured indiscriminately. [102], [103] However, the cost can be reduced to $30 per culture if only *Campylobacter, Salmonella,* and *Shigella* are sought and if only liquid stools are cultured. Special rules apply to the culture of stool in hospital-acquired diarrhea [104], [105] (see section "Infectious Nosocomial Diarrhea"). The use of antibiotics in infectious diarrhea is also controversial. [82], [99], [106] Therefore, the questions revolve around who should undergo a diagnostic evaluation, who should be treated and when, and whether treatment should consist of only symptomatic therapy or symptomatic therapy plus specific antibiotics. The algorithm in Figure 42-6 uses discriminating symptoms to determine whether fecal specimens should be sent for laboratory diagnosis. [99], [103] Fecal leucocyte stains [107] are not useful for inpatients [108] and have poor sensitivity for ruling out invasive infectious diarrhea. [109] Stool excretion of granulocyte marker proteins is being evaluated as perhaps a better surrogate for fecal leukocytes. [110], [111], [112] and [113] In addition, certain organisms that can cause diarrhea are not generally identified by routine diagnostic methods. For example, certain causes of bloody diarrhea, such as *Yersinia, Plesiomonas,* and enterohemorrhagic *E coli* O157:H7, may require specific special culture techniques or can be identified only with type-specific antisera. [114] Similarly, *Aeromonas, Cryptosporidium, Cyclospora, Microspora,* and noncholera *Vibrio* organisms, which cause watery diarrhea, may require special laboratory attention for culture and identification. The enterotoxigenic, enteropathogenic, enteroinvasive, enteroadherent, and enteroaggregative *E coli* organisms are diagnosed only by methods available in research laboratories. Therefore, the physician may need to communicate the presumptive diagnosis to the laboratory. The enteroadherent bacteria and certain parasites such as *Giardia* and *Strongyloides* may be difficult to detect in stool and may best be diagnosed by intestinal biopsy. *C difficile* is best diagnosed by toxin assay, [84], [85] and [86] although the rapid enzyme-linked immunosorbent assays commonly used in hospitals have a sensitivity of only 70% to 90%, so false-negative results can occur. [115] Finally, 20% to 40% of all acute infectious diarrheas remain undiagnosed even with the application of all laboratory techniques.

Treatment of Acute Infectious Diarrheas

The treatment of diarrhea can be divided into symptomatic therapy (fluid replacement and antidiarrheal) and specific antimicrobial therapy. [116], [117] and [118] Because death in most instances of acute diarrhea is caused by dehydration, a cardinal principle in the management of any diarrhea consists of assessment of the degree of dehydration and replacement of fluid and electrolyte deficits. [99], [118], [119] Severely dehydrated patients, particularly those with altered mental status, should be rehydrated with intravenous Ringer lactate or saline solutions to which additional K^+ and $NaHCO_3$ may be added as necessary. Alert patients should be given oral replacement solution (ORS). Whereas experience in developing countries has demonstrated the efficacy of ORS in treating severe dehydrating diarrhea, ORS use in developed countries has lagged behind. This may account in part for some of the morbidity and mortality still observed in the United States. [119], [120], [121] and [122] In mild

to moderate dehydration, ORS can be given to infants and children in volumes of 50 to 100 mL/kg over a period of 4 to 6 hours; adults may need to drink up to 1000 mL/h. [120], [122] After the patient is rehydrated, ORS is given at rates equaling stool loss plus insensible losses until the diarrhea ceases. The WHO solution is endorsed for use in both rehydration and maintenance therapy worldwide, although some are concerned that the high Na^+ content (90 mM) may lead to hypernatremia and the high osmolarity (311 mOsm/L) may worsen diarrhea. Consequently, many clinicians recommend alternating full-strength WHO ORS with equal volumes of water or giving a mixture of two parts ORS with one part water or formula during the postrehydration, maintenance phase of ORS therapy. Studies are emerging proving the superiority of hypotonic ORS solutions (Na 75 mM, osmolarity 245 mOsm/L). [120], [123]

The addition of amino acids to glucose-based ORS or the substitution of rice gruel or cereal for glucose has created “super ORS” solutions that may be even better than the conventional WHO solution. [118], [124] A newer concept for rehydration is to add amylase-resistant starch (pectin) to the ORS. This starch escapes digestion and absorption in the upper bowel and is then broken down to short-chain fatty acids by bacteria in the colon, where it promotes fluid absorption. [125], [126] Clearly, the WHO solution and the commercial ORS solutions are superior to Gatorade, Coca-Cola, or fruit juices, which were used in the past for rehydration in this country (Table 42-9). ORS can be used safely with loperamide antidiarrheal medications in traveler’s diarrhea. [127]

SOLUTION	Na (mM)	K (mM)	Cl (mM)	CITRATE (mM)	GLUCOSE* (mM)
WHO solution	90	20	80	30	111 (20)
Reduced osmolarity ORS	75	20	65	10	75 (13.5)
Rehydralyte	75	20	65	30	139 (25)

TABLE 42-9 Composition of Oral Replacement Solutions for the Treatment of Diarrhea

A devastating effect of recurrent diarrheal diseases is malnutrition. At one time, complete or partial bowel rest was recommended during acute diarrhea. It is now clear that patients with acute diarrhea should be fed, not starved. [128], [129] Continued breast-feeding or half-strength formula for infants is recommended. Ad libitum diets low in fiber, Na^+-rich soups, and foods with high sugar content are preferred for older children and adults.

Bismuth subsalicylate (Pepto-Bismol, Procter & Gamble, Cincinnati, OH) is safe and efficacious in bacterial infectious diarrheas. [99], [116], [117] and [118] It may not have antidiarrheal activity in viral diarrhea, raising the question whether its main effect in traveler’s diarrhea relates to its antibacterial or antiinflammatory action or perhaps to the ability of its clay vehicle to adsorb enterotoxins. Kaolin-pectin or smectic preparations may be minimally effective. [130], [131] Because of the possibility of worsening the colonization or invasion of the organism by paralyzing intestinal motility and evidence that the use of motility-altering drugs may prolong microorganism excretion time, neither opiates nor anticholinergic drugs are recommended for infectious diarrheas. [99], [117], [118] However, it has been shown that loperamide can be both useful and safe in traveler’s diarrhea, provided it is not given to patients who have high fever or to those with blood or pus in the stool, especially when the drug is administered concomitantly with effective antibiotics. [99], [117], [118] The anxiolytics and antiemetics that decrease sensory perception may make symptoms more tolerable and are generally safe.

Antibiotic therapy in the infectious diarrheas is controversial. [82], [99], [106], [117], [118] There are certain infectious diarrheas in which treatment is recommended: shigellosis, cholera, traveler’s diarrhea, pseudomembranous enterocolitis, parasitic infections, and sexually transmitted diseases. Patients with mild disease and those who are clearly improving may not need antibiotic treatment. There are other diarrheas in which treatment may not be indicated because there is no effective therapy: viral diarrhea and cryptosporidiosis. Treatment of *E coli* O157:H7 infection is not recommended at present because current antibiotics do not appear to be helpful, and the incidence of hemolytic uremic syndrome may be greater after antibiotic therapy. [132], [133] There are several diseases in which the indications are less clear but treatment is usually recommended: infection with the noncholera vibrios, prolonged or protracted infection with *Yersinia,* early in the course of campylobacteriosis, *Aeromonas* and *Plesiomonas* infections, and nursery outbreaks of enteropathogenic *E coli* diarrhea. Regardless of the cause of infectious diarrhea, patients should probably be treated if they are debilitated with malignant disease, are immunosuppressed, have an abnormal cardiovascular system or valvular, vascular, or orthopedic prostheses, have hemolytic anemia (especially if salmonellosis is involved), or are extremely young or old. Treatment is also advised for those with prolonged symptoms and those who relapse. These guidelines were developed for patients with salmonellosis, [134] but they are useful guidelines for all infectious diarrheas. Chapter 74, Chapter 75, Chapter 88, Chapter 125, and Chapter 126 outline the antimicrobials of choice for the various infections, as do references [82], [106], and [116], [117] and [118]. Although there is evidence that early treatment alters the course of infectious diarrhea, [134] it usually it takes 3 to 5 days after obtaining stools before specific organisms can be grown and identified. If treatment was warranted while awaiting laboratory diagnosis, the quinolones (e.g., ciprofloxacin), which have efficacy against most enteric infections, are the treatments of choice. [82], [106], [116], [117] and [118] Trimethoprim-sulfamethoxazole is second-line therapy in this setting. If the symptom complex suggests *Campylobacter* infection, erythromycin should be added. Prolonged diarrhea suggesting giardiasis or bacterial overgrowth should be treated with a course of metronidazole even if stools are negative for cysts.

PROLONGED INFECTIOUS DIARRHEAS

Severe Protracted Diarrhea in Infants and Children

Although classically a postinfectious diarrhea syndrome in infants and children of developing countries, [135], [136] severe protracted diarrhea can occur in milder forms (*postenteritis syndrome*) [137] or in a severe form in developed countries as well. Postulated causes of the syndrome are enteroadherent bacterial infection, uncleared cryptosporidial or *Cyclospora* infection, bacterial overgrowth, or infection with unknown organisms, which lead to disaccharidase deficiency in mild cases and profound generalized malabsorption in severe forms. [138], [139] Severe malnutrition and death (mortality up to 50%) can ensue. [140] Treatment includes dietary lactose exclusion in mild disease [137] and controlled feeding or total parenteral nutrition in those severely affected. [129] Metronidazole, tetracycline, trimethoprim-sulfamethoxazole, folic acid, and zinc therapy also may be of help. [140], [141] Where this disease ends and tropical sprue begins is uncertain; the difference may be only the age of the patient. [139]

Tropical Sprue

This disease of unknown origin affects those in certain tropical parts of the world, including the Indian subcontinent and Asia, the West Indies, northern part of South America, parts of Central America, and central and southern Africa (see Chapter 75). It can occur in visitors residing in these areas for as short a time as 1 to 3 months. Its acute onset suggests an infectious origin, perhaps with a coccidia protozoa, or another unknown infection that either persists or in some way leads to brush border damage and bacterial overgrowth with perpetuation of the disease. [138] Small bowel histology may show minimal villus blunting and inflammatory infiltrate or may reveal severe villus atrophy and crypt hyperplasia. Abnormal pancreatic exocrine function may occur in tropical sprue as it does in celiac sprue. [142] If the patient is removed from the tropical areas and the mucosal change is mild, the disease may remit spontaneously. [143] A combination of tetracycline and folic acid is effective therapy.

Persistent Diarrhea in Travelers

Protracted diarrhea lasting more than 3 to 4 weeks has been seen in up to 10% of returned travelers. [143], [144] Undiagnosed infection with bacteria or protozoal organisms that typically causes long-lasting diarrhea may be the cause (see section that follows), and stool cultures and evaluation for ova and parasites as well as antimicrobial treatment may lead to cure. Because these patients usually have already received routine traveler’s diarrhea antibiotics (e.g., trimethoprim-sulfamethoxazole or quinolones) tetracycline or metronidazole, which may be effective against enteroadherent *E coli,* protozoal organisms, and

nonspecific bacterial overgrowth, may be given when the results of stool evaluations for pathogens are negative. [144], [145] The pathophysiological mechanisms proposed here are similar to those proposed for severe protracted diarrhea and tropical sprue (see earlier). The point at which protracted traveler's diarrhea ends and tropical sprue begins may be a matter of obtaining a biopsy specimen for small bowel histology.

Protracted Infectious Diarrhea in Adults

In the United States, some organisms typically cause a prolonged course of diarrhea. Organisms that are difficult to diagnose and are known to cause protracted or prolonged diarrheas include enteropathogenic (enteroadherent) *E coli,* [145] *Giardia,* [146] *Amoeba,* [82] *Cryptosporidium,* [147] *Aeromonas,* [72], [148] and *Yersinia enterocolitica.* [149], [150] *C difficile* infection is often difficult to clear, and five or more relapses have been observed. [85], [86], [89], [90], [91] and [92] Patients with chronic diarrhea should have these diagnoses excluded. If none of these organisms are found, a therapeutic trial of metronidazole or trimethoprim-sulfamethoxazole may be indicated. [143], [144]

Infectious Diarrhea–Induced Irritable Bowel Syndrome and Brainerd or Epidemic Chronic Diarrhea

As many as 25% of patients will experience IBS–like symptoms (pain, bloating, urgency, sense of incomplete evacuation, loose stools) for 6 months or longer after documented infectious diarrhea. [151], [152], [153] and [154] The pathophysiology is thought to be unresolved, mild intestinal inflammation. In some patients, the syndrome may cause acquired bile acid malabsorption, and these patients may respond to cholestyramine therapy (see section " Bile Acid Diarrhea"). [153], [154] and [155]

Severe and prolonged diarrhea after raw milk ingestion was reported in outbreak form in Brainerd, Minnesota in the 1980s. [156] Patients developed prolonged chronic watery diarrhea with weight loss and were often mistakenly diagnosed as having IBS. It also has been reported in other states in association with raw milk ingestion or untreated water ingestion. Many of these patients have microscopic inflammation on colonic biopsy. The disease occurs in sporadic form and probably represents a severe form of infectious diarrhea–induced IBS, as discussed earlier. It may also be the same as *chronic idiopathic diarrhea* discussed in the section "Chronic Diarrheas."

NOSOCOMIAL DIARRHEAS

Diarrhea is either the first or second most common nosocomial illness [157] among hospitalized patients and those residing in chronic care facilities for the retarded, the mentally disturbed, or the elderly. Often this is a hidden problem, known only by the nurse's aide who changes the bed sheets. In the intensive care setting, it occurs in 30% to 50% of patients, [15], [158] and in chronic care facilities more than one third of patients have a significant diarrheal illness each year. [159], [160] This is a multifactorial condition whose recognized causes are discussed in the following subsections.

Fecal Impaction

Clinical lore has it that the most common cause of diarrhea in hospitalized or institutionalized patients is fecal impaction. Such paradoxical diarrhea and incontinence appear to be most common in patients with dementia or psychosis. [161] Although the validity of this clinical impression remains uncertain, performing a rectal examination and perhaps a flat and upright abdominal radiograph in such patients can certainly be recommended.

Medications and Weight-Reducing Agents

Any of a patient's medications may initiate diarrhea. However, certain medications are more apt to cause diarrhea than others [162] (see Table 42-3 and Table 42-4). Antibiotic-associated diarrhea (see earlier) is certainly the most common manifestation of drug-related diarrhea. Orlistat, a lipase inhibitor used to treat obesity, and acarbose, an a-glucosidase inhibitor used to treat diabetes, can both cause diarrhea. [162] Olestra, a nonabsorbable fat substitute used for frying foods, may also cause diarrhea at doses greater than 40 g/d. [163]

Elixir Diarrhea

Drugs such as theophylline or KCl made up in liquid formulations (elixirs) may cause diarrhea because of the high content of sorbitol used to sweeten the elixir. [164] This is the iatrogenic equivalent of "chewing gum diarrhea" (see section " Sorbitol and Fructose Diarrhea"). Patients receiving medications in the liquid form through feeding tubes may receive more than 20 g of sorbitol daily.

Enteral Feeding

An important but poorly understood cause of diarrhea is tube feeding, particularly in the critically ill patient. [165], [166] and [167] Up to 35% of patients receiving tube feeding develop diarrhea. Various pathophysiological factors are hypothesized: bacterial contamination of the enteral formula; administration of hypertonic solutions that cause diarrhea by inducing a form of "dumping syndrome"; administration of lactose-containing formulas to lactase-deficient subjects; administration of sorbitol-containing elixirs; administration of low-Na^+ formulas that result in considerable blood-to-lumen Na^+ diffusion in addition to fluid movement if the formula is hypertonic as well; and hypoalbuminemia in malnourished patients, a condition that alters the oncotic or Starling forces in the gut capillaries, thus preventing absorption or inducing secretion. Although there are experimental studies that support all these possibilities, there are no clear data supporting any single or group of pathophysiological processes (see Chapter 53). Furthermore, more mundane causes of diarrhea (e.g., concomitant medication, *C difficile* infection) can also occur in these patients.

Infectious Nosocomial Diarrhea

Patients in mental institutions have high incidences of infection by bacterial pathogens, protozoan parasites (*Entamoeba histolytica* and *Giardia*) and helminths. [160], [168] Infectious diarrheas are also common in acute-care hospitals; these illnesses account for more than 20% of nosocomial infections and are second only to respiratory infections on pediatric wards. [160] The rates are particularly high in intensive care settings (8 cases per 100 admissions). [169] In the intensive care setting, a role has been postulated for tube feeding as a source of infection in combination with histamine (H_2) blockers, which eradicate the gastric acid barrier. The most common cause in the past was infection with *Salmonella* species, and it still occurs. [170] However, since 1980, *C difficile* has accounted for more than 50% of hospital cases. [171] Although shigellosis still occurs, it is now a rare nosocomial infection in hospitals. [172] The likelihood of a nosocomial infection caused by *Salmonella* or *Shigella* organisms in the tertiary hospital is so rare that routine cultures for *Salmonella* and *Shigella* and ova or parasite examinations are not cost effective and should not be ordered if diarrhea begins 3 to 4 days after hospital admission, provided the patient is not more than 65 years old and has no preexisting diseases, the patient does not have AIDS or neutropenia, there is no evidence of a nosocomial outbreak, and the patient has no nondiarrheal manifestation of infection (e.g., fever, abdominal pain, erythema nodosum). This dictum is known as the *modified 3-day rule*. [104], [105]

Immunosuppressed patients are another important group susceptible to nosocomial diarrhea. Viral infections (rotavirus, astrovirus, adenovirus, and coxsackievirus) may be important causes of nosocomial infectious diarrheas in bone marrow transplant units. [169], [173] In this setting, infectious diarrhea must be differentiated from the diarrhea of graft versus host disease.

Outbreaks of hemorrhagic *E coli* and *C difficile* infections have been recognized in hospitals and nursing homes. [94], [174], [175] Some of the strokes, injuries from falls, and even myocardial infarctions occurring in nursing home settings could be caused by the hypovolemia and toxic state induced by these nosocomial diarrheas. Infection control measures and restricting use of broad-spectrum antibiotics may reduce the incidence of nosocomial *C difficile* diarrhea. [176]

Hospital-acquired diarrheas may be a causative factor in other nosocomial hospital infections, such as infection of the urinary tract. [177] The impact of nosocomial diarrhea on the duration and cost of hospitalization and on morbidity is probably substantial.

Cancer Treatment

The incidence of acute, mild diarrhea with chemotherapy or radiation therapy is quite high, approaching 100% with some agents or irradiation regimens. [178] Radiation therapy also causes chronic diarrhea (see Chapter 132). Nausea, vomiting, and diarrhea are dose- and age-related phenomena. Chemotherapy diarrhea is more likely with specific forms of chemotherapy, such as the following: 5-fluorouracil, irinotecan (CPT-11), interferon-a2A, topotecan, and IL-2. [178], [179] and [180] The combination of 5-fluorouracil plus leucovorin causes severe watery diarrhea. [178], [179] The incidence of diarrhea with IL-2 therapy approaches 80%. [180] Radiation may induce diarrhea either through damage to segments of bowel during pelvic irradiation or through damage to the entire bowel if high-dose, total body radiation is received (see Chapter 132). Total-body radiation at low doses (1.5 Gy) causes only nausea and vomiting; watery or bloody diarrhea ensues at total-body doses of greater than 6 Gy. Pelvic irradiation over a period of 4 weeks with doses of 3 to 4 Gy also may cause diarrhea. Current treatment for both chemotherapy- and radiation-induced diarrhea is symptomatic and includes antimotility drugs and cyclooxygenase blockers. [178] Octreotide may be helpful in severe chemotherapy- or radiation-induced diarrhea. [178]

RUNNER'S DIARRHEA

Gastrointestinal disturbances including anorexia, heartburn, nausea, vomiting, cramps, urgency, and diarrhea are quite common in those who exercise vigorously, particularly marathon runners and triathletes. [181] Watery, self-limiting diarrhea may occur in 10% to 25% and is particularly common (40%–70%) in women runners. The mechanisms operative in runner's diarrhea are unclear but may involve release of gastrointestinal hormones such as gastrin, motilin, or vasoactive intestinal polypeptide (VIP) or release of inflammatory mediators such as prostaglandins. [182], [183] A role for ischemia has been postulated because of the occurrence of ischemia colitis in marathon runners. [184], [185] Many treatment regimens have been used, but none have been studied thoroughly. Because mouth-to-cecum transit time is either normal or delayed with exercise, [186] antimotility drugs may not help, but they may be tried. Nonsteroidal antiinflammatory agents (NSAIDs) are taken by many runners, but it is not clear whether they help in this condition.

CHRONIC DIARRHEAS: DEFINITION, CLASSIFICATION, AND EPIDEMIOLOGY

Definition and Classification

Chronic diarrheas are those of at least 4 weeks' duration and, more certainly defined, 6 to 8 weeks' duration. They fall into three categories: osmotic (malabsorptive) diarrhea (see Table 42-3), secretory diarrhea (see Table 42-4), and inflammatory diarrhea (see Table 42-5). It would be convenient clinically if the character of the stool correlated well with the pathophysiology; that is, if an obviously steatorrheic stool occurred with all cases of malabsorptive diarrhea, watery stool only with secretory diarrheas, or bloody stool only with inflammation. Unfortunately, this is not the case. Carbohydrate malabsorption causes watery diarrhea, as does inflammation that is not severe enough to cause intestinal ulceration. Inflammation also may cause malabsorption; for example, celiac sprue, whose hallmark is intestinal malabsorption, is actually caused by inflammation. [187] Furthermore, malabsorptive diseases often have an element of intestinal secretion. [188] For clinical purposes, it is reasonable to classify diarrheas as steatorrhea, watery diarrhea, or inflammatory diarrhea, realizing that these categories are mixed with regard to pathophysiology. Such a categorization directs the physician to certain diagnostic algorithms.

Epidemiology

Although specific prevalence and incidence figures for the major diarrheal diseases are provided in the chapters on those specific entities, the precise incidence or prevalence of chronic diarrhea is not known because the appropriate population studies have not been performed. The best estimate is that chronic diarrhea occurs in approximately 5% of the United States population. [189], [190]

STEATORRHEA (MALABSORPTIVE DISEASES)

Although the three major nutrients—fat, carbohydrate, and protein—all may be malabsorbed, clinical symptoms usually follow from malabsorption of either carbohydrate or fat. [189], [190], [191] and [192] Protein or amino acid malabsorption (azotorrhea) occurs but is not clinically recognized unless it is severe enough to cause malnutrition or unless specific amino acid transport defects cause congenital systemic disease (see Chapter 19 and Chapter 77). Malabsorption of electrolytes and water is also part of the pathophysiology of malabsorptive diarrheas. The gut's limited ability to absorb high concentrations of divalent ions (i.e., Mg^{2+}, sulfate [SO_4], and phosphate [PO_4]) results in clinically evident diarrhea if these ions are ingested in excess. Nonetheless, the generalized malabsorptive diseases present as steatorrhea. Therefore, an understanding of fat absorption is necessary to understand malabsorptive diseases. Based on the normal physiology of fat absorption (see Chapter 18), fat malabsorption can be divided into three broad categories: intralumenal maldigestion, mucosal malabsorption, and postmucosal malabsorption related to lymphatic obstruction. The diseases listed in Table 42-2 can be allocated to one or more of these three general categories.

Intralumenal Maldigestion

Cirrhosis and Bile Duct Obstruction Bile duct obstruction from cancer of the pancreas can cause steatorrhea, presumably through both pancreatic and bile salt insufficiency. There is a 25% to 100% incidence of mild steatorrhea in patients with cirrhosis. This may result from inadequate micelle formation from bile salt insufficiency; [193], [194] however, secondary factors, including malnutrition, portal hypertension, bacterial overgrowth, and drugs (e.g., neomycin), also may play a role. In both cancer of the pancreas and severe liver disease, diarrhea is not usually a significant clinical problem; the fat malabsorption is usually mild. Certainly, the weight loss in these two conditions is multifactorial.

Pancreatic Exocrine Insufficiency Chronic pancreatitis may cause weight loss because of anorexia or because of fear that eating will initiate pain by activating pancreatitis. After at least 90% of the exocrine secretory capacity of the pancreas is lost, chronic pancreatic exocrine insufficiency supervenes, and malabsorption leads to continued weight loss in spite of a good to excellent appetite (see Chapter 95). Increased intestinal transit time may add to the poor intralumenal digestion and malabsorption. [195] Up to 70% of patients with pancreatic calcification have chronic pancreatitis severe enough to cause malabsorption. Major degrees of pancreatectomy also cause fat malabsorption that is poorly responsive to pancreatic enzyme replacement. [196] Cystic fibrosis is a childhood equivalent of chronic pancreatic insufficiency, but the weight loss in this disease is probably caused as much by the anorexia of chronic infection [197] as it is by the malabsorption induced by pancreatic enzyme and bile acid deficiencies. [198] Schwachman syndrome is another pediatric cause of pancreatic insufficiency, although some patients improve with age. [199] Somatostatinoma is a rare pancreatic islet tumor with highly variable symptoms that may present with gallstones, diabetes, and diarrhea. [200] It is the one neuroendocrine tumor in which the diarrhea is caused by steatorrhea rather than by intestinal secretion. Presumably, the steatorrhea is secondary to inhibition of pancreatic secretion.

Mucosal Malabsorption

Drugs The chronic ingestion of drugs such as colchicine, [201] neomycin, [202] paraaminosalicylic acid (PAS), [203] and the fenamate class of NSAIDs induces steatorrhea by enterocyte damage. Cholestyramine causes mild steatorrhea by binding bile acids. [204]

Infectious Diseases Parasites can cause malabsorption through brush border damage, particularly the protozoa *Giardia, Cryptosporidium,* and *Isospora* [205], [206] and [207] and the helminth *Strongyloides*. [208] Because these are treatable infections, they must be sought and rigorously excluded by stool examination or small intestine biopsy. Whipple disease and *Mycobacterium avium-intracellulare* complex are infectious agents that cause malabsorption. [209], [210] Unfortunately, *Mycobacterium avium-intracellulare* complex responds poorly to treatment (see Chapter 124). Chronic enteric infections, such as giardiasis associated with the agammaglobulinemias or cryptosporidiosis accompanying AIDS, also cause malabsorption. [211]

Autoimmune Enteropathies

Autoimmune enteropathy has been described in both newborn infants and children [212] and adults. [213] The histology of the small bowel resembles celiac disease, with subtotal or complete villous atrophy and increased lamina propria inflammatory cells, but test results for antigliadin and antiendomysial antibodies (AEAs) are negative, and patients do not respond to a gluten-free diet. Circulating autoantibodies have been found in these patients directed against the enterocytes, goblet cells, smooth muscle, thyroid, islet cells, and parietal cells and against the hemidesmosomes of epithelial cells (the same autoantibodies as in bullous pemphigoid). These patients require glucocorticoids and azathioprine or cyclosporine for control of their disease.

Nongranulomatous chronic idiopathic enterocolitis, also known as *ulcerative jejunitis,* presents with more severe inflammation than autoimmune enteropathy, manifesting superficial ulcerations in addition to the villous atrophy. [214] This disease is prominent in the small intestine but may involve the colon in half the patients. Patients with nongranulomatous chronic idiopathic enterocolitis may have an abrupt onset of their diarrhea and weight loss in early or middle adult life, and they often develop complications such as obstruction, perforation, and hemorrhage. Mortality is high (approximately 30%), although the patients appear to respond to corticosteroids and immune suppression therapy.

Immunoproliferative small intestinal disease is a collective term for immune enteropathies developing in patients in the Middle East or Mediterranean countries who have diseases otherwise known as *a-heavy-chain disease* or *Mediterranean lymphoma*. [215] Like patients with the autoimmune enteropathies, these patients present with malabsorption and sprue-like intestinal histology. a-Heavy-chain disease tends to be benign, but it may progress to malignant Mediterranean lymphoma. A common clonal origin of lymphocytes can be detected in both. Current views are that immunoproliferative small intestinal disease is one end of the spectrum of B-cell maltomas. [215]

T-cell lymphomas of the bowel may also be the cause of malabsorption and sprue-like histology, sometimes with intestinal ulcers (see section “ Celiac Sprue”). [216]

Mastocytosis and Eosinophilic Gastroenteritis Infiltrative immune system diseases include systemic mastocytosis [217], [218] and eosinophilic gastroenteritis, [219] in which gross distortion of the mucosa is associated with fat malabsorption. On occasion, steatorrhea may be profound, and these patients present with a sprue-like syndrome. In other patients, the watery diarrhea, systemic flushing, abdominal pain, tachycardia, and protein-losing enteropathy overshadow the steatorrhea.
Celiac Sprue The use of highly specific antibody tests for celiac disease—AEAs and antitransglutaminase (anti-tTG) antibodies, which have 95% to 100% sensitivity and specificity—have revolutionized our concepts of this disease. [220], [221], [222], [223], [224] and [225] Instead of being a rare (1 in 10,000 population) disease with a classical “malabsorption/malnutrition” presentation, screening studies suggest that the disease may be as common as 1 in 200, with many subclinical manifestations (Table 42-10). Some symptoms result from intestinal inflammation or malabsorption; other presentations occur as a result of coexisting autoimmunity. Furthermore, certain unrelated diseases are common to the human leukocyte antigen (HLA) phenotypes that are prevalent in patients with celiac disease: HLA DQ2, B8, DR3 and, rarely, DR5 or 7. [220], [221], [224]

TABLE 42-10 Clinical Presentations of Celiac Sprue

The term *sprue* comes from the Dutch *spruw,* which means *thrush,* in recognition of the extraintestinal manifestation of oral aphthae. These nonabsorptive/nonmalnutrition, extraintestinal manifestations may be an important clue to the disease (see Table 42-10). Currently, physicians do a poor job of diagnosis of celiac disease: only 50% of patients consider that they were diagnosed “promptly”; 27% consulted two or more gastroenterologists before the diagnosis; and only 30% to 50% consider their physician knowledgeable about diagnosis and treatment. [226] Given the frequency of celiac disease in certain associated disorders, screening should be considered for groups in which the incidence of celiac disease had been shown to be greater than 2.5%: first-degree family members [221], [224] and patients with type 1 diabetes, [227] selective immunoglobulin A deficiency, [228] autoimmune thyroid disease, [229] Sjögren syndrome, [230] Down syndrome, [231] IBS, [232] cerebellar ataxia, [233] unexplained osteoporosis, [234] epilepsy with posterior cerebral calcification, [235] lymphocytic gastritis, [236] and microscopic colitis. [237] Many other diseases in Table 42-10 have incidence approximating 2.5%, and patients with these diseases may, in the future, be candidates for screening. Patients with Sjögren or Down syndrome may not show intestinal disease on biopsy. [230], [231] It is not clear, therefore, whether there is a certain incidence of false-positive test results in these patients or whether they have occult disease. [231] Celiac disease appears to have a significant adverse effect on menses, fertility, pregnancy, miscarriage rate, intrauterine growth rate, and eventual birth weight. [238] Low birth rates have also been reported when it is the father who has celiac disease. [239] Patients with celiac disease have a 300-fold relative risk of small bowel T-cell lymphoma and probably a severalfold incidence of small bowel adenocarcinoma, [224], [228], [240] so patients presenting with these tumors should be screened for celiac disease as well. Some of these patients with T-cell lymphomas will present as having celiac disease unresponsive to gluten-free diet (refractory sprue). [240], [241] Patients labeled as having refractory sprue may have been misdiagnosed as having celiac disease and really suffer from autoimmune enteropathy. [241] The treatment of true “refractory sprue” is with steroids and immunosuppressive drugs. [241]
Dermatitis Herpetiformis This form of skin disease is associated with sprue-like intestinal morphology in 70% to 80% of cases. [242] The specificity and sensitivity of anti-tGT antibodies in this disease is unclear, with reports ranging from 50% [243] to 90%. [244] This blistering skin disease, which is characterized by IgA deposits in the dermal papilla, usually responds to dapsone, whereas the mucosal lesion responds to a gluten-free diet. The diet also seems to have a beneficial effect on the skin lesion, and about 50% of diet-adherent patients are able to stop dapsone medication. [242], [243] Cyclosporine may be useful in patients resistant to conventional therapy. [245] These patients may experience many of the same “extraintestinal” complications as patients with celiac disease, including thyroid disease [246] or lymphoma. [247]
Whipple Disease This is a systemic infectious disease (see Chapter 75) caused by an actinomycete, *Trophermyma whipplei,* [248] and classically involving middle-aged men (male-to-female is 5:1). [209], [210] The peak incidence occurs at ages 40 to 50 years, but it is reported in infants and in octogenarians. It presents with all the signs and symptoms of severe mucosal disease but has some additional characteristics: arthralgias in 65%, chills and fever in up to 40%, hypotension (blood pressure <110/60 mm Hg) in 70%, lymphadenopathy in more than 50%, and, most important, involvement of the central nervous system in a plethora of ways. [209], [210] A unique neuromuscular syndrome caused by central nervous system involvement is oculofacioskeletal myorhythmia. [210]
Lipoproteinemias Abetalipoproteinemia and hypobetalipoproteinemia are rare defects in chylomicron formation caused by abnormalities in microsomal transfer proteins or to molecular defects in apolipoprotein B itself. [249] Both conditions present with steatorrhea, acanthocytic red cells, ataxia, and retinitis pigmentosa (see Chapter 18 and Chapter 77). Patients with Tangier disease (absence of apolipoprotein A-I and apolipoprotein A-II) have yellow-orange streaks and spots in the tonsils and colonic mucosa. They may have diarrhea but not steatorrhea.

Postmucosal Obstruction

Intestinal lymphangiectasia can be either congenital or acquired in association with trauma, lymphoma, carcinoma, or Whipple disease. [250] This condition causes protein-losing enteropathy with significant steatorrhea. [250], [251] It is the classic form of postmucosal obstruction malabsorption. The unique clinical presentation—malabsorption of fat with loss of protein and lymphocytes, but normal absorption of carbohydrates—relates to the obstructed lymphatics channels, which are the route of absorption for fat and for the recovery of lymphocyte and protein-laden lymph. The absorption of carbohydrates and amino acids takes place by way of the portal circulation and remains unaffected. Immune deficiency, both humoral and cellular, may result. [252] Octreotide has been used successfully to treat this disease. [253]

Mixed Causes of Steatorrhea

Bacterial Overgrowth Stasis syndromes cause steatorrhea as well as an inflammatory and secretory form of diarrhea in patients with anatomic bowel obstruction (e.g., Crohn’s disease), small bowel diverticulosis, and motility disorders or in the elderly. Steatorrhea results from deconjugation of bile salts, causing poor micelle formation. However, brush border injury, mucosal inflammation, hydroxylation of fat with resulting fatty acid diarrhea, and changes in intestinal motility all play a role in this disease. Surgical correction of obstruction, antibiotics for bacterial overgrowth, and stimulation of motility with octreotide or prokinetic agents may improve symptoms, depending on the cause (see Chapter 78).
Short Bowel Syndrome Extensive intestinal resection that leaves less than 200 cm of jejunum-ileum remaining represents another complicated, multifactorial form of steatorrhea resulting from the lack of sufficient absorptive surface, decreased transit time, and diminished bile salt pool [254] (see Chapter 79). It is part of a larger syndrome called *intestinal failure,* which also includes parenchymal bowel disease (e.g., Crohn’s disease) and motility disorders in which nutrition is in peril. [255] The diarrhea is heightened by the osmotic effect of nonabsorbed solutes, by gastric hypersecretion, perhaps by bacterial overgrowth, and conceivably even by intestinal secretion. Glutamine-rich diets, exogenous growth factors, and long-acting octreotide hormones show promise as new treatments. [256], [257]

Metabolic Diseases Diseases such as thyrotoxicosis, [258] adrenal insufficiency, [259] autoimmune polyglandular syndrome, [260] protein-calorie malnutrition [261] and prolonged fasting [262] may result in malabsorption through different mechanisms. Thyrotoxicosis may simply shorten transit time and disturb the intralumenal phase of the fat absorption. Adrenal insufficiency appears generally to disturb intralumenal and mucosal absorption, as do protein-calorie malnutrition and prolonged fasting, which also cause villus atrophy. The malabsorption of polyglandular syndrome type I is related to a deficiency of cholecystokinin-producing enteroendocrine cells. As with liver disease, the clinical picture usually overshadows the diarrhea and malabsorption, and certainly the weight loss in these conditions is only partly related to the malabsorption.

WATERY DIARRHEAS

Ingestion of Nonabsorbable Solutes

Magnesium-Induced Diarrhea Persons ingesting significant amounts of magnesium-based antacids or high-potency multimineral-multivitamin supplements may have significant diarrhea with stool weights up to 2000 g/24 h. [263], [264] Occasionally, magnesium-containing laxatives are a cause of surreptitious diarrhea. [263], [264] and [265] Magnesium in tube-feeding preparations may play a role in the diarrhea of patients receiving high-volume liquid feedings. [266] These diarrheas are diagnosed with measurements of stool Mg^{2+} and osmotic gap (see section " Evaluation of Severe or Elusive Diarrhea ").

Sodium Anion Diarrheas Nonabsorbable sodium anion laxatives such as Na_2PO_4 (neutral phosphate) or Na_2SO_4 (Glauber or Carlsbad salt) and high concentrations of SO_4 in naturally occurring drinking water [267] induce osmotic diarrhea. When these substances are ingested factitiously, these diarrheas may be difficult to detect because these substances do not result in a calculated osmotic gap on stool analysis (see section " Evaluation of Severe or Elusive Diarrhea ").

Carbohydrate Malabsorption

Sorbitol and Fructose Diarrhea Carbohydrate malabsorption may be either specific or generalized (see Table 42-3). Diarrhea can result from the long-term ingestion of dietetic foods, candy, chewing gum, or medication elixirs that are sweetened with unabsorbable carbohydrates such as sorbitol (chewing gum and elixir diarrhea). [268], [269] Sorbitol and fructose are also present in pears, prunes, peaches, and apple juice, [270] and excessive ingestion of these foods results in diarrhea as well. Long-term ingestion of drugs that cause malabsorption of fat (discussed earlier) also causes carbohydrate malabsorption. Fructose may be malabsorbed if ingested in high concentrations, particularly if it is ingested alone and not as a component of sucrose. [271], [272] Primary fructose malabsorption also has been documented secondary to defects in the GLUT 5 transport system. [273] Toddler's diarrhea in children may be secondary to drinking large amounts of fructose-containing fruit juice, [270], [274] and colic in infants has been postulated to be caused by carbohydrate malabsorption. [275] Occasional adult diarrhea also appears to be related to ingestion of large volumes of fruit juice or soft drinks that are sweetened with fructose-containing corn syrup.

Glucose-Galactose Malabsorption and Disaccharidase Deficiencies Congenital absence of enterocyte brush border carbohydrate hydrolases and transport proteins may cause diarrheas because of various disaccharidase deficiencies: lactase, sucrase-isomaltase, and trehalase. These are discussed in more detail in Chapter 77. Lactose intolerance usually presents in childhood or adolescence, but it may not be recognized in adults. [276] The high-risk groups for lactase deficiency include Asians and Native Americans (90% prevalence), African Americans, Jews, Hispanics, and southern Europeans (60%–70% prevalence). However, lactase deficiency should be considered in cases of unexplained watery diarrhea, especially if accompanied by abdominal cramps, bloating, and flatus, even in people not considered to be among the high-risk groups, [277], [278] because a 10% to 15% prevalence of lactase deficiency can be expected in northern or western Europeans and their American descendants. A trial of a lactose-free diet, a breath hydrogen test, or a lactose absorption test may be diagnostic. Disaccharidase deficiency can occur secondary to intestinal insults such as IBD or celiac disease and can last for months. [279], [280] Some patients with lactase deficiency are misdiagnosed as having IBS. [278], [281] Conversely, many truly lactase-deficient patients attribute intestinal symptoms to lactose intolerance when, in fact, they can tolerate reasonable amounts of lactose and probably do have IBS. [281], [282] Patients with low trehalase activity report abdominal symptoms on ingestion of mushrooms, which contain high levels of trehalose. [283]

Rapid Intestinal Transit As much as 50 g of a normal 200-g carbohydrate diet may be unabsorbed by the normal small intestine and passed into the colon, where it is metabolized by colonic flora. [284], [285] Diets high in carbohydrate and low in fat may cause more carbohydrate malabsorption and osmotic diarrhea because the low fat content allows rapid gastric emptying and rapid small intestine motility. A primary intestinal motility abnormality in which the migrating motor complex is not disrupted by eating resulting in a continuation of the propagative motility pattern may be the cause of carbohydrate malabsorption and osmotic diarrhea in some children with toddler's diarrhea. [286] Similar abnormalities of the migrating motor complex have been reported in patients with the painless diarrhea variant of IBS, and a rapid orocecal transit time has been demonstrated. [287], [288] Carbohydrate wastage from rapid transit may be part of the pathophysiology of diarrhea in thyrotoxicosis [289] and ulcerative colitis. [290] Because carbohydrate is metabolized to H_2 and CO_2 by colonic bacteria, the symptoms of excess flatus, abdominal bloating, and cramping abdominal pain may be important clues to the diagnosis of carbohydrate malabsorption.

Prior Surgery

Bile Acid Diarrhea Three types of bile acid–induced diarrhea are proposed type 1, which results from severe disease, resection, or bypass of the distal ileum; type 2, or primary bile acid malabsorption (see Chapter 77); and type 3, in which bile acid malabsorption follows upper abdominal surgery, either truncal vagotomy or cholecystectomy. [291] Ileal disease, resection, or bypass (e.g., because of Crohn's disease or postoperative adhesions) allows dihydroxy bile salts to escape absorption. If concentrations higher than 2 mmol are attained in the colon, intestinal secretion and diarrhea ensue. [36] Because fasting prevents gallbladder contraction, so large boluses of bile do not enter the intestine, type 1 bile acid diarrhea commonly disappears on fast. This form of diarrhea can be recognized by the history of previous ileal surgery or the presence of ileal disease. Bile acid diarrhea must be differentiated from fatty acid diarrhea, which occurs if ileal disease or resection involves such a large segment of ileum (>100 cm) that hepatic synthesis cannot maintain an adequate intralumenal bile salt pool. [292], [293] Under these circumstances, steatorrhea ensues, and fatty acid–induced intestinal secretion complicates the picture. It is important to differentiate these two related syndromes because bile acid diarrhea responds to bile salt binders such as cholestyramine, but the diarrhea of fatty acid malabsorption does not and may worsen with such therapy. Therapy for fatty acid diarrhea is a low-fat diet that is supplemented with medium-chain triglycerides to prevent severe weight loss. Bile acid malabsorption has been associated with active or previous infections of the ileum, [153], [294] after radiation treatment, [295] and with motility disturbance. [296], [297] Type 2 bile acid diarrhea, or primary bile acid malabsorption, may be congenital or acquired. The acquired variety is described as a disease of excess bile acid loss responsive to cholestyramine, but not associated with other types of ileal dysfunction. [298] It may occur as the result of absence of bile acid receptors or transport proteins (see Chapter 77) similar to findings in congenital type 2 bile acid diarrhea. [299] Patients have been found with documented bile acid malabsorption who have [300] or do not have [301] histological abnormalities of the terminal ileum, including subtotal villus atrophy and crypt hyperplasia. Some investigators believe that this is a common cause of diarrhea-predominant IBS, and some of these patients clearly have cholestyramine-responsive diarrhea. [154], [155], [302] There are also well-studied patients with bile acid malabsorption and normal stool fat excretion; however, the diarrhea of these patients did not respond to cholestyramine. [295], [296] This appears to be a form of idiopathic diarrhea in which bile acids are malabsorbed, but the diarrhea may not be caused by the bile acids. Measured increases in fecal bile acids in patients with postcholecystectomy diarrhea suggest that it is one of the type 3 bile acid malabsorption syndromes. [303], [304] and [305] It is unclear why interruption of gallbladder storage would lead to increased bile acid wastage. Although many patients respond to cholestyramine, some do not, raising the question whether other pathophysiological mechanisms are involved in this form of diarrhea.

Postvagotomy Diarrhea Truncal vagotomy combined with some type of drainage procedure was previously the most common operation for peptic ulcer disease. It is accompanied by diarrhea in 20% to 30% of patients. [306], [307] Because the incidence of diarrhea is much less after selective or superselective vagotomy, a vagus-mediated discoordination of gastric motility, intestinal secretion, or intestinal absorption may be involved. [308], [309] The idea that bile acids play an important role in the diarrhea accounts for its classification as a type of bile acid diarrhea. [308] The treatment for this condition is not always rewarding. Motility-altering drugs (opiates and anticholinergics) or cholestyramine may benefit some patients. [308], [310] In addition, celiac sprue may make its first appearance after gastric surgery or vagotomy; it is a diagnosis that is treatable and should not be missed. [311]

Functional Watery Diarrheas (Irritable Bowel Syndrome)

Among patients defined as having IBS, a few (approximately 25%) have a predominant symptom complex of painless diarrhea. [312], [313] Over the years, the size of this category of IBS becomes smaller as new conditions are discovered such as occult lactose intolerance, collagenous or microscopic/lymphocytic colitis, primary fructose malabsorption, rapid transit with carbohydrate-wasting diarrhea, primary bile acid malabsorption (type 2), food hypersensitivities, and postinfectious diarrhea-IBS. Adult celiac disease is now added to the list; it has been shown to occur in 10% of patients with IBS who meet the Rome criteria for diagnosis. [232] All these examples should give the clinician pause before attributing the painless diarrhea variant of IBS to any psychosocial cause, particularly in men, in whom IBS is

rare in the first place. Perhaps such patients are better labeled as having idiopathic chronic diarrhea.

TRUE SECRETORY DIARRHEAS

Endocrine Tumor Diarrheas

Carcinoid Syndrome Patients with metastatic carcinoid tumors of the gastrointestinal tract or, rarely, primary nonmetastatic carcinoid tumors of the bronchial epithelium, may experience a syndrome that includes the following: watery diarrhea; cramping abdominal pain with borborygmus; episodic flushing; skin changes including telangiectasia, cyanosis, and pellagra-like skin lesions; bronchospasm with asthma attacks and dyspnea; and cardiac murmurs, usually related to right-sided valvular lesions. [314], [315] and [316] The symptoms are caused by secretion of 5-HT, histamine, catecholamines, kinins, prostaglandin, and tachykinins (e.g., substance P) by the tumor mass. All these agents, excluding catecholamines, are potent intestinal secretagogues (see Chapter 14). Up to one third of these patients do not report flushing episodes, and the pellagra-like skin changes and heart murmurs may take some time to develop to clinical appearance. Therefore, this disease should be considered in patients with secretory diarrhea, even if the patient does not have the classic history or physical examination findings.
Gastrinoma Zollinger-Ellison syndrome develops from sporadic, gastric-producing tumors, except in about 20% of cases, when it is part of multiple endocrine neoplasia syndrome 1 (MEN1). [317] Although 70% to 90% of patients with Zollinger-Ellison syndrome present with pain and develop peptic ulcers at some time during the course of their disease, diarrhea also occurs in 25% to 75% of patients and may precede the ulcer symptoms. [317] Furthermore, in 10% of patients, diarrhea may be the major pathophysiological manifestation of the disease. The diarrhea is not strictly an intestinal secretory diarrhea. [318] It is caused in part by high volumes of hydrochloric acid (HCl) secretion, and it can be reduced by nasogastric aspiration or effective antisecretory therapy. [319] Maldigestion of fat owing to inactivation of pancreatic lipase and precipitation of bile acids because of the low pH may also play a role. Because Zollinger-Ellison syndrome is the most common of the neuroendocrine tumors, it must be definitively ruled out as a cause of secretory diarrhea. Rarely, this syndrome can develop from non–small cell lung cancer [320] or ovarian mucinous cystadenomas. [321]
Vipoma or Watery Diarrhea-Hypokalemia-Achlorhydria Syndrome Non–beta-cell pancreatic adenomas (pancreatic endocrine tumors) secrete a host of peptides, including VIP, pancreatic polypeptide, peptide histidine isoleucine, and occasionally secretin, gastrin inhibitory polypeptide, neurotensin, calcitonin, and prostaglandins. [322], [323] Of these, only VIP has been found to be elevated in virtually all patients with watery diarrhea-hypokalemia-achlorhydria (WDHA) syndrome. Because infusions of this hormone can produce all the symptoms, it seems likely that VIP is the primary mediator of this syndrome. Vipoma may therefore be a reasonable and perhaps a more descriptive name than pancreatic cholera or WDHA syndrome. Patients with this tumor have secretory diarrhea, with 70% of patients having more than 3 L of stool per day and virtually all having more than 700 mL/d. Diarrhea with 10 to 20 L of stool per 24 hours has been reported. With high levels of circulating VIP, all segments of the intestine may secrete Na^+, K^+, Cl^-, and HCO_3^-, as well as water, thus accounting for the dehydration, hypokalemia, and acidosis that may accompany this disease. [324], [325] Abdominal pain is not an important symptom of this disease. Patients exhibit flushing (20%) and hypercalcemia (without hyperparathyroidism) occurs in more than 70% of patients, probably caused by the tumor release of neuroendocrine products. Other features of the syndrome include achlorhydria, hypokalemia, hypomagnesemia, enlarged gallbladder, hypokalemic myopathy or nephropathy, hyperglycemia, and lacrimal gland hypersecretion (tearing). In the pediatric age group, vipomas may present as neural crest (sympathetic chain) tumors—ganglioneuromas, neuroblastomas, neurofibromas, and pheochromocytomas. Some of these tumors secrete VIP and produce secretory diarrheas that resolve after the tumor is removed. [326], [327] A rare patient has pancreatic islet tumors and watery diarrhea with normal VIP levels, suggesting that some other peptide, such as pancreatic polypeptide, neurotensin, calcitonin, or prostaglandins, may cause the intestinal secretion. [326]
Medullary Carcinoma of the Thyroid This cancer may present in sporadic form or, in 25% to 50% of patients, as part of MEN2 with pheochromocytomas and hyperparathyroidism. [328], [329] MEN2 is caused by activation of the cellular oncogene *RET,* and mutations of these gene are found in a subset of patients with sporadic medullary carcinoma. [330] Watery (secretory) diarrhea is a prominent part of the syndrome. The diarrhea is thought to be caused by the secretion of calcitonin by the tumor; however, these tumors also elaborate other secretagogues, such as prostaglandins, VIP, substance P, and sometimes 5-HT or kallikrein. [331] Although studies in some patients have shown small intestine secretion, [331] others have shown severely shortened colonic transit time. [332] Therefore, the pathophysiology in this disease may not always be a straightforward secretory one. Usually, by the time watery diarrhea occurs (30% of cases), it indicates metastasis with poor prognosis.
Glucagonoma Patients with glucagon-secreting pancreatic islet tumors present with diabetes (90%), a form of eczematous skin rash called *migratory necrolytic erythema,* and, occasionally, glossitis, cheilitis, mild diarrhea (25%), psychiatric or neurological aberrations, and thromboembolic propensities. [333] The cause of the diarrhea in these patients is unclear.

Nonendocrine Malignant Diseases

Villous Adenomas Villous adenomas of the rectum or rectosigmoid may cause a secretory form of diarrhea with K^+ loss. [334], [335] and [336] Diarrhea in the range of 500 to 3000 mL/24 h has been recorded. Tumors that are capable of causing such secretory diarrhea are usually large—more than 3 to 4 cm in diameter and often as large as 10 to 12 cm. [336] Although the cause of the secretion may be intrinsic to the nature of this neoplastic epithelium, secretagogues such as prostaglandins have been found in both the tumor and rectal effluent of such patients, [337], [338] and [339] and indomethacin administration reduces the diarrhea in some patients. [338], [340]
Systemic Mastocytosis If mast cell proliferation is limited to the skin, it is termed *urticaria pigmentosa*. [217] If it involves the bones, liver, spleen, lymph nodes, and gastrointestinal tract, it is known as *systemic mastocytosis.* The diarrhea of systemic mastocytosis may be continuous and accompanied by steatorrhea secondary to infiltration of the mucosa and the resulting villus atrophy. [217], [218] However, the diarrhea may be intermittent and may be associated with flushing, tachycardia, hypotension, and, occasionally, headache, cognitive disorders, nausea and vomiting, peptic ulcers, syncope, itching, and urticaria, which may be provoked by alcohol ingestion. [217] In this form of the syndrome, histamine or another mast cell mediators such as prostaglandin D_2 may be the secretagogue responsible, by either stimulating gastric acid secretion (much as in Zollinger-Ellison syndrome) or having a secretory effect on the intestine. Antihistaminics (H_1 blockers), H_2 blockers or proton pump inhibitors, cyclooxygenase inhibitors, and disodium cromoglycate may be helpful in treatment. [217], [218], [341] Blockade of mast cell mediator receptor or of mast cell degranulation may reduce all these symptoms and the diarrhea, but not the steatorrhea, which may be better treated with corticosteroids. [217], [218], [341]

Factitious Diarrhea

Approximately 15% of patients referred to secondary or tertiary centers for diarrhea [342] and 25% of patients with proven secretory diarrheas [343], [344], [345], [346], [347] and [348] are found to be surreptitiously ingesting either laxatives or diuretics. These patients present with severe chronic watery diarrhea, often with abdominal pain, weight loss, nausea, and vomiting, sometimes with hypokalemic myopathy and acidosis. Occasionally, they have severe protein-losing enteropathy as well. They have 10 to 20 bowel movements per day, with 24-hour stool volumes in the range of 300 to 3000 mL, and may have nocturnal diarrhea as well. The most common drug causing this syndrome in the United States is probably bisacodyl. [349] Anthraquinones, which include senna, cascara, aloe, rhubarb, frangula, and danthron, are other abused laxatives. [348], [350] Osmotic laxatives such as Na_2SO_4, Na_2PO_4, $MgSO_4$, and magnesium citrate are occasionally used. [347], [348] Because there is no readily available assay for dioctyl sodium sulfosuccinate (the docusate salts), one of the more common laxatives, its frequency of use in this syndrome is uncertain. Some patients ingest large quantities of diuretics.

More than 90% of these patients are women. It is unclear why they ingest these drugs to the point of requiring hospitalization. There appear to be two different clinical syndromes: [345], [351]

1. Women younger than 30 years of age in whom some elements of eating disorders (e.g., anorexia nervosa and bulimia) appear to be part of the psychic abnormality
2. Middle-aged to elderly women with histories of extensive medical care who seem to gain some kind of secondary benefit from the sick role and the attendant personal attention

Many of these latter patients are health care workers, such as nurse's aides, and this is particularly true among the few men who present with this syndrome. On confrontation, patients may either deny the drug ingestion and leave the physician's care or admit the aberrant behavior and submit to psychiatric care. After laxatives are discontinued, these patients develop edema as a result of secondary hyperaldosteronism or pseudo-Bartter syndrome, [352] but it subsides spontaneously within 1 to 2 months if left untreated. Another complication of chronic laxative abuse is the development of ammonium urate renal calculi, presumably secondary also to the dehydration and acidosis of severe diarrhea. [353]

This syndrome also exists in pediatrics, where it has been called *Munchausen syndrome by proxy* or *Polle syndrome*. [354], [355] (Polle was Baron von Munchausen's son, who died at an early age of unknown causes.) In these circumstances, it is a form of child abuse in which the guilty parent, usually the mother, again derives some

kind of secondary gain from the extensive hospitalizations and evaluations of the child. The frequency of this factitious disorder as a cause of severe diarrhea is high enough to warrant laxative screening to rule out this syndrome before initiating extensive medical evaluation for the other causes of diarrhea.

Chronic Idiopathic Diarrhea and Pseudopancreatic Cholera Syndrome

Patients in whom extensive evaluation for a cause of secretory diarrhea is negative, including a search for hormone-secreting tumors and laxative and drug ingestion, are said to have either *chronic idiopathic diarrhea* or *pseudopancreatic cholera syndrome,* depending on whether the fasting stool volumes are less than or greater than 700 mL/24 h, respectively. [356], [357] Some of the patients with this syndrome are found to have microscopic/lymphocytic colitis, Brainerd diarrhea, or type 2 bile acid diarrhea variant. Others could be ingesting laxatives or drugs for which assays are not readily available. These cases defy diagnosis, and, importantly, these patients outnumber those with neuroendocrine secretory tumors. If no diagnosis is revealed, symptomatic therapy with bile salt–binding drugs, opiates, or anticholinergic medications may be tried. Follow-up studies suggest that in most of these patients, the diarrhea is self-limited and disappears spontaneously in 6 to 24 months. [357] One current hypothesis is that these patients may be suffering from severe, postinfectious IBS, that is, Brainerd diarrhea (see section “ Prolonged Infectious Diarrheas”).

Diabetic Diarrhea

The most common gastrointestinal symptom in patients with diabetes of either type is constipation (25% of patients) and not diarrhea (2.5%–3.7%). [358], [359] Nevertheless, up to 20% of young to middle-aged people with type 1 diabetes that has been poorly controlled for more than 5 years (particularly men between 20 and 40 years of age), may have profuse watery, urgent diarrhea, often occurring at night with incontinence. [360], [361] These patients usually have severe neuropathy and often have both nephropathy and retinopathy. Some patients have exocrine pancreatic insufficiency or bacterial overgrowth secondary to the motility disturbances of the autonomic neuropathy. Because patients with type 1 diabetes may have concomitant celiac disease, [227] the single most important test in these patients, at least in terms of diagnosing a potentially treatable disease, is the AEA or anti-tTG serology tests. The most common cause of “diabetic” diarrhea in those with type 2 disease is therapy with metformin. [358]

Unfortunately, most diabetic patients with severe diarrhea do not have a treatable cause of steatorrhea, and the cause of their diarrheal condition is unknown. Animal studies suggest that diabetes induces specific sympathetic denervation of the bowel. [362], [363] This leaves unopposed cholinergic tone, which impairs fluid and electrolyte absorption or actually stimulates frank intestinal secretion. It is on this basis that clonidine, a specific a $_2$-adrenergic agent, has been recommended as a treatment for diabetic diarrhea. [364] Diarrhea may improve when patients take this drug, although it is uncertain whether this response is the result of the nonspecific antisecretory effect of a $_2$-adrenergic agents or whether the response confirms the proposed sympathic denervation. These patients with neuropathy frequently have impaired anal sphincter function, and this contributes to their incontinence. [358], [365] Octreotide therapy may be helpful. [366]

Alcoholic Diarrhea

Binge drinking of alcohol causes a brief episode of diarrhea that usually lasts less than 1 day. This may result from acute damage to both the microvasculature and the epithelium [367], [368] and [369] and is accompanied by alterations in water, electrolyte, and nutrient absorption. [370]

Patients with chronic alcoholism often have severe watery diarrhea that persists for days or even weeks after hospitalization. Physiological abnormalities described in patients with alcoholism include more rapid oral-cecal and colonic transit, [371], [372] decreased intestinal disaccharidases, decreased bile secretion (particularly in those with cirrhosis), and decreased pancreatic secretion. [351] Folate or vitamin B $_{12}$ deficiency or protein malnourishment also may play a role. With abstinence, renourishment, and replenishment of vitamin deficiencies, most patients’ diarrhea slowly improves.

Congenital and Neonatal Diarrheas

Several causes of congenital diarrhea have been documented: a congenital short bowel syndrome [373]; a primary form of ileal dysfunction with bile acid malabsorption, also called *familial microvillus atrophy* [299], [300], [374]; congenital insulin-dependent diabetes mellitus with secretory diarrhea [375]; congenital chloridorrhea [376], [377] and [378]; congenital Na diarrhea [379], [380] and [381]; microvillus inclusion disease [382], [383]; congenital enterocyte heparan sulphate deficiency [384]; “tufting” enteropathy and epithelial dysplasia [385]; mitochondrial encephalomyelopathies with diarrhea, immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX) [386]; and Satoyoshi syndrome. [387] Some of these diseases are discussed in more detail in Chapter 77.

INFLAMMATORY DIARRHEAS

Inflammatory Bowel Disease

Patients with either Crohn’s disease of the small or large intestine or ulcerative colitis have diarrhea with stool volumes usually less than 1 L/24 h that frequently, but not always, improve with fasting. Decreased Na^+, Cl^-, and water absorption or frank secretion can be demonstrated in both the small intestine and colon of patients with IBD. [26], [27] and [28], [45], [388] Patients with severe ulcerative colitis may have water and electrolyte secretion in the unaffected small intestine, suggesting the presence of circulating secretagogues. [388] The abnormalities of transport are caused by inflammatory mediators, such as histamine, prostaglandins, leukotrienes, platelet-activating factor, and cytokines (interleukins), that are released from mast cells, phagocytes, and mesenchymal cells (see section “ Pathophysiology of Inflammatory Diarrheas”). The abnormalities of electrolyte transport brought about by these secretagogues are further enhanced by a damaged absorptive surface epithelium and even denuded mucosa with leakage of plasma or blood into the lumen. Effective treatment of IBD with salicylates, steroids, antibiotics, antiinflammatory drugs, and immune mediating drugs is accompanied by reductions in the levels of inflammatory mediators, improved histology, and reduction in diarrhea. [389]

Eosinophilic Gastroenteritis

Infiltration of the gastrointestinal tract of either adults or children with eosinophils is a recognized clinical entity that is accompanied by diarrhea. [390], [391] and [392] Diarrhea occurs in 30% to 60% of patients with eosinophilic enteritis regardless of whether the eosinophils are infiltrating the mucosa, the muscle, or the serosal layers of the gut. [392] Peripheral eosinophilia is present in 75% of these patients. The disease may involve the entire gastrointestinal tract from esophagus to anus, or it may be isolated to the colon. Abdominal pain, nausea, vomiting, and weight loss are other prominent symptoms of this disease. Steatorrhea and protein-losing enteropathy are present in 10% to 30% of these patients. A few patients with peripheral eosinophilia, but no evidence of gastrointestinal infiltration, appear to have symptoms similar to those with gastrointestinal involvement. [392] The cause of this disease is unknown, but approximately 50% of patients have atopic (allergic) histories. Food allergy is suspected in these patients, but elimination diets are only occasionally successful. [391] Parasites, particularly *Strongyloides,* should be rigorously ruled out before making a diagnosis of eosinophilic gastroenteritis. [393] Steroids remain the mainstay of therapy. [390], [391] and [392] Sodium cromoglycate may be useful. [394]

Milk and Soy Protein Allergy

Intolerance to cow’s milk and soy protein is a well-established cause of enterocolitis in infants. [395], [396] and [397] The disease involves both the small intestine and the colon and may present within the first 6 months of life with either acute or gradual onset of vomiting and diarrhea, occasionally with bloody stools caused by ulcerative proctocolitis. Approximately 50% of the patients who are allergic to one of these proteins are also allergic to the other. In older children, milk allergy can present with constipation. [398]

Food Allergy

Dietary hypersensitivity is clearly recognized in infants and adults (see earlier), and systemic anaphylaxis has long been recognized in association with peanuts and seafood ingestion. [399] Diarrhea, constipation, and gastroesophageal reflux as a result of food allergy are increasingly recognized. [400], [401] (see Chapter 129).

Commonly suspected allergens include milk, eggs, seafood, nuts, artificial flavors, and food coloring. [399], [400]

Microscopic Colitides

Collagenous colitis and lymphocytic colitis are two diseases grouped together as atypical or microscopic colitides. [402], [403] and [404] Microscopic or lymphocytic colitis seems to be equally prevalent in men and women, whereas collagenous colitis occurs 10 times more often in middle-aged or elderly women. These diseases are categorized as either inflammatory diarrheas, because intraepithelial lymphocytes and lamina propria lymphocytes are prominent, [405] or as secretory diarrheas, because intestinal secretion is present in the disease. [406] In many cases, the secretory process is mild, and diarrhea stool volumes may return to normal with fasting. [356] Other patients with more severe diarrhea continue to have elevated stool volumes on fasting. It is now clear that many patients (perhaps 15%) with lymphocytic colitis have celiac sprue. [407] Increased lumenal prostaglandin levels suggest that this inflammatory mediator is being released by the subepithelial immune cells and is causing the diarrhea in this disease. [406] An epidemiologic relationship with long-term NSAID use also has been reported. [408] In addition to gluten sensitivity, bile has been proposed as the trigger for such prostaglandin release. Sensitivity to these agents may be the reason that symptoms disappear with fecal stream diversion. [409] Bismuth subsalicylate, 5-aminosalicylates, steroids, immunosuppressants, octreotide, calcium channel blockers, diverting ileostomy, and gluten-free diet have all been successful as therapies. [402], [403], [404] and [405], [407]

Chronic watery diarrhea also occurs in patients whose small intestine and colonic biopsies reveal microscopic eosinophilic infiltration in the crypt region with a normal surface or villous epithelium. Such patients have been labeled as having *pericrypt eosinophilic enterocolitis*. [410] Fifty percent of these patients have a collagen-vascular disease. The diarrhea responds well to corticosteroids.

Protein-Losing Enteropathy

Severe protein loss through the gastrointestinal tract occurs in a variety of disease states: [411], [412], [413] and [414]

Infection: *C difficile* infection, *Salmonella* infection, enterocolitis, shigellosis, viral gastroenteritis, parasite infestation, bacterial overgrowth, Whipple disease
Diseases with mucosal erosion or ulcerations: gastritis, gastric cancer, collagenous colitis, IBD
Diseases marked by lymphatic obstruction: congenital intestinal lymphangiectasia, sarcoidosis, lymphoma, mesenteric tuberculosis, as a sequela of surgical correction of congenital heart disease with Fontan operation, long-term peritoneal dialysis
Mucosal diseases without ulceration: Ménétrier disease, sprue, eosinophilic gastroenteritis, amyloidosis
Immune diseases: systemic lupus erythematosus or food allergies, primarily to milk

Although the protein losses caused by ulceration with denudation of mucosal capillaries and lymphatics and resulting from obstructed lymphatics are easy to comprehend, new knowledge about the immune vascular injury in other sites (e.g., lung, kidney) allows a better appreciation of this phenomenon in the gastrointestinal tract. The condition usually responds to corticosteroids or other antiimmune therapy.

Chronic Radiation Enterocolitis

Although acute radiation diarrhea is common (see previous discussion), patients receiving pelvic radiation for malignant diseases of the female urogenital tract or the male prostate may develop chronic radiation enterocolitis 6 to 12 months after total doses of radiation greater than 4 to 6 Gy (see Chapter 132). The terminal ileum, cecum, and rectosigmoid are the segments usually involved because they are fixed in the pelvis and therefore may receive the full brunt of the weekly radiation dosages. The histology is one of obliterative arteritis, occasionally with lymphangiectasia, partial villus atrophy, fibrosis, and strictures. With time, severely bleeding rectal telangiectasias develop in many patients. The diarrhea may be caused by bile acid malabsorption if the ileum is involved, by bacterial overgrowth if small intestine strictures occur, or by chronic inflammation of the small intestine and colon. [415] Antiinflammatory drugs such as sulfasalazine and corticosteroids have been tried with little success; occasionally, cholestyramine and NSAIDs may help, as may opiate antidiarrheal medications. The bleeding rectal telangiectasia may respond to electrocoagulation, laser ablation, or intrarectal formalin [416] (see also Chapter 132).

Miscellaneous Diseases

Although *acute mesenteric arterial* or *venous thrombosis* presents as acute bloody diarrhea, *chronic mesenteric vascular ischemia* may present as watery diarrhea with spotty endoscopic inflammation (see Chapter 131) that can be mistaken for a symptom of IBD. Chronic infections including gastrointestinal *tuberculosis* [417] and *histoplasmosis* [418] present with diarrhea that may either be bloody or have characteristics of a secretory process. Immunologic diseases such as *Behçet disease* [419] may have diarrhea as a symptom. There seems to be geographic heterogeneity among these patients, with those in Japan having more gastrointestinal involvement than those in Turkey or Israel. [420] *Churg-Strauss syndrome* may present with diarrhea. [421] Diarrhea is the hallmark of acute *graft versus host disease* after allogeneic bone marrow transplantation. [422] The triad of dermatitis, hepatic cholestasis, and enteritis with diarrhea define this disease, and the volume of diarrhea has even been proposed as part of clinical staging. *Neutropenic enterocolitis* is ileocolitis occurring in neutropenic patients with leukemia. Some cases of this may be caused by *C difficile* infection. [423] The *Cronkhite-Canada syndrome,* usually listed under the polyposes because of the characteristic retention (inflammatory) polyps, has most of the hallmarks of an immune disorder, and severe gastrointestinal protein loss and diarrhea are present. [424], [425] Long-term NSAID use can lead to colonic ulcers (*NSAID colitis*) with diarrhea or right-sided colonic weblike strictures (*diaphragm disease*). [426]

CLINICAL EVALUATION OF CHRONIC DIARRHEA

The goal of the gastroenterologist in evaluating a patient with chronic diarrhea is to make a definitive diagnosis as quickly and inexpensively as possible. This section outlines an approach to diagnosis of adult patients; the diagnostic approach in infants and children may be different. [211], [427] Experienced clinicians [189], [190], [428], [429] and [430] suggest that 75% to 80% of chronic diarrheas can be diagnosed by an expert history and physical examination, coupled with certain screening and focused laboratory examinations (Fig. 42-7). This expert opinion is backed by clinical studies. [431], [432] The remaining 25% of patients with severe or elusive diarrhea may need hospitalization and extensive testing. Three tests—quantitative stool fat, colonoscopy with biopsy, and the response to fasting with measurement of stool volume and osmotic gap—lead to a definitive diagnosis in most of these remaining patients. [189], [190], [428], [429] and [430]

FIGURE 42-7. Approach to the evaluation of chronic diarrheal disease.

Malabsorption

History and Physical Examination The causes of generalized malabsorption are outlined in Table 42-2, and the signs and symptoms in Table 42-10, Table 42-11 and Table 42-12. [189], [190], [191] and [192], [433] The approach to evaluation is shown in Figure 42-8. Mild degrees of malabsorption may be entirely asymptomatic and may not result in the classic gastrointestinal manifestations of flatulence, bulky or greasy foul-smelling stools, and weight loss. For these reasons, malabsorption sometimes presents as an aberration of one of the other body systems (see Table 42-10 and Table 42-11).

TABLE 42-11 Correlation of Clinical Manifestions, Pathophysiology, and Laboratory Findings in Malabsorptive Processes

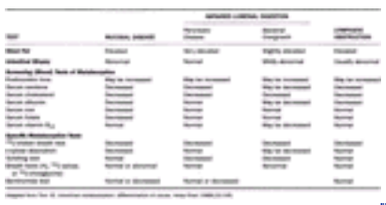

TABLE 42-12 Comparison of Laboratory Results in the Three Types of Malabsorption: Mucosal Disease, Impaired Intralumenal Digestion, and Postmucosal or Lymphatic Obstruction

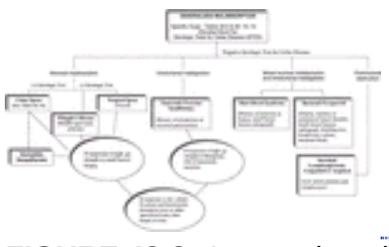

FIGURE 42-8. Approach to the evaluation of malabsorption.

Clues that help differentiate clinically severe mucosal disease, such as celiac sprue or Whipple disease, from the malabsorption caused by exocrine pancreatic insufficiency are the presence of cytokine-induced anorexia, lethargy, and malaise as well as extraintestinal signs and symptoms in patients with intestinal mucosal disease. Severe abdominal pain from repeated bouts of pancreatitis may be a useful clue to pancreatic insufficiency. The character of the stool may be a useful differentiating symptom. The fat content of the stool in pancreatic insufficiency is considerably higher than in mucosal disease (see Table 42-12). [434] At body temperature, the fat may be present as oil, and the oil may separate from the stool, manifesting as oily seepage from the anus or as oil droplets floating in the toilet bowl after passage of the steatorrheic stool. Patients with pancreatic insufficiency rarely have flatulence and bloating, perhaps because salivary or gastric amylase ameliorates somewhat the carbohydrate malabsorption. Stools tend to float and are difficult to flush in malabsorptive diseases as a result of the gas content, which is caused by carbohydrate malabsorption and subsequent fermentation and gas formation, and not fat malabsorption. [435] Total serum protein concentrations are usually lower in intestinal mucosal diseases, most likely because of concomitant protein-losing enteropathy, and anemia is more common because of both iron and folate malabsorption. The understanding of an association of certain diseases or syndromes with subclinical celiac disease (see Table 42-10 and section “Celiac Sprue”) requires knowledge of those diseases and conditions in which screening for celiac disease is appropriate.

Screening Tests for Malabsorption

Blood tests. Tests that may yield important clues to the presence of significant malabsorption include a complete blood count, prothrombin time, serum protein determination, and alkaline phosphatase (see Table 40-12). These may signal the presence of iron, folate, vitamin B_{12}, vitamin K, or severe vitamin D malabsorption with osteomalacia. Serum carotene, cholesterol, albumin, serum iron, folate, and vitamin B_{12} determinations give additional clues to the presence of malabsorption, and these usually point to intestinal mucosal disease. Serum carotene may be low simply from poor intake, but not usually less than 50 µg/dL, as is commonly seen in severe malabsorption.

Serologic tests for celiac disease. Patients suspected of having celiac disease, either because of signs and symptoms or malabsorption or resulting malnutrition or because of concomitant diseases in which there is a high incidence of celiac disease (see Table 42-10 and Chapter 76), should be screened with serologic tests for celiac disease. AEA tests are highly sensitive (90%) and specific (90%–95%). [221, 222, 223] and [224, 231] Simple, accurate tests for anti-tTG antibodies (both IgA and IgE subclass) using guinea pig or human tissue transglutaminase are being developed that are even more sensitive and specific (95%–100%) and will diagnose the disease in patients who are IgA deficient, a not uncommon concomitant condition in those with celiac disease. [222, 223, 225] Screening with AEA testing alone can underestimate celiac disease by as much as 11%. [222] Use of any IgA test alone will fail to diagnose those with IgA deficiency. Patients with Down syndrome and Sjögren syndrome may have false positive test results. [231]

Radiography (Malabsorption) Radiology should be viewed as an adjunct to the diagnosis of malabsorption and not as a primary test. A flat plate of the abdomen may demonstrate pancreatic calcification. Pancreatic ultrasound, computed tomography, and endoscopic retrograde cholangiopancreatography can be used if necessary to confirm the presence of pancreatic disease as a cause of malabsorption. Small intestine disease also can be revealed by barium contrast radiographs, [436] either an upper gastrointestinal series with small intestine follow-through or, preferably, an enteroclysis examination (see Chapter 152). Previous gastric surgery, gastrocolic fistulae, blind loops from previous intestinal anastomoses, small intestine strictures, multiple jejunal diverticula, and abnormal intestinal motility that could lead to bacterial overgrowth may be demonstrated. Certain diseases may present radiographically as uniform thickening of the valvulae conniventes (e.g., amyloidosis, lymphoma, Whipple disease); uniform or patchy diseases such as lymphoma or lymphangiectasia also may be seen. Patients with sprue show dilation of the small intestine with little mucosal abnormality. Segmentation of the barium column also occurs in sprue or in any of the malabsorptive or severe secretory diarrheas if there is sufficient intralumenal fluid to cause precipitation or flocculation of the barium. Endoscopic ultrasound has been reported to be useful in raising the suspicion of celiac disease. [437]

Upper Gastrointestinal Endoscopy and Biopsy Upper gastrointestinal endoscopy with distal duodenal biopsy should be undertaken if diagnostic clues or positive celiac disease serology suggest small bowel mucosal malabsorption, especially in patients with proven steatorrhea (see later). Even a negative biopsy result can be helpful if it redirects the clinician to the pancreas. Occasionally, inflammatory disease of the upper small bowel is evident on upper endoscopy and biopsy.

Endoscopic appearance. The presence of scalloping or a reduced number of duodenal folds or the presence of a mosaic pattern or nodularity has a positive predictive value in the 95% to 100% range for celiac disease in adults [438] and children. [439] However, other diseases may have similar appearances: eosinophilic enteritis, tropical sprue, giardiasis, human immunodeficiency virus–related enteropathy, graft versus host disease, and amyloidosis. [440, 441] and [442] The addition of magnification endoscopy and chromoendoscopy may be useful in the diagnosis of villous atrophy. [443, 444] Push enteroscopy may be useful in the evaluation of “refractory sprue,” [445] but it does not add much to the evaluation of routine malabsorption. [446]

Duodenal histology. When history, physical examination, and screening tests (especially serologic tests for celiac disease) strongly suggest malabsorption, and certainly when steatorrhea is documented, small intestine biopsy is probably the most cost-effective way to determine whether the steatorrhea is caused by intestinal or pancreatic sources. Endoscopic grasp biopsies are usually as good as small bowel biopsy instruments such as the Rubin-Quentin multipurpose tube, the Crosby-Kugler capsule, or the Watson or Carey capsule for distal duodenal biopsy. [447] The capsule technique is still used in infants because of its safety and the ease of passing it orally in the suckling child. [448, 449] and [450] There are a few diseases in which small bowel biopsy is absolutely diagnostic (Table 42-13). Diseases that have a patchy distribution within the gastrointestinal tract may be missed on small bowel biopsies. Our newer understanding of celiac disease as a mild, occult, or latent disease requires new histological rigor for diagnosis of this disease. [451] The presence, location, and number of intraepithelial lymphocytes are becoming important criteria for the diagnosis of subtle celiac disease, although intraepithelial lymphocytes are also seen in other immune-mediated diseases (e.g., tropical sprue, food allergy, autoimmune enteropathy). [452, 453] Miscellaneous lesions not included in Table 42-13 that may be discovered with small bowel biopsy include benign lymphoid hyperplasia, milk or soy protein hypersensitivity, lipid storage diseases such as Fabry or Niemann-Pick disease, histoplasmosis, capillariasis, cytomegalovirus enteritis, schistosomiasis, and Waldenström macroglobulinemia. [454, 455] and [456]

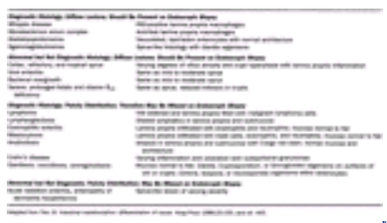

TABLE 42-13 Diagnostic Reliability of Peroral Small Intestine Biopsy

Stool Tests for Malabsorption

Collection and appearance. Early examination of stools for ova and parasites should be considered before beginning 24-hour stool collections or obtaining barium radiographs, although this is not always cost effective. The presence of barium interferes with the ability to find ova or parasites, even 1 to 3 weeks after the procedure. Outpatient qualitative tests on single stool collections and quantitative tests, usually requiring hospitalization and 48- to 72-hour stool collections, can be useful in defining the cause of diarrhea. Stool can be collected in the outpatient area for analysis. The patient can be given preweighed paint cans and toilet bowl inserts to facilitate separation of stool from urine. The stool is transferred from the insert to the can and kept cold in an inexpensive Styrofoam ice chest containing dry ice or one of the refreezable "blue-ice" packs. Collections are made for 48 hours, or better still, for 72 hours. An important adjunct to diagnosing the cause of diarrhea is to look at the stool. The bloody stool of gut inflammation is not easily confused with watery diarrhea. Similarly, the diagnosis of watery diarrhea to the exclusion of steatorrhea can be made with 80% to 95% accuracy. [457] However, patients with steatorrhea sometimes have watery diarrhea, and then stool appearance and weight can be misleading. [457], [458] Thus, it is usually wise to measure stool fat. It is also important to be sure your patient is not taking orlistat for treatment of obesity or consuming large quantities of food that has been fried in olestra, [459] because these agents can cause or simulate steatorrhea.

Qualitative fecal fat tests. The usual intake of fat in the typical North American diet is 100 to 150 g/d, mostly as triglycerides (see Chapter 18). Previously, it was thought that 93% to 97% of this fat was absorbed and that this percentage capability extended up to an intake of 200 g/d. [460] This relationship was recognized not to hold for neonates, whose stool fat may normally exceed 10% of intake. [10] It is now clear that the normal coefficient of absorption of dietary triglycerides is 99%, but for phospholipid of endogenous sources (e.g., bile, sloughed enterocytes, bacteria), it is only 90% or so. Therefore, 5 to 6 g of normal fecal fat is unabsorbed phospholipid from the 40- to 50-g endogenous pool, and 1 g is derived from the diet. [461] Thus, if total stool fat exceeds the normal 7 g/24 h, it is abnormal. Stool fat content exceeding 6 to 7 g/24 h or triglyceride content exceeding 1 g/24 h can be detected by a simple qualitative fecal fat determination with approximately 90% sensitivity and 90% specificity. [462], [463] and [464] The test loses some sensitivity with mild steatorrhea (fecal fat in the range of 6–10 g/24 h). There are also false-negative results if fat intake is inadequate; therefore, it is wise to ensure that the patient is ingesting a normal diet (approximately 100 g fat/24 h). False-positive results can occur if mineral oil laxatives, rectal suppositories (cocoa butter), or orlistat are given to the patient before stool collection or if the patient ingests large quantities of olestra. To perform the qualitative stool fat examination, stool is mixed with water and alcohol and is heated, and then Sudan 3 or 4 stain is added to stain for neutral fat (triglycerides). Fatty acid soaps can be dissociated by mixing glacial acetic acid and Sudan stain with the stool and heating it to boiling. A positive test is recorded if there are more than 100 orange-red globules of fat at least 6 to 75 µm in diameter (bigger than red blood cells) per medium power (40×) field. There is a positive correlation between the number of droplets and the fat content of the stool and a less clear relationship between the size of the droplets and the fat content. [464] The accuracy of the test also depends on the experience of the laboratory personnel, and there seem to be fewer and fewer laboratories that perform this test well. Because of the problems of completely collecting infants' stools, various investigators have studied the validity of the steatocrit test, a gravimetric method that is performed on random stool samples. [465], [466] and [467] The test correlates well with other fecal absorption tests in infants and children and, because of its simplicity, needs to be investigated in adolescents and adults.

Quantitative fecal fat tests. The quantitative fecal fat determination is the standard against which all malabsorption tests are compared. Homogenized stool specimens are analyzed by the techniques of Van de Kamer, [468] which involve the saponification of wet feces with alcohol and sodium hydroxide, liberation of the fatty acids with HCl, extraction with petroleum ether, and then titration of the fatty acids. A spectroscopic method of fat determination has been reported. [469] The major problem with the quantitative fecal fat analysis is ensuring that an adequate stool specimen has been collected. Because a patient's bowel movements may vary from day to day, this is possible only with a 72-hour collection. Even so, fewer than 50% of patients pass more than 90% of ingested stool markers in 3 days. [470] Because of the skills necessary to perform it accurately, the Sudan quantitative test for fecal fat seems to be disappearing from hospital laboratories; the 3-day fecal quantitative fat determination remains the single best test for detection of steatorrhea. Although stool fat excretion for 24 hours may be the same for mucosal and pancreatic disease, mucosal disease usually causes more water malabsorption or outright secretion. [434] The result is stool fat that is excessive but is diluted by the excess fluid. Consequently, the *stool fat concentration* (grams of fat/100 g wet stool weight) is usually less than 9.5% in mucosal diseases such as celiac sprue and greater than 9.5% in chronic pancreatic insufficiency. Other studies have questioned the value of this refinement of the fecal fat test. Although it has been repeatedly confirmed that a fecal fat excretion of more than 7 g/24 h exceeds by more than two standard deviations of the mean normal fat excretion, it is important to realize that diarrhea of secretory or osmotic origin can wash fat from the bowel lumen and can simulate steatorrhea. Therefore, if diarrhea is severe (>800 g stool/24 h), stool fat excretion can be as high as 14 g/24 h. [471] Problems arise because patients with mild forms of true steatorrhea have stool fat excretion in the range of 8 to 14 g/24 h. Obviously, patients with diarrhea whose stool fat excretion falls in this borderline range could have secretory, osmotic, or malabsorptive diarrhea, and these patients need more definitive evaluation.

^{14}C-Triolein Breath Test for Fat Maldigestion/Malabsorption Measurements of the respiratory excretion of labeled CO_2 after oral administration and metabolism of radioactive carbon-labeled substrates, or of H_2 after administration of carbohydrates, can be used to assess fat, carbohydrate, and bile salt malabsorption or bacterial overgrowth. [472] All CO_2 breath tests, both those using ^{14}C and those using the stable isotope ^{13}C, are based on the idea that either intralumenal (bacterial) or cellular (intermediary) processes convert the substrate into CO_2, which is excreted in expired air. The stable isotope (^{13}C) tests require mass spectrometric detection techniques. After enzymatic hydrolysis by pancreatic proteins and micelle formation with bile salts, triglycerides are absorbed within the first 150 cm of jejunum. If a triglyceride such as triolein, labeled with ^{14}C at the carboxyl groups, is given with 20 to 30 g of nonlabeled triolein (to promote biliary emptying), it should be efficiently absorbed and essentially completely metabolized to CO_2 and water, and the $^{14}CO_2$ should appear in the breath. This forms the basis for the ^{14}C-triolein breath test. [473], [474] and [475] In patients with impaired fat absorption, there is a reduction in the $^{14}CO_2$ excreted. Either cumulative or peak values provide discrimination, with 85% to 95% sensitivity and specificity. False-positive results are obtained if there is poor gastric emptying (e.g., in diabetes or after gastric surgery), if there are conditions that lead to dilution of $^{14}CO_2$ (e.g., obesity, hyperlipidemia, and ascites), if there is impaired metabolism (e.g., severe liver disease), or if there is CO_2 retention (e.g., chronic lung disease). False-negative results (increased CO_2 production) can theoretically be seen in fever, starvation, and hyperthyroidism. The amount of radioactivity is approximately the same as that received in a chest film and is confined almost exclusively to the lungs. The usefulness of the test is limited by the false-positive results in healthy persons (20% in IBS) and the false-negative results in patients with mild degrees of fat malabsorption.

D-Xylose Absorption Tests D-Xylose is a five-carbon sugar that is incompletely absorbed in the duodenum and jejunum and is metabolized by intralumenal bacteria, so it can be used as a test of both bacterial overgrowth and mucosal disease [476], [477] Xylose is not completely metabolized; therefore, its excretion into urine or its concentration in blood after ingestion of a standardized dose has been used for more than 30 years as a small intestine absorption test. [477] After an overnight fast, either 5 or 25 g is given orally. Patients with normal renal function therefore excrete more than 4 g after a 25-g dose. The test has poor sensitivity in mild mucosal disease, although sensitivity can be increased by obtaining blood values after the oral dose. A blood level of greater than 25 mg/dL 1 hour after the 25-g dose, or greater than 20 mg/dL 1 hour after the 5-g dose, can be expected. [476] Because the test depends on normal renal function, it is less useful in elderly patients in whom the glomerular filtration rate is reduced, or in patients with known renal disease. Because it can be distributed into sequestered fluids, it is less useful in patients with ascites. Indeed, increased portal pressure alone has been shown to decrease xylose absorption. Furthermore, NSAIDs impair either absorption or urinary excretion. It has false-positive and false-negative rates of 20% to 30%. It should be considered in those mucosal diseases in which a patchy distribution of the histological lesion may invalidate the endoscopic biopsy (see Table 42-13). A D-xylose breath test has been proposed. [478]

Pancreatic Function Tests

Tubeless pancreatic function tests. Pancreatic chymotrypsin cleaves free paraaminobenzoic acid (PABA) from the synthetic peptide *N*-benzoyl-L-tyrosyl-paraaminobenzoic acid; this is the principle behind the *Bentiromide test*. If 500 to 1000 mg is administered orally and normal pancreatic chymotrypsin is present, the free PABA should be absorbed, conjugated in the liver, and excreted in the urine. With severe pancreatic insufficiency, less than 57% of the PABA is excreted in 6 hours. [479], [480], [481] and [482] Unfortunately, severe intestinal mucosal disease, renal disease, diabetes, and severe liver disease all diminish PABA absorption or excretion in the absence of pancreatic insufficiency, and the test is not very sensitive in patients with mild pancreatic insufficiency. Furthermore, several ingested substances, including medications (e.g., acetaminophen, benzocaine, lidocaine [Xylocaine], procaine, sulfa-containing antibiotics, chloramphenicol, chlorothiazide, furosemide) as well as certain foods (prunes and cranberries), interfere with the laboratory determination. [482] To overcome some of these limitations, the *pancreolauryl test* was developed. [479] Fluorescin is conjugated with two molecules of lauric acid and is given orally to be hydrolyzed by pancreatic cholesterolase. The fluorescin release is absorbed and excreted in the urine. It has many of the same limitations as the bentiromide test. [479], [480]

Blood tests of pancreatic function. The *amino acid consumption test* is based on the idea that a stimulated healthy pancreas will deplete plasma amino acids to

make zymogens to a greater extent that than will a damaged pancreas. The specificity of this test is very low, although the sensitivity seems to be high. [480] Low plasma levels of *apolipoprotein B-48* after a 40 g lipid meal have been shown to indicate chronic pancreatitis with exocrine insufficiency. [483], [484] The usefulness of this determination as a diagnostic test remains to be proven.

Pancreatic stimulation tests. After duodenal intubation with a double-lumen tube (one lumen having an aspiration port to remove contaminating gastric juice), the pancreas can be stimulated with intravenous secretin, or cholecystokinin, or by an intragastric liquid meal containing fat, protein, and carbohydrates (Lundh meal). [479], [485], [486] Pancreatic juice is aspirated from the duodenal port, and the serially collected samples are analyzed for volume, HCO_3^- concentration, and, in some laboratories, pancreatic enzymes (lipase, colipase, trypsin, or chymotrypsin). An HCO_3^- concentration lower than 90 mM suggests chronic pancreatitis, and in research laboratories there are normal values for specific pancreatic enzyme concentration or output. Although the test may be accurate and sensitive, it requires intestinal intubation and is time consuming. Therefore, this test is not uniformly used clinically and may be better suited for research protocols.

Fecal pancreatic enzymes. Measurements of fecal chymotrypsin, trypsin, lipase, and elastase have all been proposed as tests for pancreatic insufficiency and have sensitivity and specificity in the 80% to 90% range. [479], [480]

Tests for Bacterial Overgrowth

Schilling test. Vitamin B_{12} (cobalamin) is not absorbed unless it is bound to intrinsic factor, and intrinsic factor cannot bind if salivary and gastric R proteins are not degraded by the pancreatic proteolytic activity in the upper small intestine. Approximately 50% of patients with severe pancreatic insufficiency are found to have impaired vitamin B_{12} absorption measured with the Schilling test. Obviously, this is not very specific because of diminished vitamin B_{12} absorption in patients with pernicious anemia, bacterial overgrowth, severe mucosal intestinal disease, or extensive ileal disease or resection. The Schilling test may be useful in distinguishing between bacterial overgrowth and mucosal disease in the setting of an abnormal D-xylose test, especially if the test reverts to normal after oral antibiotic treatment. [487]

Bacterial growth from duodenal aspirates. The growth of more than 10^6 bacterial colonies per milliliter of duodenal fluid suggests bacterial overgrowth. Care should be taken to collect samples anaerobically, and they should be plated for aerobic and anaerobic cultures immediately. [488] The test has not been standardized, and contamination with oropharyngeal bacteria can be a problem.

H_2 and ^{14}C breath tests for bacterial overgrowth. The breath hydrogen test can be used to diagnose bacterial overgrowth and has the advantage of not using radioactive isotopes. However, up to 20% of people are colonized by bacteria that do not produce H_2; thus, the sensitivity and specificity of this test may be poor (see Chapter 78). The *^{14}C–D-xylose breath test* is said to be more specific for bacterial overgrowth, with 85% of patients having an increase in exhaled $^{14}CO_2$ within 60 minutes of ingesting 1 g of ^{14}C–D-xylose. [489] Because most of the ^{14}C-labeled xylose is absorbed in the small intestine, less reaches the colon, where it can be metabolized to CO_2 by bacteria confounding interpretation of the test. The test can be complicated by delayed gastric emptying. Champions of the test claim almost 100% specificity and sensitivity and an even greater reproducibility than that found in duodenal intubation with culture [489], but others report little advantage over glucose breath hydrogen tests. [490] The *cholyl-^{14}C-glycine breath test* is based on the rationale that conjugated (glycine or taurine) bile acids are reabsorbed passively throughout the jejunum and actively absorbed in the terminal ileum. [491], [492] Bacterial overgrowth hydrolyzes the peptide bond, releasing the ^{14}C-labeled glycine, which is then absorbed, metabolized to $^{14}CO_2$, and exhaled in expired air. Unfortunately, the test is not specific, and it gives similar results in patients with terminal ileal disease or resection and may be misleading in severe mucosal disease.

Watery Diarrheas

History and Physical Examination Useful clues to the cause of watery diarrheas include the volume of diarrhea, the number of stools, the presence of nocturnal diarrhea, incontinence, and a history of hypokalemia (Fig. 42-9). A detailed dietary and medication history, history of past surgeries, and positive Rome criteria for IBS may facilitate a diagnosis of diarrheas caused by ingested substances, carbohydrate malabsorption, bile acid diarrhea, postvagotomy status, or IBS. These diarrheas often respond, at least partially, to fasting.

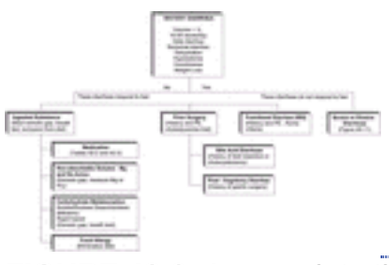

FIGURE 42-9. Approach to the evaluation of watery diarrheas.

Conversely, a history of 10 to 20 bowel movements per day, particularly nocturnal bowel movements with incontinence, should suggest the secretory diarrheas, as should documented electrolyte abnormalities (hypokalemia and acidosis) or dehydration, particularly if accompanied by systemic symptoms such as flushing. The presence of long-standing diabetes or alcoholism obviously is necessary for a diagnosis of these forms of diarrhea. Weight loss is not usually a component of most of the watery diarrheas, except for advanced neuroendocrine tumors and mastocytosis. Physical examination is helpful only if the thyromegaly of medullary carcinoma, the cutaneous flushing of the neuroendocrine tumors, and systemic mastocytosis are evident, or if there are the dermatographism of systemic mastocytosis and the migratory necrolytic erythema of glucagonoma. [323] The concomitant presence of peptic ulcer should suggest gastrinoma or systemic mastocytosis. Scars from previous surgery raise the question of postvagotomy diarrhea or terminal ileal resection, causing bile acid diarrhea. Autonomic dysfunction (e.g., postural hypotension, impotence, gustatory sweating) is almost invariably present in diabetic diarrhea. More details of clues to the diagnosis of pancreatic endocrine tumor syndromes are given in Chapter 97.

Screening Tests for Watery Diarrheas There are no screening tests for these diarrheas. Elimination diets (therapeutic trials) for the carbohydrate diarrheas and food allergy may be used.

Radiography (Watery Diarrhea)

Contrast radiographs. Routine films of the gastrointestinal tract are not usually helpful in the diagnosis of watery diarrheas unless there is evidence of a previous vagotomy, extensive small bowel resection or cholecystectomy, the presence of a tumor (carcinoid or villous adenoma), or a bowel filled with fluid (endocrine tumor). The radiographic appearance of an ahaustral colon with focal areas of spasm (pseudostrictures) may suggest chronic laxative abuse (the cathartic colon). [493]

Special radiologic tests. Suspected pancreatic endocrine tumors and metastatic medullary carcinoma of the thyroid can be accurately localized with a combination of abdominal ultrasound, abdominal computed tomography, magnetic resonance imaging, and selective abdominal angiography, along with radiologic somatostatin receptor screening [494], [495] and endoscopic ultrasound [496] (see Chapter 67 and Chapter 97). Medullary carcinoma of the thyroid lesions have also been localized with octapeptide (^{111}In-OTPA)-cholecystokinin analog scanning. [497] Somatostatin receptor scintigraphy has proven to be both sensitive and useful in the diagnosis and evaluation of Zollinger-Ellison syndrome. [494]

Flexible Sigmoidoscopy or Colonoscopy and Biopsy Patients with severe watery or elusive diarrhea should have colonoscopy to rule out villous adenomas of the rectosigmoid and biopsy to rule out microscopic or collagenous colitis, mastocytosis, or early Crohn's disease. Colonoscopy also may reveal melanosis coli secondary to chronic anthracene laxative use, and this can be confirmed by biopsy. Melanosis coli can develop as early as 4 months after starting to use such laxatives and may require a year after discontinuance to resolve. [498], [499] Investigators have suggested that IBD alone can cause melanosis coli. [500] Terminal ileal biopsy may give an indication of type 2 bile acid diarrhea, Crohn's disease, or infectious disease. [501] Colonoscopy and biopsy have proven very useful for diagnosis in the tertiary referral setting. However, they have been shown to have poor yield as *initial tests* in patients presenting with diarrhea and a normal gross appearance of the colon. [502], [503] Biopsy can be useful to distinguish acute self-limited (infectious) colitis from IBD. [504]

Stool Tests for Watery Diarrhea

Fecal carbohydrate tests and fecal pH. Tests used for the determination of urine sugar can be applied as qualitative tests for stool carbohydrate, although these tests have not been standardized. [189] Urine dipsticks will give a positive reaction to glucose, but not to other sugars. Clinitest tablets (Bayer Corp., Mishawaka, IN) will give a positive reaction to glucose, galactose, fructose, maltose, and lactose, but not to sucrose, lactulose, sorbitol, or mannitol. Carbohydrate malabsorption can be detected by measuring pH on a homogenized stool sample. The breakdown of unabsorbed carbohydrate by colonic bacteria to short-chain fatty acids reduces stool pH to less than 5.3 in pure carbohydrate malabsorption. However, in generalized malabsorptive disease, stool pH is more than 5.6 and is usually 6.0 or greater. [31], [32]

Laxative screen. To screen for laxative abuse in factitious diarrhea, it is necessary to send stool or urine to specific reference laboratories for qualitative tests for emetine (a component of ipecac), bisacodyl, castor oil, or anthraquinone. [189], [342], [343], [344], [345], [346], [347], [348], [349], [350] and [351], [505] Screening is not available for the docusate salts (dioctyl sodium sulfosuccinate), which are present in many of the over-the-counter cathartics. Stool SO_4, PO_4, and Mg analysis detects those factitious diarrheas caused by osmotic cathartics. Although there is controversy regarding the ethics and legality of a room search for laxatives and diuretics, most

believe that it is warranted because of the expense and risk to the patient of the extensive evaluation. [189] Certainly, a room search can be a test with the highest diagnostic yield for surreptitious laxative abuse. [342], [343], [344], [345] and [346]

Tests for Carbohydrate Malabsorption

Lactose tolerance test. To detect either congenital or acquired lactase deficiency, 50 g of lactose is administered, and plasma glucose is measured at 1 and 2 hours. A plasma glucose increase of more than 20 mg/dL is a normal response. [276] Patients who lack lactase and therefore the ability to split lactose into glucose and galactose have little increase in plasma glucose. This test does not have good sensitivity and has largely fallen out of favor because of the more sensitive and simple breath H_2 lactose test (see later).

H_2 breath test for carbohydrate malabsorption. H_2 breath tests can be used to study carbohydrate malabsorption or bacterial metabolism because the sole source of H_2 in the mammal is bacterial fermentation. In patients in whom therapeutic trial of carbohydrate-restricted free diet is inconclusive, breath H_2 testing may be indicated. [189], [472], [506] Because H_2 is produced only by bacterial fermentation of carbohydrates, increased breath H_2 excretion after a carbohydrate challenge can be used to uncover small intestine bacterial overgrowth, disaccharidase deficiency, and even excess carbohydrate wastage that might occur with motility disorders. [507] Patients with small intestine mucosal disease and pancreatic exocrine insufficiency also may have mild carbohydrate malabsorption. Bacterial overgrowth of the small bowel may cause an early peak of increased H_2 production within 2 hours of giving a carbohydrate meal. In disaccharidase deficiency, small intestine mucosal disease, or pancreatic insufficiency, the peak in H_2 may come later, between 3 and 6 hours after ingestion, when the carbohydrate reaches the colonic bacteria. [508], [509] The increase in H_2 excretion by patients with pancreatic insufficiency can be reduced by concomitant administration of pancreatic enzymes. Therefore, depending on what kind of carbohydrate malabsorption is sought, an oral dose of lactose (0.25 to 1.0 g/kg body weight), glucose (50 g), lactulose (10 g), fructose (1 g/kg), or rice flour (100 g) may be given after an overnight fast. To test for lactose intolerance, a lactose dose of 25 g is frequently used, although a 50-g test dose may be more sensitive and a 12.5-g dose more specific. [506] A breath H_2 test using D-xylose has been proposed. [478] Breath H_2 tests must be standardized for each carbohydrate and dose, but generally an increase of over 20 ppm in exhaled H_2 over baseline values within the first 3 to 8 hours of ingestion is diagnostic. It is important to realize that the breath H_2 test measures only carbohydrate malabsorption, and 10% to 20% of people have a gut flora incapable of producing H_2. [472]

Tests for Bile Acid Malabsorption

Cholyl-^{14}C-glycine breath test. This test can be used also to identify impaired ileal absorption of bile acids, although it is neither specific nor sensitive. [491], [492] The measurement of cholyl-^{14}C-glycine excreted in the stool may increase the sensitivity but adds to the difficulty of performing the test.

^{75}SeHCA Test. Because selenahomotaurocholic acid (SeHCA) is an analog of taurocholic acid and has a similar enterohepatic circulation, it may be of value in detecting ileal dysfunction as a cause of bile acid diarrhea. ^{75}Se-labeled HCA is given orally, and the patient is scanned with the gamma camera; those who retain less than 34% of the administered dose after 3 days are considered to have increased bile acid loss. [510], [511] and [512] This test has not been approved for use in many countries.

Serum HCO concentration. With impaired bile acid absorption, cholesterol 7a-hydroxylase increases in the liver, and serum levels of 7a-hydroxy-4-cholesten-3-one (HCO) rise. These levels have been shown to correlate well with the ^{75}SeHCA test and thus may become useful for diagnosing bile acid malabsorption. [513]

Blood and Urine Hormone Levels Endocrine tumors such as carcinoids, gastrinoma, vipoma, medullary carcinoma of the thyroid, systemic mastocytosis, and glucagonoma can be diagnosed by demonstrating elevated blood levels of 5-HT or urinary 5-hydroxyindoleacetic acid (5-HIAA) and elevated serum levels of gastrin, VIP, calcitonin, histamine, somatostatin, and glucagon, respectively (see Chapter 97). These may be obtained through commercial (e.g., ARUP Laboratory, Salt Lake City, UT) or research laboratories (the National Institutes of Health, Bethesda, MD). There is little diagnostic usefulness in measuring other hormones secreted by these tumors. [189], [514], [515] These tests must be viewed cautiously because no endocrine cause of diarrhea is found in a significant percentage of those with elevated blood hormone levels. The finding of an elevated blood hormone level may signify the presence of incurable metastatic disease. [514] Provocative tests such as pentagastrin stimulation for the diagnosis of Zollinger-Ellison syndrome or calcitonin-secreting tumors are addressed in Chapter 67 and Chapter 97.

Inflammatory Diarrheas

History and Physical Examination The important clinical manifestations of inflammatory diarrheas are the signs and symptoms of inflammation and the effects of severe chronic protein loss (Fig. 42-10). Fever with acute or chronic abdominal pain, particularly if it is localized to either right or left lower quadrants, may be an important clue to IBD ileitis or colitis. Eosinophilic, allergic, and immunologic enteritis usually causes diffuse pain and tenderness. Severe protein-losing enteropathy is manifested either as peripheral edema, ascites, or anasarca in the absence of liver disease or proteinuria. Diarrhea in these inflammatory diseases may be meager (e.g., the pseudodiarrhea of proctitis), or it may be fairly severe. Exsanguinating hemorrhage, as in fulminant colitis, or moderately severe secretory watery-type diarrhea, as in graft versus host disease, can occur. Milder watery diarrheas may occur in microscopic or collagenous colitis and eosinophilic gastroenteritis. Crohn's disease, radiation enteritis or colitis, and milk or soy protein allergy may present with either watery or bloody diarrhea.

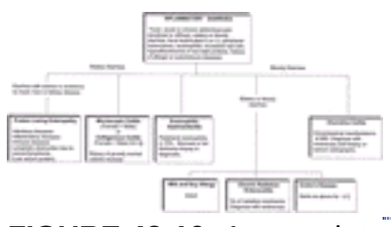

FIGURE 42-10. Approach to the evaluation of inflammatory diarrheas.

Systemic manifestations of inflammatory disease may be prominent in these patients. These include oral aphthous ulcers, polymigratory arthritis, uveitis, and various dermatitides, including erythema nodosum, pyoderma gangrenosum, and the palpable purpura of vasculitis. As is the case with the mucosal malabsorptive disease with severe subepithelial inflammation, anorexia can be an important cause of the weight loss.

Screening Tests for Inflammatory Diarrheas Peripheral blood findings of leukocytosis, eosinophilia, elevated sedimentation rate, C-reactive protein, hypoalbuminemia, or low total serum proteins suggest the presence of inflammation, hypersensitivity, or severe protein-losing enteropathy. Low serum albumin and globulins should always alert one to the possibility of protein-losing enteropathy. The hallmark of the inflammatory diarrheas, however, is the presence of blood, either gross or occult, or leukocytes in the stool. Stool examination for leukocytes should use methylene blue stain and not Gram stain for best results. [107] Fecal leukocyte tests have poor sensitivity for ruling out inflammatory diarrheas [108], [109] and are gradually being supplanted by tests of granulocyte markers such as lactoferrin and calprotectin (see later).

Radiography (Inflammatory Diarrheas)

Contrast radiographs. Plain films or contrast examinations may show diagnostic evidence of IBD or the inflammation that may be present with eosinophilic gastroenteritis or radiation enterocolitis. [516] Edema of the valvulae conniventes may suggest protein-losing enteropathy. Early or mild gut inflammation may be missed entirely by radiography. Computed tomography may also be used for the detection of inflammatory disease of the colon. [517]

Special radiologic tests. Indium-labeled leukocyte scans may be useful in detecting bowel inflammation not evident by endoscopy or contrast radiography. [111], [518], [519] Imaging with ^{99m}Tc antigranulocytic antibodies [520] and ^{123}I-IL-2 [521] has shown promise.

Endoscopy and Biopsy Clues to the diagnosis of any of the inflammatory diseases of the colon and terminal ileum can be made earliest with colonoscopy and biopsy. Thus, colonoscopy and biopsy become very useful, if not mandatory, tests. Upper endoscopy and biopsy can be useful to diagnose gastroduodenal inflammatory diseases.

Fecal Lactoferrin and Calprotectin Tests In specific laboratories, stool excretion of fecal lactoferrin or calprotectin (constituents of leukocytes) can be used as a quantitative index of fecal leukocyte loss. [110], [111] It seems to have reasonable sensitivity (=60%), specificity (80%–90%), and cost effectiveness. [112], [113]

Tests for Enteric Protein Loss

^{51}Cr-albumin clearance. Measurements of enteric protein loss are sensitive tests for inflammatory diarrhea. This can be accomplished by measuring 24-hour stool excretion or clearance of ^{51}Cr-labeled albumin. Clearance is determined by 24-hour stool excretion divided by mean serum activity, just as in the creatinine clearance calculation. [522], [523] More recently, endogenous labeling of albumin can be accomplished by injecting 50 µCi of $^{51}CrCl_3$ 2 days before collecting 24- to 72-hour stool samples. A sample of blood is drawn during the stool collection to determine serum activity and calculate clearance.

a_1-Antitrypsin clearance. a_1-Antitrypsin clearance of native endogenous proteins, particularly, has proven to be as sensitive as ^{51}Cr-labeled protein clearance and avoids the administration of radioactive material. [522], [523], [524] and [525] The principle of the clearance studies is the same as with radioactive albumin. a_1-Antitrypsin is measured in serum and stool either by radial immunodiffusion or by laser nephelometry with monospecific antisera. Stool determination requires an aliquot of lyophilized stool to be extracted with saline. When combined with a protein pump inhibitor, it can be used to diagnose protein-losing gastropathy. [526]

^{99m}Tc-albumin scintography. The sequestration of the albumin in the protein-weeping bowel can be made by ^{99m}Tc-albumin scintography. This may become a useful, noninvasive test for protein-losing enteropathy. [527], [528]

Evaluation of Severe or Elusive Diarrhea

To evaluate severe or elusive diarrheas, measurements of stool fat, electrolytes, and osmolality on timed stool collections, combined with observing the response of stool volume to fasting, are very useful (Fig. 40-11). A 48- to 72-hour stool collection must be obtained while the patient is on a 100-g fat diet and the collection repeated while the patient has fasted. The fasting portion of the collection must be performed in the hospital; however, the nonfasting part of the collection can be obtained on an outpatient basis. The stool should be analyzed for appearance, weight, quantitative fecal fat, electrolytes (Na^+, K^+, and if thought necessary, Cl^-, PO_4, and Mg^{2+}), osmolality, fecal pH, and laxative screen.

Stool Weight, Response to Fast, and Stool Osmotic Gap There are many theoretical and practical problems encountered in using the response to fasting and feeding and the measurements of stool osmotic gap to diagnose the cause of diarrhea. [31], [32], [33] and [34], [189], [529], [530], [531], [532] and [533] First, in some diseases, the ingestion of a drug or feeding itself initiates the secretory phenomenon. Under these circumstances, the fasting stool may return to normal, and yet the pathophysiology is that of a secretory diarrhea. Examples are the patients who factitiously ingest laxatives and some patients with microscopic (lymphocytic) or collagenous colitis. Second, the stool specimen may be accidentally contaminated with urine or purposefully diluted with water. Third, there may be malabsorptive diseases that also have a secretory component. For example, in celiac sprue there is secretion by the small intestine, and malabsorbed fat also can initiate active secretion in the colon. Similarly, in viral diarrhea, there may be simultaneous secretion by the hyperplastic crypts and malabsorption by the damaged villus epithelium. Nonetheless, there are some general responses of stool volume to fast in the various diarrheas, especially the watery diarrheas, as shown in Figure 42-9 and Figure 42-11. Steatorrheic stools are usually less than 700 g, and stool weight returns to normal on fasting. Stool osmotic gap measurements are often indeterminate in these patients. Inflammatory diarrheas are variable in weight, but usually less than 1000 g, and have a variable response to fasting. As is the case in steatorrhea, the stool osmotic gap is not usually helpful.

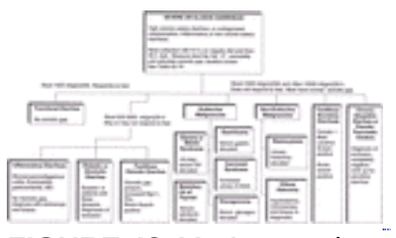

FIGURE 42-11. Approach to the evaluation of severe or elusive diarrheas.

The measurements of stool electrolytes for calculation of osmotic gap are useful only as guidelines for the classification of diarrhea. [189], [190], [265], [529], [530], [531], [532] and [533] In practice, to calculate the stool osmatic gap, it is not correct to use measured stool osmolality; it may be falsely altered by bacterial degradation of carbohydrate after the stool is passed. Therefore, the use of normal plasma osmolality, 290 mOsm/kg H_2O, is recommended because newly passed stool is essentially isosmotic with plasma. Na^+ and K^+ concentrations must be measured in the stool and then multiplied by 2, to account for the obligate (mainly organic) anions in the stool. The osmotic gap, or the difference between stool osmolality (or 290 mOsm) and 2 × [Na^+ + K^+] concentrations, should normally be less than 125 and is usually less than 50 (Table 42-14). This number takes into account unabsorbed divalent cations (Ca^{2+} and Mg^{2+}) and ammonium and their obligate anions.

TABLE 42-14 Stool Osmotic Gap as a Guide to the Pathophysiology and Diagnosis of Diarrhea

In secretory diarrheas, the solute causing the movement of water from blood to bowel lumen is composed of the secreted Na^+ and K^+ molecules. Thus, in secretory diarrheas, twice the sum of the stool Na^+ plus K^+ concentrations will approximate stool osmolality. Furthermore, unless the secretory stimulus is being ingested (e.g., laxatives), the diarrhea and stool weight should be only minimally or moderately reduced if the patient fasts; fasting stool weight should remain higher than 200 g/24 h. In general, therefore, if stool Na^+ concentrations are greater than 90 mM and the osmotic gap is less than 50, then a secretory diarrhea is present (see Table 42-14). Conversely, if stool Na^+ is less than 60 mM and the osmotic gap is greater than 125, then it is likely to be an osmotic form of diarrhea. In osmotic diarrhea, it is the ingestion of nonabsorbable (or nonabsorbed) solutes that displaces Na^+ from the stool and causes the osmotic gap and the diarrhea. Osmotic diarrhea should disappear if the patient fasts, and stool weights should return to values of less than 200 g in 24 hours. Stools with Na^+ concentrations of 60 to 90 mM and calculated osmotic gaps of 50 to 100 can result from either secretory or malabsorptive abnormalities or from diseases that have as their pathophysiological basis some element of both secretion and malabsorption. [31], [34], [189], [529], [530], [531], [532] and [533] Stool osmolality, measured by the freezing point depression method, may have some utility in diagnosis because a low stool osmolality suggests contamination of the stool inadvertently with urine, or purposefully with water in the case of factitious diarrhea [31], [34], [189], [529], [530], [531], [532] and [533] (see Table 42-14). In patients suspected of having magnesium-induced diarrhea, fecal analysis reveals stool Mg^{2+} concentrations greater than 45 mM (usually greater than 100 mM) or Mg^{2+} output greater than 15 mmol/24 h. In patients in whom the magnesium ingestion is innocently motivated, the diarrhea disappears on fasting. In those ingesting magnesium surreptitiously, or in an infant or child being purposefully fed magnesium, stool analysis demonstrates an osmotic gap greater than 100 mOsm/kg H_2O, and the excess stool weight and osmotic gap do not disappear on fasting. [263], [264], [265] and [266] In patients suspected of having sodium anion–induced diarrheas, the stool Na^+ concentration is 90 mM or greater, and twice the concentrations of Na^+ + K^+ equal approximately 290 mOsm (see Table 42-14). This type of diarrhea mimics secretory diarrhea, even though it is an osmotic diarrhea, because the stool Na^+ content is high (>90 mM), and there is not an osmotic gap. This type of diarrhea can be diagnosed, in the absence of a history of ingestion of Na_2SO_4- or Na_2PO_4-containing substances, by determining stool Cl^- concentration. If nonabsorbable anions have been ingested, they displace stool Cl^-, and the resulting stool Cl^- value is usually less than 20 mM. [31], [189] There are technical and practical problems with using stool analysis as a guide to the diagnosis of diarrhea. [31], [34], [529], [530], [531], [532] and [533] Some hospitals are unable to measure stool electrolytes and osmolality, and therefore an aliquot of the homogenized stool sample must be sent frozen on dry ice to a reference laboratory for analysis. Therefore, the response to fast may be a more practical way to distinguish secretory from osmotic diarrheas. [529]

ANTIDIARRHEAL THERAPY

Mechanisms of Action

Antidiarrheal agents can be divided into two categories: agents useful for mild to moderate diarrheas (Table 40-15) and those helpful in secretory and other severe diarrheas (Table 42-16). A major drawback of current antidiarrheal drugs is that some have no antisecretory activity; for example, the bulk-forming agents only increase the consistency of stool and do not decrease its elaboration. [534] Other antidiarrheal agents have only mild proabsorptive or antisecretory action. [535], [536] and [537] Although in vitro and in vivo studies in experimental animals suggest that many of the agents listed in Table 42-15 and Table 42-16 have proabsorptive or antisecretory activity, most of them are lacking this effect in human studies, or else it is minimal. Most of the current antidiarrheal agents have their activity by altering the intestinal motility. Bismuth salicylates, loperamide, clonidine, phenothiazine, and somatostatin have mild antisecretory activity, but they also cause dilation of the small intestine and colon and decrease peristalsis. [535], [536] and [537] The opiates also cause disordered contractions of the distal large bowel and increased anal sphincter tone. [538], [539], [540], [541] and [542] The sum of these effects is to trap fluid within the intestine and to put it in contact with the mucosa for a greater period of time, allowing more complete absorption.

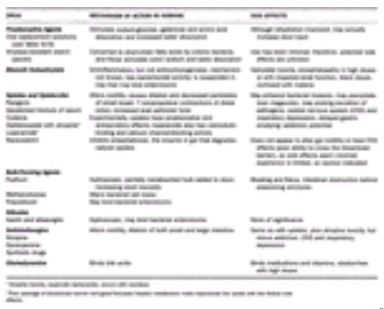

TABLE 42-15 Antidiarrheal Agents for Mild to Moderate Diarrheas

TABLE 42-16 Agents Helpful in Secretory and Other Severe Diarrheas*

More recently discovered (or rediscovered) effective proabsorptive agents include the enkephalinase inhibitors, [543] and newer or natural preparations of amylase-resistant starch or pectin. [126] The enkephalinase inhibitor racecadotril (Acetorphan) inhibits the breakdown of natural endogenous opiates (enkephalins) by intestinal tissue, including the intestinal epithelia. It is effective against experimental secretory diarrheas, and its proabsorptive effect is prevented by naloxone, indicating the role of endogenous opiates in its proabsorptive action. [544], [545] and [546] Pectins are a form of amylase-resistant starch that are not hydrolyzed by amylase and therefore are not absorbed in the small intestine. They are converted to short-chain fatty acid by colonic bacteria, and these short-chain fatty acids stimulate colonic water and electrolyte absorption. [125] (see later). Other potential new antisecretory agents are the new 5-HT $_3$ receptor antagonists [547] and enteric nervous system neurotransmitter antagonists such as antisubstance P or VIP. [3]

Agents for Mild Diarrhea

Bismuth subsalicylate [99], [102], [118], [548] and loperamide preparations [99], [102], [118], [540], [549] continue to prove effective and safe in mild to moderate diarrhea of all types (see section “ Treatment of Acute Infectious Diarrheas”). The antimobility efforts of the opiates listed in Table 42-15 may be symptomatically useful in mild diarrheas, but they may result in inadequate fluid replacement therapy in severe diarrheas if one is relying on stool output as a gauge for replacing fluid losses. The problems may be especially significant in infants and children. Furthermore, the antimotility effects are not desired if the diarrhea is caused by microbiologic organisms because stasis may enhance their invasion even to the degree of causing a narcotizing enterocolitis. [550] These drugs also delay subsequent clearance of the microorganisms from the bowel, thus increasing carriage time. Clinical evidence also suggests that such drugs are dangerous in severe IBD, reportedly precipitating the development of toxic megacolon in severe ulcerative colitis. Therefore, although they appear to be safe, their use must be tempered in severe secretory diarrheas, in invasive traveler’s diarrheas and in severe IBD.

The newer antienkephalinase, racecadotril, has been shown to be effective in controlled trials in children [544], [545] and adults. [551], [552] Similarly, the use of amylase-resistant starch (pectin) has been effective in controlled trials of treatment of protracted infectious diarrheas. [125], [126] Because experience with these newer agents is limited, potential side effects are unknown. 5-HT antagonists have proven useful in diarrhea-predominant IBS, [547] but the occurrence of ischemic colitis during their use has resulted in temporary removal from the market and severe use restrictions.

Agents for Secretory Diarrhea

The use of drugs with potentially serious side effects (see Table 40-16) can be justified for treatment of severe secretory diarrheas such as the diarrheas of carcinoid syndrome and neuroendocrine tumors, diabetic diarrhea, graft versus host disease, 5-fluorouracil–leucovorin diarrhea, short bowel syndrome, and AIDS diarrhea. [535], [536] and [537], [553], [554], [555], [556], [557], [558], [559], [560], [561], [562], [563] and [564] The somatostatin analog octreotide appears to have its major antisecretory effect in carcinoid syndrome and in some other neuroendocrine tumors because it inhibits hormone secretion by the tumor. It also may prevent some of the other clinical manifestations of hormone release (e.g., flushing, tachycardia, skin rash). Unfortunately, patients with large tumor burdens may escape from the drug, and then their management may require debulking surgery or agents such as phenothiazine or calcium channel blockers, which have serious side effects. Octreotide may not be helpful in the diarrhea of medullary carcinoma of the thyroid [557] and it is of only limited usefulness in short bowel syndrome [555], [561] and the refractory diarrhea of AIDS. [559], [564] Furthermore, resistance may develop if neuroendocrine tumors are treated for a long period. [560] The newer long-acting preparations, Sandostatin-LAR (Novartis) and Lanreotide-PR (Ipsen-Biotech), have made therapy with this drug more convenient for the patient. [556], [563]

Although clonidine is very useful in the diarrhea of opiate withdrawal and sometimes in patients with diabetic diarrhea, particularly those who already have severe postural hypotension that cannot be made much worse by the agent, such side effects become a limiting factor. [364] Lithium carbonate, bromocriptine, nicotinic acid, and berberine have all been reported to be useful in certain secretory diarrheas. [535], [536] and [537]

Indomethacin, a cyclooxygenase blocker that inhibits prostaglandin production, may occasionally be useful in neuroendocrine tumor and in patients with irritable bowel and possible food allergy (see previous discussion), but it may be harmful in IBD. Indomethacin is most useful in patients with acute radiation diarrhea, AIDS diarrhea, and the diarrhea accompanying villous adenomas of the rectum or colon. The response of these diarrheal diseases to specific cyclooxygenase-2 agents has not been reported.

Agents for Inflammatory Diarrhea

In IBD, glucocorticoids have an effect within 72 hours on both prostaglandin and leukotriene production, [565] and they can be shown to have a proabsorptive effect on the intestine within 5 hours of administration. [565], [566] and [567] Thus, in IBD, steroids are both antiinflammatory and antidiarrheal.

Newer treatment options for inflammatory diarrhea include drugs with immune suppression and immunomodulation activity such as 6-mecaptopurine, methotrexate, cyclosporine, infliximab, thalidomide, and budesonide. [389], [568] These agents can be considered to be antidiarrheal medications by virtue of being antiinflammatory agents. Probiotics show promise in inflammatory diarrheas. A *probiotic* is defined as a viable microbial dietary supplement that affects the host in a beneficial way through its effects on the intestinal tract. [569], [570] Several different species are available: *Lactobacillus* GG, *L acidophilus, Bifidobacterium* species, and *Saccharomyces boulardii* are some of those more widely used. [93], [570], [571] They have been proposed and explored in trials for both prevention and, in some instances, treatment of antibiotic-associated diarrhea, viral diarrhea, bacterial diarrhea, lactose intolerance, IBD, and others. [93], [572], [573] and [574] It is too early to tell whether these probiotics will have efficacy. For every positive trial, there seems to be a negative outcome in another study. This issue will be clarified over the next few years.

CHAPTER 43

Arnold Wald

APPROACH TO THE PATIENT WITH CONSTIPATION

Although constipation is a common gastrointestinal complaint in clinical practice, [1] some uncertainty exists as to the precise definition of the term. Patients complain of constipation if they think that they defecate too infrequently or with too much effort, if their stools are too hard or too small, if defecation is painful, or if they have a sense of incomplete evacuation. This lack of objectivity has contributed to the controversy concerning the incidence, pathogenesis, and treatment of constipation and defecation disorders. Furthermore, the availability of over-the-counter laxatives and their long-term and often inappropriate use may result in laxative dependence, may damage the bowel, and may lead to problems where none previously existed.

DEFINITIONS

Although no single definition is applicable to all constipated persons, it is useful to review the most common definitions to provide guidelines for clinical practice. *Bowel frequency* lends itself to quantification and is a convenient measurement with which to evaluate patients or to survey large populations. Because population surveys have found that most people consuming a Western diet defecate at least three times per week, [2], [3] *constipation* has been defined as a frequency of defecation of twice weekly or less. Other smaller surveys suggest that the lower limit of normal is five times per week, varying according to sex and race [4]; however, this has not been widely adopted as the standard. Furthermore, frequency alone may not be a sufficient criterion because many constipated patients complain of excessive straining at defecation, with or without hard stools, even though frequency of defecation is within the normal range. *Difficulty during defecation* is highly subjective and difficult to quantify. Attempts to do so have used expulsion of water-filled balloons, solid spheres of different volumes, [5], [6] and synthetic stool with the use of radiologic or scintigraphic techniques. [7], [8] These techniques have methodological shortcomings and cannot be used for large population surveys because of their invasive nature or exposure to radioactivity. Even more problematic are measurements of *stool weight* and *consistency.* Normal stool weight varies widely among individuals, with considerable day-to-day fluctuation [9]; stool consistency is unpleasant to measure and difficult to quantify. [10] The clinician should use a combination of subjective and objective criteria as a starting point in assessing such complaints. These include a frequency of defecation less than three times weekly, alone or in conjunction with subjective complaints of difficulty with defecation, [11] especially if there has been a distinct change in regular bowel habit.

SOCIOECONOMIC AND MEDICAL CONSEQUENCES

The costs of constipation are considerable. In the United States, more than $800 million are spent for laxatives; many of these drugs are used unnecessarily, and some may be harmful. Constipation accounts for about 20,000 hospitalizations per year and 2.5 million office visits. [12] No data exist regarding additional costs generated as a result of medical evaluations, diagnostic studies, surgery, and absences from work related to constipation. [13]

Management of problems secondary to constipation adds to the economic burden of this condition. For example, chronic constipation may be associated with urinary tract infections, [14], [15] and in children it may be associated with enuresis and vesicoureteral reflux, as well as fecal soiling. [16] These conditions often improve or disappear with treatment of constipation.

Fecal impaction resulting from constipation is the most common cause of fecal soiling in institutionalized elderly persons. Together with urinary incontinence, it is a contributing factor in the removal of elderly persons from their homes. Chronic constipation also may lead to pudendal nerve damage and fecal incontinence in middle-aged and older women. [17], [18] In more advanced cases, rectal prolapse may result.

In young women, chronic severe constipation is associated with an increased incidence of unnecessary surgery, particularly appendectomy, hysterectomy, and ovarian cystectomy. [19] The reasons for this are unknown. In older persons, dilated loops of colon may result in volvulus or ischemic colitis. Stercorous ulcers with bleeding or perforation constitute a hazard in patients with fecal impaction. [20] Finally, there is some evidence that links constipation with colon and rectal cancer in women. [21]

PATHOPHYSIOLOGICAL CONSIDERATIONS

Constipation may be conceptually regarded as disordered movement through the colon or anorectum because transit through the more proximal regions of the gastrointestinal tract is normal in most constipated patients. From a pathophysiological viewpoint, impairment of large intestine transit can occur because of a primary motor disorder, in association with many diseases, or as a side effect of many drugs (Table 43-1 and Table 43-2). Diseases associated with constipation include metabolic and endocrine disorders and those neurogenic disorders that affect the gastrointestinal tract.

Metabolic and Endocrine Disorders
Diabetes mellitus
Hypothyroidism
Hypercalcemia, hypokalemia
Pregnancy
Porphyria
Panhypopituitarism
Pheochromocytoma
Glucagonoma
Neurogenic Disorders
Peripheral
Hirschsprung disease
Chagas disease
Neurofibromatosis
Ganglioneuromatosis
Autonomic neuropathy
Hypoganglionosis
Intestinal pseudoobstruction (myopathy, neuropathy)
Central
Multiple sclerosis
Spinal cord lesions
Parkinson disease
Shy-Drager syndrome
Trauma to nervi erigentes
Cerebrovascular accidents
Collagen Vascular and Muscle Disorders
Systemic sclerosis
Amyloidosis
Dermatomyositis
Myotonic dystrophy

TABLE 43-1 Secondary Causes of Functional Constipation

Analgesics
Anticholinergics
Antispasmodics
Antidepressants
Antipsychotics
Antiparkinsonian drugs
Cation-Containing Agents
Iron supplements
Aluminum (antacids, sucralfate)
Calcium (antacids, supplements)
Barium sulfate
Metallic intoxication (arsenic, lead, mercury)
Neutrally Active Agents
Opiates
Antihypertensives
Ganglionic blockers
Vinca alkaloids
Anticonvulsants
Calcium channel blockers
$5\text{-}HT_3$ antagonists

TABLE 43-2 Drugs Associated with Constipation

Chronic illnesses often lead to physical and mental impairments that can produce or exaggerate constipation. This condition may be further exacerbated by inactivity or physical immobility, which can lead to fecal retention. A bedridden patient may be unable to respond to defecatory signals because of inadequate toileting arrangements; as a result, fecal retention may lead to megarectum, diminished rectal sensation, and fecal impaction. Other factors that may contribute to constipation in the bedridden patient include underlying illness, medications, and dietary inadequacies. Generalized weakness or striated muscle diseases, such as dermatomyositis, may result in significant constipation because of poor expulsion efforts. [22]

Metabolic and Endocrine Disorders

The most common of the endocrine disorders that cause constipation are diabetes mellitus and hypothyroidism. Constipation was reported by 60% of an unselected clinic population of diabetic patients. [23] Although constipation may occasionally be severe, in our experience symptoms tend to be mild and responsive to relatively simple measures. Constipation associated with hypothyroidism is also usually mild and improves with thyroid replacement therapy, but it can present with life-threatening megacolon in patients with myxedema. [24] Constipation is said to be common during pregnancy, [25] and some women report that they are constipated immediately before menstruation. [26] Alterations of progesterone and estrogen may be responsible because pregnancy is also associated with decreased lower esophageal sphincter pressures, [27] delayed orocecal transit times, [28] and increased gallbladder volume. [29] Similar changes in orocecal and gallbladder function have been documented during the luteal phase of the menstrual cycle. [30] Although delayed colonic transit also has been reported during the luteal phase, [31] one study failed to substantiate such changes in a nonconstipated population. [32] Other less common endocrinopathies that cause constipation are listed in Table 43-1.

Neurogenic Disorders

Because colonic and anorectal motor functions are coordinated by both the enteric nerves and the extrinsic innervation of the sympathetic and parasympathetic nerves (see Chapter 11), diseases of the central and peripheral nervous systems are often associated with constipation (see Table 43-1).

Disorders of Extrinsic Innervation The distal colon is supplied by parasympathetic innervation derived from the sacral nerves that pass through the pelvis and enter the bowel wall in the lower part of the rectum. [33] Transection of these nerves or lesions in the sacral cauda equina may produce constipation associated with hypomotility, colonic dilation, decreased rectal tone and sensation, stasis of the distal colon, and impaired defecation. [34], [35] Similar findings occur in patients with injury to the lumbosacral spine, [36] in patients with meningomyelocele, [37] and after low spinal anesthesia. [38] Constipation also may occur with high spinal cord damage, but in these patients colonic reflexes are intact, and defecation can often be triggered by digital stimulation of the anal canal. [39] Although the motor response of the sigmoid colon after a meal is reduced in persons with high spinal injuries, responses to pharmacological stimuli are normal. [40] Anal sphincter pressures are normal, but rectal sensation may be impaired, and rectal compliance is reduced in patients with high spinal injuries. [40], [41] The prevalence of constipation in patients with multiple sclerosis is high and is associated with neurogenic dysfunction of other organ systems. [42] Constipation may be exacerbated by physical inactivity or by use of medications with constipating side effects. Severely disabled and constipated patients with multiple sclerosis demonstrate absent colonic motor responses after eating a meal as well as high pressure/volume colonmetrograms that probably result from interruption of normal cortical inhibition of colonic motor activity. [43] Other investigators have found prolonged colonic transit and anorectal changes suggestive of rectosphincteric dyssynergia (see discussion later in this chapter), leading to poor rectal evacuation. [44] Whether these findings apply to most patients with multiple sclerosis with bowel dysfunction is unknown.

Disorders of the Enteric Nervous System

Hirschsprung disease. The classic form of this disorder is characterized by obstipation from birth and colonic dilation proximal to a contracted nonpropulsive segment of distal bowel. Rectal examination reveals an empty rectal vault, but the abdomen is markedly distended by a colon filled with stool. Barium enema discloses the characteristic findings in the distal colon and rectum. In contrast to normal function, the internal anal sphincter does not relax after rectal distention [45] and, indeed, often contracts. The absence of this rectosphincteric inhibitory reflex is universal in Hirschsprung disease, [46] reflecting the absence of intramural ganglion cells of both the submucosal and myenteric plexuses; this results from a developmental arrest of caudal migration of neural crest cells from the notochord during embryonic development. Characteristic histochemical findings include increased acetylcholinesterase and catecholamine activity. [47], [48] In addition, neurons containing hydroxytryptamine are absent, [49] and there is a depletion of inhibitory neurotransmitters such as substance P and vasoactive intestinal polypeptide. [50], [51] The demonstration by manometry of the rectosphincteric inhibitory reflex excludes Hirschsprung disease from diagnostic consideration. However, rectal biopsies to document the absence of neurons must be obtained to confirm the diagnosis. Tissue specimens may be obtained by suction biopsy techniques or by a full-thickness biopsy of the rectal wall. In addition to absent neurons, increased acetylcholinesterase staining also can be useful to establish the diagnosis. [47] Although most patients with Hirschsprung disease are diagnosed by 6 months of age, some patients have a clinically milder disease, and the diagnosis may be delayed well into adulthood. [52], [53] Although some of these patients have a very short aganglionic segment, clinical severity correlates poorly with the length of the aganglionic segment. Some investigators have postulated the existence of ultrashort-segment Hirschsprung disease, in which the disease is limited to the anal canal. [21] Because this area normally contains no ganglia, the rectal biopsy results are not useful, and barium study results are normal. Therefore, the diagnosis rests entirely on the manometric demonstration of an absent rectosphincteric inhibitory reflex. However, the most common reasons for failure to elicit internal sphincter relaxation are technical. The recording instrument must be calibrated correctly, settings must be of adequate sensitivity, the probe must be properly positioned, and balloon inflation of the rectum must be of sufficient volume, particularly in patients with megarectum. In addition, the rectum should be emptied before manometry because relaxation may not be elicited if the rectum is filled with stool. Finally, there often is no inhibitory reflex in premature or low-birth-weight neonates, in whom the reflex may take up to 2 weeks to appear. [54] The existence of ultrashort-segment Hirschsprung disease is therefore doubtful.

Other neurological diseases. Constipation has been reported in patients with both decreased [55] and increased [56] numbers of ganglion cells in the colon, although

quantification of ganglion cells in biopsy specimens is difficult. [21] There also have been reported cases of a condition termed *zonal colonic aganglionosis,* in which discrete areas of the colon are devoid of enteric neurons. [57] These disorders may be congenital or acquired secondary to a vascular accident. Abnormal-appearing enteric neurons in the large intestine have been described as a paraneoplastic phenomenon in patients with generalized intestinal pseudo-obstruction and in patients with severe chronic constipation associated with slow transit (see section " Severe Constipation in Young to Middle-Aged Adults"). The role of long-term laxative use in producing damage to the enteric neurons is unproven. [58], [59] Diagnosis requires special staining and labor-intensive quantification of neurogenic elements of colon specimens [60]; it is also susceptible to interpretive bias. Autonomic neuropathy may be associated with constipation, [61] and secondary autonomic dysfunction is believed to underlie constipation in patients with diabetes mellitus. [22] Diabetic patients with constipation may have delayed or absent [62] gastrocolonic response after a meal.

Idiopathic Constipation

Most constipated patients have no obvious cause to explain their symptoms but are presumed to have an underlying disorder of colonic or anorectal motor function. The precise categorization of distinct subtypes of idiopathic constipation is somewhat difficult because of inconsistent definitions and methodologies. However, it is possible to classify patients with idiopathic constipation into several broad groups based on age at presentation, symptoms, duration of complaint, colonic transit characteristics, and anorectal sensorimotor function.

Idiopathic Childhood Constipation Chronic constipation in childhood is multifactorial in origin and involves both psychological and physiological factors. [63] Although severe behavioral problems may occur and should be identified, idiopathic constipation in children is not synonymous with psychogenic constipation; indeed, behavioral abnormalities are usually mild in affected children and may be secondary to bowel dysfunction. [64], [65] Constipation in children is often associated with fecal impaction and dilation of the rectum and sigmoid colon. [66] Many children have slow colonic transit, usually localized to the distal colon and rectum, [67] which suggests either voluntary withholding behavior or abnormal anorectal function. Although many constipated children complain that they do not sense an urge to defecate, demonstration of rectal sensory impairment has been inconsistent. [68], [69] and [70] In one report, impaired perception of sustained distention of a rectal balloon persisted for as long as 3 years in five of eight children who had been successfully treated. [71] If confirmed, such findings could, in part, explain the high frequency of clinical relapse in successfully treated children. However, another study found that rectal sensory impairment had little effect on therapeutic outcome. [70] Studies of anal sphincter pressures also have been contradictory: resting anal canal tone has been reported to be increased, [68], [72], [73] decreased, [74] or similar [70] compared with that in nonconstipated children. Relaxation of the internal anal sphincter is usually normal, [70] and its absence suggests short-segment Hirschsprung disease. Finally, up to 63% of constipated children with fecal soiling fail to relax the puborectalis and external sphincter muscles when they are asked to defecate, [70], [75] a phenomenon that has been termed *anismus* or *rectosphincteric dyssynergia.* This may be a learned behavior acquired at an earlier age, for example, if attempts to evacuate a large fecal bolus were associated with discomfort or an anal fissure (see section " Behavioral Approaches"). Rectosphincteric dyssynergia could lead to further retention of stool, continuing the vicious cycle of events. However, the contribution of this finding to the pathogenesis or maintenance of constipation in children appears to be negligible. [76]

Severe Constipation in Young to Middle-Aged Adults Chronic constipation in this age group is predominantly confined to women. Abdominal pain is uncommon, and megacolon is rare. Patients may complain of infrequent defecation, excessive straining when defecating, or both, and the condition often fails to improve with fiber supplements or mild laxatives. There are several subtypes within this group of patients who, despite similarities with respect to their clinical pictures, may be distinguished by studies of bowel function and psychological profiles. Approximately 30% of patients who consult a physician for complaints of infrequent defecation and who are unresponsive to therapeutic intervention have normal colonic transit. Patients with normal transit constipation may consciously or unconsciously deny that they defecate and often exhibit evidence of increased psychosocial distress. [77] Because these patients do not complain of abdominal pain, they cannot be diagnosed as having irritable bowel syndrome, but their psychological profiles are similar to those of patients with irritable bowel syndrome. [77], [78] Some patients with normal transit constipation demonstrate abnormalities of anorectal sensory and motor function that are indistinguishable from those in patients with slow transit constipation (see section " Colonic Transit Studies"); the relation of these findings to the patients' complaints is unclear. The remaining 70% of patients with severe constipation exhibit slow colonic transit. Many have *colonic inertia,* defined simply as the delayed passage of radiopaque markers through the proximal colon (Fig. 43-1). Unlike patients with normal colonic transit, those with slow transit have significantly lower psychological distress scores that are similar to those of nonconstipated patients with other gastrointestinal disorders. [77]

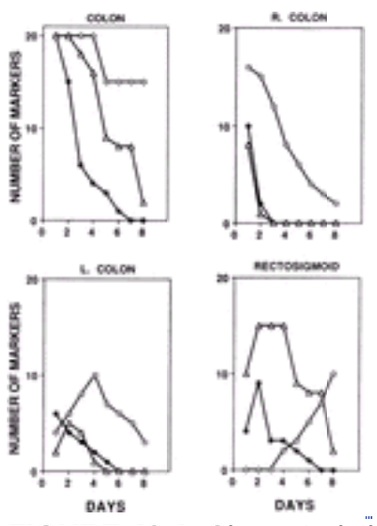

FIGURE 43-1. Characteristic transit patterns of 20 radiopaque markers through the colon during an 8-day period in three groups of constipated patients. With normal transit (*closed circles*), there is rapid disappearance of markers from the colon. In colonic inertia (*open circles*), there is prolonged transit through the right and left colon segments with delayed appearance in the rectosigmoid colon. In outlet obstruction (*open triangles*), transit is normal in the right and left colon, but stagnation occurs in the rectosigmoid colon. (Adapted from Wald A. Colonic transit and anorectal manometry in chronic idiopathic constipation. Arch Intern Med 1986;146:1713.)

Controversy exists concerning the validity of the concept of colonic inertia. Some investigators [39] have argued that colonic transit can vary considerably in the same person on different days and is affected by diet and the menstrual cycle (potentially important in young women). Furthermore, criteria for colonic inertia are imprecise, because colonic stasis could occur as a result of decreased propulsion (hypomotility) or increased distal motility and retropulsion (hypermotility) of markers. Our experience suggests that the menstrual cycle affects colonic transit of markers minimally, if at all, [32] and that significantly slow colonic transit is sufficiently reproducible for clinical purposes. However, one should reserve the term *colonic inertia* for cases in which transit in the proximal colon is delayed without evidence of retropulsion of markers from the left colon; the use of multiple markers of different shapes and shorter sampling intervals may be helpful. Perhaps colonic scintigraphy to measure transit in these patients may help to clarify terminology and pathophysiology. [79] It is not entirely clear which pathophysiological mechanisms are important in patients with colonic inertia. At rest, colonic motility in these patients appears to be similar to that in normal control subjects, [80], [81] and [82] but several studies have demonstrated no increase of motor activity after meals [83] or after administration of bisacodyl. [80], [81] Such findings suggest that abnormalities of the enteric nerve plexus or colonic smooth muscle may exist. Certain histological abnormalities have been demonstrated in resected colon specimens from such patients. [84] These abnormalities include decreased numbers of neurons and axons as well as nuclear abnormalities in the ganglia. Other investigators have demonstrated abnormalities of the contractile properties of colonic smooth muscle. [85] Patients with slow transit constipation have been demonstrated to have decreased numbers of interstitial cells of Cajal, which are thought to play a critical role in intestinal motility. [86] Patients with severe colonic inertia may have symptoms and abnormalities in other areas. These include esophageal dysmotility, [82] delayed transit through the small intestine, [87] and a high incidence of bladder dysfunction and urinary symptoms. [15], [88] Although such disturbances suggest possible neurogenic dysfunction, the precise mechanisms of colonic disturbances remain to be defined. The term *outlet obstruction* [89] has been used to designate a form of idiopathic slow transit constipation in which markers progress normally through the proximal colon but stagnate in the rectum (see Fig. 43-1). This pattern is not specific and may be seen in children with Hirschsprung disease or idiopathic constipation, in nonambulatory or infirm elderly persons with fecal impaction, [90] in patients with megarectum, [91] and in young and middle-aged adults with idiopathic slow transit constipation who demonstrate abnormal responses of the pelvic floor muscles during defecation. [92] This last entity provides another plausible mechanism by which constipation may be produced or exacerbated. Normally, defecation involves the coordinated relaxation of the puborectalis and external anal sphincter muscles together with increased intra-abdominal pressure and inhibition of colonic segmenting activity, which propels stool toward the rectum. In patients with rectosphincteric dyssynergia, ineffective defecation appears to be associated with failure to relax, or inappropriate contraction of, the puborectalis and external anal sphincter muscles. [70], [75], [92], [93] This narrows the anorectal angle and increases the pressures of the anal canal, so evacuation is less effective. Such patients also have difficulty in expelling spheres, water-filled

balloons, or artificial stool from the rectum, compared with most nonconstipated subjects. [75], [92], [94] Because relaxation of these muscles involves cortical inhibition of the spinal reflex during defecation, this pattern may represent a conscious or unconscious act. It can be modified, as has been demonstrated by studies in which biofeedback has normalized defecation patterns in both children and adults with this abnormality. [95], [96] and [97] The pathogenesis of rectosphincteric dyssynergia is not completely understood but is probably multifactorial. Because it can often be modified with operant conditioning training, it is probably an acquired, learned dysfunction rather than an organic or neurogenic disease. Studies indicate that rectosphincteric dysfunction occurs in constipated patients with normal transit and can occur in patients with colonic inertia as well as in those with outlet obstruction. [39] The presence of rectosphincteric dyssynergia can be established in various ways, ranging from simple to sophisticated. During the rectal examination, the contraction of the puborectalis and external anal sphincter muscles can be felt by asking the patient to strain. During anorectal manometry, if the patient is asked to expel the manometer, the characteristic normal pattern is one in which intrarectal pressure increases and external sphincter pressure decreases; in rectosphincteric dyssynergia, in contrast, external pressure increases during attempted expulsion of the manometer. This also can be demonstrated with electromyographic recordings of either or both muscles; normally, electromyographic activity is inhibited during defecation, but it increases with rectosphincteric dyssynergia. Finally, defecography has been advocated to evaluate the expulsion of thickened barium from the rectum radiographically. [7], [98], [99] and [100] In rectosphincteric dyssynergia, the anorectal angle either does not widen or actually narrows during attempts to expel the barium, so little or no expulsion occurs. [21], [101] In our experience, there is agreement on the diagnosis of rectosphincteric dyssynergia between manometry and defecography in approximately 67% of cases. [102] A review of the literature concluded that defecography was of unproven value in evaluating anorectal function and had poor interobserver reliability. [103]

Irritable Bowel Syndrome Constipation in patients with irritable bowel syndrome is most often seen in young to middle-aged adults and is more common in women than men. It is differentiated clinically by the presence of abdominal pain, especially in the lower abdomen, and by the passage of small, hard stools, often with a sense of incomplete evacuation and excessive straining. Not uncommonly, patients also complain of abdominal bloating, flatulence, and upper gastrointestinal as well as nongastrointestinal symptoms. [104] These include heartburn, dysphagia, nausea, genitourinary complaints, back pain, and, in women, dyspareunia. Patients with irritable bowel syndrome frequently demonstrate evidence of increased psychosocial distress. [79] Colonic transit times in these patients are often normal or only modestly slowed. [105] Suggestive findings on colonic radiographs and patterns of colonic dysmotility have been described. These changes are more fully described in Chapter 73 and Chapter 86.

Constipation in the Elderly Some elderly patients with chronic constipation had similar complaints when they were younger. Others develop constipation because of colonic or systemic disorders or as a side effect of medications. There are few data to suggest that aging significantly affects colonic motor function. [106], [107] However, laxatives are used more commonly by elderly women, [106] and physician visits for constipation are more frequent in persons 65 years of age and older. [12] This may be because elderly people often define constipation as the need to strain to defecate, rather than infrequency of bowel movements. [108] Population surveys that rely on bowel frequency alone [2] significantly underestimate the prevalence of constipation in the elderly population. Fecal impaction is a significant problem in elderly patients who are institutionalized. [107] Mental confusion, immobility, or inadequate toilet arrangements may cause such persons to ignore or not act on the urge to defecate, and the fecal bolus may become too large or uncomfortable to pass. The development of megarectum often leads to blunting of rectal and anal sensation that persists even after disimpaction. [90] This predisposes such patients to reaccumulation of feces unless a scrupulous toileting program or periodic evacuation is instituted. Fecal impaction is the most common cause of spurious diarrhea and of fecal incontinence in institutionalized elderly persons. [109]

Megarectum and Megacolon Although only a few patients with constipation have megacolon or megarectum, most patients with a dilated colon or rectum have constipation or defecatory difficulties. In addition, megarectum and megacolon may occur separately or together. [39], [110] Although radiographic criteria exist to diagnose these entities, [111] radiologic assessment does not always correlate with manometric evaluation of rectal elasticity. [66] Idiopathic megacolon may be divided into primary (congenital) megacolon and secondary (acquired) disease. *Primary megacolon* is thought to be associated with neurogenic dysfunction, although histological changes may not be evident without specialized neurohistological staining. [60] In contrast, *secondary megacolon* and megarectum often develop later in life and may occur in response to chronic fecal retention. These patients have increased rectal compliance and elasticity, blunted rectal sensation, an increased threshold, and decreased depth of internal anal sphincter relaxation. [91] To avoid misdiagnosing Hirschsprung disease by anorectal manometry, effective rectal cleansing and larger volumes of rectal distention are often necessary to induce internal anal sphincter relaxation in these patients. Megarectum is generally associated with fecal impaction and soiling, which often occur in children and in physically and mentally impaired elderly persons. [109] In addition, megarectum can occur in Hirschsprung disease, meningomyelocele, and other lesions of the lumbosacral cord and in patients with poor toileting routines. The sensory and motor abnormalities associated with megarectum may be reversible with appropriate therapy in many patients, but this has not been established in the elderly, and abnormalities may persist long after successful treatment in children. [71]

EVALUATION OF CONSTIPATION

History

Evaluating complaints of constipation involves a careful delineation of its duration and characteristics and a review of any previous diagnostic studies and treatment. This information should be obtained with knowledge of the many potential causes of constipation previously detailed.

A critical question concerns the onset and duration of the complaint. Constipation that is present from birth or the neonatal period is most certainly congenital in origin, whereas onset in later life suggests an acquired disorder. A recent change in bowel habit demands a workup for organic disorders, especially in adults, whereas complaints of several years' duration or longer are more likely to be caused by functional disorders.

Next, establishing the nature of the symptoms is important in suggesting various categories of bowel dysfunction and in addressing the specific concerns of the patient. Inquiry concerning frequency of defecation and defecatory difficulties such as excessive straining, discomfort, or sense of incomplete evacuation of the rectum may help to identify specific areas of concern. A complaint of small or hard stools is subjective; it may be helpful to ask the patient to draw a typical stool and an "ideal" one, to determine whether misperceptions or unrealistic expectations exist. The presence of pain or bleeding with defecation should be noted.

Abdominal pain or bloating in association with constipation leads to consideration of the diagnosis of irritable bowel syndrome. Upper gastrointestinal symptoms such as dysphagia, heartburn, early satiety, or vomiting also suggest irritable bowel syndrome or a more diffuse disorder of gastrointestinal function. Genitourinary symptoms, although not specific for constipation from any particular cause, may indicate a central or peripheral neurogenic disorder. Inquiry concerning laxative use and its duration is important, as are questions concerning similar gastrointestinal complaints in other family members and parental views on laxatives and bowel habit. Finally, a gentle but careful assessment for evidence of affective disorders, dysphoria, emotional distress (e.g., litigation, psychological counseling), and the use of mood-altering drugs helps to establish potential contributing factors to subjective complaints in the patient. Questionnaires such as the SCL-90-R [112] may be helpful in this regard; it takes less than 15 minutes to complete, is acceptable to most patients, and correlates well with the Minnesota Multiphasic Personality Inventory. These instruments should be used as an adjunct to careful history taking and not as substitutes for it. In children, inquiry should be made concerning nightmares, enuresis, school performance, and intrafamilial tensions. A history of bowel disturbances in the family should be elicited because there is an increased incidence of constipation and defecatory difficulties in one or both parents of children with encopresis. [113]

Physical Examination

Physical examination includes a search for evidence of nongastrointestinal diseases that can cause or exacerbate constipation. Particular attention should be given to a careful neurological examination, including an assessment of autonomic function and abdominal palpation for evidence of bowel distention, retained stool, or previous surgical procedures.

Anorectal and perineal examinations should search for perineal disease or deformity, abnormal location of the anal orifice, atrophy of the gluteal muscles, and rectal prolapse. Digital examination can elicit the pain of an anal fissure, detect a fixed stenosis of the anal canal, assess tone and strength of the anal canal at rest and with squeeze, or detect the presence of a rectal mass or fecal impaction. While the patient strains, the physician should look for the presence of rectosphincteric dyssynergia, a rectocele bulging anteriorly into the vagina, perineal descent, or rectal prolapse. Gaping of the anal canal when the examiner pulls the puborectalis muscle posteriorly or immediately on withdrawing the finger from the anal canal suggests denervation of the external anal sphincter. Perineal sensation should be assessed, and reflex contraction of the anal canal after pinprick of the perianal area (*anal wink*) also can be used to test neurological function of the perineal areas.

Studies of Colorectal Structure

Studies of colorectal structure are important to exclude organic disease. However, they provide little information about colonic and anorectal function and are

generally overused in patients with long-standing symptoms.

Flexible sigmoidoscopy is a technique to assess bowel mucosa and intralumenal characteristics. It can be used to identify lesions that narrow or occlude the bowel and can detect *melanosis coli,* a brown-black discoloration of the bowel mucosa that is produced by lipofuscin deposits in the lamina propria with long-term use of anthraquinone laxatives. [114] Flexible sigmoidoscopy also can be used to estimate bowel diameter and to detect the featureless characteristics of the distal bowel in patients with long-standing laxative abuse.

If patients complain of constipation of short duration or a recent change in bowel habit, *barium radiographs* are an important complement to sigmoidoscopy to detect organic causes and also to diagnose megacolon and megarectum. Contrary to studies that have found a poor relationship between rectal size on radiography and rectal elastic properties, [66] some investigators have found reasonably good correlation between these two parameters. [91], [102] However, barium enema provides limited information about colonic transit and motor function in most patients with chronic constipation. [115] On balance, studies of anorectal manometry and compliance provide more useful measurements of anorectal function than do barium studies in patients with functional constipation.

Barium radiographs do show the characteristic denervated bowel segment with proximal dilation of the colon in classic Hirschsprung disease. In such circumstances, bowel cleansing should not be ordered, so the characteristic changes will be accentuated. Complete filling of the colon is not necessary for diagnosis of this disorder. Plain films of the abdomen can be useful in the evaluation and treatment of chronic constipation. They can detect significant stool retention in the pelvic colon or throughout the entire colon, can suggest the diagnosis of megacolon, and can be used to monitor the adequacy of bowel cleansing of patients with fecal retention if there is uncertainty on physical examination.

Rectal biopsies are useful only in patients with suspected Hirschsprung disease. Suction biopsy samples should be obtained at least 3 cm above the distal portion of the internal anal sphincter to exclude the disease. For patients with idiopathic constipation, rectal and colonic biopsy samples with the use of endoscopic forceps are thought to be too superficial to be of clinical utility. However, some studies have demonstrated that mucosal levels of serotonin, [116] 5-hydroxyindoleacetic acid, [116] and substance P [117] are characteristically altered in patients with idiopathic constipation. If confirmed, analysis of biopsy specimens could be useful in the diagnosis and investigation of motor disorders of the colon.

Studies of Colonic and Anorectal Function

Function tests are usually reserved for patients with severe idiopathic constipation who fail to respond to relatively simple therapeutic measures (see section “Diagnostic Strategies”). They are also useful in defining the patterns of bowel function in various subgroups of patients with constipation, to identify potentially useful therapeutic strategies.

Colonic Transit Studies A colonic transit study is most useful in evaluating a patient with severe constipation whose major complaint is that of infrequent defecation. Although the methods vary somewhat, the principle of the test is the same. The patient ingests a high-fiber diet (20–30 g/d) while abstaining from the use of laxatives, enemas, and medications that may affect bowel function. Radiopaque markers are ingested, and their transit through the colon is monitored by abdominal radiographs until at least 80% of the markers have passed or a defined period of time has elapsed (usually 6 to 8 days). Transit is then correlated with bowel habit before and during the test. The original technique described by Arhan and colleagues [118] involved the ingestion of 20 radiopaque markers cut from a 5.25-mm (16-French) radiopaque Levin tube. Abdominal radiographs were obtained at 24-hour intervals; markers were counted in the right, left, and rectosigmoid colons, as defined by certain anatomic landmarks, and could be followed as they moved distally until expelled. The markers in each segment each day were totaled and multiplied by a factor of 1.2 to obtain segmental and total transit times. The original technique has been modified to reduce exposure to radioactivity and the number of patient visits to the radiology suite. Daily doses of markers are given for 2 days, [32] 3 days, [119], [120] or 6 days, and radiographs are obtained at various intervals (Fig. 43-1 and Table 43-3). Using fast-film techniques with up to 110 keV, radiation exposure can be significantly reduced and sufficient detail is obtained to identify the markers and anatomic landmarks.

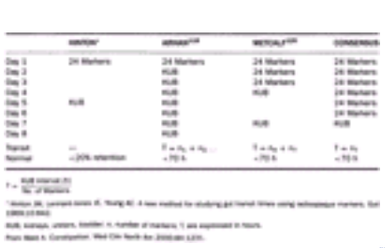

TABLE 43-3 Colonic Transit Studies

Notwithstanding differences in patients with respect to cultural practices, diet, and other factors that may affect colonic transit, studies of physiologically normal subjects on diets containing 20 to 30 g of fiber per day indicate an upper limit of normal for most adults of approximately 70 hours. [32], [119], [120] Although transit times differ between men and women, these differences are not important for clinical purposes. In addition, there are no significant differences between the two phases of the menstrual cycle, [32] which is an important consideration because women are more commonly evaluated for severe constipation. Despite some limitations of the test, [103] colonic marker studies are helpful instruments in evaluating patients with severe intractable constipation, and these tests have prognostic and therapeutic implications as well. Patients with normal colonic transit who complain predominantly of infrequent defecation may consciously or unconsciously misrepresent or misperceive bowel habit and, as a group, exhibit higher levels of psychological distress than do patients with slow transit constipation. [78] In contrast, patients with painless constipation and slow colonic transit have less psychological dysfunction. [78] Patients with the pattern of colonic inertia often respond poorly to therapeutic intervention. [121] In general, therefore, patients with slow transit may have a physiological basis to their symptoms, and those with normal transit may have a significant psychological or behavioral component to their complaints, although this view may be simplistic. A newer method measures colonic transit by scintigraphy. [79] This technique involves ingestion of a resin containing a radioisotope followed by nuclear imaging at various intervals. Although it appears promising as an investigational tool, it provides no more clinical information than does the conventional marker study. [122] In addition, the invasiveness of the procedure and the need for nuclear medicine facilities limit its clinical utility. Finally, one can assess bowel transit by collecting and examining stools radiographically after the administration of radiopaque markers or by inspection of the stools after ingestion of liquid markers. Because these techniques are unpleasant for both patients and technicians and can quantitate only total gastrointestinal transit rather than assess segmental colonic transit, they are not widely performed.

Anorectal Manometry Anorectal motility studies may provide useful information in many patients with severe constipation. The most useful parameters are rectal sensation, viscoelasticity, relaxation of the internal anal sphincter, and defecatory patterns produced on attempted expulsion of the apparatus. Satisfactory measurements of anal sphincter responses can be obtained with open-tipped perfused catheters, direct on-line pressure transducers, or air-filled balloons of various sizes and configurations. If rectal sensation is impaired, as in many patients with severe constipation, it is helpful to know whether impairment is associated with increased rectal compliance or megarectum. Compliance can be measured by sequentially inflating a balloon placed in the rectum and measuring pressures at each level of distention. Pressures should be corrected by subtracting those obtained by inflation outside the patient. The investigator should note the volume at which the first urge to expel the balloon occurs and also the symptoms elicited with increasing inflation of the balloon. Patients with constipation associated with irritable bowel syndrome often have low compliance and tolerate distention poorly, in striking contrast to patients with megarectum. [91] The absence of internal anal sphincter relaxation strongly suggests Hirschsprung disease; in the presence of megarectum, it is important to use larger volumes of rectal distention and to evacuate the rectum to avoid an inappropriate diagnosis of aganglionosis. Manometry has been used to assess anorectal patterns during attempted expulsion. Intrarectal pressures give some indication of intra-abdominal pressures generated during expulsion, whereas pressure recordings in the anal canal indicate relaxation or inappropriate contraction of the external anal sphincter or gluteal muscles. [70] Manometry can be supplemented by electromyographic (EMG) studies with the use of surface recordings of the external anal sphincter or by electrodes on the surface of an anal plug. However, concern has been expressed that results of studies performed in the laboratory may be primarily laboratory artifacts and that true dyssynergia is rare. [123]

Studies of Defecation Defecation can be evaluated by both radiographic and nonradiographic techniques, and these studies may be especially useful in patients who complain of excessive straining during defecation or who employ digital manipulation to facilitate evacuation. These tests vary in their complexity and in the information they provide, and each has potential limitations. [124] *Defecography* is a technique in which barium thickened to a consistency that approximates stool is introduced into the rectum. Evacuation of the barium is monitored by fluoroscopy and videotape while the patient sits on a specially constructed commode. Assessment of the anorectal structures, including the anorectal angle, are obtained at rest and during defecation; also, anatomic abnormalities such as rectoceles and intussusceptions that are not observed at rest may be apparent during defecation. However, emptying is semiquantitative, subjective, and liable to bias. It is probable that many patients feel embarrassed by the nature and setting of the procedure; such inhibitions can potentially result in an abnormal study. Defecography results

should be interpreted cautiously because anatomic abnormalities such as rectocele and intussusception are not uncommon in normal volunteers without constipation. [99], [125] More experience with this technique is needed before definitive decisions can be made on the basis of radiographic findings. [103] Scintigraphic techniques using radioisotope-labeled artificial stool can provide quantitative information concerning rectal emptying but provide little or no anatomic information. [8] Expulsion of water-filled balloons or solid spheres of different sizes and volumes [126] provides some information about expulsion but no information about anatomic changes or relations in the anorectum.

DIAGNOSTIC STRATEGIES

Most chronically constipated patients do not require extensive diagnostic studies beyond a careful history and physical examination and the appropriate exclusion of systemic or gastrointestinal causes for their complaints. Functional evaluation of the colon and anorectum should be reserved for patients who fail to respond to initial simple therapy and who express continued dissatisfaction with their bowel habit. Most patients with constipation-predominant irritable bowel syndrome do not require extensive diagnostic testing and rarely complain of persistent constipation beyond 3 to 6 months' duration.

The functional evaluation of chronic severe constipation begins with carefully defining the complaint and choosing studies that are most likely to yield diagnostic information concerning that complaint (Fig. 43-2). Intuitively, it may not seem important to measure colonic transit if a patient defecates several times per day but does so only with excessive straining or digital manipulation. Likewise, performing anorectal manometry would appear to add little to the evaluation of a patient who claims to have a bowel movement once every 8 days but has normal colonic transit. However, it has been shown that symptoms do not discriminate among physiological subgroups of patients with severe idiopathic constipation. [127] Thus, the workup in patients with severe constipation should be similar regardless of presenting symptoms.

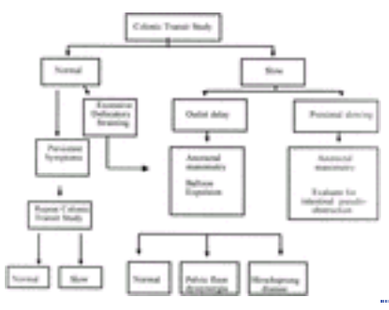

FIGURE 43-2. Algorithm for evaluation of chronic severe constipation that has not responded to dietary measures or fiber supplements. (From ref. [13].)

For the patient with infrequent defecation who fails to respond to initial therapy, a 2-week, prospectively obtained bowel diary with measurement of colonic transit time is the single most useful diagnostic study to obtain. [128] A normal study together with a defecation frequency within the normal range eliminates the need for further diagnostic tests of gastrointestinal function and may serve to reassure both physician and patient that colorectal function is not seriously impaired. In contrast, significant slowing of colonic transit suggests the need for additional studies to characterize various aspects of gastrointestinal motor function further (see Fig. 43-2).

Patients with *colonic inertia* usually have persistent complaints and respond poorly to medical therapy. [77] Anorectal manometry should be performed to characterize sensorimotor function of the bowel such as rectal sensation and viscoelasticity. Appropriate studies of upper gastrointestinal motor function should be obtained to look for evidence of gastrointestinal pseudo-obstruction (see Chapter 65 and Chapter 73) because such information may have both prognostic and therapeutic implications (see section " Colonic Inertia "). In contrast, the pattern of *outlet delay* suggests a more localized problem of the anorectum that can be further characterized by anorectal manometry, defecography, and a search for anatomic or functional abnormalities. The finding of normal anorectal function in a patient with outlet obstruction may suggest possible withholding behavior and is common in children.

For the patient who complains of *excessive defecatory straining* in the absence of an organic cause, both colonic transit studies and studies of anorectal function may be helpful. Normal anorectal motility and defecography may help to reassure patients that there is nothing seriously wrong from a functional standpoint; many of these patients exhibit high levels of psychological distress similar to that of patients with normal transit constipation. [129] The importance of anatomic abnormalities in such patients remains to be established.

TREATMENT CONSIDERATIONS

Much has been written about the treatment of constipation. There is general agreement that selecting therapeutic strategies requires understanding of the whole patient, fiber supplements should be added to the diet, establishing proper toileting arrangements can help certain patients, and long-term use of stimulant laxatives should be judicious. Treatment should be individualized, taking into consideration the age of the patient, duration and severity of constipation, potential contributing factors, and the patient's concerns and expectations. Although this approach is reasonable, there is little objective evidence to support it, in part because of the paucity of controlled trials and the heterogeneity of the population who consult for constipation. In addition, short-term results do not always reflect long-term outcome, and there is probably a significant placebo component to most therapeutic approaches. Broadly speaking, nonsurgical treatment can be separated into several categories: dietary approaches such as fiber supplementation; behavioral approaches such as habit training, contingency management, and biofeedback; and pharmacological approaches. Surgery has a role in selected patients with severe constipation in whom abnormal bowel function can be ameliorated by operative intervention.

Dietary Approaches

Dietary adjustments are the first line of intervention for most adults with constipation. Inadequate intake of dietary fiber is widely believed to contribute to constipation in industrialized nations because high fiber consumption in other parts of the world is generally associated with the daily passage of several bowel movements of considerable volume. [130] Indeed, increased consumption of dietary fiber by nonconstipated persons increases stool weight and frequency of defecation and decreases gastrointestinal transit time. [131] Although constipation appears to result from dietary fiber inadequacy in some persons, there is no evidence that constipated patients in general consume less fiber than do nonconstipated persons. [39] This is not to say that fiber supplementation should not be attempted. Many constipated patients do respond to increases in fiber intake to between 20 and 30 g per day, especially when the fiber is accompanied by water supplementation. [132]

Fiber components are not equivalent in their ability to modify stool characteristics and bowel habit. For example, wheat bran is most effective in increasing stool weight, followed by fruits and vegetables, oats, mucilages, corn, cellulose, soya, and pectin. [131] In animal studies, wheat bran accelerated colonic transit, whereas cellulose produced no change compared with fiber-free controls; pectin, sugar, and oat bran had variable effects on different regions of the colon. [133] The bulking effect of fiber is not so much related to water retention capabilities as to mechanical factors and colonic microbial ecology and interaction with intralumenal contents. Fiber may serve as a substrate for colonic bacteria and thus may increase stool bulk by proliferation of bacteria and production of gases that are trapped in the stool. [131], [134] Microbial breakdown products such as short-chain fatty acids also may stimulate colonic motility. [129] The net effect is increased stool bulk and shortened colonic transit in many persons. [135]

It is reasonable to recommend a high-fiber diet for all ambulatory adult patients who have constipation without megacolon (Table 43-4). It is of greatest help in patients with low fiber intake and in patients with constipation-predominant irritable bowel syndrome, in whom fiber intake should be increased gradually, to avoid undue cramping and bloating. [131] Fecal impactions should be removed before initiating fiber supplementation. Patients with obstructive lesions anywhere in the gastrointestinal tract should not be given fiber supplements. Fiber is not indicated in patients with megacolon or megarectum, especially if such patients are confined to bed, are demented, or have neurogenic constipation. Such patients are better managed by reducing colonic contents and instituting periodic timed evacuation.

	AMOUNT OF SERVING (g)	AMOUNT/100 g OF FOOD
Breakfast Cereals		
All-Bran	9.9	26.70

TABLE 43-4 Food Sources of Dietary Fiber

Behavioral Approaches

Habit training and contingency management are often employed in children with idiopathic constipation with or without soiling. [63] The goal is to achieve regular evacuation, to prevent buildup of stool and fecal soiling. A similar approach may be useful in patients with neurogenic constipation, with or without soiling.

Before embarking on a behavioral approach, the patient's colon must be disimpacted and evacuated effectively. This can be accomplished with twice-daily saline or tap water enemas for 3 days and can be monitored by palpating the abdomen or obtaining an abdominal radiograph. Occasionally, a child may have to be hospitalized if cleansing cannot be achieved at home. Colonic evacuation may be accomplished by having constipated children drink a balanced electrolyte solution containing polyethylene glycol 3350 in amounts totaling 5 to 19 L. [136]

After bowel cleansing, polyethylene glycol, 8.5 to 34 g in 240 mL fluids or lactulose 15 to 30 mL/d, is given to produce at least one stool per day. In addition, the child is instructed to use the bathroom after breakfast or dinner to take advantage of meal-stimulated increases in colonic motility. If there is failure to defecate after 2 days, a cleansing enema is given to prevent recurrence of fecal impaction. After defecation occurs regularly for 2 to 3 months, weaning from the polyethylene glycol or lactulose is attempted gradually. Positive reinforcement is given for successful toileting, and punishment for failure is prohibited. Contact with the child and at least one parent should be maintained regularly.

These behavioral approaches have achieved success rates of up to 78% in children, [65], [137], [138] although relapses are not uncommon. [65], [139] The relative importance of each component of such strategies is unknown. [63] Treatment failures have been traditionally attributed to patient and family behavioral disturbances and noncompliance, but underlying disturbances of bowel function may play a role in some children. [68], [69], [70], [71], [72], [73], [74] and [75]

Another behavioral approach is the use of biofeedback to correct inappropriate contraction of the pelvic floor muscles and external anal sphincter during defecation. Studies have used EMG recordings concurrently with anal plugs [95] or anorectal manometers to monitor external and sphincter pressures during attempted expulsion of the apparatus. [96], [97] The patient watches the recordings of EMG or pressure responses and is told to modify inappropriate responses through trial-and-error efforts. Although this approach is useful in adults, a large study found that biofeedback therapy did not result in higher success rates than did conventional therapy alone. [76]

Despite the widespread belief that childhood encopresis is secondary to behavioral disturbances, the importance of behavioral factors is uncertain. Controversy centers on differences in the reported frequency and severity of behavioral disorders in encopretic children and whether they precede soiling or occur as a result of the underlying bowel dysfunction. Inconsistencies among various studies may be caused by differences in study populations: children with encopresis who were evaluated in psychiatric settings exhibited significant psychological dysfunction, whereas those referred to medical settings were less likely to do so. Several studies have reported only mild behavioral dysfunction and unremarkable toilet experiences in encopretic children treated in medical settings. [64], [137], [140] In contrast, others have reported more anxiety, less tolerance for demands, more submission in the face of peer aggression, less control of aggressive impulses, and more academic difficulties among encopretic children than among matched controls. Landman and colleagues [141] found that children with encopresis tended to feel less in control of positive life events and had lower self-esteem than children with other chronic illnesses such as recurrent abdominal pain, enuresis, or headache. Although other investigators made similar observations, they concluded that such personality characteristics developed because of negative experiences associated with soiling. [142], [143] Consistent with this interpretation, Levine [65] found that successfully treated encopretic children became better adjusted and exhibited no evidence of symptom substitution as long as 3 years after therapy. These observations imply that poor coping skills, low self-esteem, and passivity are potentially reversible with successful treatment of fecal soiling.

Pharmacological Therapy

The use of laxatives is deeply rooted in medical and social traditions, [144] and vast amounts are consumed in the Western world, [12] especially by elderly persons. [109] Laxatives are classified into five groups on the basis of their presumed mode of action (Table 43-5).

LAXATIVE	USUAL ADULT DOSE*
Bulk-forming Laxatives	
Natural (e.g., psyllium)	7 g/day
Synthetic (e.g., methylcellulose, polycarbophil)	4–6 g/day
Emollient Laxatives	
Mineral oil	15–45 mL/day
Hyperosmolar Laxatives	
Polyethylene glycol	8–25 g/day
Lactulose	15–30 mL/day
Sorbitol (70%)	15–30 mL/day
Glycerine	3 g suppository
Saline Laxatives	
Magnesium hydroxide	2400 mg (30 mL)
Magnesium citrate	200 mL
Stimulant Laxatives	
Castor oil	15–60 mL
Diphenylmethanes	65–130 mg
Phenolphthalein	30 mg
Bisacodyl	10 mg suppository
Anthraquinones	
Aloe (casanthranol)	30–60 mg
Cascara sagrada	2–5 mL
Senna	17–34 mg

* Oral except where indicated otherwise.

From Wald A. Constipation. Med Clin North Am 2000;84:1231.

TABLE 43-5 Laxatives for the Management of Constipation

The *bulk-forming laxatives* comprise natural (psyllium) or synthetic polysaccharides or cellulose derivatives that act in a manner similar to that of fiber naturally contained in the diet. Because fluid intake should be increased with these preparations, [132] they should be used cautiously in patients who require severe fluid restriction. Sugar-free bulk laxatives may contain aspartame (NutraSweet) and are contraindicated in patients with phenylketonuria.

Emollient laxatives consist of mineral oil and docusate salts. Mineral oil can be given orally or by enema; it penetrates and softens the stool. Although some mineral oil is absorbed and deposited in the liver, spleen, and mesenteric lymph nodes, [145] there are no described harmful effects. Because mineral oil may decrease the

absorption of fat-soluble vitamins A, D, and K, it should be administered between meals. Aspiration with lipid pneumonia is well described; therefore, mineral oil is contraindicated in patients with esophageal dysmotility or dysphagia and in elderly or debilitated patients and should not be given at bedtime. It is an unattractive agent in view of the availability of other effective products.

Docusate salts are anionic surfactants that lower the surface tension of stool to allow mixing of aqueous and fatty substances. This action softens stool to permit easier defecation. These agents also stimulate intestinal fluid and electrolyte secretion by increasing mucosal cyclic adenosine monophosphate. [146] Although not absorbed, they alter intestinal mucosal permeability and increase the absorption of other laxatives, such as mineral oil, phenolphthalein, and danthron. Placebo-controlled studies failed to demonstrate changes in stool water content, stool weight, frequency of defecation, or colonic transit times after administration of docusates in the recommended doses. [147]

Hyperosmolar agents include polyethylene glycol and nonabsorbable sugars such as lactulose and sorbitol. Sorbitol and lactulose are degraded by colonic bacteria to low-molecular-weight acids that increase stool acidity and osmolarity and lead to accumulation of fluid in the colon. Doses should be adjusted to reduce abdominal bloating and flatulence and to modulate defecation. Sorbitol and glycerin are given intrarectally and may produce rectal irritation. Polyethylene glycol electrolyte solutions are most often given for bowel cleansing before colonoscopy or before institution of bowel programs. One formulation consists of polyethylene glycol without electrolytes that is given in varying doses on a daily basis. Formulations with or without electrolytes have proven effective when given on a daily basis. [148], [149]

Saline laxatives contain relatively nonabsorbable cations and anions that exert an osmotic effect to increase intralumenal water content. Magnesium increases intestinal motor activity; because an appreciable amount of magnesium may be absorbed, these agents should be avoided in patients with renal insufficiency because of the danger of magnesium toxicity. [150] Other side effects include hypocalcemia in children and mineral imbalances. Saline laxatives can also be administered by enemas or suppositories.

Stimulant laxatives consist of castor oil, anthraquinones (cascara sagrada, senna, casanthranol, and danthron), and diphenylmethanes (phenolphthalein and bisacodyl). Castor oil is hydrolyzed by intestinal lipases to ricinoleic acid, which stimulates intestinal secretion, decreases glucose absorption, and increases intestinal motility. [151]

The anthraquinone laxatives increase fluid and electrolyte accumulation in the distal ileum and colon through incompletely understood actions. [12] All are absorbed from the small intestine to some extent (especially danthron) and are metabolized by the liver. Anthraquinones are converted to a pharmacologically active state by contact with intestinal microorganisms. Pathological changes in the colon produced by long-term anthraquinone use include melanosis coli, a benign and reversible condition. Although smooth muscle atrophy and damage to the myenteric plexus were suggested in earlier studies, [152] there is no evidence that anthraquinones given in clinically relevant doses cause enteric damage in either experimental animals or humans. [58], [59]

Approximately 15% of phenolphthalein is absorbed from the small intestine and undergoes an enterohepatic circulation, which explains its often long duration of action. It acts directly to stimulate colonic motor activity and inhibits glucose and sodium absorption to increase intralumenal fluid content. Side effects include fixed-drug skin eruptions, erythema multiforme, and photosensitive bullous skin lesions. Fatalities have been reported in allergic patients who were rechallenged with the drug. [144]

In 1997, the United States Food and Drug Administration (FDA) reclassified phenolphthalein as “not generally recognized as safe and effective” after a study in rodents found an increased incidence of nongastrointestinal neoplasms. [153] Subsequently, most phenolphthalein-containing laxatives were voluntarily withdrawn in the United States. However, these animals were given doses 10 to 1000 times the human dose, in terms of body surface area. Studies of persons who use laxatives have not suggested that the risk of these cancers is increased in humans. [154] Similarly, concerns about a possible relationship between melanosis coli and the development of colonic neoplasms [155], [156] were not substantiated in a prospective case control study. [157]

Bisacodyl is structurally similar to phenolphthalein and exhibits similar actions on small intestine fluid accumulation and colonic motor activity. [80] Because the drug is a gastric irritant, tablets are enteric coated and should not be broken or chewed. [144]

The use of drugs to enhance colonic transit by increasing propulsive motor activity has been hampered by limited knowledge of the control of various aspects of colonic motility (see Chapter 11) and the pathophysiology of severe idiopathic constipation. *Cholinergic agents* such as bethanechol have been used with little success and exhibit moderate side effects in patients with colonic inertia. *Cholinesterase inhibitors* such as neostigmine may have fewer side effects, but there is no evidence of increased efficacy, [40] except in acute megacolon. [153]

Prokinetic agents are drugs that stimulate gastrointestinal motor activity to enhance transit of intralumenal contents. Metoclopramide has been used to treat upper gastrointestinal motor disorders but exerts little effect on colonic motility and is not effective in constipated patients. [13] Cisapride appeared to enhance transit through the proximal colon and has been shown to stimulate colonic motility and improve rectal sensation in chronically constipated patients. [154], [155] Although some studies suggest that clinical improvement occurred with the drug, [154], [155] and [156] others report highly variable and often disappointing results in patients with severe idiopathic constipation. Cisapride was withdrawn by the FDA because of the risk of cardiac toxicity. Some patients with severe constipation have been treated successfully with misoprostol, a prostaglandin used to prevent peptic ulcers associated with nonsteroidal antiinflammatory drugs. [158], [159] Another small study reported that colchicine (0.6 mg three times daily) was effective in patients with refractory constipation. [160] Further studies are needed to assess the possible efficacy of these agents in severely constipated patients.

There has been intense interest in the pharmacological actions of serotonin (5-hydroxy-tryptamine [5-HT]) agonists on gastrointestinal motility. 5-HT $_4$ agonists stimulate intestinal motility, in part by facilitating enteric cholinergic transmission. [161], [162] Clinical trials indicate that several 5-HT $_4$ receptor agonists accelerate colonic transit time and improve symptoms in patients with constipation predominant irritable bowel syndrome or constipation. [163], [164]

It has been hypothesized that motility disorders leading to chronic constipation are caused by excessive endogenous opioids. Several patients with severe constipation have been treated successfully with intravenous naloxone, an opioid receptor antagonist. [165] As shown by scintigraphic techniques, naloxone accelerates transit in various parts of the colon in normal volunteers. [166] Preliminary studies suggest that oral naloxone, compared with placebo, may increase stool volumes in elderly constipated persons. [167] Such agents have been used successfully to treat constipation associated with long-term use of narcotic agents. [168]

Surgical Treatment

With several important exceptions, the indications for surgical intervention in managing patients with chronic constipation are somewhat controversial. The generally agreed indications and contraindications for surgery are discussed in the next section.

Hirschsprung Disease Surgery is the treatment of choice for all forms of this disease but varies according to the length of the aganglionic segment. In patients with short-segment or ultrashort-segment disease, anal myotomy, in which the internal sphincter and a varying length of rectal smooth muscle are incised, can be very beneficial. [169], [170] In the classic form of the disease, more extensive procedures are used to overcome the obstructing effect of the aganglionic segment. These include the following: removal of the segment, as in the Swenson operation [171]; bypassing it, as in the Duhamel operation [172]; or using the endorectal pull-through techniques of Soave [173] and Boley. [174] The choice of surgical technique depends on the surgeon, but excellent results have been reported for all of them. [175], [176] For good results to be obtained, thorough cleansing of the colon before surgery is mandatory. [170]

Colonic Inertia In selected patients with colonic inertia, subtotal colectomy with ileorectal anastomosis can be dramatically beneficial in ameliorating incapacitating symptoms that are unresponsive to medical management. [177], [178] and [179] Limited resection of the colon, however, produces unsatisfactory results and a high rate of anastomotic leaks. [177] Radiologic or manometric studies should be performed preoperatively to document that the disorder is confined to the large intestine and to establish normal esophageal, gastric, and small intestine motor function. Nevertheless, abnormal gastroduodenal manometry does not necessarily predict failure of colectomy, [180] and normal studies do not guarantee success. Patients who have evidence of a more extensive dysmotility disorder can be anticipated to have less satisfactory results, [181] as do those with coexisting psychiatric disorders. [182] Such procedures should be done only if colonic distention is life-threatening or severely incapacitating. There is a fairly high complication rate, and patients with bloating and abdominal pain are less likely to have improvements with surgery. [183]

Rectocele Surgical therapy consists of reducing or eliminating the pouch. Because rectoceles are common in nonconstipated persons, care must be taken before attributing defecatory problems to this entity. Ideally, one should observe improved rectal evacuation after the patient exerts finger pressure on the posterior wall of the vagina during defecography. Rectocele repairs often do not alleviate symptoms of difficult defecation.

Rectal Intussusception and Prolapse Surgical therapy consists of various resuspension procedures and abdominal rectopexy with sigmoid resection. [170] However, most patients who undergo surgery experience no improvement in their defecatory problems. [184] As with rectoceles, rectal intussusceptions are not uncommon in nonconstipated persons, and their presence in constipated patients should not imply causation.

Rectosphincteric Dyssynergia Surgery for this disorder is contraindicated because patients receive no benefits from posterior division of the puborectalis muscle, and fecal incontinence commonly occurs postoperatively. [185]

CHAPTER 44

Raphael B. Merriman and Marion G. Peters

APPROACH TO THE PATIENT WITH JAUNDICE

Jaundice (icterus) is the yellow discoloration of skin, sclera, and mucous membranes caused by the excessive accumulation of bilirubin pigments. It is usually apparent when bilirubin levels exceed 3 mg/dL or 50 µmol/L. [1] Hyperbilirubinemia results from one or more derangements in the complex multistep process that balances bilirubin production with bilirubin clearance. Consequently, jaundice can indicate a disorder in bilirubin metabolism, hepatic function, or biliary disease or combinations thereof. The optimal approach to the patient with jaundice demands precise localization of the site of disordered bilirubin handling and appropriate diagnostic tests. A review of the causes and management of jaundice logically begins with a clear understanding of the structure, formation, uptake, and conjugation of bilirubin, its clearance through the liver, and its subsequent excretion into the biliary tree and gastrointestinal tract.

Cholestasis is characterized by the constellation of physiological, morphologic, and clinical manifestations that result from the impairment of the bile excretory system in the liver and biliary tree. [2], [3] Reduced bile flow resulting in the accumulation of conjugated bilirubin, bile salts, and cholesterol in the blood is the hallmark of cholestasis. However, an impairment of organic ion transport, decreased excretion of biliary lipids, a release of liver plasma membrane enzymes, and a decrease in intestinal bile also occur. In patients with cholestasis, total serum bilirubin may be normal while serum alkaline phosphatase and bile acids are elevated. [4] *Bile acids* or bile salts are soluble, amphipathic end products of cholesterol metabolism formed in the pericentral hepatocytes and accounting for approximately 85% of the constituents of bile. [5] The primary bile acids (formed in the hepatocyte) chenodeoxycholic and cholic acids are the most common. The secondary bile acids are formed by anaerobic bacterial dehydratase conversion of primary bile acids to lithocholic and deoxycholic acids, respectively. Primary and secondary bile acids account for 99% of the bile acids in human bile. Another bile acid, ursodeoxycholic acid, so termed after its isolation from bile of the polar bear, is present in trace amounts. The bile acids' hydroxyl groups are water soluble and thus hydrophilic, whereas the opposite pole is relatively hydrophobic, giving bile acids their detergent properties. The hydrophilic activity of bile salts increases as the number of hydroxyl groups increases. Thus, lithocholic acid is more hydrophobic than chenodeoxycholic acid and cholic acid, with ursodeoxycholic acid the most hydrophilic. Bile acids are absorbed in the distal small intestine and are returned to the liver mostly protein bound and resecreted, constituting the enterohepatic circulation. The bile acid pool of 2 to 3 g in adults cycles several times with each meal, and although bile acid synthesis averages 0.3 g/d, total bile acid secretion is 12 to 18 g/d. Bile acids are critical for cholesterol elimination, by conversion of cholesterol to bile acids, by stimulation of biliary cholesterol and phospholipid secretion, and by micellar solubilization of cholesterol and phospholipids within bile, ultimately facilitating fecal elimination. Bile acids also induce bile flow, and through negative feedback, they can inhibit bile and cholesterol biosynthesis. Bile is a major conduit for the elimination of other endogenous and exogenous pigments including porphyrins and urobilins, in addition to the elimination of most rare metals (copper, zinc, manganese, chromium, selenium, molybdenum, and cadmium and organic anions). [6] In the small intestine, bile acids promote dietary lipid absorption through the formation of mixed micelles.

BILIRUBIN

Structure and Formation

Bilirubin, a yellow tetrapyrrole pigment, is the principal end product of the degradation of the heme moiety of hemoglobin and other hemoproteins. The catabolism occurs largely within the reticuloendothelial cells of the liver, spleen, and bone marrow. The heme iron protoporphyrin IX ring is opened by oxidation of the a-bridge carbon by heme oxygenase, present in many cell types, particularly Kupffer cells, macrophages, hepatocytes, and renal epithelial cells. The reaction forms biliverdin, a green tetrapyrrolic pigment, and equimolar quantities of carbon monoxide, which binds to hemoglobin and is excreted through the lungs (Fig. 44-1). Biliverdin is then rapidly reduced to bilirubin by biliverdin reductase. Bilirubin IXa, derived from protoporphyrin isomer IX with cleavage at the a bridge, is the predominant bile pigment in plasma, where its concentration generally does not exceed 1 mg/dL (17µmol/L) in healthy people. [7] Hydrogen bonds stabilize the molecule in a folded, ridge-tile conformation restricting exposure of the molecule's polar groups to aqueous solvents. These structures form the basis of bilirubin's hydrophobic behavior and slow (indirect) diazo reactivity. [8] Opening of the heme ring at non–a-carbon positions would lead to isomeric pigments that are more water soluble and do not require conjugation for efficient excretion in bile and urine. However, although heme catabolism generates almost exclusively a single form of bilirubin, other stereoisomers are formed from this by exposure to light as the pigment circulates through peripheral tissues. Being more polar, these photoisomers do not require conjugation for excretion in bile. Their formation is clinically important in phototherapy of neonatal jaundice, in which they accelerate bilirubin elimination but otherwise have no known significance. [8] With the exception of bilirubin IXß found in meconium, significant quantities of these isomers are not detectable.

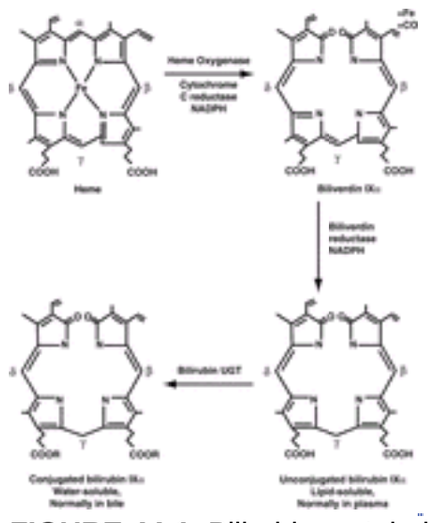

FIGURE 44-1. Bilirubin metabolism. The first step in the degradation of the heme group to bilirubin is the cleavage of its a-methene bridge to form biliverdin, a reaction catalyzed by heme oxygenase. The enzyme is a monooxygenase, and O_2 and NADPH are required for the cleavage reaction. The reaction releases CO, iron, and biliverdin. The CO binds to hemoglobin and is excreted through the lungs, and most of the iron is reincorporated into new heme proteins. The second step in heme catabolism is the reduction of biliverdin IXa to bilirubin IXa by biliverdin reductase and NADPH. The result is unconjugated bilirubin. After bilirubin IXa is formed, it is released into the bloodstream, where it rapidly binds to plasma proteins, especially albumin. These complexes are poorly filtered by the glomerulus. Bilirubin is rendered more soluble in the liver by conjugation: the attachment of sugar residues such as glucuronates to its propionate side-chains. This reaction requires the enzyme bilirubin UDP glucuronosyltransferase (bilirubin UGT).

Most bilirubin (80%) derives from senescent and sequestered erythrocytes. [1] The remainder is largely derived from the degradation of hepatic and renal heme, which constitutes a cytosolic pool of heme destined for incorporation into specific heme proteins including cytochrome P450, peroxidase, and catalase. One third of the bilirubin derived from the hepatic heme proteins passes directly into bile as conjugated bilirubin, and the rest refluxes into plasma. [9] Myoglobin heme, because of its slow turnover, contributes less than 1% to bilirubin formation. Normally, less than 3% of bilirubin is derived from ineffective erythropoiesis in the bone marrow, but this fraction may be considerably increased in hemoglobinopathies, congenital and acquired dyserythropoietic anemias, and megaloblastic anemia. Normal daily human bilirubin production averages 4 mg/kg body weight, equivalent to approximately 250 mg of bile pigment.

Unconjugated bilirubin is normally insoluble in water. In bile, however, it is solubilized by weak interactions with mixed micelles of bile salts and other lipids. [6] When the capacity for bilirubin solubilization is exceeded in bile, the unbound pigment may precipitate as a calcium salt and may form bilirubin pigment stones. Most bilirubin formed peripherally is transported in plasma tightly bound to albumin. The concentration of unbound bilirubin remains very small until the bilirubin concentration exceeds 35 mg/dL. [10] Increased unbound bilirubin pigment may cross cell membranes resulting in tissue injury, a key factor in the pathogenesis of bilirubin encephalopathy and kernicterus in the newborn. [11] In its albumin-bound state, bilirubin is poorly filtered at the glomerulus, limiting its renal elimination. Therefore, the conjugation of bilirubin by hepatocytes facilitates the excretion in bile of a potentially toxic substance.

Uptake, Binding, and Conjugation

The hepatocyte has evolved specialized mechanisms to facilitate the uptake of the nonpolar, tightly albumin-bound molecule across the sinusoidal membrane, to maintain solubility by binding to cytosolic proteins and to convert it to more polar compounds by conjugation, permitting subsequent excretion. Initially, albumin spontaneously dissociates from its bilirubin ligand, the principal determinant of which is the unbound bilirubin concentration. [12] Subsequent hepatocyte uptake of unconjugated bilirubin is often considered a facilitated process involving several transporters, possibly including liver-specific forms of the organic anion transporting polypeptide (OATP) family, a sodium-independent transport system, [13] although the identity of bilirubin transporters for uptake remains controversial and uncertain. Once inside the hepatocyte, hydrophobic bilirubin is maintained in solution by binding nonenzymatically to the cytosolic fatty acid binding proteins and ligandins (isoforms of proteins of the glutathione *S*-transferase gene family [GST]). [14] GSTs are important in creating intracellular gradients, in determining bilirubin's movement, in compartmentalization, and in presentation to microsomes for conjugation.

The conjugation of bilirubin in the endoplasmic reticulum is the physiological process whereby bilirubin is rendered soluble and more hydrophilic for ultimate excretion into the canaliculus. Conjugation is achieved by the esterification of one or both of the propionic side-chains through the addition of polar groups. Glucuronic acid esterification predominates, but xylose or glucose esterification can occur. Bilirubin is conjugated with uridine 5'-diphospho (UDP)-glucuronic acid by bilirubin UDP-glucuronosyltransferase (bilirubin UGT, also known as UGT-1A1). This produces bilirubin monoglucuronides and subsequently the diglucuronide. Normal human bile principally contains bilirubin diglucuronide (70%–90%) and smaller amounts of monoglucuronides (5%–25%). Their proportions change when the ratio of unconjugated bilirubin to available enzyme is increased (with an increased bilirubin load in hemolysis or reduced enzyme activity in Gilbert syndrome), favoring the formation of monoglucuronides. [15] It is becoming apparent that there are many distinct UGT isoforms. However, in humans, conjugation of bilirubin is exclusively carried out by the substrate specific microsomal enzyme, UGT-1A1 encoded by the UGT-1 gene subfamily that is located on chromosome 2. [16] Apart from bilirubin, other substrates for glucuronidation include drugs such as testosterone, estradiol, 1,25-dihydroxyvitamin D_3, digoxin, and propranolol, in addition to thyroid hormones and catecholamines. Understanding of the sequence of bilirubin UGT and subsequent identification of mutations have facilitated the understanding of several disorders characterized by deficient bilirubin conjugation, such as Gilbert syndrome and Crigler-Najjar syndrome.

Clearance and Excretion

Hyperbilirubinemia results from a combination of increased bilirubin turnover or decreased bilirubin clearance. Isotope labeling studies permit an estimation of daily hepatic bilirubin clearance but are available only in a research setting. [7] Hepatic extraction of unconjugated bilirubin from plasma is 4.6 µg/min/kg under normal conditions. Almost 40% refluxes unaltered back into plasma, as does a small proportion of esterified bilirubin. The proportion of unconjugated to conjugated can change from more than 9:1 in nondisease states to 1:1 in cholestatic disease.

The generation of bile flow is highly regulated and involves the coordinated action of several transporter proteins located at canalicular and sinusoidal domains in the hepatocyte. The canalicular ATP-dependent export pumps include the multidrug resistance 1 P-glycoprotein (MDR1), the phospholipid multidrug resistance 3 P-glycoprotein (MDR3), the canalicular bile salt export pump (BSEP), and the canalicular multispecific organic anion transporter (MRP2 or cMOAT), all members of the ATP binding cassette family, in addition to several putative ATP-independent transport systems. More recent advances have provided an enhanced understanding of these canalicular excretory processes. [13] The transporters are the rate-limiting step in bile salt export. Conjugated bilirubin is excreted across the canalicular membrane by a saturable process capable of functioning against a concentration gradient of 40- to 100-fold. Bilirubin monoglucuronides and diglucuronides are excreted into bile by the transporter MRP2. This carrier is also responsible for excreting leukotriene 4, some hydrophobic bile acids, oxidized glutathione, indocyanine green, sulfobromophthalein, and cholecystographic contrast. Definitive evidence of a potential sensitive membrane transporter is currently lacking.

After conjugated bilirubin reaches the bile ducts, it flows into the gallbladder, where sodium, bicarbonate, and water are actively absorbed. Cholecystokinin coordinates gallbladder contraction and sphincter of Oddi relaxation, permitting the controlled flow of bile into the small intestine to participate in the digestive process. Conjugated bilirubin is not absorbed from the gastrointestinal tract. However, it may be deconjugated and degraded by bacterial ß-glucuronidases and other enzymes in the terminal ileum and colon to form a large variety of urobilinogens. Some urobilinogen is reabsorbed from the colon resulting in small plasma concentrations. Most of this is re-excreted by the liver, although the kidney filters a small proportion. Increased urine urobilinogen may represent increased bilirubin formation and subsequent enterohepatic circulation of urobilinogen or, alternatively, decreased hepatic clearance of urobilinogen and therefore does not distinguish between hemolysis and liver disease. [17] In circumstances of complete biliary obstruction, jaundice may be apparent in the absence of urobilinogens because of the lack of delivery of bilirubin to the intestine. Urine urobilinogen levels may rise before jaundice becomes clinically apparent. Because unconjugated bilirubin is very tightly bound to albumin, the free fraction is very small and consequently never appears in the urine. Bilirubin conjugates are much less tightly bound to albumin. Therefore, in the presence of cholestasis, bilirubin conjugates formed in the hepatocyte are diverted back into the circulation, and the larger unbound fraction is filtered in the kidney. Thus, urine bilirubin is an absolute indication of conjugated hyperbilirubinemia. In the neonate, increased ß-glucuronidases and deconjugation may contribute unconjugated bilirubin to the physiological jaundice of the newborn. In the colon, the unstable urobilinogens are oxidized to urobilins, orange pigments that are excreted in the feces. Bilirubin itself is rarely found in human feces unless intestinal flora is underdeveloped or altered by antibiotics. Although the reticuloendothelial system has the capacity to metabolize heme from hemoglobin to form up to 1500 mg of bilirubin daily, a substantial increase in hemoglobin

turnover is necessary before an increase in bilirubin levels is apparent. Consequently, jaundice seldom results from hemolysis unless it is severe or accompanied by hepatic dysfunction. [18]

Measurement

The upper limit of normal for total plasma bilirubin concentration is 1.0 to 1.5 mg/dL (17 to 26 µM), with indirect-reacting bilirubin 0.8 to 1.2 mg/dL (14 to 21 µM) and direct-reacting bilirubin usually less than 0.2 mg/dL (largely a technical artifact); the ranges reflect variations in analytical methods. [19] The distribution of plasma bilirubin in the population is not normal, but it is skewed toward the upper end values. Males have slightly higher values than females. Unconjugated bilirubin IXa accounts for 95% of circulating isomers, and bilirubin monoesters and diesters account for about 4%. [20]

Diazo Method Accurate measurement of total bilirubin and its fractions in serum is a crucial first step in the approach to a patient with jaundice. [21] The formation of diazo derivatives of bilirubin, as originally described by van den Berg in 1913, provides the basis for most clinical methods of quantifying bilirubin. [7] The addition of the diazo reagent (e.g., diazotized sulfanilic acid) ultimately resulted in the generation of two azopyrromethane molecules from the tetrapyrrole, the amount of which formed could be determined spectrophotometrically. Van den Bergh and Müller first noted in 1916 that conjugated bilirubin reacted rapidly with the diazo reagent. The direct-reacting bilirubin (a proxy for conjugated bilirubin) and total bilirubin were measured, and indirect-reacting bilirubin (a proxy for unconjugated bilirubin) was then calculated by subtraction. However, it became apparent that measurements of the two pigment fractions lacked specificity and often did not reflect the actual concentrations of conjugated and unconjugated bilirubins for many technical reasons, including the exquisite sensitivity of the reaction conditions to small changes in pH, light exposure, and storage temperature. This was especially a problem when accurate pigment fractionation was most needed, that is, at low concentrations of total bilirubin (<5 mg/dL), to differentiate hemolysis from unconjugated hyperbilirubinemia.
Delta Bilirubin Glucuronides are chemically reactive metabolites. In adults, with prolonged cholestasis, especially if it is accompanied by renal failure, a fraction of the bilirubin conjugates reacts nonenzymatically and irreversibly with serum albumin to give yellow biliproteins in which bilirubin is covalently bound to albumin. [22] This fraction increases with the duration of cholestasis. Designated *delta bilirubin,* it retains its direct-reacting properties. Chromatographic studies had indicated the presence of this fourth form of bilirubin in serum, and its existence was subsequently confirmed after separation by high-performance reversed-phase liquid chromatography. [23] Because delta bilirubin is irreversibly bound to albumin, it is not filtered at the glomerulus, and its half-life reflects that of albumin (14 days). Consequently, it remains in plasma long after other bilirubin esters have been eliminated. Clinically, this is suggested by persistent conjugated hyperbilirubinemia in the absence of bilirubinuria and is particularly evident in the recovery phase of cholestasis. [24] Delta bilirubin can be calculated as follows: delta bilirubin = total bilirubin - (conjugated + unconjugated bilirubin).
Dry Film Method The adoption of dry film technology represented a major advance in accuracy and is now standard in most clinical laboratories. [25] Using the Ektachem or Fuji dry chemistry slides, diazo coupling proceeds on a buffered porous layer, and the azo derivatives become bound to a cationic polymeric mordant, resulting in a spectral change. Measurements are made at two different wavelengths to account for spectral interferences. Protein-conjugated bilirubin is retained on only one of the slides and therefore can be removed from the sample being measured. One slide is used to measure total bilirubin, and a second slide measures both unconjugated bilirubin and conjugated bilirubin, the difference being delta bilirubin. The test is accurate, reproducible, and amenable to automation, and the method correlates well with high-performance reversed-phase liquid chromatography for the fractionation of serum bilirubin species.

HYPERBILIRUBINEMIA

Hyperbilirubinemia results from a disruption at one or more steps in the complex metabolic pathways previously described, extending from excess bilirubin formation, altered uptake, defective conjugation, and diminished excretion into the biliary tree and subsequently into the gastrointestinal tract. Bilirubin levels correlate directly with bilirubin production and inversely with hepatic bilirubin plasma clearance. Practically, hyperbilirubinemia is classified as excess of either conjugated (direct-reacting) or unconjugated (indirect-reacting) bilirubin. This distinction is crucial to guide the evaluation of the patient, the differential diagnoses to be considered, and subsequently the optimal investigative approach. A pure increase in unconjugated bilirubin is usually indicative of defective conjugation. A parallel increase in both fractions in proportion to normal is usually indicative of increased pigment production. A normal or increased unconjugated bilirubin level with a markedly increased conjugated bilirubin level occurs in hepatobiliary disease. [20] Mixed conjugated and unconjugated hyperbilirubinemia may occur in the setting of multiple transfusions postoperatively, in fulminant liver failure with hemolysis resulting from Wilson disease, and in bacteremia. Many patients with chronic hemolytic disorders such as sickle cell anemia or thalassemia have underlying liver disease from transfusion-related iron overload or transfusion-related viral hepatitis, resulting again in a mixed pattern of hyperbilirubinemia.

Unconjugated Hyperbilirubinemia

Overproduction of bilirubin may occur with excess destruction of red cells, with ineffective erythropoiesis, or with increased catabolism of heme compounds in the liver. Hemolysis may be intravascular (heme in plasma), extravascular (in cells of the reticuloendothelial system), or a combination of both. The bone marrow is capable of an eightfold increase in erythrocyte production in times of chronic hemolysis, with a maximum achievable steady-state bilirubin turnover of approximately 40 mg/kg/d, resulting in a serum unconjugated bilirubin level of 4 mg/dL. [19] With normal hepatic function, a 50% reduction in erythrocyte survival does not result in jaundice. [26] Even in the context of more severe hemolysis, unconjugated bilirubin levels rarely exceed 4 to 5 mg/dL unless there is concomitant impairment of hepatic clearance.

Hemolysis and Ineffective Erythropoiesis Hemolysis and ineffective erythropoiesis are the only relevant causes of bilirubin overproduction in humans. Hemolysis, even if severe, usually results in mild hyperbilirubinemia (<5 mg/dL) unless there is coexistent liver disease, which may contribute to concomitant conjugated hyperbilirubinemia. Hemolytic anemia may result from inherited disorders of the red cell membrane (sickle cell anemia), of hemoglobin (thalassemia), or of red cell enzymes (glucose-6-phosphate dehydrogenase or pyruvate kinase deficiency). Acquired hemolytic conditions may result from ABO blood group incompatibility, iron or vitamin B_{12} deficiency, and lead toxicity. Ineffective erythropoiesis shortens red cell life span and can be associated with hyperbilirubinemia. Impaired hepatic blood flow from congestive heart failure, cirrhosis, and portacaval shunting decreases bilirubin delivery to the liver and decreases clearance with resulting increased unconjugated hyperbilirubinemia. Other causes include hypothyroidism and hyperthyroidism, sepsis, and drugs (e.g., isoniazid, a-methyldopa, phenothiazines, nonsteroidal antiinflammatory drugs, rifampicin, sulfonamides, thiazides, and ribavirin).
Bilirubin Uridine Diphosphate Glucuronosyltransferase Deficiencies These disorders are characterized by abnormalities of the bilirubin UGT enzyme UGT-1A1 and consequently are manifest by unconjugated hyperbilirubinemia. Whereas Gilbert syndrome is common, the other disorders remain rare, but their study has provided invaluable insights into the complexities of bilirubin metabolism.
Gilbert syndrome. This condition is a characterized by unconjugated hyperbilirubinemia occurring in the absence of overt hemolysis or liver disease. [27] Typically, there are mild, chronic, or intermittent episodes of jaundice that increase with intercurrent illness, fasting, stress, fatigue, menses, and ethanol and nicotinic acid intake. Three to 8% of the population is affected, with a male predominance. It is usually inherited in an autosomal recessive pattern and is rarely manifest before puberty. Patients are generally asymptomatic, and nonspecific symptoms of fatigue and abdominal pain do not correlate with bilirubin levels. Mildly lemon-tinged sclera are usually the only physical findings. About 50% of patients may have mild hemolytic anemia of uncertain origin. [27] Serum bilirubin concentrations are usually higher than 3 mg/dL but may increase to 5 to 8 mg/dL during stress. However, bilirubin levels may fluctuate in anyone, and it may be difficult to differentiate these from the higher end of the normal spectrum. Other hepatic biochemical indices are normal. A presumptive diagnosis can be made in a patient with isolated, asymptomatic, unconjugated hyperbilirubinemia if a careful history and physical examination do not suggest alternate diagnoses. Provocative fasting studies to confirm the diagnosis are seldom indicated or useful. Routine use of liver biopsy is not indicated. The significance of reports of increased lipofuscin pigment within the centrilobular cells is uncertain. Fasting serum bile acid levels are normal, in contrast to the hyperbilirubinemia of liver disease. Bilirubin UGT activity is reduced to approximately one-fourth of normal. [28] Patients have reduced bilirubin diesters and increased bilirubin monoglucuronides. Molecular studies have indicated that the phenotype results from different mutations. One mutation is an expansion of thymidine-adenine (TA) repeats in the promoter region of the *UGT-1A1* gene (autosomal recessive) for which homozygosity is predicted in 16% of whites. Another mutation is found in exon 1A1 of the same gene, occurring in Japanese and Asian populations (autosomal dominant negative), and is associated with serum bilirubin levels in the range of 3 to 10 mg/dL. [29] The genetic variation described in Gilbert syndrome may lead to pharmacological variation in drug glucuronidation and may explain the occasional unexpected drug toxicities reported. [29], [30] and [31] The use of pharmacological agents that induce hepatic microsomal enzymes such as phenobarbital, which normalizes plasma unconjugated bilirubin levels and correcting ratios of monoesters and diesters but does not increase UGT-1A1 activity, leaves questions regarding phenobarbital's true mode of action. Gilbert syndrome is a benign condition, and no therapy is routinely required.
Crigler-Najjar syndrome. This syndrome is characterized by unconjugated hyperbilirubinemia, which may occur from birth. [27], [32] Type I is a rare autosomal recessive disorder and is characterized by a complete deficiency of the enzyme bilirubin UGT. It results from a mutation in one of the five exons of the gene encoding bilirubin UGT. Mutations may occur in exon 1A1 or exons 2 to 5 of the *UGT-1* gene locus encoding the enzyme UGT-1A1, resulting in complete absence of the enzyme in type I. Crigler-Najjar type I bile contains only traces of bile conjugates. Heterozygotes have normal bilirubin levels. Infants develop severe unconjugated hyperbilirubinemia within 7 days of birth, followed by kernicterus and bilirubin encephalopathy if prompt therapy is not initiated. Death follows within 18 months if untreated. Treatment

consists of the rapid initiation of phototherapy with exchange transfusions. Type I does not respond to phenobarbital. Orthotopic liver transplantation is curative. Reports have indicated temporary success with isolated hepatocyte transplants. [33] Type II (Arias disease) is an autosomal dominant disorder with variable penetrance that results in various levels of unconjugated hyperbilirubinemia. Type II is caused by a variety of mutations in exons 1A1, 2, and 5 of the *UGT-1* gene locus, the functional consequence of which is partial inactivation of bilirubin UGT. Affected persons have about 10% of normal bilirubin UGT activity. Bilirubin monoconjugates and even some diconjugate are present in bile. Jaundice often is not apparent until the second year of life. Bilirubin levels rarely exceed 20 mg/dL. Therapy with phenobarbital results in a decrease in serum bilirubin by 30% but is usually unnecessary unless there is a risk of kernicterus.

Conjugated Hyperbilirubinemia

Conjugated hyperbilirubinemia is defined by a conjugated bilirubin level greater than 30% of the total bilirubin level. [18], [26] Broadly, causes may be congenital, familial, or acquired (Table 44-1).

TABLE 44-1 Causes of Conjugated Hyperbilirubinemia

Congenital Hyperbilirubinemias

Rotor syndrome. First described in 1948, this is a rare, asymptomatic, benign, congenital disorder that is manifested as conjugated or mixed hyperbilirubinemia. [34] It is an autosomal recessive disorder that becomes apparent in childhood. Total bilirubin levels are usually 2 to 5 mg/dL, which are greater than 50% conjugated bilirubin, with bilirubinuria and exacerbation of hyperbilirubinemia during illness. Other liver tests, including bile acids, are normal, as is liver histology. Although the result of an oral cholecystogram is normal, radionuclide scans show absent or markedly delayed excretion. It is unclear whether the primary defect is impaired secretion or impaired storage of bilirubin. Urinary coproporphyrins are markedly increased, especially type I.

Dubin-Johnson syndrome. This is an autosomal recessive syndrome resulting in impaired ATP-mediated transport of bilirubin diglucuronide as well as other organic ions. [35] Bilirubin refluxes back into plasma, and hyperbilirubinemia results. Total bilirubin levels are usually between 2 and 5 mg/dL; other liver tests are normal. Patients usually present after puberty, and exacerbations occur during intercurrent illness and with some drugs. The secretory defect in patients with Dubin-Johnson syndrome results in abnormal radionuclide scans and oral cholecystographic studies. Bile salt secretion is normal. Although total urinary coproporphyrin levels are normal, there is an increase in type I levels in the urine and a decrease in type III levels. Liver histology reveals a darkly pigmented liver that is black on gross inspection. The importance of diagnosing Rotor or Dubin-Johnson syndrome is to establish a diagnosis, to assure the patient that there is not a more serious problem, and to avoid repetitive testing for more serious disorders, including porphyrias.

Familial Cholestasis The disorders termed *progressive familial intrahepatic cholestasis* (PFIC) have disparate pathogeneses but share the following common features: chronic persistent hepatocellular cholestasis usually leading to cirrhosis; exclusion of other metabolic and anatomic defects; autosomal recessive inheritance patterns; and characteristic combined clinical, biochemical, and histological features. All these disorders share a defect in the generation of bile flow. The identification, cloning, and characterization of bile transport proteins have allowed a more precise definition of the diverse PFIC syndromes. [36], [37] PFIC-1 describes syndromic forms of defects in the *FIC1* gene. Byler disease is the best known and is named after Jacob Byler, of Amish ancestry. Patients typically have recurrent and later persistent cholestasis, evolving to cirrhosis. Clinically, the disease is characterized by jaundice, steatorrhea, growth retardation, hepatosplenomegaly, and watery diarrhea. Biochemically, although bilirubin, alkaline phosphatase, and serum bile acids are elevated, ?-glutamyltransferase and biliary bile acid concentrations are low. Mutations in the *FIC1* gene in PFIC-1 relate to a member of the subfamily of P-type ATPases, involved in aminophospholipid transport. [38] Byler syndrome describes non-Amish kindreds with a disorder similar to Byler disease but with linkage to other genetic loci.

Benign recurrent intrahepatic cholestasis. Mutations in the *FIC1* gene have also been identified in some patients with benign recurrent intrahepatic cholestasis (BRIC), which has different phenotypic manifestations. BRIC is a familial disorder characterized by recurrent episodes of painless intrahepatic cholestasis, beginning in early childhood or adulthood. [39] Episodes last weeks to months and may be associated with steatorrhea and weight loss, but they resolve spontaneously without permanent liver injury. Biochemical alterations are similar to those of Byler disease. Mutation analyses suggest that phenotypic differences in PFIC-1 and BRIC relate to quantitative differences in FIC1 protein function. [38] PFIC-2 designates a group of patients with phenotypic features similar but not identical to those with PFIC-1. In PFIC-2, the initial presentation and progression are more severe. Liver biopsy often shows evidence of giant cell hepatitis. The disorder was mapped to mutations in a gene encoding the canalicular bile salt export protein (BSEP), a gene related to the MDR family of the ATP-binding cassette transporter superfamily. [40] This results in defective canalicular excretion of bile acids with accumulation within hepatocytes and ongoing injury that is not responsive to treatment with ursodeoxycholic acid. PFIC-3 shares similar features with PFIC-1 and PFIC-2, except for elevated serum levels of ?-glutamyltransferase and extensive bile ductular proliferation. Patients have less jaundice, often present later in life, and may respond to ursodeoxycholic acid. Mutations have been described in the MDR3, a canalicular phospholipid transporter, [41] the absence of which permits toxic bile acid accumulation and exposure to hepatocytes and cholangiocytes. Other rare syndromes that may mimic PFIC are 3-ß-OH steroid dehydrogenase deficiency and cholestasis with lymphedema or hypertrichosis. [36]

Choledochal cystic disorders. These disorders, including Caroli disease, are inherited anomalies of the biliary ducts. Caroli disease involves the congenital dilation of the segmental intrahepatic biliary tree, whereas choledochal cysts involve the cystic dilation of the common bile duct. Patients can present at any age with jaundice or with symptoms of cholangitis, such as fever and right upper quadrant pain. Choledochal cysts are three times more frequent in female patients. Jaundice in a patient with Caroli disease or a choledochocele should raise suspicion of cholangiocarcinoma because these patients are at increased risk of developing such tumors.

Hepatocellular Diseases Hyperbilirubinemia may accompany acute or chronic hepatocellular disease and must be considered in the differential diagnosis and distinguished from diseases whose manifestations are predominantly cholestatic. All hepatocellular diseases may present as cholestasis, especially when severe, and they constitute the most common causes of intrahepatic cholestasis. Therefore, cholestatic forms of viral hepatitis and alcoholic liver disease are more common than primary sclerosing cholangitis or primary biliary cirrhosis. These hepatocellular diseases are described individually elsewhere in this book. Viral hepatitis may have a prolonged cholestatic phase after acute infection. Patients may come to medical attention only during this phase of lowered serum aminotransferases and high bilirubin, with or without prolonged prothrombin time. Patients with elevation in prothrombin time resulting from poor absorption will respond to parenteral vitamin K, whereas those with submassive necrosis or fulminant hepatic failure will not. Even patients with hepatitis A, which does not ever become chronic, may rarely have a prolonged cholestatic phase up to 18 months after acute infection. [42] Bilirubin may be elevated in 10% to 20% of patients with alcoholic hepatitis, and usually right upper quadrant pain, fever, and leucocytosis accompany this condition. [43] Finally, with end-stage liver disease of any cause, bilirubin may become elevated. However, physical signs of cirrhosis should be readily apparent. Patients with cholestatic immune-mediated liver diseases such as primary biliary cirrhosis, primary sclerosing cholangitis, and autoimmune cholangiopathy are cholestatic early (elevated serum alkaline phosphatase) but develop jaundice only later in the course of disease. [44], [45] Drug hepatotoxicity may produce a broad spectrum of liver injury that results in jaundice, cholestasis, or bile duct damage. [46]

Infiltrative Disorders These disorders may also result in cholestasis. When jaundice occurs in patients with primary or metastatic tumors, much of the liver is usually replaced, and the prognosis is poor. [47] However if a tumor obstructs a major bile duct, such as in cholangiocarcinoma, jaundice may occur earlier. Diffuse lymphomatous infiltration occurs with Hodgkin disease and periportal lymphadenopathy with non-Hodgkin lymphoma, and both may cause jaundice. Granulomatous hepatitis has a diverse etiology, and patients may occasionally present with jaundice. [48], [49] In systemic amyloidosis, either primary or secondary, histological evidence of hepatic involvement is common but usually clinically quiescent. However, a subgroup may develop marked cholestasis, which often portends a poor prognosis. [50]

Renal Disease The association between renal dysfunction and cholestatic jaundice is long established. A postoperative fall in glomerular filtration rate is observed in 60% to 75% of patients undergoing surgery for obstructive jaundice. [51] Acute renal failure may occur in 8% to 10% of those patients and is a contributing cause of

death in 70% to 80% of those who develop it. [52] The pathophysiology is complex and multifactorial, and not surprisingly, no clearly effective therapeutic strategy has emerged. Intrahepatic cholestasis, with or without jaundice, can occur as a paraneoplastic manifestation of renal cell carcinoma (Stauffer syndrome) in the absence of liver metastases. [53]

Infection Infections may cause jaundice through extrahepatic obstruction (e.g., ascariasis), granulomatous inflammation (e.g., tuberculosis), or, more commonly, through intrahepatic cholestasis. [54] The predominant mechanism of sepsis-associated cholestasis (especially gram-negative sepsis) is related to endotoxins derived from the bacterial cell wall, which are potent inducers of proinflammatory cytokines tumor necrosis factor-a and interleukin-1 (IL-1) and IL-6. [55] A disproportionate elevation of bilirubin to alkaline phosphatase and aminotransferases is suggestive of sepsis-related cholestasis. [56] Persistent or increasing hyperbilirubinemia with ongoing infection correlates with the worst outcome. Patients infected with human immunodeficiency virus (HIV) infection are susceptible to various hepatic processes that are related to immunosuppression or are associated with the risk factors of homosexuality and parenteral drug abuse. These disorders include hepatic granulomas, cytomegalovirus hepatitis, multimicrobial HIV cholangiopathy, Kaposi sarcoma, and lymphoma. The differential diagnosis also includes other opportunistic infections and neoplasms, as well as concomitant chronic viral hepatitis B, C, and D and drug-related (including antiretroviral) hepatotoxicity. [57] Systematic evaluation and treatment are necessary to ensure that morbidity and mortality are minimized and quality of life and medical care costs are optimized. [58]

Bone Marrow Transplantation Bone marrow transplant recipients may develop jaundice for many reasons. Venoocclusive disease is a common cause of hyperbilirubinemia, especially after autologous bone marrow transplantation, [59] and it is associated with increased morbidity and mortality. Other complications include drug- and chemotherapy-induced hepatitis, sepsis-related liver injury, and recurrent disease. Acute or chronic graft versus host disease affects as many as half of long-term transplant survivors and is associated with elevated alkaline phosphatase levels and a poor prognosis.

Total Parenteral Nutrition Total parenteral nutrition (TPN) is associated with a spectrum of hepatobiliary complications that are a major cause of morbidity and mortality and increase with the duration of therapy. Cholestasis is the most common hepatic complication in infants receiving TPN. Although cholestasis is less common in adults, steatosis and steatohepatitis in addition to biliary sludge and gallstone formation predominate. [60] The cause of TPN-induced cholestasis is uncertain but is likely multifactorial. [61], [62] Direct hepatotoxicity may result from individual TPN components including excess lipids and amino acids such as tryptophan and peroxides. Cholestasis may be related to specific nutritional deficiencies in TPN of substances such as taurine and methyl-donor molecules. Defective or altered bile acid secretion may be relevant and may have therapeutic implications. The lack of enteral intake and inadequate stimulation of the enterohepatic circulation and gut function lead to diminished cholecystokinin release and stimulation of the gallbladder. This has numerous potential pathological consequences including gallbladder and bile stasis. Gut hypomotility and small bowel bacterial overgrowth results with production and absorption of lithocholic acid, a cholestatic bile salt, and enhanced endotoxin absorption, often exacerbated by concomitant sepsis. Liver biochemical tests are of limited use as sensitive or specific indicators of TPN-related hepatobiliary disease. Liver biopsy is rarely necessary. Jaundice may reflect the development of biliary sludge (50% incidence at 4 to 6 weeks of TPN and present in 100% of patients after more than 6 weeks) and calculous or acalculous biliary tract disease (the former occurring particularly with preexisting ileal disease). With long-term TPN, a rising alkaline phosphatase level may reflect the development of intrahepatic cholestasis or, alternatively, may reflect progression of TPN-associated steatohepatitis to decompensated cirrhosis. [63] Approaches that may ameliorate the hepatobiliary impact include the minimization of duration of TPN, cycling of TPN, optimization of caloric components, and reduction of excess lipids and amino acids. Attempted limited enteral intake, selective gut decontamination, and the use of ursodeoxycholic acid and cholecystokinin may further limit the TPN injury.

APPROACH TO THE PATIENT WITH JAUNDICE

The investigation of a patient with jaundice begins with a thorough review of the history of presentation, medication use, past medical history, examination, and evaluation of liver-related laboratory tests. With an understanding of the pathophysiology of cholestasis, a systematic approach to the jaundiced patient can be applied. Identification of the correct diagnosis can lead to an appropriate therapeutic intervention. The implications of jaundice in certain conditions can be life-threatening, and thus a timely diagnosis is important. Several questions must be answered initially:

1. Is the elevated bilirubin conjugated or unconjugated? In general, most jaundiced patients will not have isolated unconjugated hyperbilirubinemia.
2. If the hyperbilirubinemia is unconjugated, is it caused by increased production, decreased uptake, or impaired conjugation?
3. If the hyperbilirubinemia is conjugated, is the problem intrahepatic or extrahepatic?
4. Is the process acute or chronic?

Patients with conjugated hyperbilirubinemia usually have acquired disease, and the physician must identify an intrahepatic or obstructive cause. Acute disease can usually be differentiated from chronic disease by the patient's history, physical examination, and laboratory tests. For example, clinical evaluation may demonstrate xanthelasmas, spider angiomata, ascites, or hepatosplenomegaly. Laboratory evidence of chronic disease may consist of a hypoalbuminemia, thrombocytopenia, and a prolonged prothrombin time that is not corrected with vitamin K administration.

Chronic cholestasis may arise from such diseases as cirrhosis, primary sclerosing cholangitis, primary biliary cirrhosis, or carcinoma, or it may result from drugs. Patients with chronic cholestasis do not usually have hepatitis or gallstones. [64] The presence of fever, right upper quadrant pain, tenderness, hepatomegaly, and new-onset bilirubinuria usually indicates acute disease. An adult with asymptomatic, isolated unconjugated hyperbilirubinemia who is not taking any drugs and has no evidence of hemolysis probably has Gilbert syndrome and can be monitored with bilirubin determinations for 12 months. If no abnormality develops, no further evaluation is needed.

The patient's history, physical examination, and laboratory tests are crucial to the diagnosis of hyperbilirubinemia. [65] Physicians are 80% to 90% accurate in diagnosing extrahepatic disease by these means, but obstruction is often overdiagnosed. [66] When first evaluating a patient with hyperbilirubinemia, the physician must make a quick assessment of the emergency of the situation. Fever, leukocytosis, and hypotension point to ascending cholangitis, which requires immediate therapy. Asterixis, confusion, or stupor may indicate severe hepatocellular dysfunction or fulminant hepatic failure and mandates immediate therapy. After immediate life-threatening causes of hyperbilirubinemia have been excluded, a systematic approach to the patient helps to make the diagnosis.

Diagnosis by Age of the Patient

The most common causes differ according to the age of the patient. In neonates, physiological jaundice is overwhelmingly the most common cause of jaundice, with biliary atresia, infections (TORCHES), and metabolic diseases together accounting for less than 25% of cases. In adolescents, Gilbert syndrome and viral hepatitis account for 80% of cases, with the remainder including toxins, drugs, and autoimmune and biliary tract diseases. A careful history will elicit drug use or abuse, risk factors for viral hepatitis, amenorrhea associated with autoimmune hepatitis, or symptoms associated with biliary tract disease.

In young adults, viral hepatitis is the most common cause of jaundice, followed by biliary tract disease, alcoholic liver disease, and autoimmune diseases. Genetic diseases (hemochromatosis and Wilson disease) may present solely as elevation in aminotransferases but rarely as cholestasis at this age, and evaluation should include ceruloplasmin, urine copper, ferritin, and transferrin saturation in these patients.

In contrast, malignant disease accounts for half of the cases of jaundice seen in elderly patients. Drug toxicity is common with increasing polypharmacy in the elderly and should always be included in the history of these patients with jaundice. Multiple drugs have been associated with hyperbilirubinemia, whether hepatocellular (acetaminophen), cholestatic (anabolic steroids), or mixed (sulfonamides). Ten percent of abnormal liver tests in hospitalized patients are associated with drug toxicity. Autoimmune disease has a second peak in the elderly and should be sought. Antinuclear antibodies may be weakly elevated in healthy elderly patients, and other laboratory evidence of autoimmune disease should be sought (elevated IgG in autoimmune hepatitis, IgM in primary biliary cirrhosis). Biliary tract disease, viral hepatitis, and alcoholic liver disease also occur in elderly patients

Neonatal and Childhood Jaundice

The neonate is predisposed to the development of jaundice because of an increased production of bilirubin, reduced bilirubin UGT levels, and impaired excretory ability. Physiological jaundice (with a serum bilirubin of 5 to 6 mg/dL) occurs in full-term infants in the first few days of life and is more common in premature infants, usually resolving over several weeks. Exaggerated physiological jaundice is characterized by hyperbilirubinemia up to 17 mg/dL, but higher levels in a term infant should prompt a search for a pathological cause. [11] The consequences and optimal treatment of neonatal hyperbilirubinemia are controversial. [67] Neonates should have follow-up examinations 2 to 5 days after delivery, and jaundiced infants require early measurement of total bilirubin. Phototherapy is the mainstay of therapy. Exchange transfusions are rarely necessary.

Neonatal infection, birth trauma, and hypothyroidism may compound hyperbilirubinemia. Increased bilirubin production occurs in certain racial groups such as Native

Americans. Inherited defects in red cell enzymes such as glucose-6-phosphate dehydrogenase deficiency, red cell structural defects such as elliptocytosis, or blood group incompatibility may result in pathological jaundice. Icterus is neonates may be related to Gilbert syndrome. In Crigler-Najjar syndrome type I, bilirubin encephalopathy may occur in the first few days or months of life, whereas in Crigler-Najjar syndrome type II, bilirubin levels are rarely greater than 20 mg/dL. Neonates, particularly if they are not feeding well or are exclusively breast-fed, have lower levels of intestinal bacteria. As a result, bilirubin deconjugated in the gut is not reduced to urobilinogen and excreted but undergoes enhanced enterohepatic circulation. Later-onset breast milk jaundice is seen in 0.5% to 1% of newborns during days 4 to 10 after birth. Unconjugated bilirubin levels may rise to 10 to 20 mg/dL. The infant remains well, interruption of breast-feeding will result in a rapid decline in bilirubin levels, and resolution occurs by 4 to 6 weeks. [68] Transient familial neonatal hyperbilirubinemia (Lucy-Driscoll syndrome) results from a serum inhibitor of bilirubin UGT that disappears by 2 weeks of life.

Severe neonatal hyperbilirubinemia has neurotoxic sequelae in the form of bilirubin encephalopathy. *Kernicterus* describes the pathological findings of yellow staining and necrosis of neuronal cells of the basal ganglia, hippocampal cortex, and subthalamic area, and clinically, it may follow an acute or chronic course with potentially debilitating outcomes. Early hospital discharge and a less aggressive approach to treatment may have contributed to a possible recent re-emergence of this disorder. [69], [70] The free fraction of unconjugated bilirubin crosses the blood-brain barrier, especially if it is impaired by infection, prematurity acidosis, or hyperoxia. The neurotoxic effects are related to the concentration of bilirubin in the brain and the duration of exposure, although serum bilirubin levels correlate poorly with encephalopathy in nonhemolytic hyperbilirubinemia. Hypoalbuminemia and drugs that displace bilirubin from albumin further exacerbate the toxicity.

In the older neonate and infant, the diagnostic algorithm must reflect knowledge of the age-specific onset of disorders and their predominant presenting features, combined with the use of selected diagnostic tests. [71] Whereas jaundice may be obvious, more subtle manifestations of chronic cholestasis may exist such as the consequences of fat-soluble vitamin deficiency (neurological and hematologic), xanthomata, and growth failure. In the initial evaluation of an infant with cholestasis, if hepatic synthetic function is impaired, causes of liver failure must be considered such as neonatal iron storage disease, tyrosinemia, galactosemia, fructosemia, and mitochondrial cytopathies. In the absence of liver failure, other metabolic causes such as a $_1$-antitrypsin deficiency and cystic fibrosis and viral causes such as herpes must be evoked.

Anatomic causes of cholestasis that may be corrected surgically must be distinguished. Biliary atresia is the single most common cause of neonatal cholestasis and accounts for 50% to 60% of pediatric liver transplantations. Two phenotypes are apparent: the less common (congenital) form presents in the first few weeks of life, and the more common phenotype (acquired form) presents in the first to second month of life. Numerous theories attempt to provide rational etiologic explanations. [72] Jaundice, pale stools, and hepatomegaly are the dominant clinical features. Rapid diagnosis is essential for definitive surgical intervention. Portoenterostomy results in successful biliary drainage in 80% of patients, but it must be performed as early as possible. In infants, idiopathic neonatal hepatitis is the second most common cause of cholestasis and refers to a heterogeneous group of disorders that includes infectious, toxic, metabolic, and genetic defects in bile acid synthesis. [36]

Alagille syndrome is a cause of cholestasis before the age of 6 months. The five main features are hepatic, cardiovascular, vertebral, and ocular and a peculiar facies. [73] Expression is variable, and the first two manifestations are most common. Jaundice may be intermittent, but cholestasis is persistent, with its attendant complications. Histologically, paucity of interlobular bile ducts is typical. The mode of transmission is autosomal dominant with reduced penetrance. Mutations in the coding sequence of the *JAGGED1* gene have been identified in a large proportion of patients with the Alagille syndrome. *JAGGED1* codes a ligand for the NOTCH1 receptor, implicated in a fundamental mechanism controlling cell fate during embryogenesis.

Liver Disease in Pregnancy

Liver disease in pregnancy includes disorders unique to pregnancy and those coincident with or exacerbated by pregnancy. [74], [75] and [76] Normal changes during pregnancy include a lower mean serum albumin (3.1 g/dL), resulting from hemodilution, and a higher alkaline phosphatase level (two to four times normal), mainly of placental origin. Fibrinogen, transferrin, and cholesterol levels are also increased. Serum aminotransferases, bilirubin, serum bile acids, and ?-glutamyltransferase levels are unchanged. Spider angiomata and palmar erythema may be seen in more than 60% of pregnant women. [77] The differential diagnosis of hepatic disorders of pregnancy is dependent on the time of onset in relation to the stage of gestation and the type of symptoms and signs. Careful history of present and past pregnancies, as well as parity, including a family history of complicated pregnancies, may provide important clues to diagnosis.

Liver Disease Unique to Pregnancy

Hyperemesis gravidarum. Intractable nausea and vomiting in the first trimester are key features of hyperemesis gravidarum, which may result in dehydration, electrolyte disturbances, and malnutrition. More common in young women with a multiple gestation, it may be associated with reduced fetal wastage. Mild elevations of alkaline phosphatase and hyperbilirubinemia (<4 mg/dL) occur, although aminotransferases may rarely increase markedly. Treatment includes hydration and careful management of electrolytes and nutrition.

Intrahepatic cholestasis of pregnancy. Intense, often debilitating pruritus is the hallmark of intrahepatic cholestasis of pregnancy (ICP), which typically begins in the third trimester. [78] Although rare in most countries, the endemic occurrence in Chilean Indians and Scandinavians suggests a strong genetic predisposition in some persons. ICP recurs in 45% to 70% of subsequent pregnancies and with the use of birth control pills. It is more common in twin pregnancies. In some women, defects in the MDR3 transporter involved in bile salt secretion may contribute to a subset of women with ICP who also have an increased ?-glutamyltransferase levels. [79] Hyperbilirubinemia, up to 5 mg/dL, is detected in 20% of cases, with minimal elevations in hepatic alkaline phosphatase. An increase in total serum bile acids (often up to 100-fold) with pruritus is highly suggestive of ICP. [80] Fetal morbidity is increased because of premature births (19%–60%) and intrapartum fetal distress (22%–33%). The perinatal mortality of 10% to 11% is poorly predicted by maternal disease severity or conventional antepartum fetal testing. [78] Limited controlled data suggest that early treatment with ursodeoxycholic acid is safe, improves pruritus, lowers bilirubin and aminotransferases, normalizes some bile acid ratios, and may contribute to improved fetal outcome. [81], [82] and [83] Early delivery for fetal distress, preferably after establishment of fetal lung maturity, is usually followed by complete resolution.

Other disorders. In the third trimester (and rarely in the postpartum period), three other disorders unique to pregnancy have predominantly hepatocellular patterns of injury with elevated aminotransferases. If severe, they may be associated with cholestasis and significant maternal and perinatal morbidity and mortality. [74], [75], [84] *Acute fatty liver of pregnancy* is characterized by a spectrum of disease that may extend from mild disease to fulminant hepatic failure. Histology reveals a microvesicular steatosis. In some cases, inherited disorders of mitochondrial ß-oxidation of long-chain fatty acids are evident in the fetus and mother. [85] *Preeclampsia* is a multisystem disorder associated with proteinuria, hypertension, peripheral edema, and hyperreflexia. It is common (5%–7%) among primigravidas, especially those with a multiple gestation. Hepatic involvement indicates severe disease and increased risk of eclampsia. Serum aminotransferases may be massively increased. Acute, severe, right upper quadrant pain may raise the specter of complicating hepatic infarction or rupture. *HELLP syndrome,* characterized by hemolysis, elevated liver enzymes, and low platelet counts, may occur in a subset of patients with preeclampsia/eclampsia or acute fatty liver of pregnancy. Indeed, it may be difficult to distinguish the latter three disorders because they share many overlapping features. [75] However, prompt recognition and expedited delivery remain the cornerstone of management of the more severe cases. Liver biopsy is reserved for patients in whom the result will affect immediate obstetrical management. Oil red O staining of fresh tissue is required for confirmatory diagnosis of microvesicular steatosis. Complete recovery usually follows delivery.

Diseases Coincident with Pregnancy Disorders that are exacerbated by pregnancy include acute hepatitis E virus in travelers from endemic areas, where maternal mortality may approach 29% in the third trimester. Herpes simplex hepatitis may be more common in pregnancy; it has a high mortality rate, and prompt antiviral therapy improves survival. Some patients with Dubin-Johnson syndrome may experience asymptomatic, isolated, conjugated hyperbilirubinemia during the third trimester. A hypercoagulable state exists in pregnancy and can be associated with the development of Budd-Chiari syndrome. Pregnancy is associated increased gallstone formation, and extrahepatic cholestasis from choledocholithiasis or biliary sludge may be encountered, extending into the postpartum period. Surgical management may be appropriate only in the second trimester. For women with known severe chronic liver disease, amenorrhea may be present. However, autoimmune hepatitis and primary biliary cirrhosis are usually better controlled in pregnancy because of increased endogenous glucocorticoid production. Patients with portal hypertension may develop variceal bleeding, and there is a higher degree of fetal wastage. [86]

Postoperative Jaundice

Jaundice is uncommon after elective abdominal surgery (<1%), but it may occur in up to 17% of patients who are in the intensive care unit or after major surgery. The cause is multifactorial, and liver failure is rarely associated with the jaundice. Specific treatment is not usually required. Postoperative jaundice may be classified into three major categories. [87]

1. Bilirubin overproduction may result from hemolysis of transfused blood or absorption of hematomata; hemolysis may be related to administered drugs, prosthetic valves, or underlying hemolytic anemias; or Gilbert syndrome may occur. One liter of transfused blood will generate 5 g of bilirubin. Ten percent of red blood cells within a transfused unit are hemolyzed within 24 hours of storage.

2. Hepatocellular dysfunction may result from a diverse group of insults [88]: anesthesia, ischemia, drugs, and TPN. Ischemia, related to cardiogenic or noncardiogenic shock, may be apparent only after careful examination of the anesthetic records. Most forms of anesthesia reduce hepatic blood flow. Anesthetic drugs, especially the halogenated hydrocarbon anesthetics such as halothane, typically cause acute hepatitis within 21 days of initial exposure. Seventy-five percent of patients have an accompanying fever, and 20% to 60% of patients have peripheral eosinophilia. [89] Recurrent exposure may result in icterus within 7 days. Features predictive of an adverse outcome include age greater than 60 years, obesity, multiple exposures, short latent period to the development of jaundice, serum bilirubin more than10 mg/dL, and prothrombin time longer than 20 seconds. A careful review of drugs (including TPN) employed in the perioperative period is essential. Posttransfusion hepatitis is now rarely encountered because of screening of the donor population. Preexisting liver disease is an important risk factor and may be exacerbated by an operative procedure, potentially leading to decompensation if the patient has cirrhosis. Ascites is frequent in cirrhotic patients who decompensate after surgery as a result of poor volume handling. Jaundice with abnormal biochemical test results is commonly seen in patients who have bacteremia, especially with intra-abdominal sources of infection. The mechanisms are uncertain and may relate to direct infection of the liver, endotoxin production, or hemolysis. [90]
3. Acalculous cholecystitis is a cause of jaundice in hospitalized patients, especially after vascular surgery, trauma, or burns. The mortality is high, usually related to comorbid conditions. Proposed etiologic mechanisms include bile stasis, infection, and gallbladder ischemia. Patients affected are often volume depleted, receiving opiates and hyperalimentation. A high index of suspicion is necessary in a hospitalized patient with right upper quadrant pain, fever, leukocytosis, and cholestatic hepatic biochemical abnormalities. Ultrasound is usually the favored and feasible imaging study, and typical sonographic features include a thickened wall, pericholecystic fluid, intramural gas, and sloughed mucosal membrane. [91] Treatment should consist of antibiotics and possible cholecystostomy.

Any evaluation of postoperative jaundice should include a careful review of the operative notes, blood products requirements, microbiology culture results, and medications. In patients with cholestasis, an ultrasound interrogation of the biliary tree should be performed.

Cholestasis after Liver Transplantation

Cholestasis occurring after liver transplantation may be categorized as related to conditions occurring early, within 6 months of transplantation or late, after 6 months from transplantation, though overlap may occur. [92] Early cholestasis may be related to the condition of the donor liver, vascular and biliary problems, infections, and acute rejection. Functional cholestasis related to donor liver preservation injury (cold or rewarming ischemia or reperfusion injury) peaks between 10 and 16 days postoperatively and usually resolves with supportive management. Prolonged ischemia, especially cold type, is associated with an increased risk of later biliary strictures. Bacterial infection may result in cholestasis and mandates a systematic evaluation of potential sources, particularly the biliary tree. Cholestasis may result from viral infection, especially by cytomegalovirus, chiefly within 3 months of transplantation. Direct viral culture, the faster shell vial culture technique, or histological documentation of the cytopathic effects and microabscesses may confirm the diagnosis. Most transplant recipients experience at least one episode of acute cellular rejection, although a predominant cholestatic pattern of liver enzyme abnormalities is uncommon. Complex drug regimens used after transplantation predispose to drug-related cholestasis. Cyclosporine, tacrolimus, and azathioprine (but not mycophenolate mofetil) have been implicated, in addition to sulfonamides. The integrity of the bile ducts is dependent on the hepatic arterial supply. Subacute or incomplete hepatic arterial thrombosis can result in chronic ductal ischemia, bacteremia from cholangitis, and ultimately nonanastomotic biliary strictures.

Cholestasis after 6 months may result from chronic rejection, recurrent disease, and bile duct damage. Chronic rejection is characterized histologically by bile duct atrophy and loss leading to progressive cholestasis and graft failure that is unresponsive to antirejection therapy. Primary biliary cirrhosis may recur in 17% of patients. [93] Fibrosing cholestatic hepatitis is an early aggressive posttransplantation form of recurrent viral hepatitis, especially hepatitis C. It rapidly leads to graft failure and is characterized histologically by intrahepatic cholestasis with perisinusoidal fibrosis and minimal inflammation. [94] Retransplantation is often necessary.

DIAGNOSTIC APPROACH

Figure 44-2 and Figure 44-3 depict algorithms useful in the differential diagnosis and evaluation of a patient with jaundice, respectively. The initial step is to determine whether the jaundice is conjugated or unconjugated. The causes of conjugated hyperbilirubinemia range anatomically from the ampulla of Vater to the hepatocyte. If the history and physical examination do not provide a clue to the cause, the initial approach should be a right upper quadrant ultrasound scan to evaluate the liver, the biliary system, and the porta hepatitis.

FIGURE 44-2. Differential diagnosis of the jaundiced patient.

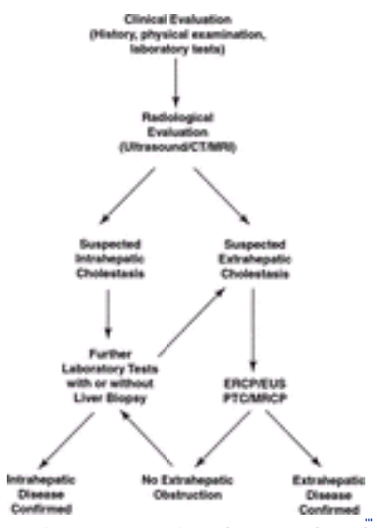

FIGURE 44-3. The evaluation of the jaundiced patient.

History

A family history of liver disease, alcohol and drug history, sexual history, transfusion history, and nutrition history are important clues to the possible cause of hyperbilirubinemia. Exposure to environmental toxins, persons with jaundice, drugs (e.g., prescription, nonprescription, and intravenous drugs and nutritional herbal supplements), and outbreaks or epidemics in the community should be sought. Previous liver biochemical tests are valuable, as is a history of biliary or pancreatic disease.

Constitutional symptoms, such as fever, chills, weight loss, and flulike symptoms, are also important clues. For instance, shaking chills or fevers point toward

cholangitis or bacterial infection and should steer the clinician away from viral hepatitis. Abdominal pain may indicate pancreatic disease, especially if it radiates to the back, but it is otherwise not helpful. [95] Viral hepatitis can cause a right upper quadrant ache, but it is not usually described as a pain. Weight loss, anorexia, nausea, and vomiting are not helpful signs because most patients with hepatobiliary disease or obstruction have anorexia and some weight loss. [26] The absence of weight loss does not rule out a diagnosis of malignant disease. Pruritus can be associated with both intrahepatic cholestasis as well as biliary obstruction, especially if the latter lasts longer than 3 to 4 weeks.

The patient's age may be helpful in constructing a differential diagnosis, as discussed earlier. Patients younger than 30 years old are more likely to have acute parenchymal disease. Patients older than 65 years are more likely to have stones or malignant diseases. Patients between 30 and 50 years of age are more likely to have chronic liver disease. In general, children and young adults are more likely to have viral hepatitis. Women older than 30 years and men older than 50 years are likely to have biliary tract disease in the form of stones or carcinoma, respectively. In middle adulthood, cirrhosis and drug effects are common causes. Men are more likely to develop cirrhosis secondary to alcohol use, pancreatic cancer, hepatocellular carcinoma, or hemochromatosis. Women are more likely to have primary biliary cirrhosis, gallstones, and chronic active hepatitis.

Physical Examination

Physical examination should include examination of the liver and examination for evidence of chronic liver disease and extrahepatic disease. Jaundice is differentiated from other abnormalities in skin color, such as hypercarotenemia, uremic pigmentation, picric acid ingestion, or quinacrine therapy because only bilirubin stains the sclera, because of its high affinity for elastin. [26] Later, and especially if the jaundice is severe, the skin color be greenish. The general appearance of the patient may suggest chronic liver disease with cachexia, muscle wasting, palmar erythema, Dupuytren contracture, leukonychia, parotid enlargement, skin pigmentation (from melanin), or xanthelasmas. Chest evaluation may reveal gynecomastia, spider nevi, or dilated veins.

The size and consistency of the liver may be helpful. A shrunken, nodular liver may allow one to identify cirrhosis, and a palpable mass may indicate an abscess or malignant tumor. If the liver span is greater than 15 cm, the physician should consider fatty infiltration, congestion, other infiltrative diseases, or malignant disease. Liver tenderness may denote acute disease but is generally not helpful. The presence of a friction rub or bruit suggests malignant disease. Spider angiomata, palmar erythema, and distended abdominal veins in a patient with jaundice indicate cirrhosis. [95] Ascites in the presence of jaundice usually indicates cirrhosis, although it can be seen with malignant disease and severe acute disease, such as viral or alcoholic hepatitis. Splenomegaly may be seen in patients with infections, infiltrative diseases, viral hepatitis, or cirrhosis. A palpable, distended gallbladder suggests biliary obstruction, often malignant in origin. Asterixis is an unusual finding, except in fulminant hepatic failure and end-stage liver disease.

Laboratory Tests

Laboratory tests can confirm suspicions formed during the history and physical examination. The clinician must differentiate conjugated from unconjugated hyperbilirubinemia by using total and direct bilirubin assays. Patients with unconjugated hyperbilirubinemia should be evaluated for evidence of hemolysis, which includes a reticulocyte count, examination of the peripheral smear, serum level of lactic dehydrogenase, and haptoglobin levels. An abnormality in any of these values may lead the clinician to look for evidence of ineffective erythropoiesis, such as vitamin B_{12} deficiency, lead toxicity, thalassemia, or sideroblastic anemia. When hemolysis is excluded in patients with unconjugated hyperbilirubinemia, most asymptomatic healthy patients have Gilbert syndrome.

For conjugated hyperbilirubinemia, initial serum tests should include assays of serum aminotransferases and alkaline phosphatase. These test results can differentiate hepatocellular from cholestatic disease. Bilirubin levels consistently less than 5 mg/dL are not seen in obstruction, unless early, but they are common in patients with cirrhosis. [95] Bilirubin levels greater than 20 mg/dL in the presence of normal renal function, especially in elderly patients, should make the clinician suspect malignant biliary obstruction.

Although neither aspartate aminotransferase nor alanine aminotransferase levels are specific for liver disease, they rarely rise to more than 300 IU/mL in any other diseases. [26] An acute myocardial infarction can elevate the serum aspartate aminotransferase level because of necrotic cardiac muscle. In a jaundiced patient, serum aminotransferase levels less than 300 IU/mL are seen in alcoholic hepatitis and drug-induced injury, although these levels also are seen in chronic liver disease and obstruction. Levels greater than 400 IU/mL indicate hepatocellular injury, and levels greater than 1000 IU/mL usually indicate acute hepatitis, drug hepatotoxicity, or prolonged hypotension. A level of serum alanine aminotransferase greater than the aspartate aminotransferase level suggests viral hepatitis or nonalcoholic steatohepatitis.

Second-line tests for jaundice help to evaluate the patient for evidence of obstruction and exclusion of bone disease (e.g., ?-glutamyltransferase, 5'nucleotidase, leucine aminopeptidase), specific liver diseases (e.g., antimitochondrial antibody, hepatitis serologies, a_1-antitrypsin, iron levels, ceruloplasmin), malignant disease (e.g., a-fetoprotein), and autoimmune phenomena (e.g., immunoglobulins, sedimentation rate, antinuclear antibody). Bile acids are increased in virtually all forms of hepatobiliary disease and are not usually useful in determining the cause of jaundice (except in inherited disorders of bilirubin metabolism, when they are normal).

The alkaline phosphatase level can signal the cause of hyperbilirubinemia. If the alkaline phosphatase level is normal, extrahepatic obstruction is unlikely, with the exception of early acute obstruction. [95] If the alkaline phosphatase level is more than three times the minimal abnormal level, cholestasis or extrahepatic obstruction probably exists. The level of alkaline phosphatase may be elevated disproportionately compared with bilirubin in partial biliary obstruction or early intrahepatic cholestasis (e.g., primary biliary cirrhosis or primary sclerosing cholangitis) because the large reserve of nonobstructed parenchyma remains intact to excrete bilirubin. The elevation in alkaline phosphatase and bile acids reflects enzyme shedding in the hepatocyte and altered permeability in the biliary tree. [2], [96] If the alkaline phosphatase and bilirubin levels are markedly elevated, a common bile duct stone should be excluded. Therefore, the alkaline phosphatase level is a more sensitive test for biliary obstruction than bilirubin.

Bilirubin remains normal until most of the bile ducts are obstructed. ?-Glutamyltransferase is found in the liver, pancreas, heart, and lungs and is elevated in a multitude of disorders. It is elevated in patients with hepatobiliary disease, alcohol intake, pancreatitis, chronic lung disease, renal failure, diabetes, and congestive heart failure and as a result of a variety of drugs.

Albumin levels and prothrombin time should be determined to assess liver function. Protein levels help to differentiate acute from chronic liver disease. Elevated globulin with hypoalbuminemia supports the diagnosis of cirrhosis, as does failure of the prothrombin time to correct after oral or parenteral administration of vitamin K. A trial of vitamin K should be given and administered parenterally to ensure adequate absorption. Hypercholesterolemia is often seen in patients with cholestasis.

Urine tests that signal cholestasis or elevated bilirubin include urinary urobilinogen and urinary conjugated bilirubin. In acute hyperbilirubinemia, jaundice can lag behind bilirubinuria. [26] The renal threshold for conjugated bilirubin is 1 mg/dL, which is less than that needed to produce clinical jaundice. False-positive urine test results occur with salicylates, and phenothiazines and false-negative results occur if the urine is not analyzed promptly. A positive urine test result is a sensitive indicator of conjugated hyperbilirubinemia and should prompt further investigation. [97]

Noninvasive Tests

After the history, physical examination, and laboratory tests are obtained, an informed choice must be made regarding further diagnostic tests. These tests incur substantial cost and therefore should not be ordered indiscriminately for any abnormal biochemistry value. These diagnostic tests can be invasive or noninvasive. Noninvasive tests include ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and technetium 99m (^{99m}Tc)–labeled iminodiacetic acid derivative scans.

Ultrasound Ultrasound is the first test used to detect biliary obstruction. The diagnostic accuracy ranges from 77% to 94%, and the result is most accurate when the bilirubin level exceeds 10 mg/dL. Ultrasound allowed a correct diagnosis in 86% of 35 icteric patients. [98] In cases of acute obstruction, it may take 4 hours to 4 days for ducts to dilate, and the ducts of some patients with partial or intermittent obstruction may not dilate. Not all patients with dilated ducts have obstruction, and conversely, between 24% and 40% of patients with common bile duct stones have normal-sized bile ducts. Ultrasound has a sensitivity of up to 77% and specificity of 83% to 95% for bile duct obstruction. [99] The variability in sensitivity reflects limitations from overlying bowel gas, site and size of the stones, and presence or absence of duct dilation. Ultrasound is inconsistent in determining the site of obstruction, partly because of its inability to see the distal duct well in 30% to 50% of patients. [100], [101] and [102] Despite these caveats and the fact that ultrasound is operator dependent, it remains the preferred initial screening test for evaluating biliary obstruction.

Computed Tomography CT imaging has a sensitivity of 60% to 90% and results rely less on the operator's proficiency. CT is not impeded by fat. However, CT scanning is more expensive than ultrasound and requires intravenous contrast medium in many instances. Unless the patient is obese, ultrasound should be the initial test of choice. [103]

Magnetic Resonance Imaging MRI relies on the physical properties of unpaired protons in tissues to generate images, without use of ionizing radiation. [104], [105] MRI is generally insufficiently sensitive or specific in the assessment of diffuse liver disease, except for the assessment of fat and iron. It appears that MRI is more sensitive and specific than CT with contrast for the detection and evaluation of focal and malignant lesions. Using the tissue contrast inherent in the technique, MRI avoids the potentially nephrotoxic contrast agents used with CT imaging. This is particularly relevant in patients with jaundice or cholestasis. The MRI characteristics of stationary and mobile liquids makes MR cholangiopancreatography (MRCP) and MR angiography powerful noninvasive diagnostic tools. Bile duct calculi are seen particularly well with MRCP. With MRI, imaging of the biliary tree is feasible both proximal and distal to the site of obstruction. This is particularly valuable after inadequate or unsuccessful endoscopic retrograde cholangiopancreatography (ERCP), [106] although its use is more difficult to justify if there is a high probability of the need for therapeutic intervention.

Radiolabeled Technetium-Sulfur Colloid This is rapidly taken up by the reticuloendothelial system. The image generated depends on blood flow and the functional state of the reticuloendothelial system. Radionuclide imaging is an excellent means of detecting cystic duct obstruction. It is the test of choice if acute cholecystitis with cystic duct obstruction and biliary leakage is suspected, but it has little value in differentiating intrahepatic from extrahepatic causes of cholestasis. The hepatic iminodiacetic acid scan, which makes use of ^{99}Tc-labeled iminodiacetic acid scan, has a 15% to 30% false-negative rate for detecting intrahepatic lesions. The scan is not a sensitive means of detecting ductal dilation because the image seen depends on the concentration of tracer. Di-isopropyl and *p*-isopropyl iminodiacetic acid are tracers that allow biliary tree visualization in the presence of jaundice. The test result is normal if the gallbladder, common bile duct, and small intestine are seen within 60 minutes. False-negative tests occur with prolonged fasting, TPN, and bilirubin levels greater than 5 mg/dL.

Invasive Tests

Invasive tests currently used include ERCP, percutaneous transhepatic cholangiography (PTC), endoscopic ultrasound (EUS), and liver biopsy. ERCP and PTC use cholecystographic dye and radiography to visualize the biliary tree. They are excellent tests to verify ductal dilatation and permit concomitant therapeutic intervention.

PTC visualizes the biliary tree in 90% to 100% of patients with dilated ducts and localizes the site of obstruction in 90% of cases. To perform the test safely, PTC usually requires a prothrombin time of less than 16 seconds, a platelet count greater than 50,000, and the absence of ascites. Minor complications occur in 30% of patients. Major complications, including sepsis, bleeding, biliary leak, pneumothorax, arteriovenous fistula, hematoma, abscess, and peritonitis, occur in 1% to 10% of patients who undergo PTC.

ERCP can localize the site of obstruction in more than 90% of patients. It is particularly helpful in diagnosing patients with common duct stones. Because it has therapeutic capabilities, it allows some patients to avoid surgery. ERCP is also helpful if a stricture resulting from chronic pancreatitis is suspected. The major reasons for nonvisualization of the biliary tree during ERCP are prior surgery (e.g., Roux-en-Y loop) and an inability to cannulate the sphincter of Oddi. The morbidity rate is 2% to 3%, somewhat less than with PTC. The most common complications are pancreatitis, bleeding, and cholangitis. The rate of sepsis is less than 1% if prophylactic antibiotics are given when an obstruction is suspected.

EUS combines endoscopy with real-time, high-resolution ultrasound and provides excellent sonographic visualization of the biliary tree without bowel gas interference. EUS is superior to ultrasound and CT for diagnosing bile duct stones. [107] EUS is comparably accurate but safer and less expensive than ERCP when evaluating patients with suspected choledocholithiasis. If available, EUS should be considered, particularly if there is a contraindication to ERCP or if prior ERCP was unsuccessful. [108]

The decision to pursue ERCP, PTC, or EUS should depend on the presumed site of obstruction, the presence of coagulopathy or ascites, and the local expertise of the radiologists and gastroenterologists. PTC and ERCP rarely are used in combination. Benign strictures should be differentiated from cholangiocarcinoma, which often requires cytologic analysis or biopsy of the lesion.

Liver Biopsy

If high-grade extrahepatic obstruction has been excluded or hepatocellular disease is strongly suspected, a liver biopsy should be performed. [109] Liver biopsy can correct 20% of errors in clinical diagnosis. Liver biopsy kits usually include the Jamshidi (suction) needle, Klatskin needle, or Tru-Cut needle. Complications after liver biopsy occur with an incidence ranging from 0.1% to 3.0%. [110], [111] The nature of liver biopsy complications warranting hospital admission are pain, hypotension, hemoperitoneum, hemobilia, pneumothorax or hemothorax, and intrahepatic arteriovenous fistula. Overall, this is a safe procedure, but the risk-to-benefit ratio needs to be carefully assessed and explained to the patient. The use of ultrasound before the procedure may reduce the complication rate. [112] Patients with coagulopathy, thrombocytopenia, or ascites may require blood products or an alternative route for biopsy, such as the transjugular approach. [113] For patients with renal insufficiency or patients who were taking warfarin (Coumadin), an ultrasound-guided liver biopsy with desmopressin acetate or a gelatin foam plug may reduce the risk of serious bleeding complications.

In the workup of a patient with hyperbilirubinemia, a liver biopsy can be useful if other diagnostic tests are unrevealing. This diagnostic strategy is essential. If the ERCP result is nondiagnostic, a liver biopsy should be performed. Five percent of the cases of extrahepatic cholestasis are diagnosed by liver biopsy because of inadequate clinical suspicion of obstruction or an inability to visualize the ducts adequately. [114] For 15% of cases, a liver biopsy is not helpful in determining the cause of the hyperbilirubinemia. If the clinician's level of suspicion is high and the ultrasound scan is negative, a cholangiogram should be performed.

The decision tree that the clinician follows depends to a great extent on pretest probability. If there is a low suspicion of extrahepatic obstruction and the ultrasound scan is negative, further evaluation of possible dilated ducts probably is not warranted. Clinical instinct should not be ignored, however, if the radiographic tests do not confirm the physician's suspicions. Judgment based on the patient's history and physical examination is dependable in evaluating patients with jaundice. Diagnostic accuracy with subsequent adequate care relies on the judicious use of appropriate confirmatory tests and radiographic studies.

COMPLICATIONS OF CHOLESTASIS

Pruritus

Pruritus is commonly associated with cholestasis and may limit activity, cause anxiety, disturb sleep patterns, and result in secondary skin infection. The presence and severity of pruritus in cholestasis do not necessarily correlate with the degree of cholestasis. The pathogenesis of cholestasis-associated pruritus is uncertain. Formerly, proposed accumulated endogenous pruritogens of cholestasis interacting with cutaneous nerve endings were implicated. More recently, the concept that pruritus is of central origin, mediated by endogenous opioid or serotonin ligands, has gained credence. [115], [116] Conventional agents have not been adequately, objectively evaluated using reliable and validated outcome measures, [117] but they are generally safe, modestly effective, and usually the agents of first choice. Studies have suggested the efficacy of opioid antagonists. [118], [119] and [120] Table 44-2 outlines current management options for pruritus.

Topical Therapy
Lower bathing water temperature and use fewer or lighter clothing and bed coverings
Minimize dry skin by using moisturizing soaps (e.g., Dove) and applying topical moisturizers liberally (e.g., Eucerin cream)
Anion-Exchange Resins
Cholestyramine or colestipol: start with 4 g (one scoop or packet) PO bid, starting before and after breakfast, and increasing to six packets or scoops daily, separated from other medications by 2 h
Bile Salts
Ursodeoxycholic acid, 15 mg/kg/d PO qhs
Doxepin
25–50 mg PO daily
Hepatic Microsomal Enzyme Induction
Rifampin, 300–600 mg PO daily
Opioid Receptor Antagonists
Naltrexone, 12.5 mg PO daily, increasing slowly to 50–100 mg PO daily
Naloxone and nalmefene are only commonly available for parenteral use

TABLE 44-2 Management of Pruritus of Cholestasis

Hepatic Osteodystrophy

Hepatic osteodystrophy is the metabolic bone disease that occurs in patients with chronic liver disease, particularly cholestatic disease. [121] Hepatic osteodystrophy encompasses both osteoporosis and osteomalacia, although the former process is usually dominant. In cholestasis-associated osteoporosis, the precise pathophysiological roles of vitamin D receptor polymorphisms, osteoblast trophic factors such as insulin-like growth factor type I, and osteoprotegerin, an osteoclast regulator, are been actively explored. [121] Increased cytokine activation involving IL-1, IL-6, and tumor necrosis factor may be important in modifying osteoclast or osteoblast function. [122] Osteomalacia results from impaired bile salt–assisted intestinal absorption of ingested vitamin D and consequently calcium and phosphate, and it is inversely associated with the degree of steatorrhea and cholestyramine use. The management of hepatic osteodystrophy is outlined in Table 44-3 and involves the early identification through bone mineral density screening by dual-energy x-ray absorptiometry of all patients with cholestatic liver disease. [123] Intervention with antiresorptive medications is indicated for those with symptomatic fractures or confirmed osteoporosis based on bone density measurement. [124] The use of cyclical etidronate prevented bone loss in patients with primary biliary cirrhosis who were cotreated with corticosteroids and bile salts for 1 year. [125]

Baseline DEXA Scanning
Normal (T/Z Score): <1 SD below the mean
Osteopenia: 1–2.5 SD below the mean
Severe osteoporosis: >2.5 SD below the mean plus one or more fragility fractures
Laboratory Testing
Baseline: 25-OH vitamin D level (normal range 10–55 mg/mL), calcium, phosphate, thyroid function tests, intact parathyroid hormone (free serum testosterone in men and estradiol and luteinizing hormone in women)
Treatment
(Relative contraindication: patients with history of renal stones)
Calcium, 1–1.5 g qd
Before transplantation: calcifediol (Calderol), 20–50 μg three times weekly
After transplantation: calcifediol (Calderol), 20–50 μg weekly
If coexistent renal disease, calcitriol (Rocaltrol), 0.25–0.5 μg PO qd
Estrogen replacement, if no contraindications exist
If bone density worsens rapidly or if there is evidence of severe osteoporosis or symptomatic fractures, treat with bisposphonates or calcitonin
Monitoring
DEXA
For osteoporosis: Repeat 6 mo after treatment initiated and then yearly
For normal study: Repeat every 2–3 y
Repeat 25-OH vitamin D and 24-h urine calcium yearly and treat accordingly

DEXA, dual-energy x-ray absorptiometry; SD, standard deviation.

TABLE 44-3 Management of Hepatic Osteodystrophy

Fat-Soluble Vitamin Deficiency

This condition is common in patients with prolonged cholestasis, and management is outlined in Table 44-4. Replacement will depend on the extent of deficiency and response to therapy. Care should be taken to inform patients of the risks and benefits of therapy, including the need for assessment of hypercalciuria after therapeutic intervention.

Monitoring Fat-Soluble Vitamins
25-OH vitamin D level (normal range, 10–55 mg/mL) (if renal disease, check $1,25\text{-}(OH)_2$ vitamin D)
Vitamin A level (normal range, 360–1200 μg/L)
Vitamin E level, with fasting total lipid profile (normal range, 5.5–17.0 mg/L) (total lipids = cholesterol plus triglycerides [in grams]. To calculate vitamin E level: serum vitamin E [mg]/total lipid [g]. If ≥0.8, normal; if <0.6, supplement)
Vitamin K: measure prothrombin time (normal range, 11.4–13.2 s)
Replacement
Vitamin D: calcium, 1–1.5 gm PO qd
Calcifediol (Calderol) 20–50 μg PO three times weekly, before transplantation (coexistent renal disease, use calcitriol [Rocaltrol] 0.25–0.5 μmg PO qd)
Vitamin A: β-carotene 15 mg (25,000 U vitamin A) PO qd or Aquasol A 50,000 U IM qd for 2 wks
Vitamin E: Liquid E (D-α-tocopherol), water-soluble, 100 IU PO qd
Vitamin K: 10 mg subcutaneously daily, for 3 d, then monthly if cholestatic
Evaluation of Therapy
After 3 mo: 24-h urine calcium (normal range, 50–250 mg/d)
Yearly: 25-OH vitamin D ($1,25\text{-}(OH)_2$ vitamin D if renal disease), vitamins A and E, and prothrombin time

TABLE 44-4 Management of Fat-Soluble Vitamin Deficiency in Prolonged Cholestasis

CHAPTER 45

Richard H. Moseley

APPROACH TO THE PATIENT WITH ABNORMAL LIVER CHEMISTRIES

The approach to the patient with abnormal liver chemistries is not governed by any well-defined diagnostic algorithms. Instead, a systematic approach to patients with suspected underlying liver disease involves a thorough understanding of the diverse panel of available measurements of liver function and serum markers of hepatobiliary disease. From this panel, a group of indices most appropriate to the particular clinical problem is selected. A single test is rarely sufficient in the approach to most clinical problems. The selection process is, however, facilitated by several distinct patterns of hepatocellular injury. Because diagnostic tests are imperfect, they are usually discussed in terms that allow assessment of their diagnostic value. The *sensitivity* of a test is defined as the likelihood of an abnormal test result in patients known to have a disease, and *specificity* is defined as the likelihood of a normal test result in patients known to be free of the disease. The *false-positive rate* is the likelihood of an abnormal test result in patients without the disease (1- specificity), and the *false-negative rate* is the likelihood of a normal test result in patients known to have the disease (1- sensitivity). Thus, sensitivity and the false-negative rate evaluate a diagnostic test in patients with disease, and specificity and the false-positive rate evaluate a test in patients without disease. [1] This chapter discusses representative and commonly used tests and offers guidelines in the interpretation of results.

CLINICAL EVALUATION

As in most disease states, an accurate history is critical in the approach to the patient with laboratory evidence of liver disease. Although systemic symptoms of liver disease, such as anorexia, weight loss, chills and fever, nausea, and vomiting, are nonspecific and are typically of little help in the differential diagnosis, valuable information can be elicited by questions regarding family history, use of prescription drugs and over-the-counter medications, alcohol consumption, use or abuse of illicit substances, exposure history, sexual and menstrual history, occupational or environmental history, travel history, past surgery (including anesthesia records, if available), and transfusion history.

A family history of jaundice may be present in Gilbert syndrome, Dubin-Johnson syndrome, Rotor syndrome, benign recurrent intrahepatic cholestasis, and hereditary hemolytic states such as hereditary spherocytosis. Familial forms of chronic intrahepatic cholestasis, such as arteriohepatic dysplasia (Alagille syndrome), and of cirrhosis have been well described. Hemochromatosis, Wilson disease (hepatolenticular degeneration), and a $_1$-antitrypsin deficiency are examples of liver diseases transmitted by an autosomal recessive mode of inheritance; genetic factors may also play a role in other hepatobiliary disorders, including primary sclerosing cholangitis, primary biliary cirrhosis (PBC), and autoimmune hepatitis.

Given the relatively nonspecific presentation of drug-induced liver disease, drug-related hepatic injury may not be immediately suspected in a patient with impaired liver function. Difficulties in diagnosis are compounded by the unknown hepatotoxicity of newly introduced agents. Nevertheless, the possibility of drug-induced liver injury should be considered in all patients with a seemingly nonspecific change or worsening in liver chemistries, and such considerations are aided by a complete drug history. Alcohol and nonprescription medication use is an important part of this inquiry. Alcohol intake should be quantified and expressed, if possible, in terms of grams per day of alcohol (daily consumption in milliliters × 0.79 × percentage of alcohol in the form ingested). A threshold for the development of cirrhosis of 80 g/d for 15 years has been described in male patients with alcoholism, [2] and it is likely that a lower threshold exists in women. [3] Acetaminophen hepatotoxicity, secondary to induction of the cytochrome P450–dependent pathway of acetaminophen metabolism by ethanol or to low hepatic glutathione stores in the malnourished patient with alcoholism, is being increasingly recognized. [4] Patients with alcoholism who present with jaundice and profoundly abnormal serum transaminase levels should always be questioned regarding the use of acetaminophen. A high incidence of aspirin-induced hepatotoxicity, which appears to correlate with serum salicylate levels, has been observed in patients with rheumatic diseases, including juvenile rheumatoid arthritis and systemic lupus erythematosus. [5] Hypervitaminosis A is a well-recognized clinical syndrome associated with hepatic injury, intracranial hypertension, and desquamative dermatitis. [6] Although most cases of hepatic injury from vitamin A have occurred with massive long-term intakes, hepatotoxicity may be potentiated by ethanol, severe hypertriglyceridemia, and renal failure, and it may occur at vitamin doses as low as 4000 IU/day. [6] Cases of hepatitis after administration of folk remedies, such as germander (*Teucrium chamaedrys*), Jin Bu Huan Anodyne Tablets (*Lycopodium serratum*), and chaparral, document the need for specific queries about ingestion of herbal products and the use of other unconventional forms of therapy, particularly in the setting of hepatic injury of unknown origin. [7]

A history of recent ingestion of raw oysters or steamed clams should suggest infection with the hepatitis A virus (HAV), although specific risk factors that have been associated with HAV infection within the United States also include homosexual contact [8] and contact with children attending day-care centers. [9] In contrast to the well-recognized problem of nosocomial hepatitis B virus (HBV) infection, nosocomial outbreaks of hepatitis A have received little attention. [10] Questions directed at determining the source of water for patients are occasionally relevant, because private water supplies contaminated with sewage have often been implicated in outbreaks of hepatitis A. HBV infection should be suspected in patients with abnormal liver chemistries and a history of exposure to or contact with jaundiced persons, syringes or needles (including tattoo paraphernalia), or blood or blood products. Intravenous drug users and male homosexuals appear to be particularly susceptible to chronic HBV infection. The development of abnormal liver chemistries in the healthy-appearing HBV carrier warrants strong consideration of superinfection with the delta agent (hepatitis D virus, or HDV). In countries with low endemism for HBV, such as the United States, HDV infection is found chiefly among parenteral drug users. [11] Hepatitis C virus (HCV) is parenterally transmitted, and a higher prevalence occurs in persons with frequent exposure to blood, including patients who received multiple transfusions before 1992, patients with hemophilia, and current and former intravenous drug users. [12] Occupational exposure to HCV from needle-stick accidents [12] and nosocomial spread of HCV [13] should also be considered. In contrast to HBV, HCV transmission by sexual or close physical contact appears to be inefficient and uncommon. [12] Recent travel to areas endemic for viral hepatitis should be noted; water-borne outbreaks of hepatitis E have been clearly

documented in Southeast Asia and the Indian subcontinent. Abnormalities in smell (dysosmia) and taste (dysgeusia) may be noticed by patients afflicted with viral hepatitis. Arthritis, abrupt in onset and with a strong predilection for proximal interphalangeal joints, has been observed during the prodromal phase in approximately 20% of patients with HBV infection. [14] Abnormal liver chemistries may also be a direct manifestation of illicit drug use. The use of the stimulant 5-methoxy-3,4-methylenedioxymethamphetamine (MDMA), or Ecstasy, has been associated with acute hepatitis and fulminant hepatic failure. [15]

Sexually transmitted diseases are an important cause of abnormal liver chemistries, and a sexual history should be included in the evaluation of such patients. Efforts to obtain accurate historical information are usually compromised by apprehension felt on the part of the interviewer rather than the patient. Relevant historical elements include information regarding whether the patient is currently sexually active, the number of sexual partners the patient has had in the preceding 6 months, whether the patient's sexual partners are of the same or different sex, whether the patient has recently had a new sexual partner, and the sites of sexual exposure. A sexual history in the female patient should always include information on contraceptive use, which has been associated with intrahepatic cholestasis, hepatic adenoma, and hepatic vein thrombosis (Budd-Chiari syndrome). A menstrual history may reveal the presence of secondary amenorrhea, a frequent complication of chronic liver disease. Infertility may be a presenting symptom in women with autoimmune hepatitis. [16]

Although the use of hepatotoxins such as carbon tetrachloride, chloroform, and trinitrotoluene has diminished, liver injury associated with accidental and occupational exposure to workplace chemicals remains a significant problem. Although an itemized list is beyond the scope of this text, exposure to industrial and environmental hepatotoxins may be elicited by a thorough occupational history. Examples include the following: trichloroethylene, a commonly used solvent in dry cleaning, which can cause acute centrilobular hepatitis; vinyl chloride, which is used in the plastics industry and is associated with the occurrence of hepatic angiosarcomas; arsenic, used in insecticide sprays by vineyard workers and implicated in chronic liver diseases, including noncirrhotic portal hypertension and hepatic angiosarcoma; and 2-nitropropane, used in industrial construction, highway maintenance, ship building, and plastic production and implicated in instances of fulminant hepatic failure. [17]

The liver may be a target organ in a vast array of systemic disorders. In particular, but by no means exclusively, the presence of coexistent cardiac, pancreatic, or inflammatory bowel disease should be considered in the evaluation of any patient with abnormal liver chemistries. Right-sided congestive heart failure, hypotension, and shock are well-recognized causes of abnormal liver chemistries. Prolongation of the prothrombin time, often disproportionately to other signs of liver dysfunction, is the most common abnormality in patients with congestive heart failure, although elevations in serum bilirubin (primarily of the unconjugated form and rarely more than 3 mg/dL) and in serum aminotransferases can also occur. [18] Clinically inapparent left-sided heart failure or cardiac tamponade may present with a picture like that of acute or chronic hepatitis. [19] Hemochromatosis, in turn, may present as a congestive cardiomyopathy [20] or as hypogonadism, arthropathy, diabetes, or hyperpigmentation. Distal common bile duct stenosis is a well-described complication of chronic alcoholic pancreatitis to be considered in the setting of anicteric alkaline phosphatase elevations of a persistent nature. [21] The biliary tree may be similarly affected in cystic fibrosis. [22] Hepatobiliary manifestations of inflammatory bowel disease of clinical import occur in up to 10% of patients. [23] Hematologic disorders, such as polycythemia rubra vera, myeloproliferative disorders, and paroxysmal nocturnal hemoglobinuria may predispose to hepatic vein thrombosis. Hemoglobinopathies, such as sickle cell anemia and thalassemia, have been implicated as risk factors for pigment stone formation. Bacteremia, particularly with gram-negative organisms or *Staphylococcus aureus,* should be considered in any ill person with direct and total serum bilirubin values that are disproportionately elevated in comparison with levels of alkaline phophatase and aspartate aminotransferases. [24] Bilirubin elevations may become manifest before the clinical recognition of infection, and persistent or progressive hyperbilirubinemia despite antiinfective therapy portends a poor prognosis and may warrant institution of additional therapeutic agents. [25] Leptospirosis should be regarded with a high index of suspicion in the febrile patient with both hepatic and renal abnormalities and a history of potential contact with animal urine or water. Renal cell carcinoma may present with abnormalities in liver chemistries, primarily elevated alkaline phosphatase levels, in the absence of hepatic metastases (nephrogenic hepatic dysfunction syndrome). [26] Liver diseases peculiar to gravid women include intrahepatic cholestasis of pregnancy, toxemia, and acute fatty liver of pregnancy, although viral hepatitis is the most common cause of jaundice during pregnancy. [27] Membranoproliferative glomerulonephritis, chronic lymphocytic sialoadenitis, and essential mixed cryoglobulinemia have been associated with chronic HCV infection. [28] A high prevalence of elevated serum aminotransferases has been reported in patients with gluten-sensitive enteropathy; in most cases, these abnormalities resolve with a gluten-free diet. [29] Rarely, abnormal serum aminotransferases may be the sole feature that leads to the diagnosis. [29] Endocrine disorders are rare but recognized causes of abnormal liver function tests. Hyperthyroidism, independent of congestive heart failure or concomitant unrelated liver disease, can result in jaundice and a prolonged prothrombin time [30]; serum aminotransferases and alkaline phosphatase are typically less than 250 IU/L and less than threefold elevated, respectively, although exceptions have been reported. [30] Elevated serum aspartate aminotransferase levels reported in hypothyroidism are secondary to enzyme release from muscle. [31] Moderate elevations in serum aminotransferases and vague constitutional symptoms may suggest the diagnosis of Addison disease. [32]

The nature of, and indications for, previous abdominal surgical procedures should be fully ascertained. If it is available, information concerning the gross appearance of the liver at the time of operation may prove valuable. In the postoperative patient, surgical and anesthesia records should be carefully reviewed for the inhalational agent administered, the presence and duration of intraoperative hypotension, and the amount of blood product support required. Hepatic injury has been observed with most of the halogen-substituted inhalation anesthetics (e.g., halothane, methoxyflurane, enflurane); it presents initially with fever and is followed by the appearance of jaundice, with or without eosinophilia, after a latent period of several days. [33] Transfusions, particularly of stored blood, can be a factor in the development of postoperative jaundice. Progressive liver disease, including cirrhosis, has been described as a late complication of jejunoileal bypass surgery. [34] Biliary strictures, retained and recurrent stones, or papillary stenosis should be considered in the diagnosis of the abnormal liver chemistries in the patient who has undergone cholecystectomy.

Generalized pruritus may be a presenting symptom in patients with liver disease, particularly cholestatic syndromes. The exact mechanism responsible for this often disabling symptom is unclear. Despite the often favorable response to oral cholestyramine, a bile acid binding agent, there is no apparent correlation between either serum or tissue levels of bile acids and the degree of pruritus. [35] Clinical experience suggests that pruritus in the jaundiced patient is often nocturnal and is most pronounced on the palms and soles. Muscle cramps, also occurring frequently at night, and affecting largely the gastrocnemius muscle and small muscles of the foot, are common in patients with cirrhosis. [36]

The presence, or absence, and character of abdominal pain may provide some clues in the approach to establishing a cause for abnormal liver chemistries. In contrast to the intense and rapidly developing right upper quadrant abdominal pain of acute extrahepatic obstruction, such as occurs in choledocholithiasis, the pain associated with acute viral hepatitis can be best described as a heavy or dragging sensation. Pain from primary and metastatic tumors of the liver may be distinguished by its dull or boring character, although hemorrhage into the tumor may result in the sudden onset of severe pain.

Physical findings of some discriminative value in the patient with abnormal liver chemistries include stigmata of chronic liver disease (e.g., spider angiomata, palmar erythema, parotid gland enlargement, gynecomastia, Dupuytren contracture, testicular atrophy), hepatomegaly and liver consistency, splenomegaly, gallbladder distention, and abdominal tenderness. However, poor interobserver agreement for several of these clinical signs has been reported [37]; for other signs, such as Dupuytren contracture, the correlation with chronic liver disease is poor. [38] Although the degree of hepatomegaly can vary widely in all forms of hepatobiliary disease, a liver span greater than 15 cm is more often associated with passive congestion from right-sided heart failure or neoplastic and infiltrative processes (e.g., amyloidosis, myeloproliferative disorders, hepatic steatosis, and glycogen and lipid-storage disorders). [39] A pulsatile liver may be encountered in tricuspid insufficiency. A hepatic bruit or friction rub should alert the examiner to the possibility of an underlying hepatocellular carcinoma; alternatively, a friction rub can occur with a hepatic abscess or in acute cholecystitis. [40] A hepatic bruit may also be auscultated in acute alcoholic hepatitis. The presence of sunflower cataracts and of Kayser-Fleischer rings (golden-brown or greenish discoloration of the Descemet membrane in the limbic region of the cornea, initially appearing at the superior corneal quadrant) should be sought either with the unaided eye or with slit-lamp ophthalmoscopy, even if the latter finding is no longer considered pathognomonic for Wilson disease. [41] Conjunctival suffusion, with or without hemorrhage, should suggest leptospirosis. A Murphy sign, or inspiratory arrest during deep palpation of the right upper quadrant, is highly suggestive of acute cholecystitis. Punch or fist percussion tenderness can also be elicited in acute cholecystitis (and in acute hepatocellular injury) and may help to differentiate hepatobiliary from pleural-based pain. A distended gallbladder, detected by either inspection or palpation, may be a presentation of malignant obstruction of the common bile duct (the Courvoisier sign).

Jaundice, manifested by yellow pigmentation of the skin, mucous membranes, and sclerae, typically requires a serum bilirubin concentration of greater than 3 mg/dL for detection. Artificial light makes detection at low levels more difficult. Ingestion of foods rich in carotene (e.g., carrots) and lycopene (e.g., tomato juice); drugs such as Atabrine, quinacrine, or busulfan; or toxins such as picric acid may result in similar skin discoloration that is readily differentiated from jaundice by the absence of scleral icterus.

In addition to jaundice and excoriations resulting from pruritus, skin manifestations of potential aid in the differential diagnosis of patients with abnormal liver chemistries include the hyperpigmentation associated with PBC and hemochromatosis, the xanthomata and xanthelasmas present in chronic cholestasis, and the

hypertrichosis of periorbital and malar regions and eczematoid dermatitis of sun-exposed areas in porphyria cutanea tarda.

HEPATIC FUNCTION TESTS

Laboratory determinations that reflect hepatic disease are collectively called *liver function tests.* However, only some are true measurements of hepatic function, and the use of this descriptive term should be discouraged. Tests that examine the ability of the liver to excrete substances into bile, particularly organic anions, fall within this strict definition, as do laboratory assessments of the synthetic and metabolic capacity of the liver.

Bilirubin

Because bilirubin is an endogenous organic anion, derived primarily from the degradation of hemoglobin from senescent erythroid cells, tests of bilirubin metabolism are important in the assessment of hepatic function. [42] Photometric determination of the azo derivatives obtained by reaction of plasma with the diazonium ion of sulfanilic acid (the diazo, or van der Bergh, reaction) separates bilirubin into two fractions, a water-soluble direct-reacting conjugated form and a lipid-soluble indirect-reacting form representing unconjugated bilirubin. Normal plasma total bilirubin concentrations in boys and men are significantly higher than in girls and women, and virtually all the bilirubin normally present in serum is in the unconjugated fraction. Hyperbilirubinemia, clinically manifested as jaundice, can accordingly be classified as either predominantly unconjugated or predominantly conjugated, simply by subtracting direct from total serum bilirubin to estimate indirect, or unconjugated, bilirubin. Increased production of bilirubin, impaired transport into hepatocytes, and defective bilirubin conjugation within the hepatocyte characterize disorders associated with unconjugated hyperbilirubinemia. Up to 85% of total serum bilirubin is in the unconjugated form in these disease states. [39] Along with the rate of hemolysis, the ability of the liver to conjugate bilirubin determines the degree of unconjugated hyperbilirubinemia observed. Even in severe hemolytic disorders, total serum bilirubin rarely exceeds 5 mg/dL in the presence of normal hepatic function. [39] Unconjugated hyperbilirubinemia may also be observed in disease states that interfere with the delivery of bilirubin to the liver, such as congestive heart failure, or in the presence of portosystemic shunts. In contrast, in disorders with impaired intrahepatic excretion of bilirubin (the rate-limiting step in overall bilirubin metabolism) and in extrahepatic obstruction, a conjugated hyperbilirubinemia is observed. Typically, in these settings, more than 50% of the serum bilirubin is in the direct-reacting form. [39]

A direct-reacting fraction of bilirubin that is apparently covalently bound to albumin has also been identified; it is termed *albumin-bound bilirubin* or *delta bilirubin.* [43] This complex represents a significant fraction of total bilirubin in patients with either hepatocellular or cholestatic forms of jaundice if hepatic excretion of conjugated bilirubin is impaired, but it is not present in disorders associated with a predominant unconjugated hyperbilirubinemia. During recovery from jaundice, albumin-bound bilirubin tends to persist in plasma because the complex is minimally filtered by the kidney. [43] This provides an explanation for the slow resolution of jaundice in convalescent patients with otherwise apparently normal liver function.

Urine bilirubin is invariably conjugated bilirubin and is encountered only in conditions in which serum levels of direct or conjugated bilirubin are elevated. The tea-colored appearance of urine caused by the presence of bilirubin must be differentiated from similar discoloration caused by hemoglobinuria and myoglobinuria. Prolonged storage before testing may produce false-negative results; phenothiazine administration can cause false-positive findings. [39] Bilirubinuria may precede the clinical appearance of jaundice, largely because of the low (<1.0 mg/dL) renal threshold for conjugated bilirubin.

Serum Bile Acids

Two primary bile acids, cholic and chenodeoxycholic acid, are synthesized in the liver from cholesterol and are converted by intestinal bacteria to the secondary bile acids, deoxycholic and lithocholic acid. Chenodeoxycholate can also be transformed into the tertiary bile acid, ursodeoxycholate. Serum bile acid determination in the assessment of patients with liver disease has been advocated. Although serum bile acid levels are almost always elevated in moderate to severe liver disease, poor diagnostic sensitivity in patients with mild liver disease has prevented widespread application. [44] The finding of normal fasting levels of cholic acid conjugates may, however, be helpful in supporting a diagnosis of Gilbert syndrome in patients with unconjugated hyperbilirubinemia. [45] Higher sensitivity of serum bile acid levels, as compared with conventional tests, has also been demonstrated in the detection of patients with cirrhosis, [46] reflecting decreased first-pass elimination resulting from portosystemic shunting. [47] Elevated serum levels of bile acids in these patients may also have prognostic implications. [48] The increase in serum bile acids that uniformly occurs as a result of diminished hepatic uptake or biliary excretion may be absent in patients with coexisting ileal disease that interferes with the intestinal phase of the enterohepatic circulation of bile acids. Conversely, small intestinal bacterial overgrowth may elevate serum bile acid levels. [49] Furthermore, serum bile acid determination appears to be of no value in assessing the patency of surgical portosystemic shunts. [50]

Dye Tests

Sulfobromophthalein (BSP) is a cholephilic organic anion previously used to assess hepatic function. The only current clinical application of the BSP plasma disappearance test is in the diagnosis of the inherited conjugated hyperbilirubinemic states, Dubin-Johnson syndrome and Rotor syndrome. [51] Anaphylactic reactions have been reported after BSP injection, largely limiting studies of BSP uptake and biliary excretion to research settings.

Indocyanine green (ICG) is a less toxic dye with hepatic uptake and excretion characteristics similar to those of BSP. However, because of greater hepatic clearance, ICG appears to be a less sensitive indicator of mild hepatic dysfunction than BSP. [52] Negligible removal by extrahepatic tissues makes ICG an ideal indicator of hepatic blood flow. [53]

Clotting Factors

Liver disease is a common cause of impaired coagulation. Normal serum activities of the vitamin K–dependent coagulation-factor proenzymes (factors II, VII, IX, and X), as assessed by the one-stage prothrombin time, depend on both intact hepatic synthesis and adequate intestinal absorption of lipid-soluble vitamin K. Vitamin K is required for the posttranslational formation of ?-carboxyglutamyl residues that are essential for physiological activation of the factors. [54] Prolonged prothrombin times can be observed both in hepatocellular disorders that impair hepatic synthetic function, such as hepatitis and cirrhosis, and in cholestatic syndromes that interfere with lipid absorption. Hepatocellular injury can be differentiated from cholestatic causes of prothrombin time prolongation by the parenteral administration of vitamin K [55]; intact hepatic function is established by an improvement in prothrombin time greater than 30% within 24 hours of administration. A prolonged prothrombin time may occur in the absence of liver disease, such as in consumption coagulopathies; anticoagulant, antibiotic, or cholestyramine use; steatorrhea; and, rarely, dietary deficiency of vitamin K. Correction of the abnormal prothrombin time by parenteral vitamin K is observed in these conditions. Prolongation of prothrombin time in acute hepatocellular injury signifies severe hepatocellular necrosis, may antedate other manifestations of hepatic failure, and is associated with a poor prognosis. [56] Similarly, in chronic liver disease, a prolonged prothrombin time carries a poor long-term prognosis. [57] Plasma concentrations of individual proteins may be useful clinical guides; because of its short half-life, factor VII is considered the best index of severity of liver disease and of prognosis. [58] A characteristic pattern of hemostatic abnormalities occurs in patients with severe liver dysfunction; it consists of a low plasma fibrinogen level, a prolonged prothrombin time, and a normal or prolonged partial thromboplastin time. A hepatoma-associated dysfibrinogen, similar to fetal fibrinogen, has been described that produces prolonged prothrombin, thrombin, and reptilase times and inhibition of normal plasma coagulation. [59]

Albumin

Albumin is quantitatively the most important of several plasma proteins formed in the liver. Accordingly, measurement of total concentration of serum albumin is a useful test of hepatic synthetic function. The relatively long half-life of serum albumin (20 days) makes the serum albumin level a better index of severity and prognosis in patients with chronic liver disease than in patients with acute hepatic injury, in whom levels are usually normal or only minimally depressed. [52] Nutritional factors, namely, the availability of amino acids, are critical determinants of the rate of albumin synthesis. [60] Moreover, alterations in serum albumin levels may reflect not only disturbances in synthesis but also changes in the rate of catabolism, dilution by expanded plasma volume (e.g., in cirrhosis), or enhanced loss from the gastrointestinal tract or kidneys. Serum albumin levels are also decreased during normal pregnancy. [61] The shorter half-life (1.9 days) of prealbumin, a glycoprotein synthesized by the liver with a faster electrophoretic migration than albumin, was exploited to demonstrate that serum prealbumin levels may be a sensitive index of liver function after acetaminophen overdose. [62]

Immunoglobulins

Although measurement of serum globulins does not fulfill the operational definition of a liver function test, the hypergammaglobulinemia that is commonly observed in patients with liver disease indirectly represents functional impairment of the reticuloendothelial cells of the hepatic sinusoids. [52] Nondiagnostic immunoglobulin abnormalities can be detected in most acute and chronic forms of liver disease, with drug-induced and extrahepatic cholestasis being notable exceptions. Although there is considerable overlap, hypergammaglobulinemia greater than 3.0 g/dL in a patient with chronic hepatitis is more consistent with autoimmune liver disease than with viral hepatitis. Rarely, the hypergammaglobulinemia in autoimmune hepatitis may be so pronounced that it causes the hyperviscosity syndrome. [63] A predominant rise in the IgA fraction is observed in hypergammaglobulinemia associated with alcoholic cirrhosis; a disproportionate elevation of IgM is a feature that differentiates PBC from other liver diseases, specifically chronic active hepatitis, that are associated with prominent hypergammaglobulinemia. [64] However, a specific diagnosis is rarely established by quantitative determinations of immunoglobulins. The demonstration of hyperglobulinemia on serum protein electrophoresis is only a clue to the presence of chronic liver disease. [52] Conversely, hypoglobulinemia should suggest protein-losing enteropathy.

Lipoproteins

The pivotal role the liver plays in normal lipoprotein and cholesterol metabolism is reflected in the characteristic finding of abnormal lipoproteins and mild hypertriglyceridemia in acute forms of hepatocellular injury. Decreases in hepatic lecithin-cholesterol acyltransferase activity appear to account for the absence of a and pre-ß bands on lipoprotein electrophoresis commonly associated with acute viral hepatitis and alcoholic hepatitis. [65] Alterations in hepatic triglyceride lipase activity may result in the characteristic elevation in low-density lipoprotein triglyceride, which, in turn, gives rise to the broad ß electrophoretic band observed in these disorders. [66] Abnormalities in serum lipoproteins in chronic forms of liver disease are a reflection of the degree of ongoing liver injury. [52] Hypocholesterolemia is observed in acute and chronic forms of hepatic insufficiency and is associated with a poor prognosis. [67] In contrast, cholestasis is associated with hypercholesterolemia, as a result of increases in unesterified cholesterol, and the appearance of an abnormal lipoprotein, lipoprotein-X. [68] The origin of lipoprotein X appears to be biliary vesicles destined for canalicular secretion that in the setting of cholestasis are instead transcytosed to the sinusoidal membrane and released into the blood. [69]

Tests of Hepatic Metabolism

Drug metabolism is another critical hepatic function, and liver disease is frequently associated with impaired drug metabolism. The most widely performed tests of hepatic metabolic capacity are the antipyrine clearance determination and the aminopyrine demethylation breath test. Antipyrine is a minor analgesic that, on the basis of rapid and complete absorption from the gastrointestinal tract, distribution in total body water, and minimal nonhepatic elimination, would seem to qualify as an ideal probe for studies of hepatic drug metabolism. Impaired antipyrine metabolism by the cytochrome P450 oxidase system, however, appears to be more a reflection of chronic active liver disease; the extent of impairment correlates well with serum albumin and prothrombin time determinations and with the degree of necrosis and inflammation on liver biopsy. [70] Little or no impairment in antipyrine metabolism is observed in patients with acute hepatitis or well-compensated cirrhosis. [70] The aminopyrine breath test avoids the need for multiple blood determinations. [^{14}C]aminopyrine is demethylated, through a [^{14}C]formaldehyde intermediate, to $^{14}CO_2$, which is measured in expired air. Single-sample, 2-hour breath $^{14}CO_2$ determinations (expressed as a percentage of the administered dose) are significantly decreased in patients with both acute and chronic hepatocellular injury but are normal to minimally decreased in patients with intrahepatic and extrahepatic cholestasis without hepatocellular injury. [71] The aminopyrine breath test has also been used as a prognostic test in patients with alcoholic hepatitis, a value of greater than 1% of the administered dose correlating with improved 3-week survival. [72] Additional measurements of functional hepatic mass include the galactose elimination capacity, which demonstrates significant correlation with albumin synthesis in patients with cirrhosis, [73] the caffeine and phenacetin breath tests, and measurement of the hepatic conversion of lidocaine to its primary metabolite, monoethylglycinexylodide. Although these quantitative tests may be noninvasive predictors of hepatic histology, interindividual differences in the metabolism of a single drug and intraindividual differences in the metabolism of different drugs make interpretation difficult, and it is unlikely that these tests will supplant percutaneous liver biopsy, for example, in the diagnostic approach to the patient with liver disease.

There is increasing evidence to suggest that susceptibility to hepatotoxic drug reactions or disease states is related to a genetically determined capacity for oxidative metabolism. [74] Noninvasive tests have been developed that identify significant interpatient differences in hepatic concentrations and activities of certain forms of cytochrome P450 that underlie this polymorphism in oxidative drug metabolism. [75] The high incidence of impaired sulfoxidation in patients with PBC [76] may be a pathophysiological manifestation of this polymorphism.

SERUM MARKERS OF HEPATOBILIARY DYSFUNCTION

As has been discussed, routine biochemical laboratory tests are not true indices of hepatic function. Instead, they serve as markers of hepatobiliary dysfunction resulting from hepatocellular necrosis, cholestasis, or infiltrative processes.

Aminotransferases (Transaminases)

Aspartate aminotransferase (AST) and alanine aminotransferase (ALT), measured by the serum glutamic-oxaloacetic transaminase (SGOT) and serum glutamic-pyruvic transaminase (SGPT) tests, respectively, are important markers of hepatocellular injury. Whereas AST can be found in various tissues, notably cardiac and skeletal muscle, kidney, and brain, ALT is limited primarily to the liver. Within the liver cell, AST is present in two isozymic forms, one in mitochondria and one in the cytosol, [77] but ALT is localized to the cytosol. In normal serum, most of the AST activity is accounted for by the cytosolic isoenzyme. [78] Normal serum ALT levels vary according to sex and body mass index, with higher values found in male patients and in persons whose body mass index is greater than 23. [79] Given the tissue distribution of these two enzymes, elevations of serum ALT are a more specific reflection of hepatocellular disease than are elevated serum AST levels. The latter is more often elevated after acute myocardial infarction, and elevations in ALT levels that occur in this setting are commonly the result of hepatic ischemia brought on by extensive myocardial injury, congestive heart failure, or cardiogenic shock. [80] Patients with idiopathic inflammatory myopathies, such as polymyositis and dermatomyositis, may, however, present with elevated ALT levels in association with elevated creatine phosphokinase as a reflection of muscle, and not hepatic, injury. [81] The highest serum elevations of both enzymes are seen in patients with viral, toxin-induced, and ischemic hepatitis, whereas smaller (<300 U/L) elevations relative to the degree of histological necrosis are usually encountered in alcoholic hepatitis. [80] The AST/ALT ratio in serum is also regarded as a useful indicator, with a ratio greater than 2 being highly suggestive of alcohol-induced hepatic injury. [82] In contrast, in patients with acute or chronic viral hepatitis or extrahepatic biliary obstruction, an AST/ALT ratio of less than 1 is typically observed, although a correlation between an AST/ALT ratio greater than 1 and the presence of underlying cirrhosis has been described in patients with chronic hepatitis B infection. [83] An AST/ALT ratio of greater than 1 in the setting of nonalcoholic chronic liver disease should raise suspicion regarding underlying cirrhosis, but in the presence of cirrhosis, the AST/ALT ratio may be less useful in differentiating alcoholic from nonalcoholic forms of liver disease. Several mechanisms have been proposed for the disproportionate elevation of serum AST levels in alcoholic liver disease. Hepatic ALT activity in this setting is diminished to a greater extent than hepatic AST activity. [84] Pyridoxal 5'-phosphate is necessary for the activity of both aminotransferases, and there may be enhanced sensitivity of hepatic ALT to alcohol-induced pyridoxine deficiency. [85] Preferential alcohol-induced injury to mitochondria enriched in AST is an alternative hypothesis. Impaired plasma clearance of AST by sinusoidal cells [86] may play a role in the relative increase in serum AST levels observed in cirrhosis. [83]

Although these indices of hepatocellular injury are not predictive of histological findings, serial determinations of serum AST and ALT levels may reflect the extent of hepatocellular injury and are useful in following the progression of liver disease. However, decreases in AST and ALT levels in serum may be either a sign of recovery from an acute injury or, particularly in the case of fulminant hepatic failure, an indication of limited hepatic reserve after overwhelming hepatocyte necrosis. In addition, hypoaminotransferasemia in patients with chronic renal failure who are undergoing hemodialysis has been found to obscure the diagnosis of HCV infection. [87] False elevations of AST have been observed in patients receiving *para*-aminosalicylic acid and erythromycin, and AST may, rarely, exist as a macroenzyme by forming a complex with immunoglobulin, leading to an otherwise unexplained elevation in serum AST activity. [88]

Serum levels of the mitochondrial isoenzyme of aspartate aminotransferase (mAST) and the ratio of mAST to total AST have been reported to be specific and sensitive markers of chronic alcoholism. [89] Until these and other new markers of alcohol abuse, such as desialylated transferrin, are better evaluated, the ?-glutamyltransferase determination, in combination with mean corpuscular volume and serum AST levels, remains the recommended biochemical indicator of recent alcohol abuse. [90]

Other Enzyme Markers of Hepatocellular Injury

Within the liver, the mitochondrial enzyme, glutamate dehydrogenase (GDH), is preferentially localized in centrizonal hepatocytes. The observation that alcohol exerts a toxic effect predominantly on mitochondria in centrizonal hepatocytes may account for the finding, in a large series of patients with alcoholism, that serum GDH determination was more useful than serum AST levels in diagnosing patients with histologically documented alcoholic hepatitis. [91] Serum GDH levels have also been reported to be increased in the congestive hepatopathy observed in acute right-sided heart failure. [91] However, the specificity of GDH as a marker of pericentral hepatocellular necrosis in alcoholic liver disease is open to question, [92] and serum GDH determinations have not received widespread application.

Alkaline Phosphatase

In the liver, alkaline phosphatase appears to be an integral enzyme of the exterior surface of the bile canalicular membrane. [93] Although hepatocellular injury invariably results in increases in serum aminotransferase activity, significant (fourfold or greater) elevations of serum alkaline phosphatase activity are typically observed in patients with cholestatic syndromes. Lesser increases in serum alkaline phosphatase levels lack specificity and may be present in all forms of liver disease. The major mechanism underlying these elevations is increased synthesis, through enhanced mRNA translation, [94] of hepatic alkaline phosphatase, rather than impaired biliary secretion of the enzyme. The mechanisms by which increased hepatic alkaline phosphatase activity leads to elevations in serum activity are less clear. Alkaline phosphatase contained within the bile canalicular membrane may be solubilized by bile acids that accumulate during cholestasis; these, in turn, alter the permeability characteristics of the intercellular tight junctions. [95] Alternatively, the distribution of hepatic alkaline phosphatase activity may be altered, again by the high intrahepatic concentrations of bile acids in patients with cholestasis, so it is found in all domains of the hepatocyte plasma membrane and enters serum directly from the plasma membrane. [95]

Alkaline phosphatase activity can also be demonstrated in bone, placenta, intestine, kidney, and leukocytes. Liver and bone are the predominant sources of serum alkaline phosphatase activity in normal subjects, with less than 20% derived from the intestine. Elevations of the intestinal isoenzyme occur in several disorders, including chronic renal failure, as well as in individuals secreting the ABH red blood cell antigen and in those of B and O blood groups. [96] In pregnancy, a substantial fraction may be derived from the placenta. Low levels of serum alkaline phosphatase have received comparatively less attention but may be encountered in hypothyroidism, pernicious anemia, zinc deficiency, and congenital hypophosphatasia. Decreased serum alkaline phosphatase levels have also been observed in acute hemolytic anemia complicating Wilson disease. [97] Benign familial elevation of serum alkaline phosphatase in a pattern suggesting autosomal dominant inheritance has been reported. [98] Ectopic production of an alkaline phosphatase isoenzyme (Regan isoenzyme) occurs in patients with cancer, and elevations in serum alkaline phosphatase levels may, therefore, be observed in the absence of bony or hepatic metastasis. [99] Similarly, patients with stage I and II Hodgkin disease, osteomyelitis, and congestive heart failure have been found to have marked elevations in serum alkaline phosphatase levels in the absence of hepatic involvement. [100]

Other Enzyme Markers of Cholestasis

Although the alkaline phosphatase isoenzymes exhibit varied susceptibility to heat inactivation and separation is possible with polyacrylamide gel electrophoresis, [101] alternative approaches to determine the source of an elevated serum alkaline phosphatase level are commonly used. Serum ?-glutamyltransferase determination establishes the hepatic origin of an elevated alkaline phosphatase level by virtue of its localization within the hepatobiliary tree, as well as kidney, pancreas, and intestine. Alcohol ingestion produces elevated serum enzyme levels, presumably by enzyme induction, and this finding has been invoked as a sensitive marker of chronic alcohol consumption that occurs independently of any liver damage. [102] However, sensitivity varies from 30% to 80%, depending on the population studied, and elevated serum ?-glutamyltransferase levels are also encountered in pancreatic disorders, myocardial infarction, uremia, chronic obstructive pulmonary disease, rheumatoid arthritis, and diabetes mellitus, as well as in patients using microsomal enzyme-inducing drugs such as barbiturates, phenytoin, and warfarin.

Determination of serum 5'-nucleotidase or leucine aminopeptidase levels fulfills a role similar to that of serum ?-glutamyltransferase determination. Despite their presence in a wide variety of other body tissues, elevated enzyme levels in the nonpregnant patient are specific for hepatobiliary disease and correlate well with elevated alkaline phosphatase levels of hepatic origin. Serum leucine aminopeptidase levels are elevated in pregnancy, [103] and conflicting data exist concerning 5'-nucleotidase levels in pregnancy. In patients with cancer, elevated 5'-nucleotidase levels are a sensitive marker in the diagnosis of metastatic disease to the liver. [104] A normal 5'-nucleotidase level does not exclude liver disease in the setting of an elevated alkaline phosphatase level, because these enzyme markers may not increase in parallel in early or mild hepatic injury. [105]

Lactate Dehydrogenase

Although commonly available, measurement of total serum lactate dehydrogenase (LDH) has limited diagnostic specificity for hepatocellular disease, and fractionation of serum LDH to determine levels of the isoenzyme of hepatic origin (LDH_5) is rarely indicated. Moderate elevations of serum LDH are frequently encountered in hepatocellular disorders such as viral hepatitis and cirrhosis and are less common in cholestatic disorders. However, marked elevations of serum LDH are observed in ischemic hepatitis, and an ALT/LDH ratio of less than 1.5 may differentiate ischemic hepatitis from acute viral hepatitis. [106]

DISEASE-SPECIFIC MARKERS

The laboratory tests outlined earlier alert the physician to the presence of hepatobiliary disease. In the sections that follow, additional markers of specific disorders are discussed.

Viral Serology

Diagnosis of acute hepatitis A is based on serologic detection of HAV-specific IgM antibody (anti-HAV IgM). Seropositivity first becomes detectable at the onset of clinical illness and is invariably present at the onset of jaundice. This serologic marker typically persists for 120 days, far exceeding both clinical and biochemical resolution of illness, and prolonged periods of seropositivity (>200 days) have been observed. [107] Nevertheless, it is best regarded as a marker of acute or recent HAV infection. In contrast, anti-HAV IgG is present primarily in convalescent sera and persists for long periods after infection, perhaps for life.

Certain serologic tests are available to establish a diagnosis of HBV infection. Hepatitis B surface antigen (HBsAg) is the first marker detectable in serum, preceding elevations in serum aminotransferases as well as the onset of symptoms. This antigenemia typically lasts for 1 to 2 months in self-limited infections. The titer of HBsAg, although not routinely reported, appears to be inversely related to the degree of hepatic inflammation. Persistence of HBsAg beyond 24 weeks is associated with a chronic carrier state, although persistence of HBV may also occur in the absence of any conventional serologic marker. [108]

Antibody to core antigen (anti-HBc) is detected in serum approximately 2 weeks after the appearance of HBsAg; typically, a window or lag period then occurs before the appearance of specific antibody to HBsAg (anti-HBs). During this period, and in the 10% of patients who do not manifest detectable levels of HBsAg, anti-HBc may be the only detectable serologic marker of recent infection with HBV. The highest titers of anti-HBc occur in patients with the longest periods of HBsAg positivity. Antibody to the core antigen of HBV of the IgM class (anti-HBc IgM) is the most sensitive marker of acute hepatitis B. [109] The specificity of anti-HBc IgM as a test, however, is lessened by its persistence, at low levels, in some patients with chronic active hepatitis B. [110] In acute hepatitis B, the hepatitis B e antigen (HBeAg) and the other direct marker of viral replication, HBV DNA, are detectable in serum shortly after HBsAg. However, tests of these markers of active viral replication should be reserved for patients with chronic hepatitis B where they are used in determining and monitoring treatment. Testing for HBV DNA is also useful in the identification of HBV as the cause of liver disease in HBsAg-negative patients, including patients with fulminant hepatitis B, who have early clearance of HBsAg, patients with cryptogenic cirrhosis [111] and hepatocellular carcinoma, [112] and patients infected with HBV mutants. [113]

Diagnosis of blood-borne non-A, non-B hepatitis previously relied on the serologic exclusion of HAV, HBV, and other hepatotrophic viruses such as cytomegalovirus, herpes simplex, and Epstein-Barr virus. With the identification of HCV, initial screening now relies on detection of circulating antibody to HCV using enzyme-linked immunosorbent assays (ELISAs). Hypergammaglobulinemia and connective tissue disorders are associated with false-positive results, and recombinant immunoblot assay can be used to confirm ELISA results. [114] False-negative ELISA results may occur in immunocompromised patients and patients undergoing long-term hemodialysis. [115] Qualitative HCV RNA by polymerase chain reaction confirms the diagnosis and is particularly useful in patients with acute hepatitis C, before an

antibody response is detectable, and in monitoring during and after treatment. Genotyping and quantitative HCV RNA tests are performed only before treatment.

Hepatitis D should be considered in any HBsAg-positive patient with acute or chronic hepatitis, especially if the disease is severe or the patient is in a high-risk group. Serologic confirmation of hepatitis D coinfection or superinfection is accomplished by testing for HDV antigen (HDV RNA) and anti-HDV antibodies. A minimum of one acute and one convalescent serum sample should be assayed, because anti-HDV antibodies can be transient, can be present at low titer, and can appear late in infection. Total (predominantly IgG) antibodies to HDV are usually detectable in high titer in superinfections. Persistence of anti-HDV IgM typically predicts progression to chronic HDV infection. Detection of HDV RNA by reverse transcriptase–polymerase chain reaction is the method of choice for the diagnosis of ongoing HDV infection. [11]

Acute hepatitis E infections have increasingly been reported in the United States in persons returning from international travel. [116] Diagnosis rests on detection of antibodies to hepatitis E viral antigens (anti-HEV).

Immunologic Tests

Immunologic abnormalities occur in a wide spectrum of liver diseases. The antinuclear antibody (ANA) reaction in autoimmune hepatitis is of the homogenous pattern by immunofluorescence, and a titer of 1:160 or higher is usually required for diagnosis. Antibodies to double-stranded (native) DNA occur in more than 40% of patients with autoimmune hepatitis. [117] However, these antibodies are also present in similar percentages in patients with acute and chronic hepatitis B, suggesting that they represent a response to DNA released from hepatocyte necrosis. [118] Antimitochondrial antibodies (AMA) are present in more than 90% of patients with PBC and in about 25% of patients with autoimmune hepatitis and drug-induced liver injury. [119] An AMA titer higher than 1:40, even in the absence of serum alkaline phosphatase elevation or symptoms, is strongly suggestive of PBC. [120] Four major mitochondrial antigens related to PBC have been described: M2 antigen on the inner mitochondrial membrane, identified as the dihydrolipoamide acyltransferase of the branched-chain a-keto acid dehydrogenase complex, [121] and M4, M8, and M9 antigens on the outer mitochondrial membrane. he specific profile of antibodies to these antigens in patients may have clinical and prognostic importance. [122] Antibodies to the soluble Ro antigen [123] (often present in patients with Sjögren syndrome and systemic lupus erythematosus) and anticentromere antibodies [124] have also been identified in patients with PBC, particularly those with extrahepatic autoimmune disorders such as sicca syndrome and limited scleroderma, respectively.

Anti–smooth muscle antibodies, reactive to S actin, may be detected in up to 70% of patients with autoimmune hepatitis, in approximately 50% of patients with PBC, and, occasionally, in patients with acute viral hepatitis. [125] They may be the only immunologic marker present in 26% of patients with autoimmune hepatitis. [126] The presence of anti–liver/kidney microsomal antibodies (anti-LKM1), along with absent or low-titer antiactin or antinuclear antibodies, serves to identify a subset of patients with idiopathic autoimmune hepatitis characterized by a more aggressive course and a predominance in young women. [127] The antigen to which anti-LKM1 is directed has been identified as the polymorphic cytochrome P450 isozyme, CYP2D6. [128] This form of autoimmune hepatitis, termed type 2, is most prevalent in western Europe and is rare in the United States. [126] Similarly, anti-LKM2 antibodies directed against cytochrome CYP2C9 have been described in patients with hepatitis and concomitant administration of the diuretic tienilic acid (ticrynafen). [128]

Unlike PBC, a specific autoantibody useful in the diagnosis of primary sclerosing cholangitis has not been identified. Although more than 80% of patients with primary sclerosing cholangitis have detectable perinuclear antineutrophil cytoplasmic antibodies, considerable overlap with autoimmune hepatitis limits its use as a diagnostic tool. [129]

Human leukocyte (HLA) antigens have been associated with a wide spectrum of liver diseases. Specifically, HLA-B8 and HLA-DRw3 have been associated with autoimmune hepatitis. [130] However, the increased frequencies of these HLA haplotypes are neither absolute nor diagnostic. Although HLA typing provides information on gene frequencies, it is neither routinely performed nor recommended.

Copper Storage Parameters

Determination of the serum concentration of ceruloplasmin, a copper transport protein in plasma, is particularly useful in the diagnosis of Wilson disease. Although it is not directly involved in the pathogenesis of this autosomal recessively inherited copper storage disorder, low levels of ceruloplasmin (<20 mg/dL) are found in approximately 90% of homozygotes and in about 10% of heterozygotes. In contrast, serum ceruloplasmin is typically elevated in PBC, another disorder associated with increased hepatic copper concentrations. [131] Increased serum levels in this disorder and other forms of liver disease reflect the role of ceruloplasmin as a nonspecific acute phase reactant. Accordingly, normal values may occasionally be observed during the chronic active hepatitis phase of Wilson disease. [132] Pregnancy and exogenous estrogen administration may also lead to elevated values for this protein. [133] Likewise, hypoceruloplasminemia may result from the diminution in hepatic synthetic function observed in non-Wilsonian fulminant hepatic injury, [134] in chronic hepatitis, [135] and, less commonly, in severe malnutrition, other protein-losing states, and Menkes syndrome. [133] A high incidence of low ceruloplasmin levels has been described in otherwise healthy members of a single family; this benign disorder has been termed *hereditary hypoceruloplasminemia* to differentiate it from Wilson disease. [136] In contrast, an autosomal recessive disorder of iron metabolism has been described in which serum ceruloplasmin is absent. [137] Excessive iron deposition, predominantly in the brain, liver, and pancreas in patients with aceruloplasminemia, leads to movement disorders and diabetes and may be mistaken for nonclassical forms of Wilson disease. [137]

Alternative diagnostic tests in Wilson disease include determinations of urinary copper excretion, serum copper levels, and quantitative hepatic copper content in a liver biopsy specimen. In almost all patients with symptomatic Wilson disease, urinary copper excretion exceeds 100 µg/24 h. Total serum copper is composed of a predominant (~90%) fraction that is irreversibly bound to ceruloplasmin and a small fraction that is loosely bound to albumin and to amino acids. The latter, termed the *free* or *nonceruloplasmin copper,* is calculated by subtracting the amount of copper associated with ceruloplasmin (0.047 mmol/mg) from the total amount of serum copper. Normally, this value is less than 10 µg/dL; it is markedly elevated in Wilson disease, although total serum copper concentrations may be normal, given the profound decrease in ceruloplasmin-bound copper. [138], [139] Ceruloplasmin-bound serum copper can also be calculated by multiplying the ceruloplasmin concentration (in mg/dL), determined by an oxidase assay, by three. [139] Because copper is preferentially excreted in bile, caution is advisable in the interpretation of the results of these two tests in patients with chronic cholestasis or cirrhosis. Patients with untreated Wilson disease have hepatic copper levels greater than 250 µg/g dry weight.

Despite the discovery of the gene for Wilson disease, designated *ATP7B,* molecular diagnosis by direct mutation analysis has been complicated by the lack of a single dominant mutation among the more than 60 disease-specific mutations identified. [140] However, analysis of inheritance of highly polymorphic satellite markers surrounding the *ATP7B* gene has been useful in confirming or refuting Wilson disease in family members of affected patients. [141], [142]

Iron Storage Parameters

Measurements of serum iron level and total iron-binding capacity (or transferrin) are useful in the diagnosis of hereditary hemochromatosis (HHC). Transferrin is normally 20% to 45% saturated, and both the serum iron level and percentage of saturation of transferrin are elevated early in the course of this disorder. A transferrin saturation of 45% or greater is a useful screening threshold because it identifies 98% of affected persons while producing few false-positive results. [143] However, these tests have a relatively low degree of specificity in patients with liver disease; increased serum iron levels, with normal transferrin saturation, are commonly observed in patients with alcohol-induced liver injury. [144] Acute elevations in serum iron levels have also been observed in acute viral hepatitis. [145] Transferrin synthesis is inversely correlated with total body iron stores; hence transferrin levels decrease in iron overload and increase in iron deficiency. [146] Factors other than iron balance, however, affect transferrin levels. Transferrin levels are decreased in inflammation and chronic disease and are increased during pregnancy and with estrogen therapy. [146] False-positive elevations in transferrin saturation are frequently observed if a nonfasting specimen is obtained. [146] Assays of serum ferritin may more closely estimate hepatic and total body iron stores, [147] and elevated serum ferritin levels are commonly observed early in the course of HHC, even before there is any histological evidence of liver injury. [148] Ascorbic acid deficiency in patients with iron overload may lead to inappropriately low serum ferritin levels, [149] and several families have been described in which asymptomatic relatives of patients with HHC had normal serum ferritin levels despite evidence of moderate hepatic iron overload. [150] Because serum ferritin is an acute phase reactant, other forms of hepatocellular necrosis and systemic infection can be associated with elevated serum ferritin levels disproportionate to body iron stores. [151] Furthermore, in chronic hepatitis, elevated serum iron and ferritin levels in the absence of increased hepatic iron stores most likely represent increased release of iron from damaged hepatocytes. [152] Increases in serum vitamin B_{12} levels reflect release from necrotic hepatocytes and may be used to interpret elevated serum ferritin levels. [153] As a general guideline, in the presence of inflammation, ferritin levels of less than 50 µg/L usually reflect iron deficiency, and levels greater than 500 µg/L, in association with a transferrin saturation of more than 50%, usually represent HHC. A fasting transferrin

saturation level threshold associated with the homozygous genotype of more than 62% in men and more than 50% in women was exceeded in 4% of men and in 8% of women heterozygous for HHC on the basis of HLA typing. [154] For these reasons, quantitative determination of tissue iron concentration on liver biopsy had been previously required; a hepatic iron index was calculated by dividing the hepatic iron concentration (in mmol/g dry weight) by the patient's age (in years); an index value greater than 1.9 was considered diagnostic of HHC. [155] However, with the identification of the *HFE* gene and a mutation that leads to the substitution of tyrosine for cysteine at position 282 (C282Y) associated with HHC, [156] the role of liver biopsy in patients with hemochromatosis has been modified. Liver biopsy is no longer required for the diagnosis and instead is now used to assess the degree of liver injury. In certain C282Y homozygous patients, liver biopsy may be avoided even for this purpose, because age less than 40 years, serum ferritin levels less than or equal to 1000 µg/L, the absence of hepatomegaly, and normal serum AST and ALT levels reliably predicted the absence of severe fibrosis. [157], [158]

a-Fetoprotein

A sensitive radioimmunoassay for a-fetoprotein (AFP), a major serum protein during fetal life, is employed in the screening for primary hepatocellular carcinoma. About 70% to 90% of patients with hepatocellular carcinoma have elevations in serum AFP, and significant elevations are also observed in patients with germ cell tumors, other gastrointestinal malignant diseases, and nonneoplastic hepatic disorders such as autoimmune, viral, and alcoholic hepatitis and PBC. [159] To enhance the specificity of this test in the diagnosis of hepatocellular carcinoma, a minimum concentration for positivity of 400 ng/mL has usually been assumed, [160] although this arbitrary cutoff may exclude up to one third of patients with biopsy-proven hepatocellular carcinoma. A monoclonal radioimmunoassay may improve the specificity of AFP screening. [161] Although not widely available, assays for des-?-carboxyprothrombin, an abnormal prothrombin, may also be useful in the detection of primary hepatocellular carcinoma. [162]

a $_1$-Antitrypsin

a $_1$-Antitrypsin is a 52-kd glycoprotein that is synthesized in the liver and, to a lesser extent, in monocytes and macrophages, [163] and migrates in the a $_1$-globulin fraction on serum protein electrophoresis. Normal serum levels (150 to 350 mg/dL) may increase postoperatively and in association with inflammation, malignant disease, pregnancy, or estrogen therapy. The principal function of this protein is the inhibition of leukocyte elastase. The single gene coding for the synthesis of a $_1$-antitrypsin is contained within a 10-kb segment of five exons on chromosome 14. [164] More than 25 codominantly expressed alleles have been described at this locus, and the normal phenotype for the protease inhibitor (Pi) system has been designated Pi MM by electrophoretic mobility. Persons homozygous for the electrophoretically slowest of the genetic variants of this protein, designated Pi ZZ, exhibit markedly decreased serum a $_1$-antitrypsin levels and are predisposed to the early onset of chronic active hepatitis and cryptogenic cirrhosis. [165] Heterozygotes (Pi MZ) demonstrate serum levels that are 50% to 60% of normal values. [166] The inability of the hepatocyte to process and secrete the Z protein, which differs from the normal M protein by a single amino acid substitution, [167] results in the characteristic presence of periodic acid-Schiff (PAS)-positive diastase-resistant globules in periportal hepatocytes on percutaneous liver biopsy. The diagnosis of a $_1$-antitrypsin deficiency should be entertained in a patient with a hepatocellular injury pattern to liver chemistry abnormalities if an absent a $_1$-globulin peak is observed on serum electrophoresis and is confirmed by serum a $_1$-antitrypsin activity determination and genetic Pi typing.

Serum Ammonia

Urea formation in the liver, through the Krebs-Henseleit cycle, is required for the disposal of the toxic product of nitrogen metabolism, ammonia. Elevated serum ammonia levels are often observed in both acute and chronic forms of liver disease. The striking elevations seen in fulminant hepatic failure are the result of impaired conversion of ammonia to urea in the setting of severe hepatocellular necrosis, whereas the hyperammonemia present in patients with cirrhosis and portal hypertension primarily reflects portosystemic shunting of ammonia derived from colonic bacteria. [168] Additional factors that influence the level of serum ammonia in patients with cirrhosis include intestinal production of ammonia by bacterial deamination of blood or dietary protein, renal production of ammonia by glutaminase in response to metabolic alkalosis or hypokalemia, intestinal production of ammonia from urea by urease-forming bacteria in the setting of diminished renal function, and hepatic production of ammonia from amino acids in response to increased glucagon secretion. [169] Although routinely determined in patients with suspected hepatic encephalopathy and used as an index of the success of therapy, serum ammonia levels only roughly correlate with the degree of encephalopathy. [169] Hyperammonemia and encephalopathy in the absence of liver disease have been reported in patients with urea cycle enzyme deficiencies, after ureterosigmoidostomy, and in a patient with a neurogenic bladder infected with urease-producing bacteria. [170] Serum ammonia determination is best regarded merely as an aid in the differential diagnosis of encephalopathy, and serial determinations have little role in clinical practice.

Additional abnormalities that can be observed in hepatic encephalopathy include decreased serum levels of branched-chain amino acids and elevated serum levels of aromatic amino acids, methanethiol, and short-chain fatty acids. [171] This serum amino acid profile contrasts with that observed in severe autoimmune hepatitis, in which both aromatic and branched-chain amino acid levels are increased, and it does not distinguish between patients with and without clinical manifestations of hepatic encephalopathy. [171]

Liver Biopsy

Unlike most of the laboratory tests discussed earlier, a predictive value cannot be assigned to a specific morphologic feature observed with a liver biopsy. Yet liver biopsy can be extremely useful in the diagnostic approach to the patient with abnormal liver chemistries. Proper biopsy interpretation is assisted by the availability of all clinical, biochemical, immunologic, and radiographic data to correlate histological features with an etiologic diagnosis. As a general rule, direct forms of liver injury tend to cause predominant centrizonal necrosis, immunologically mediated forms of hepatocyte injury are localized to the periportal regions, and cholestatic liver injury can be recognized by the accumulation of canalicular bile and feathery degeneration of hepatocytes in the absence of a significant inflammatory infiltrate. Major applications of liver biopsy, other than in the evaluation of a patient with persistently abnormal liver chemistries, include the following: establishing the diagnosis in patients with unexplained hepatomegaly; in patients with suspected systemic disease, such as tuberculosis, sarcoidosis, or fever of unknown origin [172]; and in patients with suspected primary or metastatic carcinoma. Contraindications to percutaneous liver biopsy include an uncooperative or unstable patient, ascites, right-sided empyema, and suspected hemangioma or echinococcal cyst. Transjugular liver biopsy is an alternative to the percutaneous approach in patients with severe coagulopathy and massive ascites. [173]

GENERAL APPROACH

Extensive numbers of tests have been described in the preceding pages and in other chapters. Initially, nonhepatic causes of any observed abnormalities must be considered (Table 45-1). The dilemma then faced is in selecting a proper diagnostic approach to the patient with suspected liver disease. Liver disease can be classified into four major types: the cholestatic, hepatocellular, and immunologic forms of injury and infiltrative processes. Depending on the target of the immune response, immunologic injury results in either a cholestatic picture (if the bile ducts are preferentially involved, as in PBC) or a hepatocellular form of injury (if the primary insult is to the hepatocyte membrane, as in viral and autoimmune hepatitis). Cholestasis can be further categorized as either a functional defect in bile formation at the level of the hepatocyte (intrahepatic cholestasis) or a structural impairment in bile secretion and flow (extrahepatic cholestasis). Evaluation is aided by the presence of these relatively discrete patterns of liver injury and tests of discriminative value in the detection of these patterns. Routinely, the results of the following tests should be determined in all patients with suspected liver disease before disease-specific markers are sought:

- Serum aminotransferase (AST and ALT) activity
- Serum alkaline phosphatase
- Serum total and direct bilirubin
- Serum total protein, with albumin and globulin fractionation
- Prothrombin time

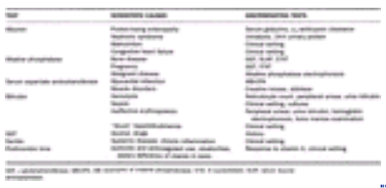

TABLE 45-1 Nonhepatic Causes of Abnormal Liver Chemistries

Patterns of abnormalities typical of the various forms of hepatobiliary injury emerge from this battery of tests, as outlined in Table 45-2. Additional diagnostic information may be provided by testing for disease-specific markers, as listed in Table 45-3. Further laboratory evaluation of any patient with evidence of chronic (>6 months) elevation in serum aminotransferases should, at the minimum, include the following tests:

- Serum protein electrophoresis
- Serum ferritin
- ANA and anti–smooth muscle antibodies
- Serum ceruloplasmin
- Hepatitis B viral serology
- Antibody to HCV

TABLE 45-2 Routine Biochemical Tests in the Patient with Idealized Hepatobiliary Disease

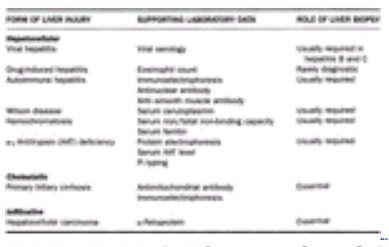

TABLE 45-3 Diagnosis of Selected Hepatobiliary Disorders

The cause of the chronic elevation in serum aminotransferases is suggested by these and other tests, as outlined in Figure 45-1. The management of minor elevations in serum ALT levels, for example, of less than 6 months' duration is less defined, although in asymptomatic persons this may represent clinically insignificant fluctuations and may resolve over time. [174]

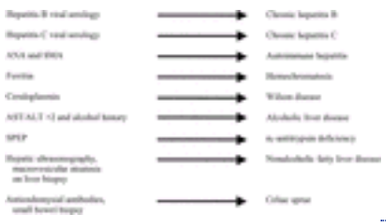

FIGURE 45-1. Evaluation of chronic serum aminotransferase elevations.

The differential diagnosis of a patient with abnormal liver chemistries consistent with cholestatic injury (i.e., elevations of serum alkaline phosphatase and bilirubin levels, with or without moderate elevations of ALT or AST) represents a formidable clinical challenge. Hyperbilirubinemia resulting from extrahepatic biliary obstruction, in contrast to that observed in acute and chronic forms of hepatocellular injury, tends to level off over time and rarely exceeds levels of 35 mg/dL in the absence of oliguria or hemolysis. The mechanism for this plateau effect appears to be related to altered bilirubin metabolism, including enhanced renal excretion of conjugated bilirubin. In addition, a daily increase of 1.5 mg/dL in total serum bilirubin is characteristic of extrahepatic biliary obstruction. [175] Nevertheless, none of the routine biochemical laboratory tests can reliably differentiate intrahepatic cholestasis from extrahepatic biliary obstruction. Furthermore, within 24 to 48 hours of acute extrahepatic obstruction, profound elevations in serum ALT and AST levels may be observed, followed by a rapid decline. [176], [177] An elevated serum bilirubin level in the absence of elevations of AST or alkaline phosphatase levels is an unusual finding and more commonly is a marker of underlying cardiac disease than any liver or biliary tract disease. [178]

Although there are no symptoms or signs that are pathognomonic for intrahepatic or extrahepatic forms of cholestasis, a history of previous biliary tract surgery, the presence of abdominal pain or significant weight loss, palpable gallbladder or abdominal mass, fever or other signs of cholangitis, and an elevated serum amylase level should point to an extrahepatic cause such as choledocholithiasis, pancreatitis, cholangiocarcinoma, or carcinoma of the pancreas. Partial obstruction or obstruction involving only a portion of the intrahepatic biliary tree may result in an elevated serum alkaline phosphatase level in the absence of hyperbilirubinemia. Conversely, a normal alkaline phosphatase level in a jaundiced patient strongly rules against the presence of extrahepatic biliary obstruction. [39] Fever and right upper quadrant abdominal pain may occur in drug-induced cholestasis and may lead to confusion if a detailed drug history is not available. A cholestatic biochemical profile with fluctuating levels of serum alkaline phosphatase in a patient with inflammatory bowel disease should suggest primary sclerosing cholangitis. Marked cholangiographic changes in the presence of advanced histological stage may, however, occur without a concomitant increase in serum alkaline phosphatase activity. [179] In the setting of acute pancreatitis, marked elevations in ALT and ?-glutamyltransferase levels point to a biliary origin. [180]

Additional laboratory tests, even liver biopsy, may not further differentiate between intrahepatic and extrahepatic cholestasis. Moreover, in drug-induced cholestasis, one of the more common causes of intrahepatic cholestasis, discontinuation of the offending drug may not be immediately followed by resolution of the cholestatic picture. As discussed in greater detail in other chapters, the most direct approach to the differential diagnosis of cholestatic injury is the use of abdominal ultrasonography to assess bile duct size, followed, if biliary dilatation is present, by endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC). Biliary tract obstruction of short duration may not be accompanied by detectable dilatation of the bile ducts, and, when there is a strong clinical suspicion of an extrahepatic cause of cholestasis, ERCP or PTC may be indicated even in the presence of a normal ultrasonographic examination. [181]

Isolated elevation of serum alkaline phosphatase, confirmed by serum leucine aminopeptidase, 5'-nucleotidase, or ?-glutamyltransferase to be of hepatic origin, is strongly suggestive of an infiltrative process, whether a localized disorder (i.e., PBC) or a systemic granulomatous disease, such as sarcoidosis, miliary tuberculosis, coccidioidomycosis, histoplasmosis, brucellosis, Q fever, or a drug reaction (e.g., allopurinol, quinidine), or, alternatively, the first indication of metastatic carcinoma to the liver. A greater than threefold elevation in serum alkaline phosphatase levels in patients with cirrhosis should raise concern for the development of hepatocellular carcinoma. The triad of an elevated serum alkaline phosphatase level, detectable titers of AMA, and an elevated serum IgM level in a middle-aged woman is of considerable discriminative value in the diagnosis of PBC. However, patients with the clinical and pathological features of PBC but with negative AMA and positive

ANA tests are becoming increasingly recognized. In the largest series of patients with this disorder, best termed *autoimmune cholangiopathy,* [182] no significant differences were observed in gender or in the laboratory findings of AMA-positive and AMA-negative patients. In a patient with a history of malignant disease, particularly breast or colon cancer, the presence of an elevated serum alkaline phosphatase level warrants an evaluation for metastases. The absence, in this setting, of diagnostic findings on abdominal ultrasound, computed tomography of the abdomen, technetium sulfur colloid nuclear imaging, and invasive tests such as ERCP, is one of the major indications for percutaneous or laparoscopic liver biopsy. A decision tree that can be used in the approach to the patient with an elevated alkaline phosphatase level is provided in Figure 45-2.

FIGURE 45-2. Diagnosing the patient with elevated serum alkaline phosphatase (*AP*) levels. *CT*, computed tomography; *ERCP*, endoscopic retrograde cholangiopancreatography; *GGT*, serum ?-glutamyltransferase; *5'NT*, 5'nucleotidase.

Although other features, such as serum bilirubin levels and prolongation of the prothrombin time, may vary and correlate with the severity of the injury, elevated serum aminotransferases are characteristically associated with hepatocellular forms of injury and reflect release of intracellular enzymes from hepatocytes undergoing necrosis. As a general rule, aminotransferase levels greater than 400 U/L are indicative of hepatocellular injury. In contrast, milder degrees of serum aminotransferase elevation (<300 U/L) are of little diagnostic benefit because they are seen in cholestatic disorders as often as in acute and chronic hepatocellular disease. Establishing the cause of hepatocellular necrosis usually requires more information than routine laboratory results provide.

As discussed previously, the nature and degree of aminotransferase elevation may be helpful in differentiating alcoholic hepatitis from ischemic, viral-induced, or drug-induced hepatitis. Leukocytosis can be a prominent feature associated with alcoholic hepatitis. Ischemic liver injury is, at times, indistinguishable from acute viral hepatitis. A disproportionate and marked elevation in serum aminotransferases in the setting of generalized malaise, anorexia, jaundice, and tender hepatomegaly characterizes both disorders. However, measures to improve hepatic blood flow (e.g., correction of hypotension or congestive heart failure) are accompanied by a faster fall in serum aminotransferase levels than is observed in the course of acute viral hepatitis. [183] Normal values are occasionally found within 48 to 72 hours in cases of ischemic hepatitis. Associated mild to moderate renal impairment also suggests ischemic hepatitis. [183] Features suggestive of drug-related hepatotoxicity include a history of recent institution of therapy and indirect evidence of a hypersensitivity reaction, such as rash, arthralgia, or eosinophilia. Profoundly abnormal aminotransferase activities, with preservation of an elevated AST/ALT ratio, are observed in patients with alcoholism and acetaminophen hepatotoxicity, [184] and a positive response to questions regarding the use of acetaminophen mandates measurement of the blood level of this drug. The liver is commonly involved in patients with typhoid fever. Lower peak serum ALT and AST, higher peak serum alkaline phosphatase, an ALT/LDH ratio of less than 4, fever, and relative bradycardia may help to distinguish *Salmonella* hepatitis from acute viral hepatitis. [185] A high index of suspicion is required in the diagnosis of Wilson disease, and, although occasional patients may be diagnosed at older ages, [186] ceruloplasmin levels should be routinely determined in patients younger than 40 years of age with hepatic (variable elevations in serum aminotransferases in the presence of mild hyperbilirubinemia and hypoalbuminemia suggesting HBsAg-negative chronic active hepatitis, autoimmune hepatitis, or cryptogenic cirrhosis) and neurological abnormalities. Although a reduced serum ceruloplasmin level may be observed in other disorders, as has been discussed, its presence in an asymptomatic person with elevated serum aminotransferase levels is highly suggestive of Wilson disease. Hemolytic anemia, with or without low alkaline phosphatase activity, [97] and hypouricosemia are additional clues to the diagnosis of this disorder. However, establishing such a diagnosis in the setting of fulminant hepatic failure is difficult. The specificity of alkaline phosphatase to total bilirubin ratio of less than 2 in distinguishing fulminant hepatic failure secondary to Wilson disease from that resulting from other causes is open to question. [187]

Furthermore, the cause of elevated serum aminotransferases may vary considerably depending on the patient population examined, with ischemic hepatitis predominating in highly developed countries and viral and toxic hepatitis more likely in developing countries. [188] Chronic hepatitis of unknown origin may occur in a substantial proportion of asymptomatic patients with mild to moderate elevation of serum aminotransferases who live in areas with a low burden of hepatotropic viruses and genetic disorders. [189]

The extent of hepatic dysfunction in any form of injury is routinely assessed by the prothrombin time and serum albumin concentration. Prolongation of the prothrombin time without improvement after parenteral vitamin K administration and a serum albumin concentration lower than 3 g/dL both reflect the worse prognosis and greater severity of underlying liver disease.

Several studies performed before the identification of HCV addressed the issue of evaluating asymptomatic patients with moderate elevations in serum aminotransferase levels. [190], [191] Apart from determinations of ferritin, ceruloplasmin, a $_1$-antitrypsin, and markers for HBV, blood tests had little discriminative value. A high incidence of obesity and regular alcohol use was demonstrated in these patients. Fatty infiltration, consequently, was the most common finding on liver biopsy; however, histological findings of chronic persistent or active hepatitis in 20% of patients in one study [189] lent support for the use of percutaneous liver biopsy in the diagnostic approach to patients with persistently elevated levels of serum aminotransferases. Furthermore, examination of a select population of patients with unexplained chronic serum ALT elevations, in whom viral, alcohol-related, or drug-related disease was excluded, demonstrated histological features of chronic active hepatitis, including cirrhosis, in more than two thirds of patients. [192] Steatohepatitis was the most frequent alternative diagnosis, with clinical and laboratory findings, including seropositivity for ANAs, indistinguishable from those of patients with chronic active hepatitis. [192]

Previously considered to be a disorder predominantly seen in middle-aged, obese women with hyperglycemia or hyperlipidemia, nonalcoholic steatohepatitis (NASH), part of the spectrum of nonalcoholic fatty liver disease, is now recognized to exhibit a broader clinical profile. [193], [194] Diagnosis relies on the presence of macrovesicular steatosis and parenchymal inflammation with or without Mallory bodies, fibrosis, and cirrhosis in liver biopsy specimens in the absence of a history of excessive alcohol consumption, [193], [194] although the role of liver biopsy in this disorder is controversial. Abnormal serum aminotransferases are the most common biochemical abnormalities in this disorder, although there is a lack of association between biochemical abnormalities and the degree of steatosis. In general, serum aminotransferases are only mildly to moderately elevated; fewer than one third of patients have serum AST or ALT levels greater than threefold elevated. [193], [194] In the absence of cirrhosis, the AST/ALT ratio is invariably less than 1.0. [193] In contrast to patients with alcoholic liver disease, patients with NASH usually have an AST/ALT ratio less than 1, [195] and an AST/ALT ratio greater than 1 is a significant predictor of severe liver fibrosis or cirrhosis. [195], [196] Serum albumin levels are normal; hyperbilirubinemia is unusual, and, when present, levels are less than 2 mg/dL. [193], [194] Increased transferrin saturation and serum ferritin levels have been described but most likely result from underlying necroinflammatory activity. [193], [194] Although not widely available, a normal ratio of desialylated transferrin to total transferrin helps to distinguish patients with NASH from patients with excessive alcohol ingestion. [197] Weight reduction in obese patients may lead to improvement in serum aminotransferase abnormalities. [198]

With the development of serologic tests for HCV, up to 17% of volunteer blood donors with asymptomatic elevations in serum ALT were found to have evidence of HCV infection. [199] Therefore, determination of antibody to HCV is now routinely performed as part of the evaluation of patients with elevated serum ALT and AST levels. Asymptomatic patients who test positive for anti-HCV antibodies often demonstrate chronic liver disease on liver biopsy even in the absence of serum ALT elevations. However, liver biopsy need not be performed in antibody-positive patients with normal ALT levels whose serum HCV RNA evaluation is negative. [200]

The role of liver biopsy in asymptomatic patients with chronic liver chemistry abnormalities in whom specific liver disorders have been excluded by serologic evaluation is not well established. Although a liver biopsy may establish a diagnosis, frequently NASH, the results of the liver biopsy are infrequently different from the presumptive prebiopsy diagnosis, and no proven therapy is available for the majority of these patients. [201], [202] Therefore, the decision to perform a liver biopsy under these circumstances needs to be individualized, taking into account the risks and benefits of this procedure. Effective therapy may soon become available for NASH,

[203] but until that time, liver biopsy is unlikely to have a significant impact on patient management.

Patients who have undergone liver transplantation are frequently evaluated for abnormal liver chemistries. The differential diagnosis is quite extensive and includes acute cellular rejection, hepatic artery thrombosis, infectious complications such as cytomegalovirus and opportunistic infections, drug-induced hepatotoxicity such as cyclosporine-induced cholestasis, and biliary complications. Abnormal liver chemistries in the transplant recipient may also herald recurrence of the primary liver disease. For example, autoimmune hepatitis may recur in up to 33% of patients who undergo liver transplantation for chronic disease. [204] Liver biopsy and Doppler ultrasonography are frequently required because a specific pattern of biochemical changes corresponding to a particular diagnosis cannot be usually identified. [205]

In conclusion, the diagnostic tests discussed in this chapter suggest but rarely provide a specific diagnosis in a patient with suspected liver disease. Nevertheless, information obtained from these tests should facilitate the efficient and proper use of other noninvasive and invasive tests such as ultrasonography, computed tomography, radionuclide hepatobiliary scanning, PTC, ERCP, liver biopsy, and laparoscopy.

CHAPTER 46

Bruce A. Runyon

APPROACH TO THE PATIENT WITH ASCITES

The word *ascites* is of Greek derivation *(askos)* and means *bag* or *sack.* The word is singular and is used to refer to the condition of pathological fluid accumulation within the abdominal cavity. The adjective *ascitic* is used to describe the fluid itself.

CAUSES OF ASCITES AND MECHANISMS OF ASCITES FORMATION

Table 46-1 lists the causes of ascites formation in a prospective series of 901 paracenteses performed on the general medical and gastroenterology/hepatology wards of two academic institutions. [1] Cirrhosis and alcoholic hepatitis cause most cases of ascites in these settings; only 15.9% of patients had a cause other than chronic parenchymal liver disease.

CAUSE	NUMBER	(% OF TOTAL)
Chronic parenchymal liver disease (cirrhosis and alcoholic hepatitis)	758	84.1
"Mixed" (portal hypertension plus another cause, e.g., cirrhosis and peritoneal carcinomatosis)	42	4.7
Heart failure	24	2.7
Malignancy without another cause	23	2.6
Tuberculosis without another cause	6	0.7
Fulminant hepatic failure	6	0.7
Pancreatic	4	0.4
Nephrogenous ("dialysis ascites")	2	0.2
Miscellaneous*	36	3.9

* Includes biliary ascites and chylous ascites resulting from lymphatic tears, lymphoma, and cirrhosis.
from ref. 1.

TABLE 46-1 Causes of Ascites in a Series of 901 Samples

Ascites Formation in Liver Disease

Portal hypertension appears to be a prerequisite for ascites formation in the setting of liver disease, even in fulminant hepatic failure. [2] Three theories of ascites formation have been developed. The *underfill theory* postulates that an alteration in oncotic-hydrostatic balance leads to loss of intravascular fluid into the peritoneal cavity with resulting intravascular underfilling. This activates plasma renin, aldosterone, and the sympathetic nervous system and results in renal sodium retention. The observation that patients with cirrhosis have intravascular *hyper* volemia rather than *hypo* volemia led to the *overflow theory.* In this hypothesis, primary renal sodium retention is proposed to lead to intravascular hypervolemia and resulting overflow of fluid into the peritoneal cavity. The most recent theory, the *peripheral arterial vasodilation theory,* includes components of both prior theories. [3] This newest theory proposes that portal hypertension leads to vasodilatation, which causes decreased effective arterial blood volume. These events are hypothesized to characterize early compensated cirrhosis, before ascites formation. As the natural history of the disease progresses, neurohumoral excitation increases, more renal sodium is retained, and plasma volume expands; this leads to overflow of fluid into the peritoneal cavity. The underfill theory is proposed to be operative early, and the overflow theory is proposed to be operative late in the natural history of cirrhosis, according to the vasodilation theory. [3]

In general, the kidneys retain sodium in response to hypovolemia to regain a euvolemic state. In patients with advanced cirrhosis, however, the kidneys retain sodium despite hypervolemia. The paradox of avid renal sodium retention in the presence of hypervolemia is explained, at least in part, by the lack of a good sensor for intravascular volume. In general, the kidneys rely on blood pressure to assess volume status indirectly; when doing so, hypotension equates with hypovolemia. Patients with advanced cirrhosis are hypotensive. [4] The kidneys retain sodium in response to this hypotensive, vasodilated state.

Since popularization of the vasodilation theory, there has been an international search for the mediator of the vascular dilation. Many substances have been investigated and ruled out, and nitric oxide appears to be the currently favored mediator. [5]

In summary, although the exact sequence of events that occur between development of portal hypertension and renal sodium retention is not entirely clear, it appears that portal hypertension leads to an increase in nitric oxide levels. Nitric oxide, in turn, mediates the splanchnic and peripheral vasodilation associated with portal hypertension. The neurohumoral excitation state (involving the renin-aldosterone system, sympathetic nervous system, vasopressin, and endothelin-1) of advanced cirrhosis is an attempt to maintain the perfusion pressure in the presence of the nitric oxide–mediated hypotension. [4] Fluid forms in the abdomen when the lymph filtering across the hypertensive sinusoid and then across the Glisson capsule exceeds the diaphragmatic lymphatics' ability to reabsorb the escaping fluid. [3]

Ascites Formation in Other Diseases

"Mixed" Ascites Approximately 5% of patients will have "mixed" ascites: that is, underlying portal hypertension as well as a second cause for ascites formation, such as cirrhosis plus peritoneal tuberculosis or cirrhosis plus peritoneal carcinomatosis (see Table 46-1). [1] A clue to the presence of a second cause of ascites formation in a patient with obvious cirrhosis is an inappropriately high ascitic fluid lymphocyte count. The assumption that a patient with cirrhosis can have only one cause for ascites formation could lead to a missed diagnosis of a curable but potentially fatal disease such as tuberculous peritonitis.
Malignant Disease Fortunately, cancer is an uncommon cause of ascites formation, but unfortunately most patients with malignancy-related ascites survive only a few weeks after the onset of fluid retention. [6] An exception to this very short life expectancy is the patient with ovarian carcinoma, who may respond to debulking surgery and chemotherapy. [7] Not all malignancy-related ascites results from peritoneal carcinomatosis; the characteristics of the ascitic fluid and the treatments vary

depending on pathophysiology of ascites formation [8] (Table 46-2).

SUBTYPE	PREVALENCE (%)
Peritoneal carcinomatosis alone	53.3
Massive liver metastases alone	13.3
Peritoneal carcinomatosis and massive liver metastases	13.3
Hepatocellular carcinoma with portal hypertension	13.3
Malignant chylous ascites	6.7

Adapted from ref. 6.

TABLE 46-2 Subtypes of Malignancy-Related Ascites and Their Prevalence

The mechanism of ascites formation in patients with malignant ascites depends on the location of the tumor. Peritoneal carcinomatosis appears to cause ascites formation by “exudation” of proteinaceous fluid from tumor cells lining the peritoneum and entry of extracellular fluid into the peritoneal cavity for reestablishment of oncotic balance. [8] In patients with massive liver metastases, liver replacement by tumor or occlusion of portal veins with tumor emboli leads to portal hypertension; then ascites forms as it does in patients with parenchymal liver disease and portal hypertension. In the United States, most patients with hepatocellular carcinoma have underlying cirrhosis and portal hypertension; some of these patients do not develop fluid retention until the tumor becomes relatively large and replaces a significant percentage of the liver parenchyma. [6] Alternatively, tumor-induced portal vein thrombosis or arteriovenous fistulae within the tumor may contribute to the patient’s portal hypertension and predispose to fluid retention. Chylous ascites resulting from malignant disease appears to be caused by lymph node involvement by tumor and rupture of chyle-containing lymphatics. [6] Tumor can occlude the hepatic veins and can lead to ascites formation.

Tuberculous Peritonitis In the United States, tuberculous peritonitis was a rare disease in the past but has become more common as the human immunodeficiency virus epidemic has evolved. [9] More than one half of patients with tuberculous peritonitis in the United States are found to have underlying cirrhosis, usually alcoholic in origin. [10] As in peritoneal carcinomatosis, tuberculous peritonitis probably causes ascites formation because of “exudation” of proteinaceous fluid by tubercles lining the peritoneum and entry of extracellular fluid into the peritoneal cavity for reestablishment of oncotic balance. At peritoneoscopy, the diffuse studding of the peritoneum by these lesions substantiates the plausibility of this mode of pathogenesis. Presumably, *Coccidioides* (a very cause form of inflammatory ascites) results in ascites formation by the same mechanism as tuberculosis. [11]

Heart Failure Ascites is currently an uncommon complication of heart disease. [12] , [13] It forms in high-output and low-output heart failure. [14] In the former situation, decreased peripheral resistance appears to initiate salt and water retention, whereas in the latter condition, a diminished cardiac output is the first event. [14] Both these initial events lead to a decreased effective arterial blood volume and subsequent activation of the vasopressin, renin-aldosterone, and sympathetic nervous systems. In turn, renal vasoconstriction and sodium and water retention occur. [14] Fluid then weeps from the congested hepatic sinusoids as lymph, as in the formation of cirrhotic ascites.

Pancreatic Ascites This rare form of ascites develops as part of severe acute (even hemorrhagic) pancreatitis or as a result of pancreatic duct rupture or leakage from a pseudocyst as a complication of chronic pancreatitis. [15] Patients with this form of ascites may also have underlying cirrhosis. Pancreatic ascites may occasionally be complicated by bacterial infection. Pleural effusions (left-sided, usually) may be associated. Ascites forms in this situation either by leakage of pancreatic juice into the peritoneal cavity or by a “chemical burn” of the peritoneum. Extracellular fluid then enters to reestablish oncotic equilibrium. The ascitic fluid retains the unique characteristics of the source fluid (e.g., high amylase concentration), modified to some degree by the added extracellular fluid. [15]

Fulminant Hepatic Failure Ascites may develop as a manifestation of acute liver failure in viral hepatitis. Because fulminant liver failure is uncommon, however, the total number of patients with ascites who have acute liver failure is small (see Table 46-1). The ascites that forms in this setting has a high (=1.1 g/dL) serum-ascites albumin concentration gradient indicating portal hypertension. [1] Ascites thus presumably forms in fulminant hepatic failure by mechanisms similar to those of the fluid that forms in parenchymal liver disease. [1]

Biliary Ascites Bile can accumulate in the peritoneal cavity when the gallbladder, bile duct, or gut ruptures, or it can develop after biliary surgery. This is an uncommon form of ascites. Biliary ascites is most commonly the result of rupture of the gallbladder, usually a complication of gangrene of the gallbladder in elderly men. [16]

Lymphatic Tear After extensive retroperitoneal dissection, as in distal splenorenal shunt or radical pelvic lymphadenectomy for testicular carcinoma, lymphatics may be transected and may leak lymph for variable periods. [17] The formation of ascites in this condition is similar to that of malignant chylous ascites, that is, lymphatic leak. The presence or absence of chyle in the ascitic fluid depends on where the tear is in the lymphatic system—in chyle-containing channels or not.

Miscellaneous Causes of Ascites In sexually active, otherwise healthy young women with fever and inflammatory ascites, chlamydial infection must be very high in the differential diagnosis. Chlamydia apparently now causes more cases of Fitz-Hugh-Curtis syndrome than does the gonococcus. [18] Chlamydia peritonitis is one of the few curable causes of ascites formation. Nephrogenous ascites develops in patients who are undergoing hemodialysis. [19] On careful evaluation, many of these patients are found to have underlying chronic liver disease, which may be the reason they develop fluid overload more readily than patients without liver disease who are undergoing dialysis. Evaluation of patients with nephrogenous ascites may include peritoneoscopy, which will assist with the differential diagnosis and will confirm or rule out tuberculosis and cirrhosis. [19] The proper treatment of this condition is uncertain, and the prognosis is poor. [19] Nephrotic syndrome is always listed as a cause of ascites as if it were common, but in fact it is rare in adults. [20] Usually, a second cause of ascites formation is also present. [20] It is postulated that, in nephrotic syndrome in the absence of another cause of fluid retention, loss of protein (in particular albumin) in the urine leads to decreased effective arterial blood volume, activated vasopressin, renin-aldosterone, and sympathetic nervous systems with resulting renal sodium and water retention. [14] Continuous ambulatory peritoneal dialysis causes an iatrogenic form of ascites that is usually under the management of nephrologists. The major problem is infection, which occurs approximately once per patient-year of treatment. Urine may accumulate in the peritoneal cavity as a result of trauma, as a complication of renal transplantation, or in the newborn—a condition known as “urine ascites.” [21] Reabsorption of urea can lead to “pseudorenal failure.” [21] Serositis with ascites formation may complicate systemic lupus erythematosus. [22] This form of ascites has been reported to respond to steroid therapy. [22] Pathogenesis presumably involves inflammation of the peritoneum, with resultant exudation of proteinaceous fluid into the cavity. In recent years, most cases of ascites caused by ovarian disease are the result of peritoneal carcinomatosis. [7] Meig syndrome—ascites and pleural effusion caused by benign ovarian neoplasms—is no longer a common cause of ascites formation (see Table 46-1). Ascites in patients with myxedema appears to be cardiac ascites, related to the subtle heart failure these patients develop. [23] As in other forms of cardiac ascites, this ascitic fluid is high in protein and has a high albumin gradient. [23] , [24] Treatment of the thyroid insufficiency cures the fluid retention. Patients with either acute or chronic Budd-Chiari syndrome frequently develop ascites from portal hypertension and venous outflow obstruction. The protein concentration of this fluid is variable, but the albumin gradient is high.

EVALUATION OF THE PATIENT WITH ASCITES

History

Most ascites results from liver disease, and much of the liver disease in the United States is caused by alcohol abuse, chronic hepatitis C, and obesity. [25] Many patients have more than one insult speeding liver injury. Ascites frequently develops as a part of the patient’s first decompensation of alcoholic liver disease, either alcoholic hepatitis or cirrhosis. Patients with alcoholic liver disease who intermittently cease or reduce alcohol consumption may experience ascites in a cyclic fashion. These cycles may be separated by many years and tend to parallel alcohol consumption. [26] In contrast, patients who develop ascites with nonalcoholic liver disease tend to be persistently troubled by ascites after its onset, probably because of the late stage at which ascites forms and the lack of effective therapy of nonalcoholic liver disease short of liver transplantation. When the patient has a very long history of stable cirrhosis and then develops ascites, the possibility of superimposed hepatocellular carcinoma should be considered.

Patients with ascites should be questioned about risk factors for liver disease, including alcohol use, intravenous drug use, transfusions, acupuncture, tattoos or other body piercing, and origination from an endemic area for hepatitis. The exposure may be so remote in time that the patient may not remember it initially or may not believe that a long-forgotten needle exposure is the cause of the liver disease decades later.

Obesity has become a recognized cause of a progressive form of liver disease—nonalcoholic steatohepatitis—that can progress to cirrhosis. [27] A decade of obesity can be an additive risk factor for cirrhosis in patients with alcoholism. [28]

Patients who have a history of cancer and who develop ascites should be suspected of having malignant ascites. Similarly, patients who have no risk factors for liver disease and who lose a significant amount of weight during ascites formation may harbor a neoplasm. Patients with cardiac ascites often have a past history of heart disease. [13] Some patients with alcoholism who develop ascites have alcoholic cardiomyopathy, rather then liver disease. Tuberculous peritonitis is usually manifested by fever and some abdominal discomfort. More than one half of patients with tuberculous peritonitis in the United States have underlying cirrhosis. [10] Patients who

develop ascites in the setting of known diabetes or nephrotic syndrome should be suspected of having nephrotic ascites; these patients have anasarca. Ascites developing in a patient with lethargy, cold intolerance, or change in the skin and voice should be considered as possibly resulting from myxedema. Connective tissue diseases may be complicated by ascites as a manifestation of serositis. [22]

Physical Examination

Increasing abdominal girth may be caused by ascites, massive hepatomegaly related to alcoholic hepatitis without fluid retention, gaseous distention of the bowel, obesity, or massive ovarian tumor without free fluid. Percussion of the flanks will rapidly determine which patients have ascites. If an experienced examiner detects no flank dullness, there is little or no ascites present (90% accuracy). [29], [30] If flank dullness is detected, the patient should be rolled into a partial decubitus position to determine whether the air-fluid interface shifts. Flank dullness was found to be a more helpful test than the puddle sign or the fluid wave in two prospective studies. [29], [30]

Physical findings that are very suggestive of the presence of significant liver disease include blotchy palmar erythema localized predominantly to the hypothenar eminence and large, three-dimensional pulsatile vascular spiders. These findings may be difficult to detect in patients with very dark pigmentation. Similarly, the presence of pathologically large abdominal wall collateral veins suggests that portal hypertension is present. Nearly 100% of patients with cirrhosis and ascites and relatively light pigmentation have at least one of the foregoing findings (Runyon BA, personal observation).

The presence of large veins on the flanks and back of the patient suggests inferior vena cava block, as in a web lesion or malignant obstruction. A firm nodule in the umbilicus, the *Sister Mary Joseph nodule,* is not common but is very suggestive of peritoneal carcinomatosis originating from a gastric, pancreatic, or hepatic primary tumor. A pathological left-sided supraclavicular node (the *Virchow node*) suggests the presence of cancer in the upper abdomen. The neck veins of patients with ascites should always be examined for distention in pursuit of a cardiac origin of ascites. Surprisingly, not all patients with cardiac ascites have peripheral edema, and most do not have rales. When patients with cirrhosis have peripheral edema, it is usually in the lower extremities only. Conversely, patients with nephrosis and those with cardiac failure may have anasarca.

Ascites may be semi-quantitated using the following system: 1+ is detectable only by careful examination, 2+ is easily detected but of relatively small volume, 3+ is large ascites but not tense, and 4+ is tense ascites.

Abdominal Paracentesis

Indications Abdominal paracentesis is the fastest and perhaps the most cost-effective method of diagnosing the cause of ascites formation. [31] In the past, *diagnostic paracentesis* was underused in the assessment of patients with ascites, in part because of concern regarding complications of the procedure itself. However, more recent studies have documented the safety of this procedure. [32], [33] Moreover, in view of the prevalence of ascitic fluid infection at the time patients with ascites are admitted to the hospital, *an admission surveillance paracentesis* is important for detection of infection. [34] Therefore, it is appropriate to sample ascitic fluid in all patients with *new*-onset ascites (as inpatients or outpatients) and in all patients with ascites admitted to the hospital. Paracentesis should be repeated (for outpatients or inpatients) if signs or symptoms of infection such as abdominal pain or tenderness, fever, encephalopathy, renal failure, acidosis, or peripheral leukocytosis develop. [31], [34]

Technique My technique of paracentesis has changed in recent years, in part because of the increased use of therapeutic paracentesis. [35] In addition, the percentage of patients with ascites who are obese has increased. Although the midline is avascular (unless there is an unusual collateral vein there), the abdominal wall is thinner in the lower quadrants compared with the midline. More fluid can be obtained from a supine patient with a lower quadrant paracentesis than from the midline. These factors have led me to perform more lower quadrant paracenteses in recent years and fewer midline procedures. Needles inserted too close to abdominal wall scars may enter the bowel, which may be fixed to the wall. [32] If there is a midline scar, the needle should be placed several centimeters from the scar, thus favoring a lower quadrant approach. If a lower quadrant is chosen, it is necessary to avoid placing the needle too near the liver or spleen and to avoid entering a subcutaneous collateral vein or the inferior hypogastric artery. A site located on either flank two finger-breadths cephalad and two finger-breadths medial to the anterior superior iliac spine is usually safe and successful. Because many of these patients are taking lactulose, the bowel may be distended with gas. The cecum distends more than other segments of the bowel. Therefore, the left side is usually tapped to avoid a distended cecum. There must be dullness in the site selected for needle entry. This usually requires that the patient be placed in the supine or lateral decubitus position. I prefer to use standard metal (no trocar, no plastic) 1.5-inch needles—22-gauge needles for diagnostic paracenteses and 15-gauge needles for therapeutic paracenteses (see section “ Therapeutic Paracentesis”). “Spinal needles,” that is, 3.5-inch needles, are needed only 6% of the time, only in the setting of a large panniculus. [32] Multiple-hole blunt (~15-gauge) needles with sharp removable trocars are now available and have been found to be safe. [36] Large-bore trocars are avoided because they leave large puncture wounds that leak ascitic fluid or cause other complications when they are placed inadvertently into vessels or the bowel. After selecting the insertion site and needle, the operator disinfects the skin with an iodine solution. The skin and subcutaneous tissue should be infiltrated with a local anesthetic. Sterile gloves should be used when the operator is actually obtaining the fluid. The sterile paper packaging of the gloves can be used as a sterile field on which to place syringes, needles, and so forth. The manner in which the needle is inserted is crucial for a safe successful paracentesis. Use of a “Z-tract” minimizes leakage of fluid after the procedure, but there is confusion about how to accomplish a Z-tract. It does *not* involve “zig-zagging” the needle in the subcutaneous tissue; this may cause laceration of vessels and hemorrhage. To create a Z-tract, the operator uses one gloved hand to move the skin (~2 cm in any direction) in relation to the deep abdominal wall while inserting the paracentesis needle, which is attached to the syringe. The other gloved hand is used to hold the syringe and pull on the plunger simultaneously; the inexperienced operator finds it difficult to manipulate the syringe with only one hand. The skin is not released until the needle has penetrated the peritoneum and fluid flows. When the needle is eventually removed, the skin slips back into its original position and seals the leak. If the needle is inserted directly into the fluid without a Z-tract, the fluid will leak out easily because of a straight line of flow. During insertion, the needle should be advanced in approximately 5-mm increments. A slow incremental insertion allows the operator to see a “flash” of blood if he or she enters a vessel; then the needle can be withdrawn before there is further damage. A slow insertion also allows the bowel to move away from the needle before the needle enters the bowel. The syringe that is attached to the needle *should not* be aspirated continuously during the entire insertion. If this is done, bowel or omentum may be suctioned to the end of the needle as soon as the needle enters the peritoneal cavity, thus giving the appearance of a “dry tap.” Therefore, the needle should be inserted approximately 5 mm, then the syringe aspirated for a few seconds while the needle is stationary, then advanced, then aspirated, and so on, until the sensation of entering the peritoneum is felt and fluid is aspirated. A slow insertion also allows time for the elastic peritoneum to “tent” over and be pierced by the needle. The quantity of fluid removed depends on the goal of the paracentesis. The requirement for optimal ascitic fluid culture plus cell count and “chemistries” (see section “ Ascitic Fluid Analysis”) is at least 25 mL.

Contraindications and Risks There are very few real contraindications to paracentesis. Because most patients with cirrhotic ascites have coagulopathy, [32] coagulopathy is not a contraindication unless there is primary fibrinolysis or clinical disseminated intravascular coagulation with clinically evident bleeding; these conditions occur less than once per 1000 paracenteses, in my experience. There is no cutoff of coagulation parameters beyond which paracentesis should not be performed. Patients with cirrhosis but without fibrinolysis or disseminated intravascular coagulation do not bleed seriously from needle sticks unless a blood vessel is entered. [32], [33] Some physicians give prophylactic fresh frozen plasma or platelets routinely before paracentesis in patients with cirrhosis and coagulopathy. This practice is not supported by data. [32], [33] A prospective study regarding paracentesis complications reports very low morbidity. [32] There were no deaths or infections related to paracentesis in this study. Complications included abdominal wall hematomas both large (in 2 of 229, 0.9%) and small (in 2 of 229, 0.9%). Seventy-one percent of the patients who underwent paracentesis had an abnormal prothrombin time, which was prolonged (=5 seconds) in 21%. [32]

Ascitic Fluid Analysis

Gross appearance. Most ascitic fluid is transparent and yellow tinged. Very dilute fluid in anicteric patients with cirrhosis may resemble water. Patients with deep jaundice have bile-stained ascitic fluid, but their fluid is less bile stained than their serum. [16] The opacity of most cloudy ascitic fluid specimens results from the presence of many neutrophils. This fluid has a shimmering effect when it is held in a glass tube in front of a bright light. Neutrophil counts lower than 1000/mm [3] may not be very cloudy, but counts greater than 50,000/mm [3] have a purulent consistency. About 20% of cirrhotic ascitic fluid is not transparent, but it is not frankly milky either. In this condition, called *opalescent ascites,* the cloudiness of the fluid is the result of triglyceride. [37] The lipid will usually stratify in the refrigerator over a 48- to 72-hour interval. A minimum of 10,000 red cells/mm [3] is required for ascitic fluid to appear pink; smaller concentrations result in a clear or “smoky” appearance. Ascitic fluid with a red cell count greater than 20,000/mm [3] is distinctly blood tinged. Most bloody ascitic fluid occurs in the setting of a “traumatic tap” in a patient with cirrhosis; this fluid is heterogenously bloody, and the fluid clots. In contrast, nontraumatic (or remotely traumatic) bloody ascitic fluid is homogenously red and does not clot because it has already clotted and lysed. Ascites in the setting of tuberculous peritonitis is seldom bloody. Overall, only 22% of malignancy-related samples are bloody. [6] Half of samples from patients with hepatocellular carcinoma are bloody, but only about 10% of samples from patients with peritoneal carcinomatosis have this appearance. [6] Pancreatic ascites may appear tea colored or even black, presumably because of the denaturing effect of the pancreatic enzymes on ascitic fluid red cells.

Which ascitic fluid tests are worth ordering? Screening tests are performed on the initial specimen as well as other tests that are appropriate, based on the probability of the presence of a cause for ascites formation other than cirrhosis. Subsequent tests may be performed (usually necessitating another paracentesis)

based on the results of the initial analysis and incoming clinical information. However, because most specimens will represent uncomplicated cirrhotic ascites, no further tap will usually be needed. Based on cost-effectiveness analysis, I have developed a list of “routine, optional, and unusual” tests (Table 46-3). The strategy of test ordering is discussed in the following sections.

ROUTINE	OPTIONAL	UNUSUAL
Cell count	Gram stain	Tuberculosis smear and culture
Albumin	Glucose	
Culture in blood culture bottles	Lactate dehydrogenase	Cytology
	Amylase	Triglyceride
Total protein		Bilirubin

TABLE 46-3 Laboratory Data to be Obtained on Ascitic Fluid

Cell count. The cell count is the single most helpful test to order. If only one drop of fluid is obtainable, it should be sent for cell count. One needs only 10 µL for a standard manual hemocytometer count. The fluid should be submitted in an EDTA tube to prevent aggregation of the cells; clumped cells make an accurate count nearly impossible. An ascitic fluid culture is difficult to interpret without a cell count. The upper limit of “normal” total white blood cell count in uncomplicated cirrhotic ascites is 500 cells/mm [3]. [38] However, during a 10-kg diuresis in a patient with cirrhosis, the mean ascitic fluid white cell count triples from approximately 300 to approximately 1200 cells/mm [3]. [39] The upper limit cutoff of absolute polymorphonuclear leukocyte (PMN) count is usually stated to be 250 PMN/mm [3]. [38] Fortunately, the PMN count remains relatively constant during diuresis, presumably because of the short half-life of PMNs. [39] Therefore, the 250 cutoff pertains even at the end of diuresis. Most cases of bloody ascites result from traumatic paracentesis in a patient with cirrhosis. If a paracentesis is traumatic, only 1 PMN per 250 red cells can be attributed to blood contamination of ascites and only 1 lymphocyte per 750 red cells. [39] Any inflammatory cause of ascites and any inflammatory complication of ascites can elevate the ascitic fluid white cell count. The most common cause of an elevated count is spontaneous bacterial peritonitis (SBP), in which the total white cell count is elevated as well as the absolute PMN count. The percentage of PMNs is almost always greater than 50% and is usually greater than 70%. In tuberculous peritonitis and peritoneal carcinomatosis, there is usually a predominance of lymphocytes. The white cell count in chylous ascites may be increased because of leakage of lymphocytes with the chyle. The red cell counts in cardiac ascites may be increased because of leakage of red cells across the congested liver, whereas red cells may be increased in chylous ascites as a result of leakage from lymph channels.

Albumin. The serum-ascites albumin gradient categorizes ascites better than the total protein concentration. [1], [40], [41] To calculate this gradient, the albumin concentrations of serum and ascitic fluid specimens are measured, and the ascitic fluid value is simply subtracted from the serum value. The specimens should be obtained relatively simultaneously—within a few minutes or hours. In addition, if the patient’s condition is so unstable that portal pressure is altered, as in shock, the albumin gradient will be less reliable. Accuracy of the albumin assay at low albumin concentrations is important. Usually, the laboratory’s albumin standards must be diluted to assess and ensure linearity of the assay at low range. The albumin gradient’s utility is based on the concept of oncotic-hydrostatic balance. [41] If a patient has a high portal pressure, there must be a high oncotic gradient to match. Of the serum proteins, albumin has the most effect on oncotic pressure of serum. There are large differences between serum and ascitic fluid albumin concentrations in patients with portal hypertension (Table 46-4 and Fig. 46-1). If serum albumin minus ascitic fluid albumin is greater than or equal to 1.1 g/dL (11g/L), the patient has portal hypertension with 97% accuracy [1] (see Fig. 46-1). The higher the gradient, the greater the portal pressure. [41] Conversely, if serum albumin minus ascitic fluid albumin is less than 1.1 g/dL, the patient does not have portal hypertension (see Fig. 46-1).

HIGH GRADIENT (i.e., ≥1.1 g/dL)	LOW GRADIENT (i.e., <1.1 g/dL)
Cirrhosis	Peritoneal carcinomatosis
Alcoholic hepatitis	Tuberculosis (without cirrhosis)
Cardiac ascites	Pancreatic ascites (without cirrhosis)
Massive liver metastases	Biliary ascites (without cirrhosis)
Fulminant hepatic failure	Nephrotic syndrome
Budd-Chiari syndrome	Ascites in patients with connective tissue disease
Portal vein thrombosis	
Veno-occlusive disease	Ascites from bowel obstruction or infarction
Acute fatty liver of pregnancy	
Myxedema	
“Mixed” ascites	

TABLE 46-4 Classification of Ascites by Serum-Ascites Albumin Concentration Gradient

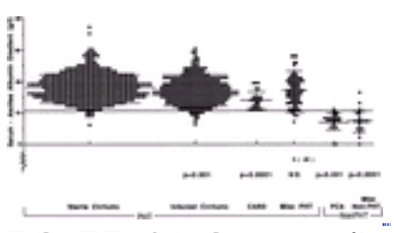

FIGURE 46-1. Serum-ascites albumin gradient, classified by the presence or absence of portal hypertension. Statistical comparisons are to the sterile cirrhotic group by unpaired *t*-test. *NS,* not significant; *CARD,* cardiac ascites; *Misc PHT,* miscellaneous portal hypertension–related; *PCA,* peritoneal carcinomatosis; *Misc Non-PHT,* miscellaneous non–portal hypertension related. Mean ± standard deviation bars are included as well as a horizontal line at 11 g/L (1.1 g/dL), the threshold for portal hypertension. (From ref. [1].)

High-albumin gradient and *low-albumin gradient* should replace the terms *transudative* and *exudative* in the description of ascites (see section “ Total Protein”). [1], [40], [41] The albumin gradient is approximately 97% accurate in categorizing ascites patients into those with and those without portal hypertension (see Fig. 46-1). [1] However, if the albumin assay is not accurate at low range, errors will occur. If a patient with cirrhosis has a serum albumin less than 1.1 g/dL (this occurs very rarely), the gradient will be falsely low. If the patient is in shock, the gradient will be low because the portal pressure is low. In most laboratories, lipid interferes with the albumin assay; therefore, patients with chylous ascites may have a falsely high albumin gradient. Patients with “mixed” ascites—that is, portal hypertension plus another cause of ascites formation—will have a high-albumin gradient, as expected. [1] The presence of tuberculosis or peritoneal carcinomatosis would not be expected to lower the portal pressure. The albumin gradient is simply a reflection of the portal pressure. Cirrhosis is the most common cause of a high-albumin gradient, and the most common cause of a low-albumin gradient is peritoneal carcinomatosis; however, there are other causes of high and low gradients (see Table 46-4). The albumin gradient need only be performed on the first paracentesis in a given patient; it need not be repeated on subsequent analyses.

Culture. The sensitivity of bacterial culture in detecting spontaneous infection in neutrocytic ascites varies dramatically depending on the method of culture used; “conventional” cultures detect approximately 40% of cases, whereas bedside inoculation of blood culture bottles with ascites results approximately 90% detection of bacterial growth in neutrocytic ascites. [42] Without fail, all prospective studies have demonstrated the superiority of the blood culture bottle method over the conventional method. [42], [43] The problem with the conventional culture is that it is designed to detect bacterial growth in polymicrobial infections that involve very high concentrations of bacteria. SBP is essentially always a monomicrobial infection with a median bacterial count of only one organism per milliliter. [42] Blood culture bottles were designed to detect monomicrobial infections involving small quantities of bacteria and are ideal for culturing ascites in suspected SBP. [42] However, not all blood culture bottles are alike. Some permit inoculation of only a few milliliters of fluid; others actually suppress growth of some bacteria. Using bottles that permit inoculation of 10 to 20 mL of ascites appears to be optimal. [42] Bedside inoculation of the blood culture bottles is preferable to delayed inoculation of the bottles in the microbiology laboratory. [43]

Total protein. Ascitic fluid was classified in the past as an exudate when the protein level was greater than or equal to 2.5 g/dL; occasionally, a cutoff of 3.0 g/dL was used. However, the exudate/transudate system of ascitic fluid classification is fraught with problems. The ascitic fluid protein level in cirrhotic ascites is entirely dependent on serum total protein concentration and portal pressure. [41] Therefore, a patient with cirrhosis with a relatively high serum protein level will have a relatively high ascitic fluid protein level without cancer or tuberculosis. Nineteen percent of uncomplicated cirrhotic ascites samples have greater than 2.5 g/dL of protein. [44] During a 10-kg diuresis, ascitic fluid total protein doubles from 1.4 to 2.9 g/dL; 67% of patients with cirrhotic ascites develop a protein level greater then 2.5 g/dL at the end of diuresis. [39] Contrary to popular belief, ascitic fluid total protein concentration does not increase during SBP, and patients with the lowest protein levels in ascites are the most prone to develop SBP. [45], [46] Almost one third of patients with malignant ascites have portal hypertension resulting from massive liver metastases or hepatocellular carcinoma as the cause of ascites formation; their fluid total protein is less than 2.5 g/dL. [6] In cardiac ascites, the protein concentration is essentially always greater than 2.5 g/dL. [13] The accuracy of an ascitic fluid total protein level greater than or equal to 2.5 g/dL in detecting an exudative cause of ascites formation was determined to be only 55.6% in a study of 901 samples (Table 46-5 and Fig. 46-2). [1] A cutoff of 3.0 g/dL yielded essentially an identical

accuracy—56.0% (Runyon BA, Montano AA, Akriviadis EA, et al., personal observations). Modified pleural fluid exudate criteria were also assessed for accuracy in detecting an exudative cause for ascites formation in this study. Exudate criteria included an ascitic fluid lactate dehydrogenase (LDH) level greater than 2.33 μkat/L (>140 U/L), ascitic fluid/serum (AF/S) total protein ratio greater than 0.5, and a ratio of AF/S to LDH greater than 0.6. Specimens with zero or one criterion were classified as transudates, and specimens with two or three criteria were classified as exudates. The accuracy of these criteria in detecting an exudative cause for ascites formation was determined to be only 57% (see Table 46-5; Fig. 46-3) (Runyon BA, Montano AA, Akriviadis EA, et al., personal observations).

PARAMETER	ACCURACY (%)
Serum-ascites albumin gradient in detecting portal hypertension	96.7
Ascitic fluid total protein concentration >2.5 g/dL in detecting exudate	55.6
LDH, AF/S LDH, and AF/S total protein criteria in detecting an exudate	57.0

AF/S, ratio of ascitic fluid to serum; LDH, lactate dehydrogenase.

TABLE 46-5 Accuracy of Ascitic Fluid Parameters

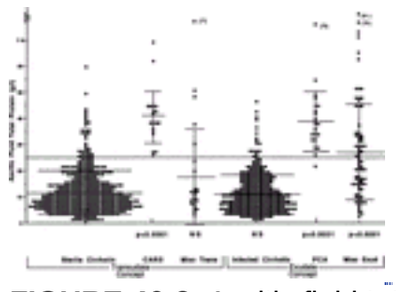

FIGURE 46-2. Ascitic fluid total protein in ascites of various types, classified by transudate versus exudate. Statistical comparisons are with the sterile cirrhotic group by unpaired *t*-test. *NS,* not significant; *CARD,* cardiac ascites; *Misc Trans;* miscellaneous transudative; *PCA,* peritoneal carcinomatosis; *Misc Exud,* miscellaneous exudative. The miscellaneous transudative category included fulminant hepatic failure, chylous cirrhotic ascites, and nephrotic and nephrogenous ascites. The miscellaneous exudative category included patients with mixed ascites (if one of the causes was exudative), infected fulminant hepatic failure samples, massive liver metastases, hepatocellular carcinoma, infected cardiac ascites, chylous lymphoma-related ascites, tuberculous peritonitis, pancreatitis, chlamydia peritonitis, and secondary bacterial peritonitis in the absence of cirrhosis. Mean ± standard deviation bars are included as well as a *horizontal line* at 25 g/L (2.5 g/dL), the threshold for exudate. (From ref. [1].)

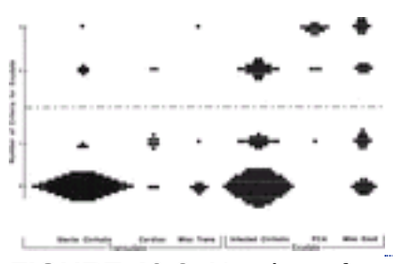

FIGURE 46-3. Number of exudate criteria in ascites of various types, classified by transudate versus exudate. *Misc Trans,* miscellaneous transudative; *PCA,* peritoneal carcinomatosis; *Misc Exud,* miscellaneous exudative. The *horizontal line* separates specimens satisfying zero or one exudate criteria from those satisfying two or three exudate criteria.

In summary, whether defined by total protein alone or by modified pleural fluid exudate criteria, the concept of transudate versus exudate is not very useful in ascitic fluid analysis. The serum-ascites albumin gradient is superior. Despite its shortcomings, the ascitic fluid total protein level is of some value. Oral quinolones have been shown to help prevent SBP in inpatients with ascites with low protein concentrations. [47] In addition, measurement of total protein, glucose, and LDH in ascites has been reported to be of value in distinguishing SBP from gut perforation into ascites [48], [49] (Fig. 46-4). Patients with ascitic fluid that is neutrocytic and meets two out of the following three criteria are unlikely to have SBP and warrant immediate evaluation to determine whether gut perforation into ascites has occurred: total protein greater than 1g/dL, glucose less than 50 mg/dL, and LDH greater than the upper limit of normal for serum. [48], [49]

FIGURE 46-4. Algorithm for differentiating spontaneous from secondary bacterial peritonitis. (From ref. [49].)

Glucose. Because of its small molecule weight, glucose enters ascites readily. Therefore, the ascitic fluid glucose concentration is similar to that of serum unless glucose is being consumed in the peritoneal cavity by white blood cells or bacteria. If the gut perforates (e.g., perforated ulcer or diverticulum) into ascitic fluid, the glucose concentration usually is low and can be as low as 0 mg/dL. [48], [49]

Lactate dehydrogenase. LDH is a much larger molecule than glucose and enters ascitic fluid less readily than does glucose. The ratio of AF/S to LDH is approximately 0.40 in uncomplicated cirrhotic ascites; in SBP, presumably because of neutrophil release of LDH, the ascitic fluid LDH level rises such that the mean ratio is 0.9±0.3. [48] If the LDH ratio is more than 1.0, LDH is being produced in or released into the peritoneal cavity; usually because of infection or tumor.

Amylase. The mean ascitic fluid amylase concentration is 42 ± 44 IU/L in uncomplicated cirrhotic ascites, and the AF/S ratio of amylase is approximately 0.4. [15] The ascitic fluid amylase concentration rises above this mean in the setting of pancreatitis or gut perforation. In pancreatic ascites, the ascitic fluid amylase concentration averages approximately 2,000 IU/L, and the AF/S ratio in pancreatic ascites averages approximately 6.0. [15]

Gram stain. Although a Gram stain of ascites is frequently ordered when SBP is suspected, careful inspection of the centrifuged sediment of 50 mL of ascites is only 10% sensitive in visualizing bacteria in early-detected SBP; a Gram stain of uncentrifuged fluid is positive in only 7%. [42] Approximately 10,000 bacteria/mL are required for detection by Gram stain; the median concentration of bacteria in SBP is only one organism/mL. [42] A Gram stain of ascites is analogous to a Gram stain of blood in bacteremia; it is positive only when there is overwhelming infection. The Gram stain is most helpful in ruling in or ruling out free perforation of the gut into ascites, in which sheets of multiple bacterial forms are found. A syringe of fluid must be submitted to the microbiology laboratory when requesting a Gram stain, in addition to cultures in blood culture bottles.

Smear and culture for tuberculosis. The direct smear of ascitic fluid has only 0% to 2% sensitivity in detecting *Mycobacteria.* [10], [50] I have seen only one positive ascitic fluid tuberculous smear, and it was falsely positive. Culture of ascitic fluid is only about 40% sensitive. [10], [50] Peritoneal biopsy is 64% to 83% sensitive. [10], [50] The sensitivity of peritoneoscopy in detecting tuberculous peritonitis approaches 100%. [10], [50] Tuberculous peritonitis may mimic the culture-negative variant of SBP, but mononuclear cells predominate in tuberculous peritonitis, rather than PMNs in the setting of SBP. The adenosine deaminase activity of ascitic fluid has been proposed as a useful nonculture method of detecting tuberculous peritonitis; however, patients with cirrhosis and tuberculous peritonitis usually have falsely low values. [10]

Cytology. Cytology smears are reported to be 58% to 75% sensitive in detecting “malignant ascites.” [51] However, only about two thirds of patients with malignancy-related ascites have peritoneal carcinomatosis; essentially 100% of patients with peritoneal carcinomatosis will have viable malignant cells exfoliating into their ascitic fluid and will have positive ascitic fluid cytologic studies. [6] The remaining one third of patients with malignancy-related ascites have massive liver

metastases, chylous ascites from lymphoma, or hepatocellular carcinoma; these patients have negative cytology. [6] The percentage of false-positive cytologic examinations approaches zero. [51] Hepatomas metastasize to the peritoneum infrequently enough to be the subject of case reports. [52] Flow cytometry occasional detects evidence of malignant disease when cytology is negative. [53] Some cytology laboratories prefer that specimens be submitted in fixative; others prefer fresh, unfixed specimens. It is best to determine the specifics of submission with each local laboratory to maximize the sensitivity of the cytology. In addition, submitting specimens in very small quantity (only a few milliliters) or submitting an unfixed specimen late on a Friday night may handicap the pathologist's ability to assist in the diagnosis of malignancy. I submit at least 50 mL of fluid for cytologic examination on the rare occasion that I request this expensive test. Malignancy-related ascites may have an elevated PMN count (16% of cases in one series), presumably because dying tumor cells may attract neutrophils into the fluid. [6] Usually in this setting, there is no predominance of PMNs; this helps in differentiating this condition from SBP.

Peritoneal biopsy. The ascitic fluid cytology is so sensitive in detecting peritoneal carcinomatosis that peritoneal biopsy is not needed in the search for tumor. The best indication for peritoneal biopsy is in the setting of suspected tuberculous peritonitis. However, one half of patients with tuberculous peritonitis in the United States have underlying cirrhosis with portal hypertension and intra-abdominal collateral vessels. Blind Cope needle or Abrams needle biopsy of the peritoneum in the setting of portal hypertension risks fatal laceration of a collateral vessel. Direct visualization of the peritoneum by peritoneoscopy is preferable to blind biopsy in the cirrhotic patient with suspected tuberculous peritonitis. Culture of the biopsy for mycobacteria is the most sensitive and specific test for tuberculous peritonitis. [10]

Triglyceride. If the ascitic fluid is milky, a triglyceride level should be obtained. Chylous ascites has a triglyceride content greater than 200 mg/dL and usually greater than 1000 mg/dL. [54] About 20% of sterile cirrhotic ascitic fluid specimens are slightly cloudy, but the cloudiness is not the result of an elevated cell count. [37] The triglyceride concentration of these specimens is approximately 60 mg/dL, compared with approximately 20 mg/dL for clear cirrhotic ascites; these specimens are called opalescent. [37]

Bilirubin. Brown ascites should be tested for bilirubin concentration. An ascitic fluid bilirubin level greater than the serum level suggests bowel or biliary perforation into ascites. [16], [49]

pH. Ascitic fluid pH was proposed in the past as a helpful test in differentiating infected or malignant ascites from uncomplicated cirrhotic ascites. Unfortunately, the studies that purported to validate the pH were small (only 6 to 18 infected patients per study) and did not use optimal culture technique. In two more recent, larger studies, the pH was not found to be helpful. [55], [56] Ascitic fluid pH appears to be simply an indirect measurement of the presence of PMNs. It also requires special processing; that is, it must be sent immediately to the laboratory on ice in a plastic syringe without anticoagulant. It is simpler and more cost effective to measure the PMN concentration directly. [55]

Lactate. The ascitic fluid lactate concentration has also been proposed as a marker of infection or tumor. However, lactic acid metabolism in ascites is linked to pH changes by the same pathophysiology. Lactate has the same problems as pH as an ascitic fluid test. It is not a helpful or cost-effective test for the same reasons that pH determination is not a helpful or cost-effective test. [55]

Carcinoembryonic antigen. Measurement of carcinoembryonic antigen (CEA) in ascitic fluid has been proposed as a helpful test in detecting malignant ascites. [57] However, the study that validated CEA did not have a subgroup of patients with malignancy-related ascites and did not study a large number of patients. No subsequent studies have been reported. In the study of CEA in ascites, all benign fluids had CEA levels less than 10 ng/mL, whereas CEA was greater than 10 ng/mL in 14 of 29 (48%) patients with malignant ascites. However, cytology was positive in only 12 of 29 (41%). Such insensitivity of cytology makes interpretation of the study difficult. CEA may be of some utility in ascitic fluid analysis, but its precise value remains unclear.

Ascitic fluid "humoral tests of malignancy". Several tests, such as fibronectin, cholesterol, a $_1$-antitrypsin, cyclic AMP, and glycosaminoglycans determinations, were proposed as useful in detecting malignant ascites. The basic premise of these studies was that the ascitic fluid cytology is too insensitive to be the only test used in detecting malignancy-related ascites. Unfortunately, these studies did not have proper controls and did not recognize that there are several subgroups of malignancy-related ascites, nor did they appreciate that the cytology would be helpful only in detecting peritoneal carcinomatosis. Therefore, patients with negative cytologies also have negative "humoral tests of malignancy." [58] In addition, patients with high-protein, noncirrhotic ascites essentially always have false-positive "humoral tests of malignancy." [6], [58] Therefore, these tests are more confusing than helpful.

Serum Analysis Measurement of serum albumin concentration is mandatory to determine the albumin gradient. If ascitic fluid infection is suspected, blood should be cultured in addition to ascitic fluid even if the patient is not febrile (only approximately two thirds of patients with SBP have fever). Calculations of protein and LDH ratios in the differential diagnosis of ascites have not been as helpful as hoped. Application of pleural fluid exudate criteria to ascitic fluid simply is not useful (see Fig. 46-3). Patients with systemic bacterial infection and cirrhosis do not convert glycogen to glucose normally and may develop profound peripheral hypoglycemia (as low as 5 mg/dL); if the ascitic fluid glucose is especially low in a patient with neutrocytic ascites, measurement of a "stat" serum glucose may explain the ascitic fluid hypoglycemia and may result in emergency administration of concentrated glucose intravenously. Measurement of serum bilirubin or triglyceride concentration may be of value in interpreting the ascitic fluid counterparts of these tests. Testing the serum for a-fetoprotein concentration may be of value in detecting hepatoma in the patient with compensated cirrhosis who suddenly develops ascites; the ascitic fluid a-fetoprotein is always lower than the serum value in a given patient. [6]

Conclusion The history and physical examination will usually provide a working diagnosis of the cause of ascites formation. Ascitic fluid analysis combined with testing of blood will usually provide a definitive diagnosis (see Table 46-3). Although the ascitic fluid cell count is the single most helpful ascitic fluid test in determining which patients need empiric antibiotic treatment and in distinguishing inflammatory from noninflammatory conditions, the albumin gradient is the test used to classify ascites into high- and low-albumin gradient categories (see Table 46-4 and Table 46-5 and Fig. 46-1, Fig. 46-2 and Fig. 46-3). Abdominal paracentesis assists in the diagnosis and treatment of patients with ascites. Performance of this procedure with appropriate analysis of the fluid is perhaps the safest and most cost-effective way to diagnose the cause of ascites formation and to rule in or rule out ascitic fluid infection.

Radiologic Assessment

Many physicians order radiologic tests in addition to appropriate testing of the fluid in the initial evaluation of the patient with ascites. Abdominal ultrasound may be of value in differentiating obesity from ascites or in detecting small-volume ascites. In the patient with ascites and multiple abdominal scars, ultrasound may be of value in determining where to insert the paracentesis needle safely. [35] Ultrasound may detect ovarian or pancreatic or mesenteric masses in the patient whose ascitic fluid analysis suggests peritoneal carcinomatosis.

Ultrasound may also be of value in detecting hepatocellular carcinoma, and ultrasound with Doppler can be diagnostic of hepatic vein or portal vein thrombosis. Worldwide, ultrasound is the most commonly used imaging modality in patients with ascites. In many parts of the world, hepatologists perform the examinations themselves.

Computed tomographic studies may complement ultrasound and may be of additional value in detecting the increased density of the liver compared with the spleen in hemochromatosis.

In the patient with infected ascites, if the initial ascitic fluid analysis meets criteria for gut perforation (see Fig. 46-4), [49] and especially if large numbers of different bacteria are noted on Gram stain, emergency plain and upright abdominal films should be obtained to determine whether free air is present. If there is free air, the patient probably needs laparotomy. If no free air is present, emergency water-soluble gut contrast studies should be performed. If the patient is young, a water-soluble upper gastrointestinal contrast study should be performed first, to look for extravasation from a perforated duodenal ulcer. If the patient is elderly, a water-soluble contrast enema should be performed first, to look for extravasation from a perforated colonic diverticulum. If extravasation is found, emergency surgical intervention should take place. The plain abdominal film may also be of value on rare occasions in detecting calcification of metastatic colonic carcinoma or ovarian neoplasms.

COMPLICATIONS OF ASCITES

Infection

Spontaneous Bacterial Peritonitis Ascitic fluid infection can be classified into five categories (Table 46-6). [34] An abdominal paracentesis must be performed before a diagnosis of ascitic fluid infection can be made. Simply culturing blood and making a clinical diagnosis of peritonitis are not adequate. The prototypic form of ascitic fluid infection is SBP: positive ascitic fluid culture (essentially always pure growth of a single organism) and an elevated ascitic fluid absolute PMN count greater than or equal to 250 cells/mm [3], without an evident intra-abdominal source of infection that requires surgical treatment.

CATEGORY	ASCITIC FLUID ANALYSIS
Spontaneous bacterial peritonitis	PMNs ≥250/mm³, single organism
Culture-negative neutrocytic ascites	PMNs ≥250/mm³, negative culture
Secondary bacterial peritonitis	PMNs ≥250/mm³, usually multiple organisms
Monomicrobial bacterascites	PMNs <250/mm³, single organism
Polymicrobial bacterascites	PMNs <250/mm³, multiple organisms

PMNs, polymorphonuclear leukocytes.

TABLE 46-6 Classification of Infected Ascites

Setting. For all practical purposes, SBP occurs only in the setting of liver disease, usually severe liver disease. [34], [59] Ninety-five percent of patients with SBP have an elevated serum bilirubin, 81% are clinically jaundiced, and 98% have an abnormal prothrombin time. [60] The liver disease may be chronic, as in alcoholic cirrhosis, subacute, as in alcoholic hepatitis, or acute, as in fulminant hepatic failure. SBP is most common in alcoholic cirrhosis (with or without chronic hepatitis C), the most common cause of ascites formation in the United States. All forms of cirrhosis, however, have been reported to be complicated by SBP. SBP is commonly encountered in patients with known hepatitis B–related liver disease and superimposed acute hepatitis. [34] Ascites is a prerequisite to development of SBP, but the fluid may not always be clinically detectable. It is unlikely that SBP precedes ascites formation. Usually, this infection develops in patients at the time of their largest ascites volume. Nephrotic ascites regularly was complicated by SBP in the preantibiotic era, but the current use of diuretics and antibiotics has made SBP uncommon in this setting. [20] Cardiac ascites rarely is complicated by SBP, and patients with peritoneal carcinomatosis hardly ever develop spontaneous peritonitis. [59], [61] About half of SBP episodes are detected at the time of admission to the hospital; the remainder develop after admission. [60]

Pathogenesis. The pathogenesis of SBP has become clearer. Most of the organisms that cause SBP are of enteric origin. [42] It had been assumed in the past that virulent gut flora simply migrated transmurally to infect ascitic fluid. However, transmural migration of bacteria has been documented only in the setting of loss of mucosal integrity. [62] If organisms could easily traverse the gut wall, polymicrobial infections would be the rule, rather the exception. In addition, the flora of the gut differs from the flora of SBP—anaerobes and enterococci predominate in the former, and *Escherichia coli, Klebsiella pneumoniae,* and pneumococci are the most common isolates in the latter. [34] "Translocation" of bacteria from the lumen of the gut to mesenteric lymph nodes is more likely to be one of the first steps in the pathogenesis of SBP, rather than transmural migration of bacteria from the gut directly into ascites. The normal gut mucosa functions as a selective filter; gram-negative aerobic bacteria translocate more readily than gram-positives and anaerobes. [63] Cirrhotic rats have been shown to translocate bacteria from the gut to mesenteric lymph nodes much more commonly than normal rats translocate; the gut mucosa in the setting of cirrhosis is "leakier" than normal. [64] Overgrowth of an organism in the gut is one of the most predictable precursors of translocation. [63] Intestinal bacterial overgrowth has been shown to precede translocation in cirrhotic rats. [65] Bacteremia may be an additional factor in the pathogenesis of SBP. Cirrhotic rats contain a localized infectious process, such as pneumonia, less well than do normal rats. They also develop bacteremia after intratracheal exposure to pneumococci and have more prolonged bacteremia and more fatalities when ascites is present compared with cirrhotic rats without ascites and compared with normal rats. [66] Therefore, it is not surprising that bacteremia is common in patients with severe liver disease. [67] Fifty percent of patients with SBP have bacteremia at the time of diagnosis of peritoneal infection. [60] Patients with cirrhosis with ascites usually have serum complement deficiency. [68] Because complement is required for the opsonization (coating for phagocyte-mediated killing) of most virulent organisms, complement deficiency would be expected to predispose to bacterial infections, including bacteremia. [68] Furthermore, neutrophil and reticuloendothelial system dysfunctions are also common in cirrhosis. [69], [70] Such abnormalities in host defense against infection would be expected to lead to frequent and prolonged bacteremia. Thus, in the setting of cirrhosis, mesenteric lymph colonization or portal bacteremia would be expected to lead to peripheral bacteremia. In turn, this systemic bacteremia could lead to bacterascites as bacteria-laden lymph forms from blood and leaks across the Glisson capsule (Fig. 46-5). Because the ascitic fluid of patients with cirrhosis is a significant dilution of their complement-deficient serum, and because the opsonic activity (endogenous antimicrobial activity) of human ascitic fluid correlates directly with the fluid's protein concentration, many of these patients have no ability to control or eradicate colonization of their ascitic fluid. [68] The protein concentration of ascitic fluid does not change with development of spontaneous infection. [45] Patients with low-protein ascites, such as less than 1 g/dL, have been shown to be particularly prone to SBP. [46] Patients with deficient ascitic fluid opsonic activity have been shown to be predisposed to SBP. [71]

FIGURE 46-5. Proposed pathogenesis of spontaneous bacterial peritonitis.

In summary, the gut mucosa of cirrhotic animals appears to be abnormally permeable to bacteria. Intestinal bacterial overgrowth of a specific organism leads to translocation of that organism. Bacteria readily enter mesenteric lymph or portal blood and could then access the peripheral circulation. Lymph that forms from bacteria-laden blood in the liver then enters ascitic fluid. Ascitic fluid that is deficient in antimicrobial properties is the fertile soil in which SBP develops.

Signs and symptoms. Eighty-seven percent of patients with SBP reported in one study had signs or symptoms of infection. [72] Prevalence of the most common signs and symptoms from a review of 489 patients was as follows: fever, 69%; abdominal pain, 59%; and mental status change, 54%. [73] However, the clinical evidence of infection may be very subtle, as in mild hepatic encephalopathy that is apparent only as a change in personality noted by the patient's family.

Prevalence. When abdominal paracentesis is performed routinely in patients with ascites at the time of admission to the hospital (whether or not they have symptoms of infection), up to 27% are found to have SBP or a variant thereof. [34], [74] Approximately 15% of hospitalized cirrhotic patients with ascites are found to have SBP, as specifically defined, on hospital admission. [34] However, the use of selective intestinal decontamination (see section " Prevention") has reduced the prevalence of ascitic fluid infection. [75] To maximize survival, it is important to perform paracentesis on hospital admission so infection can be diagnosed and treated early. In addition, paracentesis should be repeated during hospitalization if any deterioration occurs, including pain, fever, mental status change, renal failure, acidosis, peripheral leukocytosis, or gastrointestinal bleeding. There are no data on the frequency of SBP in outpatients. Fatal infection may be a common cause of death of cirrhotic patients who die at home.

Flora. Approximately 80% of SBP is caused by *E coli,* streptococci (mostly pneumococci), and *Klebsiella.* [42], [73] Anaerobes cause approximately 1% of SBP. [42] Many reported cases of anaerobic SBP are polymicrobial and probably represent misdiagnosed secondary peritonitis. [49] Presumably, the infrequency of anaerobic SBP results from the relatively high PO_2 of ascites, approaching that of arterial blood. The prevalence of pneumococcal SBP has increased as ascitic fluid culture methods have improved. [42]

Risk factors. Patients with cirrhosis are unusually prone to bacterial infections because of multiple defects in immune defense (see section " Pathogenesis"). [34] In a prospective study performed in Brazil, 47% of 170 cirrhotic patients during a single hospitalization had bacterial infection of various types ranging from asymptomatic urinary tract infections to fatal sepsis. [76] Bacteriuria is twice as common in cirrhotic patients compared with matched controls and is more common in patients with SBP compared with uninfected patients with ascites. [77] Perhaps it is this high frequency of colonization of cirrhotic patients with bacteria and the inability of these immunocompromised patients to localize infection that lead to bacteremia and colonization of ascites. Paracentesis itself appears to cause ascitic fluid infection only when the paracentesis needle enters the bowel inadvertently during attempted paracentesis. Fortunately, this is very unusual (see the later discussion of polymicrobial bacterascites); only 10 cases were found among 1578 paracenteses in a retrospective study. [78] Gastrointestinal hemorrhage has been linked to development of spontaneous bacteremia and SBP. [79] The mechanism of this predisposition is not entirely clear, but it probably involves an ischemia-reperfusion–related increase in translocation. In addition, invasive procedures performed in relation to gastrointestinal bleeding, such as endoscopy or intravascular catheter placement, may also predispose to bacteremia. Even simple, seemingly innocuous procedures such as bladder catheter insertion in the setting of a bladder infection may cause bacteremia. Certainly, leaving a catheter in place for several days guarantees cystitis; urosepsis frequently follows in cirrhotic patients because of their inability to localize infections.

Diagnosis. By definition, a positive ascitic fluid culture and an ascitic fluid PMN count greater than or equal to 250 cells/mm [3] are required before a diagnosis of SBP is made. A clinical diagnosis of ascitic fluid infection is not adequate; paracentesis must be performed. A high index of suspicion of SBP and a low threshold for performing a paracentesis are required for early diagnosis of this infection.

Survival. The infection-related mortality has decreased dramatically, from approximately 100% in the 1960s to 5% in a 1991 study. [80] This improved survival is probably a reflection of earlier detection of infection as well as the avoidance of nephrotoxic antibiotics in patients with cirrhosis. Many patients are cured of their infection and yet die of liver or renal failure or gastrointestinal bleeding.

Treatment. Patients with ascitic fluid PMN counts greater than or equal to 250 cells/mm [3] in a clinical setting compatible with SBP should be treated empirically with

antibiotics. Patients with hemorrhage into ascites, peritoneal carcinomatosis, pancreatic ascites, or tuberculous peritonitis may have an elevated PMN count that is not related to SBP. They do not require empiric treatment. If the situation is initially unclear, however, treatment should be given until the diagnosis is clarified. Usually, patients with uninfected neutrocytic ascitic fluid (except those with hemorrhage) have a predominance of lymphocytes in their ascitic fluid differential; this helps to distinguish them from patients with SBP, in whom PMNs predominate. Patients with bloody ascites should have a "corrected" PMN count calculated—one PMN is subtracted from the total absolute PMN count for every 250 red blood cells. [39] Such corrections of the PMN count may result in a negative number, that is, less than zero. Patients with bloody ascites do not need antibiotics unless their corrected PMN count is greater than or equal to 250 cells/mm [3]. Patients with suspected SBP require broad-spectrum therapy until the results of susceptibility testing are available. The recommendation for choice of empiric treatment has changed over the years. In the past, aminoglycosides were used. Now we know that gentamicin has an unpredictable volume of distribution in patients with ascites and that serum creatinine (and even the creatinine clearance) is a poor index of the glomerular filtration rate in patients with ascites. [81] Therefore, it is very difficult to give appropriate loading or maintenance doses of gentamicin in these patients. Even if overdosing is avoided, up to 73% of cirrhotic patients develop nephrotoxicity. [82] Gentamicin and gram-negative infections appear to be synergistic in leading to kidney damage. [83] Because of the difficulties in dosing and the apparent nephrotoxicity of aminoglycosides, the use of these drugs was simultaneously abandoned in the treatment of cirrhotic patients in the early 1980s in many liver units around the world. Cefotaxime, a third-generation cephalosporin, was shown to be superior to ampicillin plus tobramycin in a controlled trial. [84] This drug covered 98% of the flora (including pneumococci), was more efficacious, and did not result in superinfection or nephrotoxicity. [84] This drug, or a similar third-generation cephalosporin, probably is the treatment of choice of suspected SBP. For cefotaxime, 2 g intravenously every 8 hours is very effective. [80], [85] A randomized controlled trial demonstrated a survival advantage if albumin is given intravenously (1.5 g/kg body weight at the time of detection of infection and 1 g/kg on day 3 of treatment) in addition to cefotaxime compared with cefotaxime alone. [86] The albumin appears to help prevent the renal failure that can develop in the cirrhotic patient with bacterial infection. After susceptibility testing results are available, a narrower-spectrum drug can usually be substituted. Pneumococci are sensitive to penicillin, and most *E coli* species are sensitive to ampicillin. Ceftriaxone has not been compared with cefotaxime in a randomized trial, but it appears to be effective if given in high enough dose, such as 2 g intravenously every 12 hours. [87] Amoxicillin-clavulanic acid is effective in treated SBP but is unavailable for parenteral use in the United States. [88] Oral antibiotic (ofloxacin, 400 mg twice daily for a mean duration of 8 days) treatment of SBP has been studied and found to be as effective as intravenous cefotaxime. [89] However, only "good risk" patients were entered into the randomized trial. Thirty-nine percent of patients with SBP who were screened for entry were excluded because of ileus, gut bleeding, shock, azotemia, or encephalopathy. This study was performed on inpatients. There is no information on outpatient treatment of SBP. A 2-day course of intravenous ciprofloxacin followed by 5 days of oral ciprofloxacin was found to be as effective as 7 days of intravenous ciprofloxacin in a randomized trial. [90] Optimal duration of therapy is becoming clearer. The ascitic fluid culture becomes negative after one dose of cefotaxime in 86% of patients. [49] The ascitic fluid PMN count, in general, drops exponentially after treatment is started such that the PMN count after 48 hours of therapy is always less than the pretreatment value in SBP treated with appropriate antibiotics. [49] A randomized controlled trial of 5 days versus 10 days of treatment documented that short-course treatment is as effective as long-course therapy. [80] When the setting, organism, and clinical response to treatment are typical, follow-up paracentesis is not necessary, and 5 days of treatment are usually enough. [91] Patients have even undergone liver transplantation after only 4 days of treatment with good results. [92]

Recurrence. All series of patients with SBP report recurrences. A prospective study, reported in 1988 from Barcelona, documented a 69% recurrence rate at 1 year. [93] An ascitic fluid protein concentration less than 1.0 g/dL was the best predictor of recurrence, just as it is a good predictor of a first episode. [46], [93] In view of this impressive recurrence rate, patients who survive SBP and who are otherwise candidates for liver transplantation should be considered high priority for liver transplantation before they have a fatal recurrence of SBP.

Prevention. The impressive recurrence rate of SBP has led to multiple trials of antibiotic prophylaxis. Oral quinolone prophylaxis (norfloxacin 400 mg/d) has been documented to prevent gram-negative bacterial infections in patients who have survived one SBP episode, in patients with low-protein ascites, and in patients with fulminant hepatic failure. [75] Norfloxacin (400 mg/d orally twice daily for 7 days) has been documented to prevent gram-negative bacterial infections in inpatients with variceal bleeding. [75] Trimethoprim-sulfamethoxazole orally 5 days per week and ciprofloxacin (750 mg) once per week have also been shown to prevent bacterial infections in high-risk patients with cirrhosis. [94] One double strength tablet of trimethoprim-sulfamethoxazole daily also appears to be effective. In an animal model, trimethoprim-sulfamethoxazole improved survival in the setting of cirrhosis with ascites. [95] Use of norfloxacin to prevent a recurrence of SBP has been calculated to be cost effective. [96] Unfortunately, use of antibiotics leads to selection of resistant flora and can lead to infection by resistant flora. This has been documented in patients and rats with cirrhosis. [97], [98] Although oral norfloxacin reduced ascitic fluid infection by approximately 60% in cirrhotic rats, treated rats developed enterococcal overgrowth in the gut, and, when they developed infection, enterococcus was cultured from their ascitic fluid and mesenteric lymph nodes. [98] In addition, norfloxacin did not improve survival in the animal model. [98] Many liver units are giving their transplant candidates continuous quinolone prophylaxis. There are no data to support this practice, unless the patient has had at least one SBP episode. [93] A retrospective study has shown that an important risk factor for posttransplant fungal infection is total dose of quinolone. [99] More data are needed, preferably a controlled trial, before we know whether to use quinolones liberally in patients awaiting liver transplantation. While we wait for the results of more studies, it is appropriate to use norfloxacin or trimethoprim-sulfamethoxazole once daily for prevention of recurrence of SBP and in inpatients with an ascitic fluid protein concentration lower than 1 g/dL and to use one of these agents twice daily for 7 days for patients with cirrhosis (with or without ascites) and significant gastrointestinal bleeding. [75] Some physicians give prophylactic antibiotics to cirrhotic patients at the time of variceal sclerotherapy. However, a randomized trial has shown that this is not necessary. [100] With use of short sclerotherapy needles and clean water for the endoscope, the risk of bacteremia is so low that prophylactic antibiotics are not warranted. In addition, variceal banding is even less likely to lead to bacteremia, and banding should replace sclerotherapy in view of its superior efficacy.

Spontaneous Bacterial Peritonitis Variants SBP variants include monomicrobial nonneutrocytic bacterascites (MNB), culture-negative neutrocytic ascites, secondary bacterial peritonitis, and polymicrobial bacterascites (see Table 46-6). [49], [72], [78] /SUP>, [101] The adjective *monomicrobial* is used to distinguish this variant of ascitic fluid infection from polymicrobial bacterascites (see later). In the older literature, MNB was either grouped with SBP or was called asymptomatic bacterascites. However, many patients with bacterascites have symptoms; therefore, the modifier *asymptomatic* does not seem appropriate. The flora of MNB is similar to that of SBP. [42], [72] Because of the mortality (22%–43%) associated with monomicrobial bacterascites and the finding that MNB can progress to SBP in a matter of minutes, treatment appears to be warranted in some patients. [72], [102] Because the PMN count is not elevated (by definition) in MNB, it is reasonable to use empiric antibiotics, such as cefotaxime 2 g intravenously every 8 hours, for patients with cirrhotic ascites who have *convincing signs or symptoms of infection* regardless of the PMN count in ascitic fluid. Empiric treatment can be discontinued after only 2 to 3 days if the culture remains negative. For patients who have asymptomatic monomicrobial bacterascites, paracentesis should be repeated for cell count and culture. If the PMN count has risen to 250/mm [3] or more, treatment should be started. Patients who have developed no PMN response and no clinical evidence of infection do not require treatment. These are the patients who have probably eradicated the colonization by their own immune defenses. [73] The diagnosis of culture-negative neutrocytic ascites (CNNA) is made when

1. The ascitic fluid culture grows no bacteria.
2. The ascitic fluid PMN count is greater than or equal to 250 cells/mm [3].
3. No antibiotics have been given (even a single dose usually makes the culture negative).
4. There is no other explanation for an elevated PMN count, such as hemorrhage into ascites, peritoneal carcinomatosis, tuberculosis, or pancreatitis (see Table 46-6). [101]

Previously, the PMN criterion for CNNA was the presence of more than 500 cells/mm [3]; however, a value of greater than or equal to 250 cells/mm [3] was supported by a prospective study and is now viewed as the most appropriate criterion. [55] Inadequate culture technique explains the majority of episodes of CNNA. [42] In hospitals that use the older "conventional" culture method, negative cultures of infected ascites are common. Because improper culture techniques result in negative cultures, one of the most important methods to reduce the prevalence of CNNA in a hospital that is still using the conventional method of culture is to convince the microbiology laboratory to convert to the optimal method of culture—bedside inoculation of blood culture bottles with ascitic fluid. [42], [43] Patients who have CNNA despite good culture technique, in general, have spontaneously resolving SBP. This does not occur very often, but it is a real phenomenon. [73] Initially, one does not know that the culture is destined to be "no growth" in a patient with this variant of ascitic fluid infection. Therefore, empiric treatment should be given. When the preliminary report demonstrates no growth, it is helpful to repeat the paracentesis to assess the response of the PMN count to therapy. A decline in PMN count confirms a response to treatment and probably warrants a few more days of therapy. A stable PMN count, especially if there is not a predominance of PMNs, indicates that a nonbacterial (or mycobacterial) cause of the neutrocytosis is present. Biopsy and culture for tuberculosis may be appropriate. Secondary bacterial peritonitis is surgical peritonitis in patients with ascites. [49] Secondary peritonitis is treated with antibiotics *and* surgery, whereas SBP is always treated *only* with antibiotics. [34], [49] Performing a laparotomy in SBP or treating secondary peritonitis only with antibiotics usually results in the death of the patient. [49] Secondary bacterial infection of ascitic fluid can occur in any patient with ascites, even patients with noncirrhotic ascites. [49] Host defenses have little bearing on outcome when the gut perforates into ascitic fluid; the patient will die without surgical intervention. The possibility of secondary peritonitis should be *considered* in any ascites patient with peritonitis (see Fig. 46-4). However, because of the rarity of SBP in peritoneal carcinomatosis or cardiac ascites, a surgical source of peritonitis should be *presumed* in patients with these diagnoses until proved otherwise. [59], [61] Surprisingly, even with free perforation of the colon into ascitic fluid, patients do not develop a classical surgical abdomen. [49] Peritoneal signs require contact of inflamed visceral and parietal peritoneal surfaces. This does not happen when there is a large volume of fluid present. Therefore, clinical signs and symptoms do not separate patients with secondary peritonitis from those with SBP. Gut perforation can be suspected and pursued if ascitic fluid analysis

meets two of the following three criteria (see Fig. 46-4): total protein greater than 1 g/dL, glucose less than 50 mg/dL, and LDH greater than 225 mU/mL (or more than the upper limit of normal for serum). [49] Multiple organisms are cultured from ascitic fluids in the setting of a perforated viscus except for gallbladder rupture. [16], [49] If multiple organisms and PMNs are seen on Gram stain, the likelihood of perforation is very high. Brown ascitic fluid with a bilirubin concentration greater than 6 mg/dL and greater than the serum level is indicative of biliary or gut (especially upper gut) perforation into ascites. [16] The initial ascitic fluid analysis is very helpful in delineating which patients are likely to have ruptured gut. As noted earlier (see section "Radiologic Assessment"), these patients need an emergency radiologic evaluation, that is, within minutes, to confirm and localize the gastroduodenal or colonic site of rupture. If perforation is documented, emergency intervention is mandatory to maximize survival; survivors have been reported. [48], [49] Patients with nonperforation secondary peritonitis tend not to have a diagnostic initial ascitic fluid analysis. [48], [49] Fortunately, it is less urgent to make the diagnosis of secondary peritonitis in nonperforation peritonitis compared with perforation peritonitis. Therefore, there may be time to evaluate the response of the ascitic fluid culture and PMN count to treatment. These parameters have been shown to be helpful in distinguishing secondary from spontaneous peritonitis. [48], [49] The best time to perform a single repeat paracentesis to assess response is after 48 hours of treatment. [49] At 48 hours, essentially every patient with SBP who has been treated with an appropriate antibiotic will have a PMN count lower than the pretreatment value and the culture will be negative; in contrast, in secondary peritonitis, the culture remains positive, and the PMN count rises. [49] Patients suspected of having secondary peritonitis require broader-spectrum empiric antibiotic coverage than those with SBP, in addition to an emergency evaluation to assess the need for surgical intervention (see earlier). Cefotaxime and metronidazole together provide excellent initial empiric therapy of suspected secondary peritonitis while the radiologic workup is under way. [49] Polymicrobial bacterascites should be suspected when

1. The paracentesis is difficult because of ileus or a traumatic tap.
2. Stool or air is aspirated into the paracentesis syringe.
3. Multiple organisms but no PMNs are seen on the Gram stain (see Table 46-6). [78]

Polymicrobial bacterascites is essentially diagnostic of inadvertent gut perforation by the paracentesis needle. [78] Fortunately, this variant of ascitic fluid infection is the rarest; only 10 cases (0.6%) were found among 1578 paracenteses in a retrospective study. [78] Surprisingly, needle perforation of the bowel is relatively well tolerated. Only 18% (2) of 11 patients with needle perforation of the gut into ascitic fluid developed peritonitis; only 0.07% (2) of 2774 paracentesis procedures caused peritonitis. [78] Neither of these two patients required laparotomy, and none died because of the paracentesis-related peritonitis. [78] If needles larger than 22 gauge had been used, the results may have been different. It appears that patients with low-protein ascitic fluid are at most risk of developing a PMN response and clinical peritonitis related to needle perforation of the gut. [78] Most of the patients with high-protein ascites, that is, more than 1 g/dL, did not even receive antibiotics and yet did well. However, most physicians would probably feel uncomfortable withholding antibiotic treatment if needle perforation is suspected. If a decision to treat is made, anaerobic coverage should be included, such as cefotaxime and metronidazole. If a decision not to treat is made, follow-up paracentesis is helpful in following the PMN count and culture. If the number of organisms does not decrease or a PMN response occurs, antibiotic treatment should be initiated.

Tense Ascites

Some patients ignore their growing abdomens and do not seek medical attention until they can no longer breathe comfortably because of the pressure the fluid exerts on the diaphragm. This condition is called *tense ascites.* Truly tense ascites requires urgent treatment—therapeutic paracentesis. Tense ascites can be drained (even 20 L or more) without untoward hemodynamic effect. [103], [104], [105] and [106] Although discarding all the fluid obtained from patients who have difficulty synthesizing protein may be problematic, therapeutic paracentesis of cirrhotic ascites is less problematic than older textbooks of medicine would lead the reader to believe. The myth of paracentesis-related hemodynamic disasters was based on observations in small numbers of patients, probably coincidences. [104]

Patients who develop tense ascites are frequently the least compliant with or the most refractory to conventional therapy. Careful attention should be given to the education of these patients regarding the chronicity of their disease as well as diet and diuretic therapy.

Abdominal Wall Hernias

Abdominal wall hernias (umbilical and inguinal) are common in patients with ascites and may cause serious complications. In one study, 17% of cirrhotic patients with ascites were found to have umbilical hernias on admission. [107] During follow-up, 14% of these patients' hernias incarcerated, 35% developed skin ulceration, and 7% ruptured. [107] Unfortunately, attempts at repair of the hernias are fraught with complications. If the patient is a candidate for liver transplantation and the hernia is not thin walled or incarcerating, hernia repair can be postponed until the time of transplant.

If hernia repair is planned other than at the time of transplant, the ascites should be medically removed preoperatively, because the hernia recurs in 73% of patients who have ascites at the time of hernia repair but in only 14% of patients who have no ascites at the time of repair. [108] If skin ulceration develops, surgery should be performed on a semiemergency basis. Emergency surgery should be performed for hernia incarceration or rupture.

Hepatic Hydrothorax

Small pleural effusions are common in patients with cirrhotic ascites. They are usually unilateral and right-sided, but occasionally they may be bilateral with the right-side predominating. Only rarely is there a unilateral left-sided effusion; tuberculosis and pancreatic ascites are more common causes of left-sided effusions. [109] When the effusion is large and obscures most of the right lung, it is referred to as *hepatic hydrothorax.* This complication tends to occur in patients who are the least compliant with or the most refractory to therapy. This condition is thought to result from a congenital weakness in the membranous portion of the right diaphragm, which ruptures because of the elevated intra-abdominal pressure associated with ascites. [110] Occasionally, this results in sudden shortness of breath associated with decompression of the abdomen. On rare occasions, no ascites is detected in the presence of a huge pleural effusion; most likely this is caused by a one-way valve mechanism in the diaphragm.

The main symptom associated with hepatic hydrothorax is shortness of breath. Infection of this fluid is unusual. [111] When it does occur, it is usually a result of SBP.

The fluid resembles ascites, but the analysis is not identical to that of the ascitic fluid because the pleural fluid is in a system with different pressures than the portal bed. The pleural fluid protein is usually 0.75 to 1.0 g/dL higher than that of ascitic fluid from the same patient. [110]

Treatment of hepatic hydrothorax is usually more difficult than expected. Some authors have recommended tetracycline sclerosis using a chest tube. However, chest tube insertion with suction has been reported to lead to serious fluid and protein depletion and death in two patients. [112] Once a chest tube is inserted, too often it becomes very difficult to remove. Clamping the tube may cause fluid to leak around the tube's insertion site. Peritoneovenous shunt can be considered in the patient with large-volume ascites, but it is frequently accompanied by perioperative complications and shunt failure (see later). Direct surgical repair of the defect can be considered, but too often these patients are not good operative candidates. Sodium restriction and diuretics are the most effective conservative form of therapy of hepatic hydrothorax. A treatment for diuretic-resistant ascites, transjugular intrahepatic portasystemic stent shunt (TIPS), has been reported to be effective for hepatic hydrothorax (see later). [110] Thorascopic suturing of the diaphragmatic defect has been reported to be effective in an uncontrolled study. [113]

TREATMENT OF THE PATIENT WITH ASCITES

Not all forms of ascites respond to the same treatment. Therefore, the correct diagnosis of the cause of ascites formation is important. The diagnosis is usually apparent based on the history, physical examination, and the ascitic fluid analysis.

Ascites Not Related to Portal Hypertension

The most common form of low-albumin gradient ascites is *peritoneal carcinomatosis.* Peripheral edema in these patients responds to diuretics, but the ascites usually does not respond to diuretics; edema-free patients treated with diuretics lose only intravascular volume without loss of ascites. [8] The mainstay of treatment of peritoneal carcinomatosis is therapeutic paracentesis. [7], [103] Except for patients with ovarian carcinoma, patients with peritoneal carcinomatosis live only a matter of weeks; therefore, the total number of paracenteses required to minimize symptoms is not great. Patients with ovarian cancer may have a good response to debulking and chemotherapy. [7] Peritoneovenous shunts are said to be effective in malignant ascites and are associated with less morbidity than in cirrhotic ascites [114]; however, in view of the very short life-expectancy of these patients, hospitalization for installation of a shunt may not be appropriate.

Nephrotic ascites is rare and is also notable in that it is perhaps the only form of nonportal hypertension–related ascites that does respond to salt restriction and diuretics. [20]

Tuberculous peritonitis requires antituberculous therapy; there is no point in using diuretics unless the patient has concomitant portal hypertension from cirrhosis. *Pancreatic ascites* may resolve spontaneously or may respond to somatostatin infusion, but if it results from a duct leak it may require endoscopic stenting or operative intervention. [115] A *postoperative lymphatic leak* may also resolve spontaneously, but on occasion it may require surgical intervention or peritoneovenous shunting. [17] *Chlamydia peritonitis* is cured by tetracycline therapy. [18] *"Nephrogenous" ascites* (dialysis ascites) may respond to vigorous dialysis or kidney transplantation. [19]

Portal Hypertension–Related Ascites

Treatment of the Underlying Liver Disease The first step in treating portal hypertension–related ascites is to treat the underlying liver disease. In many patients in the United States, this requires convincing the patient to stop drinking alcohol. Patients with two liver insults, such as alcohol plus hepatitis C, should cease alcohol consumption. With time and healing of the reversible component of alcoholic liver disease, the ascites may resolve or at least convert from refractory to nonrefractory. [26] Patients with autoimmune chronic active hepatitis, iron-storage disease, or Wilson disease should receive the specific therapy for those diseases. By the time patients with nonalcoholic liver disease develop ascites, however, the amount of reversible component to their disease is minimal, and liver transplantation must be considered.

Determination of the Precipitating Cause of Ascites Formation In the initial management of ascites, it is also of value to determine the precipitating cause of ascites formation. Frequently, ascites accumulates during an episode of dietary indiscretion or discontinuation of diuretics; patients may decide that soup or whole milk is exactly what they think they need, and will consume large amounts of these high-salt foods. Education regarding these matters may help to prevent future hospitalizations.

Sodium Balance and the Importance of Dietary Sodium Restriction The importance of sodium balance in the management of patients with fluid overload cannot be overemphasized. [31, 116, 117] Water follows sodium passively. Sodium that enters the body must be excreted, or water will be retained. Nonurinary (gut, respiratory, skin) sodium excretion is only approximately 10 mmol/d in patients with cirrhosis and ascites. [118] Therefore, if sodium intake can be limited to 10 mmol/d and urinary excretion is 0 mmol/d, sodium balance is achieved and weight is stable. If urinary excretion of sodium is greater than 10 mmol/d beyond dietary intake, weight loss occurs. If urinary excretion of sodium is less than 10 mmol/d beyond dietary intake, weight gain occurs. Patients with no urine sodium excretion can be maintained free of ascites if they will follow a 10 mmol/d sodium diet. However, a 10 mmol/d sodium diet is not practical outside of a metabolic ward. Diuretics are used to increase urinary sodium excretion to permit a more liberal diet and yet achieve weight loss and a reduction in fluid overload (see later). [31, 116, 117] Twenty-four-hour urinary sodium measurements are useful in patients with portal hypertension–related ascites to assess the degree of sodium avidity, to monitor response to diuretics, and, indirectly, to assess compliance with diet. [116, 120] Even outpatients can collect complete specimens in 67% of instances if they are given written and verbal instructions, a 3-L container, and written orders for testing. [120] A "spot" urinary sodium concentration test may be a satisfactory substitute for a 24-hour collection. One study has shown that if the random urine sodium concentration is greater than the potassium concentration, 24-hour excretion is greater than 78 mmol/d in 95% of instances. [120] If diuretic treatment progresses satisfactorily, one does not need to know the urinary sodium excretion. However, if diuretic therapy is not progressing satisfactorily, this can result from inadequate natriuresis, failure of the patient to restrict sodium intake properly, or both. [117, 118] Monitoring 24-hour urinary sodium excretion (or urinary sodium/potassium ratios) and daily weight will usually clarify the problem. The completeness of 24-hour collections can be monitored by measurement of creatinine excretion. Male patients with cirrhosis should excrete 15 to 20 mg/kg creatinine body weight/d, and women should excrete 10 to 15 mg/kg/d. Patients who gain fluid weight despite excreting more than 78 mmol/d of sodium in the urine or despite urinary sodium/potassium ratios greater than 1.0 are eating more sodium than 88 mmol/d. [117, 118] In this setting, attention should be focused on diet education, not second-line treatment.

Diet In portal hypertension–related ascites, weight change is directly and predictably related to sodium balance. Dietary sodium restriction is, therefore, essential. The patient and cook (if different from the patient) should be educated by an enthusiastic dietitian. The more contact the dietitian has with the patient and cook, the better. One patient-dietitian encounter is not enough. Although a diet containing 500 mg (22 mmol)/d sodium is feasible in a hospital setting, it is an unrealistic goal for most outpatients. The advantage of a less-restricted, 2000 mg (88 mmol)/d hospital diet is the opportunity to establish a consistent diet and matching diuretic regimen that will continue to be effective in the patient's home environment. I use an 88 mmol/d sodium diet routinely. [117, 118]

No Indiscriminate Fluid Restriction Indiscriminate fluid restriction is inappropriate. Fluids need not be restricted unless serum sodium drops to less than 120 mmol/L. [31] Unless the decline in sodium is very rapid, cirrhotic patients do not have symptoms from hyponatremia until the sodium is well below this level. To restrict the fluids of everyone serves only to alienate patients, nurses, and dietitians. There is no evidence that fluid restriction speeds diuresis. It is the sodium restriction that is important.

Diuretics Spironolactone is the single best diuretic for patients with cirrhosis and ascites, starting with a minimum of 100 mg/d. Controlled trials have documented the superiority of spironolactone over furosemide for single-agent treatment. [121] Amiloride, starting at 10 mg/d, is more expensive (approximately fourfold) but does not cause painful gynecomastia, as spironolactone occasionally does. Spironolactone remains the mainstay of treatment of patients with cirrhosis and ascites. The half-life of spironolactone and its active metabolites is up to 5 days; it makes no sense to administer the drug multiple times per day. [122] Single daily doses of pills are most appropriate and enhance compliance. Because of the drug's long half-life, it takes almost 1 month for a patient to reach steady state regarding spironolactone effect. [122] It takes 2 weeks for any effect to be seen. In general, spironolactone *and* furosemide are used together to minimize the interval between starting therapy and natriuresis. The initial doses are 100 mg/d spironolactone and 40 mg/d furosemide, then increasing each drug simultaneously as needed. If weight loss or urine sodium concentration is inadequate, diuretics are increased up to a "ceiling" dose of 400 mg/d spironolactone and 160 mg/d furosemide. The ratio of spironolactone and furosemide can be adjusted to correct serum potassium problems. One hundred–milligram spironolactone pills are available. Patients with intrinsic kidney disease, such as patients with diabetes or IgA nephropathy, may become hyperkalemic on less spironolactone than patients without kidney disease. Combined with a 2000 mg/d sodium diet, this regimen will achieve successful diuresis in more than 90% of cirrhotic patients. [123] Intravenous furosemide causes an acute reduction of glomerular filtration rate in patients with cirrhosis; I avoid using intravenous diuretics if at all possible. [124] If rapid weight loss is desired, therapeutic paracenteses should be performed (see later). For patients who have massive edema, there is no limit to the diuretic-induced daily weight loss; once the edema has resolved, 0.5 kg/24 h is probably a reasonable maximum. [125] If patients develop encephalopathy, serum sodium less than 120 mEq/L with fluid restriction, or serum creatinine greater than 2.0 mg/dL, diuretics are usually stopped, and the situation is reassessed. Potassium abnormalities are seldom prohibitive because of the ability to adjust the ratio of the diuretics or to discontinue spironolactone in patients with intrinsic renal disease. Diuretic treatment will fail in many of the patients who develop serious complications of this therapy, and these patients will require second-line therapy. Prostaglandin inhibitors, such as nonsteroidal antiinflammatory drugs, should not be used in patients with ascites because they curtail diuresis, they may promote renal failure, and they commonly cause gastrointestinal bleeding. [126, 127] Complete removal of ascites may not be readily obtainable. However, theoretically, the concentration of ascitic fluid through diuresis increases the fluid's opsonic activity tenfold and may be of value in attempting to prevent SBP. [128] Because the waiting times for liver transplantation are 18 to 24 months in some parts of the United States and because 50% of patients with cirrhosis and ascites will die in 24 months, patients should be considered for liver transplantation after they have developed ascites (Fig. 46-6). [129]

FIGURE 46-6. Algorithm for the treatment of patients with cirrhosis and ascites. *TIPS,* transjugular intrahepatic portasystemic stent shunt. (From ref. [31].)

Refractory Ascites

Patients in whom inpatient diuretic treatment fail are labeled diuretic-resistant or refractory and are treated with second-line therapy. *Failure* is defined as minimal or no weight loss despite maximum tolerable doses of diuretics with urine sodium excretion approaching 0 mmol/d. [117, 118, 130, 131]

Liver Transplantation Patients with refractory ascites have a 50% 6-month survival and should be even more highly prioritized for liver transplantation, if they are otherwise good candidates for the procedure. [132] Other options for diuretic-resistant patients include therapeutic paracenteses, TIPS, peritoneovenous shunts, and surgical portacaval shunt (see Fig. 46-6).

Therapeutic Paracentesis Until the late 1940s, therapeutic paracentesis was essentially the only available therapy for ascites. [116] In the early 1950s, diuretics became available coincidentally with reports of complications of therapeutic paracentesis. [116] Therapeutic paracentesis rapidly fell out of favor as a treatment option for patients with ascites. In the 1980s, interest was renewed in therapeutic paracentesis. Scientific data regarding large-volume (5-L) paracentesis were reported. [133] Patients were treated with daily paracentesis followed by colloid infusion or a single paracentesis without intravenous colloid infusion. These patients tolerated large-volume paracenteses very well, just as patients have done since the time of the ancient Greeks. [116] In fact, if minor asymptomatic changes in electrolytes and serum creatinine are considered complications of therapy, therapeutic paracentesis is reported to be safer than diuresis, based on the randomized controlled trial performed

in Barcelona. [106] If the goal of treatment is to achieve complete removal of ascites while the patient is still in the hospital, paracenteses are also faster than diuresis. [106] Technically, performing a therapeutic paracentesis is similar to performing a diagnostic paracentesis, except a larger-bore needle (15–16 gauge), is used and much greater amounts of fluid are removed. Collapse-resistant tubing is used to connect the paracentesis needle to 2-L vacuum bottles. Vacuum speeds the paracentesis; 5 L can be removed in 20 to 40 minutes. Newer paracentesis needles and other equipment items are now available in the United States (see section " Technique"). The removal of 5 L of fluid by therapeutic paracentesis is considered "large volume." [106] Total paracentesis, that is, *removal of all ascites, even more than 20 L,* can be performed safely. [133] Patients with tense ascites and avid sodium retention represent a small subset of patients with ascites, however. Because more than 90% of these patients respond to a routine sodium-restricted diet and diuretics, routine medical therapy is the appropriate therapy of this large majority. [31], [117], [118], [123] In addition, therapeutic paracentesis lacks the ascitic fluid opsonin-conserving advantage of diuresis; removing and discarding ascitic fluid opsonins by means of therapeutic paracentesis could theoretically predispose patients to SBP. [134] It is my opinion that serial paracenteses should be reserved for patients who really need them, that is, the patients with truly diuretic-resistant ascites. These patients have a 24-hour urine sodium that approaches zero despite maximum doses of diuretics.

Albumin versus no albumin. In the first of their therapeutic paracentesis studies, the Barcelona group administered intravenous albumin (approximately 10 g/L of ascites removed) after each 5-L paracentesis. [106] In a subsequent study, these investigators randomized patients who received therapeutic paracentesis to albumin versus no albumin. [135] Again, if minor changes in electrolytes and serum creatinine are considered complications of therapy, the no-albumin group developed significantly more complications. Patients who did not receive albumin developed significant increases in renin and aldosterone, indicating evidence of volume depletion. However, the electrolyte imbalance and plasma renin increases were asymptomatic, and risk of progression to renal failure or death was not different between groups. [135] In addition, 31% of patients in this study received paracentesis for tense ascites in the absence of diuretic therapy. [135] Many of these patients could have been diuretic sensitive. In contrast to the results in Barcelona, a more recent study did not demonstrate the plasma renin activity rise after a single 4- to 6-L paracentesis in patients who were truly resistant to diuretics. [136] The key to explaining the difference between these studies may be found in a study demonstrating that patients with advanced cirrhosis have "circulatory hyporeactivity," whereas patients with less advanced disease are more sensitive to changes in intravascular volume. [137] It is possible that patients with truly diuretic-resistant ascites do not develop changes in plasma hormones after paracentesis in the absence of albumin infusion because of their "circulatory hyporeactivity," whereas patients with diuretic-sensitive ascites do develop changes in these hormones. The subset of patients who develop a rise in plasma renin after paracentesis has been shown to have a poor prognosis. [138] However, no study has demonstrated a survival advantage for patients who have received albumin after paracentesis. There has only been indirect evidence linking albumin infusion to a survival advantage; serial paracenteses without albumin infusion can lead to a rise in plasma renin in patients with tense ascites (but not necessarily diuretic-resistant ascites), and a rise in plasma renin is associated with a poor prognosis. [135], [138] This indirect evidence does not prove the need for postparacentesis albumin infusion. [139], [140] More convincing data involving appropriate subgroups of patients (e.g., truly diuretic-resistant patients) and regarding clinically relevant issues (e.g., survival) rather than asymptomatic laboratory abnormalities are required before albumin or other plasma expanders can be recommended. In addition, the proponents of albumin infuse one half of the volume of albumin immediately after the procedure and the remainder 6 hours later. [141] This approach converts an otherwise rapid outpatient procedure into an all-day clinic visit or a brief hospitalization. Albumin is also quite expensive and has become more expensive as its use has increased. The decision whether to infuse albumin is important from financial and logistical points of view.

Transjugular Intrahepatic Portasystemic Stent Shunt An interventional radiologic procedure that reduces portal pressure, TIPS, may be efficacious for treatment of patients with diuretic-resistant ascites. [142] This procedure consists of the following:

1. Inserting a 60-cm-long metal needle from the right jugular vein into the hepatic vein
2. Creating a fistula between the high-pressure portal system and the low-pressure hepatic venous system
3. Dilating the fistula
4. Inserting a stent into this shunt
5. Expanding the stent.

TIPS can dramatically decrease portal pressure and can reduce the tendency to retain sodium. [142] However, it does worsen the hyperdynamic circulation and lower blood pressure. These opposing effects of TIPS on factors that aggravate sodium retention would be predicted to lead to a nonuniform response of patients to this procedure. In addition, patent shunts have an approximately 25% chance of causing hepatic encephalopathy, some of which is very refractory to medical therapy. [143] Stenosis and occlusion occur in up to 50% of patients and lead to repeat cannulations and balloon dilations of the stent. [143] Conversely, use of medical-grade carbon dioxide as a contrast medium has reduced the contrast nephropathy associated with the procedure and reduced morbidity. Two randomized controlled trials of TIPS for this indication have had conflicting results. [144], [145] However, the larger and more recent study demonstrates a survival advantage compared with therapeutic paracenteses. [145] This has led to renewed enthusiasm for this procedure. A multicenter trial in the United States is nearing completion.

Peritoneovenous Shunts In the mid-1970s, the peritoneovenous shunt was promoted as a new "physiological" treatment in the management of ascites. Reports of complications of shunt insertion and shunt failure rapidly diminished enthusiasm for this treatment. Reported complications include pulmonary edema, variceal hemorrhage (from fluid overload), disseminated intravascular coagulation, thromboembolic phenomena including superior vena cava thrombosis, pseudocyst formation, and peritoneal fibrosis. [146] Unfortunately, shunt failure from thrombosis continues to be a serious problem. Most shunts clot in less than 1 year's time. "Second-generation" shunts, such as Denver shunts, have not reduced the shunt failure rate resulting from thrombosis. [147] Two large-scale randomized trials have documented no improved survival in patients with shunts compared with medically treated controls. [123], [148] Removal of most of the ascitic fluid intraoperatively before shunt insertion, with use of perioperative antiplatelet therapy, has reduced the incidence of disseminated intravascular coagulation, and replacement of ascites with saline and administration of intraoperative intravenous furosemide have decreased the incidence of pulmonary edema. [149] Peritoneovenous shunting is reserved for the very small group of patients in whom both diuretic *and* paracentesis therapy fail and who are not candidates for TIPS or liver transplantation.

Hepatorenal Syndrome

Hepatorenal syndrome is one of the terminal complications of advanced liver disease, most commonly occurring in patients with cirrhosis or alcoholic hepatitis. It has been the source of much confusion and has perhaps received more attention than it deserves. It is simply the mode of exodus of patients with advanced liver disease, when they do not develop a faster cause of death. The kidney is an innocent bystander in a very distorted milieu; transplanting a kidney from a patient with hepatorenal syndrome into a patient without liver disease and transplanting a normal liver into a patient with hepatorenal syndrome both lead to resolution of renal failure in the recipient. [150], [151] The concept that patients "die of hepatorenal syndrome" is erroneous. These patients are dying of liver failure *with* renal failure rather than dying *of* renal failure.

Pathophysiology Hepatorenal syndrome is the terminal phase of the spectrum of functional renal impairment that is characteristic of cirrhosis. As liver disease worsens, renal function deteriorates such that patients progress from compensated cirrhosis to diuretic-sensitive ascites to diuretic-resistant ascites and finally to hepatorenal syndrome. [152] This progression is relatively silent, with fluid retention and azotemia providing the evidence that the process is occurring. Vasodilation-related hypotension worsens as liver disease advances and progressive renal ischemia occurs.

Diagnosis The International Ascites Club has developed the following criteria for the diagnosis of hepatorenal syndrome:

1. Advanced chronic or acute liver failure with portal hypertension
2. Serum creatinine greater than 1.5 mg/dL or creatinine clearance lower than 40mL/min
3. The absence of shock, bacterial infection, nephrotoxic drug exposure, or rapid loss of fluid through the gut or kidneys
4. No sustained improvement in renal function with withdrawal of diuretics and plasma expansion with 1.5 L of isotonic saline
5. Proteinuria less than 500mg/d and no ultrasound evidence of obstructive uropathy or parenchymal renal disease. [152]

There is a misconception that hepatorenal syndrome is usually characterized by oliguria. This concept has been perpetuated despite data to the contrary. Actually, oliguria in hepatorenal syndrome is usually an immediate premortem phenomenon. Oliguria may be a manifestation of the renal failure associated with shock or exposure to a nephrotoxin. This acute tubular necrosis is frequently misdiagnosed as hepatorenal syndrome, but, as indicated earlier, these insults to the kidney preclude the diagnosis of hepatorenal syndrome (Fig. 46-7). When actual urine volumes were measured sequentially before and during evolution of hepatorenal syndrome in a study published in 1964, "… oliguria was the rule only during the late azotemic phase" when 52% of patients produced less than 500 mL/d. [153] In the preazotemic phase, no patient had a urine volume of less than 500 mL/d; in the early azotemic phase, only 11% of patients had a urine volume of less than 500 mL/d. [153]

FIGURE 46-7. Algorithm for the diagnosis and treatment of patients with suspected hepatorenal syndrome.

Hepatorenal syndrome usually develops in patients with cirrhosis and long-standing ascites. A prospective study documented an 18% 1-year and a 39% 5-year cumulative probability of hepatorenal syndrome in this setting. [154] Patients with cirrhosis who develop renal failure in the absence of prior ascites have a cause of renal failure other than hepatorenal syndrome. Much has been written about urinalysis in the differential diagnosis of azotemia in the setting of cirrhosis. Usually, the criteria for distinguishing one condition from another are placed in a table with no reference to the original data. One original study that has been quoted was published in 1937 at a time when diagnoses such as cholemic nephrosis were used. [155] It is difficult to find useful original data. In general, the urine protein is less than 500 mg/d, [152] and the urine sediment is "inactive" with only an occasional cast. In contrast, in acute tubular necrosis, the sediment is more "active" with more casts and cellular debris. If white blood cells are prominent in the urine, cystitis or even urosepsis may be present; bacterial infection in the patient with cirrhosis is regularly complicated by hepatorenal syndrome. [156] If red blood cells are present in large numbers along with protein but in the absence of white cells, the patient may have parenchymal renal disease resulting from IgA nephropathy. [157] Even the urine sodium concentration of less than 10 mmol/L, which is so often quoted as an important component of the diagnosis of hepatorenal syndrome, is not as useful as one would hope. Patients with urine sodium greater than 10 mmol/L have been reported. [158] Patients who have hepatorenal syndrome and who develop superimposed acute tubular necrosis may have a urine sodium concentration lower than 10 mmol/L. It has been my experience that many, if not most, patients who are labeled as having hepatorenal syndrome actually have a different diagnosis, most commonly diuretic-induced azotemia. Shock and nephrotoxin exposure are probably the next most common causes of azotemia that masquerades as hepatorenal syndrome. Parenchymal renal disease such as IgA nephropathy or diabetic nephropathy have also been misdiagnosed as hepatorenal syndrome. The relative stability of the azotemia and the abnormalities in the urinalysis help to distinguish parenchymal renal disease from hepatorenal syndrome. Before a patient is labeled as having hepatorenal syndrome, the International Ascites Club criteria should be fulfilled.

Treatment Patients suspected of having hepatorenal syndrome, based on serum creatinine greater than 1.5 mg/dL in the setting of advanced liver disease (see Fig. 46-7), should undergo the following:

1. Withdrawal of diuretics and nephrotoxic drugs
2. Urinalysis with microscopy and sodium concentration
3. Renal ultrasonography
4. Intravenous fluid challenge with 1.5 L of isotonic saline or perhaps 50 g of albumin.

A central line could be placed for monitoring of filling pressures, but this is seldom done unless there has been massive loss of fluid or there are plans for hemodialysis (see later). Serum urea and creatinine are monitored daily to assess the response over time. If the urea and creatinine continue to rise, there are three main therapeutic options:

1. Infusion of a vasoactive agent
2. Transjugular intrahepatic portosystemic stent shunt
3. Liver transplantation.

Clearly, liver transplantation is not seriously considered if there are psychosocial contraindications. If the patient is a candidate for liver transplantation and has not undergone evaluation, this should be urgently initiated. Transplantation is the most definitive treatment for hepatorenal syndrome. [151] However, a vasoactive agent is usually given whether transplantation is a possibility or not, because patients wait days or even weeks for an available organ. Intravenous dopamine by continuous infusion was used in this setting in the past, but parenteral octreotide and oral midodrine have been used with better efficacy, according to a study with historical controls. [159] In this study, octreotide was started at a dose of 100 µg subcutaneously three times daily and was increased to 200 µg three times daily. Midodrine was given at a dose of 7.5 mg three times daily and was increased as needed to 12.5 mg three times daily. Midodrine can theoretically cause hypertension, but I have not encountered this as a problem. These patients are very hypotensive and remain hypotensive on this regimen at these doses. Octreotide can also be given by continuous infusion, at a dose of 25 to 50 µg/h. [160] The optimal duration of treatment is not clear. If the azotemia does not improve within a few days of starting treatment, there is no point in continuing it. If there is a response, it appears to be useful to continue treatment for a few weeks. Patients have received it for months. If there is a response but treatment is stopped too soon, azotemia will recur. If diuretics are restarted during this treatment, azotemia will recur. Stable or improving renal function in patients with serum creatinine less than 2.0 mg/dL appears to be required before diuretics can be safely restarted, in my experience. In general, use of vasoactive agents simply "buys some time" for recovery of some reversible component of the liver (or unrecognized renal) injury. If there is no reversible component, this form of treatment may be futile or only of transient benefit. Patients awaiting liver transplantation should probably remain on the regimen until an organ is available. Anecdotally, this regimen can prevent the need for dialysis. Other vasoactive agents, such as terlipressin or ornipressin, have been used in Europe but are not available in the United States. TIPS has been reported in nonrandomized studies to reverse hepatorenal syndrome. [161] In view of the importance of portal hypertension in the pathogenesis of the process and the ability of TIPS to lower portal pressure, this form of treatment is appealing. However, randomized trials are needed. Many treatment options and anecdotes of success in treating hepatorenal syndrome have been disappointing when they are studied scientifically. Diuretic-induced azotemia masquerading as hepatorenal syndrome will respond to simple removal of diuretics. If another treatment is given in addition and the patient is (incorrectly) labeled as having hepatorenal syndrome, the additional treatment may be inappropriately given credit for the success. If TIPS is used for treatment of hepatorenal syndrome, the amount of iodinated contrast used during the procedure should be minimized. TIPS has a notoriously high mortality in the setting of alcoholic hepatitis and should be avoided in these patients; a new nomogram has been developed to predict 90-day survival after TIPS. [162] The peritoneovenous shunt failed to improve survival in patients with hepatorenal syndrome in the Veterans Administration randomized trial and is no longer advocated for treatment of this condition. [123] Hemodialysis is regularly discussed among the treatment options for patients with hepatorenal syndrome but is seldom used, except immediately before liver transplantation. Patients with this degree of liver failure are difficult to dialyze because of hypotension, and survival is very poor without eventual liver transplantation. [163] Continuous venovenous hemofiltration is better tolerated but very expensive because a dialysis nurse must be at the bedside continuously. [164] As indicated earlier, liver transplantation is the most definitive treatment for patients with hepatorenal syndrome. [151] Survival can be similar to that of patients who undergo liver transplantation without renal failure. [165]

SUMMARY AND CONCLUSIONS

The development of ascites in a patient who has cirrhosis and who is otherwise a good candidate for liver transplantation should lead to evaluation for transplantation. Patients should be rapidly prioritized for liver transplantation once they develop refractory ascites. Diet education and diuretics are the mainstays of treatment for patients who await transplantation and for those who are not candidates for the procedure. Serial therapeutic paracenteses are effective in controlling ascites in patients who are truly diuretic resistant. TIPS is a promising option for treatment of diuretic-resistant ascites, but its final place in our treatment armamentarium remains to be discerned.

CHAPTER 47

Umaprasanna S. Karnam and K. Rajender Reddy

APPROACH TO THE PATIENT WITH A LIVER MASS

With the increasing use of imaging modalities for evaluation of various abdominal conditions, more *liver masses* are being recognized. These lesions may be small or large and may or may not be the cause of patient's symptoms. They can occur in patients with no underlying liver disease or in those with recognized chronic liver disease. They challenge the clinical acumen of many a clinician, the novice as well as the expert. Although most of the incidentally noted masses are benign, a definitive diagnosis has to be established to reassure the patient and also to be certain that a radiologically observed lesion is not malignant. In an era of cost-effective medical practice, it behooves the physician to use the most appropriate diagnostic tools associated with minimal morbidity to reach an accurate diagnosis. This chapter is devoted to the most common liver masses found in clinical practice and the advantages and disadvantages of the various diagnostic modalities, and it addresses the approach to evaluation of liver masses in special circumstances. Liver masses can be of epithelial or mesenchymal origin, and they may be benign or malignant (Table 47-1).

BENIGN TUMORS	MALIGNANT TUMORS
Epithelial Tumors	
Hepatocellular adenoma	Hepatocellular carcinoma
Bile duct adenoma	Cholangiocarcinoma
Biliary cystadenoma	Biliary cystadenocarcinoma
Mesenchymal Tumors	
Infantile Hemangioendothelioma	Epitheloid Hemangioendothelioma
Cavernous hemangioma	Angiosarcoma
Benign mesenchymoma	Embryonal sarcoma
Angiomyolipoma	Fibrosarcoma
Leiomyoma	Leiomyosarcoma
Teratoma	Hepatoblastoma
Tumorlike Lesions	
Focal nodular hyperplasia	
Nodular regenerative hyperplasia	
Biliary hamartoma	
Von Meyenburg complex	
Mesenchymal hamartoma	
Inflammatory pseudotumor	
Miscellaneous Lesions	
Simple hepatic cyst	
Metastatic liver disease	
Lymphoma	
Focal fatty change	
Liver abscess	
Echinococcal cyst	

TABLE 47-1 Lesions Presenting as Liver Masses

CAVERNOUS HEMANGIOMA

This is the most common benign mesenchymal hepatic tumor, and the prevalence ranges from 3% to 20%. [1] These lesions vary from less than 1 cm to greater than 20 cm. Giant hemangiomas have been defined as lesions that are larger than 4 cm. [2] Most often, they are noted incidentally and are of no major clinical consequence. They are rarely diagnosed in children or adolescents, and they are mostly detected in women between the third and fifth decades of life. Women more often than men have these lesions(ratio, 2 to 6:1), and the lesions tend to be larger and more numerous in women than in men of similar age. Up to 10% of patients exhibit multiple hepatic hemangiomas, and very few of them may have such lesions in other sites of the body, such as in the brain. [3]

The origin of hemangiomas is not clear. Most consider these lesions benign congenital hamartomas with growth resulting from progressive ectasia. Cavernous hemangiomas have been observed to have estrogen receptors, an observation that is in concordance with accelerated growth of cavernous hemangiomas during pregnancy and with use of supplemental estrogens (as in the use of oral contraceptives). [4], [5] and [6]

An incidental mass on abdominal imaging is the most common clinical resentation. The lesion is usually less than 5 cm in diameter, is located in the right lobe, and is asymptomatic. Large lesions tend to be symptomatic, particularly those greater than 10 cm, in which symptoms have been reported in up to 90% of the patients. The second most common clinical presentation is abdominal pain, generally in the right upper quadrant. The pathogenesis of pain may result from intralesional hemorrhage, localized thrombosis, pressure or distention of Glisson capsule, or torsion of a pedunculated hemangioma. It is important to recognize that patients could have another disorder causing the abdominal pain, and attributing any abdominal pain to a detected hepatic hemangioma is not always appropriate. A rare complication of large cavernous hemangiomas is Kasabach-Merritt syndrome, which is characterized by bleeding from disseminated intravascular coagulation (secondary to consumption coagulopathy within the hemangioma). [7] Rupture, either spontaneously or induced by trauma, is a rare yet much feared complication of a large hemangioma. [8], [9] In such cases, patients present with hypotension or shock, severe abdominal pain, and distention. Some patients may have elevated transaminases, prolongation of prothrombin time, and evidence of disseminated intravascular coagulation. Rarer presentations include obstructive jaundice, gastric outlet obstruction, hemobilia, inflammatory pseudotumor, and caval compression. [10], [11] and [12]

Laboratory tests are generally normal, except in patients with complications such as Kasabach-Merritt syndrome or obstructive jaundice. Imaging holds the key to establishing a definitive diagnosis. Ultrasonographic appearance of this lesion is of a solitary, well-demarcated, hyperechoic and homogeneous mass in up to two thirds of patients. Larger lesions may be more heterogeneous. The sensitivity of ultrasonography for diagnosing this entity ranges from 60% to 75%, and specificity ranges from 60% to 80%. [3], [13] Hemangiomas, on unenhanced computed tomography (CT) scans, are nearly isodense to large blood vessels. Dynamic CT is better than a standard CT in detecting cavernous hemangioma because the latter may fail to delineate the lesion during the phase when the lesion becomes isodense with the liver. After a rapid intravenous bolus injection of contrast medium, hemangiomas show nodular peripheral enhancement that is isodense with large vessels, and they show progressive centripetal filling in over time. Large hemangiomas (>5 cm) may have a central necrotic area or scar that may rarely calcify. Small hemangiomas may demonstrate rapid and uniform enhancement mimicking a hypervascular tumor. Whereas hemangiomas remain hypodense to blood vessels on portal venous and delayed phases, other benign as well as malignant masses become hypodense to both liver and blood vessels. The sensitivity and specificity of dynamic CT scan to delineate cavernous hemangioma range from 75% to 85% and from 75% to 90% respectively. [14], [15] Low signal intensity on T1-weighted image, high signal intensity on T2-weighted images, and multiple intralesional lobulations are characteristic findings on magnetic resonance imaging (MRI) scans of these lesions and are of help when other imaging modalities are not definitive (Fig. 47-1). Although MRI is expensive, it has the highest sensitivity (up to 95%) and

specificity (up to 95%) in the diagnosis of hepatic hemangiomas. [16] An additional advantage of MRI is that a gadolinium-enhanced study, as opposed to a CT scan, can be done in patients with renal insufficiency or iodine allergy. Further refinements of MRI technology may make it an even better tool in the detection and characterization of very small hemangiomas. Even within a cirrhotic liver, larger hemangiomas can usually be diagnosed with CT or MRI scanning, although in patients with progressive cirrhosis, hemangiomas are likely to decrease in size and to become more fibrotic, and they are difficult to diagnose radiologically and pathologically. Single photon emission CT (SPECT) has sensitivity and specificity similar to those of MRI for lesions greater than 3 cm in diameter and is less expensive, but it fails to detect smaller lesions in deeper hepatic parenchyma. SPECT is also of limited value for lesions close to the heart or major intrahepatic vessels. The current role of SPECT may be confirmatory, by clarifying equivocal findings of ultrasonography or CT. [17], [18], [19] and [20]

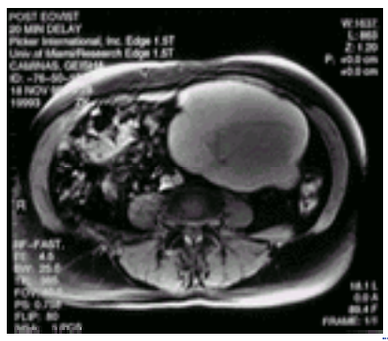

FIGURE 47-1. Characteristic appearance of hemangioma on T2-weighted MRI scan.

Laparoscopy may have to be done in a few cases to see the surface of the liver to detect these lesions. Biopsy is used as the last resort because of the potential risk of hemorrhage or rupture. Biopsies obtained with a 20- to 22-gauge needle under CT or ultrasonic guidance can be safely done, and a definitive diagnosis can be established. [21], [22] Angiography is very seldom used to diagnose these lesions.

Most hemangiomas follow a benign course, and most people live and die *with the* tumor rather than *of it*. [6] Treatment or follow-up is not indicated for asymptomatic lesions that are less than 5 cm in diameter. Follow-up may be needed in patients with asymptomatic hemangiomas greater than 10 cm in diameter. Resection is reserved for symptomatic lesions, rapidly enlarging lesions, and those that are greater than 15 cm in diameter at initial presentation, although the indication for resection based on size alone has been controversial. [23] Enucleation or resection is the surgical treatment of choice, but it may not be possible in patients with extensive hilar involvement or with multiple hemangiomas, in whom other options have to be considered. Arterial embolization has been used to control acute bleeding and to reduce blood loss at surgery. It has also been used in patients with one or only a few tumors whose vascular anatomy is unfavorable for resection but amenable to embolization. Ligation of the hepatic artery, hepatic irradiation, and intralesional steroid use have also been reported. Nonsurgical therapies should be considered only in symptomatic patients in whom the lesions are not amenable to surgery. Liver transplantation has rarely been undertaken in patients with large, unresectable tumors or in those with extensive and multiple tumors. Overall, surgical resection is indicated for fewer than 2% of diagnosed hemangiomas. [24], [25], [26], [27], [28], [29] and [30] Kasabach-Merritt syndrome can be managed by medical, radiologic, or surgical means (resection of hemangioma or liver transplantation). [31], [32]

FOCAL NODULAR HYPERPLASIA

Focal nodular hyperplasia (FNH) is the second most common benign lesion of the liver. The reported incidence of this lesion is between 2.5% and 8%. [33] This is a nodular hyperplastic lesion and has a large female predominance (female-to-male ratio of 6 to 8:1), and the average age of presentation is between 30 and 50 years. FNH represents 2% of hepatic tumors in children and is usually diagnosed between the ages of 2 and 5 years. Like hepatic hemangioma, FNH rarely causes symptoms and most often is discovered during an evaluation for abdominal pain. There are two theories regarding the pathogenesis of FNH, the vascular and the clonal. An anomalous artery supplying the lesion divides, forms a star shape, and separates the parenchyma into nodules. [34] The clonal theory holds that the cells in FNH lesion may arise from one pluripotent progenitor cell capable of differentiating into hepatocytes and biliary epithelial cells. The relationship between oral contraceptives and the occurrence of FNH has been controversial and is believed not to exist. [35], [36] and [37] Further, no correlation has been observed between the length of oral contraceptive use and the size or number of FNH lesions. However, under the influence of high hormonal states such as pregnancy or the use of oral contraceptives, the lesions may grow. [38], [39]

The lesion is most often single, subcapsular, and located in the right lobe. Multiple lesions may be seen in up to 20% of cases. Most of the lesions are 3 to 5 cm, although lesions may range from 1 mm to 19 cm. Symptoms occur more frequently in women using oral contraceptives, which could be the result of an increase in size of the lesions under the influence of these drugs. Rupture leading to hemorrhage is very rare, and malignant transformation is not a feature. Whereas physical examination is generally unremarkable, hepatomegaly and a palpable mass may be seen in a minority of patients. Histological features of FNH include a characteristic central scar with large, tortuous arteries in a matrix of connective tissue, areas of abundant intranodular bile duct proliferation, and the absence of central veins or portal triads in the nodules.

On ultrasonography, FNH is isodense to the surrounding liver tissue. Doppler scans may reveal hypervascularity secondary to enlarged arteries in the lesion. CT scan using a triple-phase protocol reveals the characteristic findings: isodense lesion in the noncontrast phase, hyperdense lesions in the arterial phase, and isodense lesion in the portal phase. FNH on an MRI is an isointense homogenous lesion on T1-weighted image and isointense to hyperintense on T2-weighted images. Contrast-enhanced MRI is probably more sensitive than CT in demonstrating the characteristic central scar, but otherwise it shows the same features as the latter (Fig. 47-2). The presence of Kupffer cells, which are capable of concentrating colloid in FNH, causes it to enhance on technetium-99m (^{99m}Tc) sulfur colloid scans. Thus, scintigraphy may help in differentiating FNH from adenomas. An MRI scan with the hepatobiliary contrast agent gadobenate dimeglumine, which demonstrates prolonged enhancement on 3-hour delayed scan, is considered very specific for FNH. The characteristic central scar may be identified in up to 20% of cases on ultrasonography, 60% on CT scans, and 78% on MRI. Angiography is rarely used to establish the diagnosis and has been used to assess arterial anatomy as part of preoperative evaluation. The combination of three-phase ^{99m}Tc diisopropyl iminodiacetic acid, ultrasound, and contrast CT, is 82% sensitive, 97% specific, and 90% accurate, as confirmed in resected lesions. Patients with lesions negative on this combination of tests and ^{99m}Tc red blood cell SPECT should undergo surgery to rule out an adenoma or malignant tumor. A needle liver biopsy is often unhelpful in the diagnosis because it may not demonstrate the features of nodularity with the central scar, which is the sine qua non for definite diagnosis, and display of such features requires a wedge biopsy. Further, these lesions are vascular and may present an added risk of bleeding. [40], [41], [42], [43], [44] and [45]

FIGURE 47-2. MRI of the liver showing a characteristic central scar of focal nodular hyperplasia.

Although surgery is not done in patients with asymptomatic FNH lesions, enucleation or wedge resection is undertaken in severely symptomatic patients or in those with rapidly enlarging lesions. Angiographic embolization and hepatic artery ligation have been done for unresectable lesions. In patients with FNH who are taking oral contraceptives, it is prudent either to discontinue these drugs in favor of other forms of contraception or to perform serial ultrasonography each year to ensure that the lesions are not increasing in size. The risk of developing symptoms and bleeding during pregnancy is remote. If there are special circumstances, serial hepatic sonography may be done during and after pregnancy. [46] /SUP>

NODULAR REGENERATIVE HYPERPLASIA

Nodular regenerative hyperplasia (NRH) is a benign proliferative process in which the normal hepatic parenchyma is replaced by diffuse regenerative nodules of hepatocytes. NRH is relatively common, and autopsy studies show a prevalence of 2%. [47] , [48] There is no clear-cut gender predilection, and NRH has been reported in children as well. The nodules vary in size from 0.1 to 1 cm. NRH has been associated with lymphoproliferative disorders, rheumatoid arthritis, primary biliary cirrhosis, bone marrow transplantation, anabolic steroids, Budd-Chiari syndrome, liver and renal transplantation, polyarteritis nodosa, hereditary hemorrhagic telangiectasia, systemic mastocytosis, amyloidosis, toxic oil exposure, partial hepatectomy, Felty syndrome, and hepatocellular carcinoma, in addition to others. [49] , [50] , [51] , [52] , [53] and [54] There are two theories regarding the pathogenesis of NRH. The vascular theory postulates that the basic lesion is portal venous obstruction that results in atrophy of hepatocytes in zone III. This leads to a compensatory proliferation of hepatocytes from portal region, which then form regenerative nodules. [55] Portal hypertension may result from compression of the intrahepatic portal radicles by the regenerating nodules. The second theory postulates that NRH is a generalized proliferative disorder of the liver. [56] Attesting to this is the observation that three-fourths of patients with NRH and hepatocellular carcinoma have liver cell dysplasia. The question of NRH as a predisposing factor to hepatocellular carcinoma is still not definitively answered.

The clinical presentation of patients with NRH varies from an incidental finding in asymptomatic patients at one end of the spectrum to hepatic failure at the other extreme. Portal hypertension with ascites may occur in 5% to 8% of patients, and esophageal varices may occur in up to 13%. [57] Patients may progress to liver failure, and liver transplantation has been performed in a few instances, although recurrence of NRH after liver transplantation has been known to occur. [58]

Hepatosplenomegaly may be noted on clinical examination, and nonspecific elevations in hepatic biochemical tests have been observed. NRH may be suspected when a patient presents with symptoms of portal hypertension and a liver biopsy fails to show cirrhosis or is interpreted as normal. Histological findings of NRH include regenerating hepatocytes, curvilinear compression of the central lobule, and lack of fibrous scar that may not be detected on a needle biopsy; laparoscopy with direct visualization of the liver or an open liver biopsy may be needed in certain cases.

Ultrasonography reveals hepatic nodules, which are isoechoic or hyperechoic. On CT scan, the nodules are nonenhancing and hypodense. Features of portal hypertension such as varices and ascites may be seen. Enlargement of the caudate lobe, peripheral hepatic hypoperfusion, and narrowing or obstruction of the hepatic veins or vena cava suggest Budd-Chiari syndrome as a cause of NRH. MRI is more accurate than CT in demonstrating vascular patency and may show more nodular lesions. The large regenerative nodules are usually hyperintense on T1-weighted images and hypointense on T2-weighted images. The scan may also show hypervascular enhancement, thus helping to distinguish NRH from cirrhotic regenerative nodules and hepatocellular carcinoma. ^{99m}Tc-sulfur colloid scintigraphy may be normal or may demonstrate uptake in nodules of larger size. [40] , [41] and [42]

HEPATIC ADENOMA

Hepatic adenoma is a lesion characterized by the benign proliferation of hepatocytes. Hepatic adenoma is found predominantly in young or middle-aged women. These lesions are usually solitary, and a few patients have multiple lesions. Up to one third of lesions are larger than 10 cm. [59] Rare before the introduction of oral contraceptives, the incidence of these tumors increased after 1960s, and they were observed more commonly in patients using high-dose estrogens, and for twice as long, when compared with controls ($P < 0.001$). [60] The incidence appears to have decreased, and this change may result from a reduction in the dose of estrogens in oral contraceptives. Although the annual incidence of hepatic adenoma is 1 to 1.3 per million in women who have never used oral contraceptives, it increases exponentially to 34 per million in long-term users of oral contraceptives. Hepatic adenomas are also seen in glycogen storage disease, diabetes mellitus, pregnancy, and use of androgens. Multiple adenomas may occur in patients with glycogen storage diseases types 1 and 3 (incidences of 50% and 25%, respectively) at an earlier age and have a male predominance. [61] Malignant transformation occurs at a faster rate in this subset of patients. Single or multiple adenomas may also arise in men and children without any predisposing conditions. There is some evidence that hepatic adenoma is derived from a single clone of hepatocytes. Altered cadherin expression (normally mediates calcium-dependent cell-to-cell adhesion) has been described in a few cases of hepatic adenoma. [62]

Hepatic adenoma is frequently symptomatic, with the most common symptom being epigastric or right upper quadrant pain; 30% of the patients may have severe and sudden pain. Bleeding within the lesion and tumor necrosis may be responsible for abdominal pain. Chronic, vague intermittent abdominal pain, hepatomegaly, and an abdominal mass may be other features. Symptoms of severe pain and signs of hypotension and shock may herald intraperitoneal or subcapsular hemorrhage, which could be potentially fatal. Perimenstrual flare of symptoms has also been noted. [63]

Laboratory parameters are usually normal. Sonography reveals a well-demarcated, smooth lesion with variable internal echogenicity, and Doppler studies may show venous signals within the lesion (Fig. 47-3). CT demonstrates most adenomas as sharply demarcated masses with smooth borders (Fig. 47-4). In contrast to FNH, hepatic adenoma may be heterogenous because of the presence of hemorrhagic necrosis or fat. When hepatic adenoma occurs in association with glycogen storage disease, the initial image may appear hypodense to the surrounding parenchyma. CT scan may demonstrate calcification, fat, and hemorrhage and tumor capsule, in a minority of patients. MRI has a low signal on T1-weighted images, and the lesion heterogeneously enhances on T2-weighted images. Recent hemorrhage or increased glycogen may increase the T1 signal, whereas central necrosis appears as low signal intensity on T2. Even though adenomas contain well-differentiated hepatocytes and may form bile, they characteristically lack the bile ductules to excrete bile. ^{99m}Tc sulfur colloid scintigraphy may show some traces of uptake in hepatic adenoma, but in contrast to FNH, there is no delayed excretion. One characteristic of hepatic adenoma seen on all imaging modalities is the well-encapsulated features of the adenoma with well-defined borders. Angiography has been performed to differentiate hepatic adenoma from hepatocellular carcinoma, with vascular leaking, arteriovenous shunting, and portal venous invasion suggesting the latter. [64] , [65]

FIGURE 47-3. Ultrasonogram showing the well-encapsulated character of hepatic adenoma.

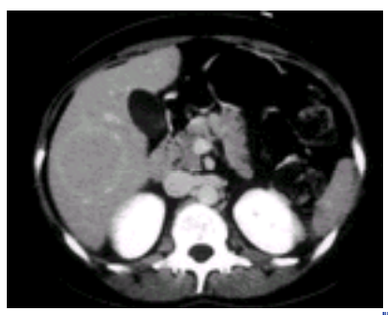

FIGURE 47-4. CT scan showing the characteristic appearance of a hepatic adenoma.

Liver biopsy to make a diagnosis is not preferred if adenoma is clinically suspected because of the risk of bleeding from these vascular lesions. Further, these lesions may have a focus of a malignant lesion that may not be evident on a biopsy done from a particular area. [66], [67] Risk of malignancy and symptomatic complications mandate surgical removal of suspected hepatic adenomas. In women taking oral contraceptives, a brief period of observation after removal of estrogens may be prudent, because adenomas have been reported to regress when patients discontinue oral contraceptive use, starting as early as 6 months. [68] However, a disadvantage is that these lesions may rarely de-differentiate into hepatocellular carcinoma even after they have been observed to regress radiologically. Avoidance of oral contraceptives permanently is necessary. In female patients whose adenomas are not resected, pregnancy should be undertaken with caution and with an understanding that there is an increased risk of tumor growth, hemorrhage, and fatality. Surgery is safe in the elective setting, with a mortality rate of less than 1%, but the rate increases when intraperitoneal bleeding has already occurred. [69] Arterial embolization has been used to control bleeding, to reduce the tumor size preoperatively, and to relieve symptoms in patients who are not candidates for operation. Multifocal adenomas may require orthotopic liver transplantation. In glycogen storage disease, adenomas may regress with nocturnal continuous feeding, but orthotopic liver transplantation is likely to correct the primary metabolic defect and should be considered. If liver transplantation is not feasible in patients with glycogen storage disease, twice yearly ultrasonography is recommended to monitor these lesions. Patients with glycogen storage disease and hepatic adenoma have not shown changes in number or size of these lesions during pregnancy.

The condition of liver adenomatosis (more than 10 adenomas) is a distinct entity, and no association exists between it and either oral contraceptive use or glycogen storage disease. These patients are at greater risk of bleeding, rupture, and malignant transformation of the lesions. This entity should be a diagnosis of exclusion because metastatic disease and multifocal hepatocellular carcinomas are more common causes of multiple solid liver masses. Diagnosis hinges on histology, and orthotopic liver transplantation may be considered in these patients. [70], [71]

CYSTIC LESIONS

Biliary Cystadenoma

Biliary cystadenoma and its malignant counterpart, cystadenocarcinoma, are the most commonly encountered primary cystic neoplasms of the liver. This lesion is more common in women, ranges in size from 2.5 to 28 cm, and can occur at extremes of age, although the mean age of presentation is usually in the fourth decade. [72] These lesions usually arise in the liver parenchyma, although rarely they arise from the extrahepatic biliary tree or gallbladder. There is no association between biliary cystadenoma and oral contraceptive use. The most common presenting symptom is right upper quadrant abdominal discomfort. Imaging studies show a focal mass with thick walls, cystic spaces, and septations. Malignant transformation to cystadenocarcinoma has been described in up to 25% of cases, and no imaging modality can clearly distinguish the benign from the malignant lesion. Hence complete surgical excision is the treatment of choice in patients with suspected cystadenomas. [72], [73]

Solitary Hepatic Cyst

These lesions have a prevalence of 4% and are usually discovered incidentally in women (female-to-male ratio, 4:1). The cyst is commonly found in the right hepatic lobe, and only a few of the lesions are larger than 5 cm in diameter. Although lesions are often asymptomatic and noted incidentally, patients infrequently have the clinical presentation of right upper quadrant abdominal pain, and this pain usually occurs in patients with cysts larger than 5 cm in diameter. Intracystic hemorrhage, infection, and neoplasia are some of the reported complications. Asymptomatic solitary hepatic cysts are best managed conservatively. Laparoscopic unroofing of accessible lesions is the preferred treatment of symptomatic solitary cysts. Several therapeutic approaches have been used for large simple cysts, including needle aspiration, with or without injection of sclerosing solution, internal drainage with cystojejunostomy, wide unroofing, and varying degrees of liver resection. [74], [75]

Echinococcal Cyst

Echinococcal (hydatid) cysts of the liver are caused by the larval form of *Echinococcus granulosus,* acquired usually from infected dogs. These cysts are fluid-filled structures limited by a parasite-derived membrane, which contains germinal epithelium. Hydatid cysts of the liver are uncommonly encountered in the United States, and patients are often asymptomatic. Symptoms may result from the mass effect of an enlarging cyst or from complications such as intraperitoneal leakage, infection, or biliary obstruction. Communication with the biliary tree is found in at least 25% of patients. Minor leakage of cyst content into the peritoneal cavity may produce a mild acute allergic reaction that may manifest with urticaria and abdominal discomfort. In cases of major rupture, patients often have acute peritoneal signs and associated acute anaphylaxis that may be fatal. Echinococcal cysts most often present as a hepatic mass with a typical appearance on abdominal imaging, coupled with confirmatory serologic testing by indirect hemagglutination or enzyme-linked immunosorbent assay. These tests have a sensitivity of 85% to 100% and a specificity of 88% to 96% for echinococcal infection. Ultrasonography, CT, and MRI typically demonstrate a multilocular cystic lesion with daughter cysts or calcification of the cyst walls. In complicated disease, the images may also show communication of the cyst with the biliary system or external leakage of cyst material. Examination of the stool is unhelpful, because fecal eggs are not present in the human host. The Casoni skin test has largely been abandoned because of its low specificity and potential danger of a severe local allergic reaction. Asymptomatic cysts that have a completely calcified wall and are associated with a negative or low indirect hemagglutination test may contain no active scolices. These cysts have a very low likelihood of complications and should probably be treated conservatively. In the rest of the cases, the treatment of choice consists of either surgery or percutaneous drainage. Medical therapy with mebendazole or albendazole is reportedly not effective in most cases of hydatid disease. However, the use of these drugs has been advocated as a preoperative measure. Therapeutic approaches consist of surgical evacuation and resection or excision of the cysts, with prior irrigation by hypertonic saline as a scolicidal agent. Other scolicidal agents that have been tried for this purpose include formalin, hydrogen peroxide, silver nitrate, and absolute alcohol. It has been suggested that percutaneous drainage combined with albendazole therapy may be an effective and safe alternative to surgery for the treatment of uncomplicated hydatid cysts of the liver, although this approach has not been widely accepted in North America. [76], [77]

Bile Duct Hamartoma

Also known as bile duct adenoma and von Meyenburg complexes, this benign focal lesion is characterized by disorganized proliferation of bile ductules in a matrix of fibrocollagenous stroma. The lesions are almost always asymptomatic, less than 1 cm in diameter (although rarely they may coalesce into larger lesions), and seen on the surface of the liver during laparoscopy or laparotomy. They may be mistaken for metastases or microabscesses. [78] On CT scan, they appear as hypodense lesions on either nonenhanced or contrast-enhanced studies. The further addition of MRI in the evaluation of these lesions is of little value. There is no risk of malignant degeneration, and no treatment is warranted. Von Meyenburg complexes (biliary microhamartomas) are 2 to 4 mm in diameter

and can be considered the diminutive counterpart of biliary hamartoma. These are often multiple and may occur in association with fibrocystic disease of the liver such as polycystic liver disease, congenital hepatic fibrosis, and Caroli disease. [79]

Mesenchymal Hamartoma

An extremely rare benign tumor thought to arise from the portal tract mesenchyme, it usually presents in boys before 3 years of age; cases have been reported in adults as well. A few case reports suggest a relationship between mesenchymal hamartoma and embryonal sarcoma of the liver. It usually presents with abdominal enlargement or a mass. Congestive heart failure (secondary to arteriovenous shunting) and ascites (secondary to cyst rupture) are uncommon presenting features. The lesion is usually large, single, and well demarcated. It has a smooth surface, and it is soft and fluctuant when palpated at surgery. Lesions may calcify and regress in size. Ultrasound scans show cystic locules that are isoechoic or anechoic, and CT scans show a low-attenuation multilocular mass with septations. In general, these lesions have low signal intensity on T1-weighted images and high signal intensity on T2-weighted images. Large and symptomatic tumors may be resected. [80], [81] and [82]

HEMANGIOENDOTHELIOMA

This entity includes the *infantile form,* which is the most common benign hepatic tumor in children, [83], [84], [85] and [86] and the *epitheloid form,* which is a malignant lesion of adults. [87], [88] The former presents in infancy with mass effect, hepatomegaly, cardiac failure, or consumptive coagulopathy (Kasabach-Merritt syndrome). Cutaneous hemangiomas are found in the majority of cases (in contrast to the epithelioid variant), and other associated entities include renal agenesis, patent ductus arteriosus, myelomeningocele, and atrial septal defect. Epithelioid hemangioendothelioma presents in adults with hepatomegaly, abdominal pain, and low-grade fever, and patients may have normal hepatic biochemical tests. Its development has been associated with the use of contraceptive steroids, exposure to polyvinyl chloride, arsenic, and radiocontrast medium (Thorotrast). Sonographic appearance is variable, and the lesions may be hypoechoic or hyperechoic. Unenhanced CT scans usually reveal a low-attenuation mass, and calcification may be noted in 50% of cases. Large tumors demonstrate peripheral pooling of contrast material on arterial and early portal venous images before filling in from the periphery. The lesions are hypointense on T1-weighted images and hyperintense on T2-weighted images. The enhancement after gadolinium administration is similar to that on contrast CT scan. [89], [90] On all imaging modalities, the infraceliac aorta is abnormally small, related to shunting of a large part of cardiac output into the tumor through the celiac vessel. The infantile type is sometimes responsive to medical therapy (steroids) or hepatic artery embolization. Surgical resection is resorted to when other measures fail. Overall, this entity carries a favorable prognosis. In contrast, the epithelioid variant is poorly responsive to medical therapies, and resection or liver transplantation is favored. [91], [92]

ANGIOMYOLIPOMAS

Angiomyolipomas are solitary, benign hepatic tumors that occur predominantly in women between the fourth and seventh decades of life. This lesion is composed of varying proportions of fat, as well as smooth muscle with thick-walled blood vessels. This lesion is also considered to be a choristoma (a mass of maldeveloped tissue not usually found in the organ). [93] Unlike its counterpart in the kidney, hepatic angiomyolipomas are rarely associated with tuberous sclerosis. Large tumors may be symptomatic, with abdominal pain. The tumor stains positively with antibodies to HMB-45 (a marker of melanocytic differentiation), and this characteristic feature aids in its diagnosis. [94] Ultrasonography reveals a homogeneously hyperechoic mass. CT is more specific for the diagnosis, and most lesions show a density component of -20 Hounsfield units on CT, indicative of adipose tissue (Fig. 47-5). Because the fat component can range from 5% to 90% in the lesion, it may be difficult to differentiate these tumors from hepatocellular carcinoma. Angiography may reveal a hypervascular lesion. Malignant transformation is unknown, and resection is the treatment for symptomatic or suspicious lesions. [93], [95]

FIGURE 47-5. CT scan showing a variegated appearance suggestive of hepatic angiomyolipoma.

FOCAL FATTY INFILTRATE

Focal fatty infiltrate is an ill-defined lesion, seen on imaging, resulting from macrovesicular steatosis involving contiguous acini with no distortion of acinar architecture. These lesions may be single or multiple and may mimic malignant tumors. Focal fatty infiltrate is associated with alcoholism, obesity, malnutrition, total parenteral nutrition, chemotherapy, hypertriglyceridemia, diabetes mellitus, and acquired immunodeficiency syndrome. Nonspecific abnormalities in hepatic biochemical tests have been observed. Ultrasonography reveals a hyperechoic lesion with ill-defined borders. On CT scans, the lesions are hypodense and sharply demarcated, and the demonstration of normal caliber vessels traversing the lesion on helical CT is characteristic. MRI shows a hyperintense lesion on T1-weighted images. Because the Kupffer cells are not affected, ^{99m}Tc sulfur colloid scintigraphy is not helpful. A liver biopsy may be needed to rule out malignancy definitively. Resolution of the lesions on correction of the underlying medical problem has been observed.

INFLAMMATORY PSEUDOTUMOR

Inflammatory pseudotumor represents less than 1% of all benign focal lesions of the liver and presents primarily in middle-aged men with fever, jaundice, weight loss, abdominal pain, and malaise. Although cultures of the lesion are negative, this entity is thought to result from a localized infection. Leucocytosis, elevated erythrocyte sedimentation rate, and normal a-fetoprotein values help in differentiating it from a neoplastic process. Sonography reveals a mosaic pattern. CT scans show an irregular, clearly demarcated lesion that does not enhance with contrast. Spontaneous regression has been reported in a few instances. When there is any doubt about the diagnosis, resection is in order. [96], [97]

Hepatocellular carcinoma, cholangiocarcinoma, and meta- static diseases of the liver are discussed in other portions of this textbook.

LAPAROSCOPY

Laparoscopy is a minimally invasive modality that has the advantage of direct visualization of the liver. Advances in technology make it an attractive option when results of noninvasive techniques are equivocal and when the clinician is reluctant to embark on exploratory laparotomy. Laparoscopy is currently done as an outpatient procedure. In addition to visualizing the lesions present on the surface of the liver, it also provides valuable information about the rest of the liver parenchyma (e.g., fatty liver or cirrhosis). Peritoneal involvement secondary to metastatic disease can be appreciated even when CT and MRI findings are negative. Biopsies of hepatic lesions can be obtained under direct visualization, thus increasing the accuracy of diagnosis.

CLINICAL APPROACH

> In medicine we have diagnosis, which is a matter of faith; prognosis, which is a matter of hope; and treatment, which is only too often an affair of charity. But the greatest of these is diagnosis. For without a proper diagnosis, it is impossible to forecast the course and outcome of a disease or to treat it satisfactorily.
>
> Sir Robert Hutchison

The foregoing quotation is very apt in the evaluation of liver masses. The approach to a liver mass is predicated on several factors such as the age and gender of the patient, the mode of presentation, methods used in diagnosis, the presence of underlying liver disease, and the degree of certitude desired by the clinician and the patient. The diagnosis and therapy of a liver mass have to be tailored to a given case, and rigid adherence to any protocol may be detrimental. The algorithms in this chapter serve as a broad framework, and the astute clinician can *doctor* this approach to

reach a favorable outcome. In some situations, referral to a tertiary care center would be prudent.

Advances in imaging technology have increased the precision of establishing a definitive diagnosis. In a prospective study, preoperative diagnoses was established by means of clinical history, serum tumor markers, sonography, and spiral CT scan in 160 patients having 225 focal liver lesions. [98] MRI, angiography, and lipiodol CT were added to the foregoing tests when deemed necessary. All patients underwent surgery, and a definitive pathological diagnosis was obtained for all the lesions. The preoperative diagnosis was confirmed in 98.2% of the lesions, and the indications for resection were correct in 97.5%.

The sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of this approach for benign lesions, for cholangiocarcinoma, and for metastases were also high (Table 47-2). Thus, clinical acumen with appropriate radiologic studies does provide a high degree of accuracy in the appropriate diagnosis of lesions in the liver and should be reassuring to patients. However, exceptions do occur, and histological examination, either by a needle biopsy or by wedge resection, may ultimately be needed before a definitive procedure. *A simplified algorithm for evaluation of focal liver masses is presented in* Figure 47-6.

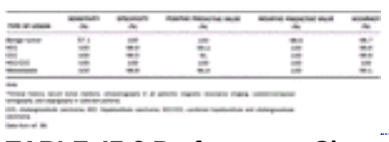

TABLE 47-2 Performance Characteristics of Diagnostic Workup* in Evaluating Liver Mass Lesions

FIGURE 47-6. A simplified algorithm for evaluation of patient with a liver mass.

CHAPTER 48

Peter C. Hayes and Kenneth J. Simpson

APPROACH TO THE PATIENT WITH FULMINANT (ACUTE) LIVER FAILURE

Fulminant (acute) liver failure (FLF) is a relatively uncommon condition characterized by hepatocyte necrosis and disruption of liver function in proportion to the degree of liver cell death. With extensive hepatocellular necrosis comes the development of clinically obvious hepatic encephalopathy, which defines the clinical condition of FLF. The challenge for physicians is to recognize this condition before the onset of encephalopathy, thus allowing early transfer of patients to specialized units that can offer the prospect of liver transplantion for those patients who are deemed to have a poor prognosis. The most common causes of FLF are acetaminophen poisoning and acute viral hepatitis or presumed viral hepatitis (non-A, non-B, non-C hepatitis). The development and clinical introduction of a bioartificial liver will, one hopes, lead to an improvement in the prognosis of this devastating condition.

The chapter first discusses the definition, pathogenesis, and etiology of FLF. Thereafter, the clinical management is divided into pre–intensive care unit (ICU) and ICU management of patients with FLF. Subsequently, liver transplantation and developments in transplantation are discussed, as well as the available bioreactors for use in patients with FLF.

FLF is the consequence of severe hepatic injury. This results in a sudden deterioration in hepatocellular function and leads to a characteristic clinical syndrome with hepatic encephalopathy and, in severe cases, multiorgan failure and death. There are many causes of FLF, which vary in their relative contribution in different parts of the world. Supportive therapy allows both functional and structural regeneration of the liver after FLF, without the development of chronic liver disease. However, in certain cases, the prognosis is grave and is greatly improved by emergency liver transplantation. One hopes that, with the development and refinement of bioartificial liver systems, hepatocyte transplantation, and gene therapy, this reliance on emergency liver transplantation will eventually be of historical interest only.

DEFINITIONS

The original clinical syndrome of FLF was defined by the Fulminant Hepatic Failure Surveillance Study in 1970 as a “potentially reversible condition, the consequence of severe liver injury, in which the onset of hepatic encephalopathy was within the 8 weeks of the first symptoms of illness and in the absence of pre-existing liver disease.” [1] Subsequently, there has been considerable debate about refining this definition. Patients developing hepatic encephalopathy within 8 to 24 weeks of the onset of symptoms were defined as having “late-onset hepatic failure.” [2] Several authors have suggested that the interval between the first detection of jaundice and the onset of hepatic encephalopathy would allow more accurate timing of the duration of illness. Indeed, the duration of illness, as defined by the interval between the onset of jaundice and the development of hepatic encephalopathy, has been shown to be of prognostic significance in patients with FLF that is not induced by acetaminophen. [3] However, there is a lack of agreement regarding the crucial time period between the onset of jaundice and the development of hepatic encephalopathy. Workers from the Hospital Beaujon, in Paris, France use the term FLF to describe the onset of encephalopathy within 2 weeks of the development of jaundice and subfulminant hepatic failure when hepatic encephalopathy develops between 2 weeks and 3 months from the development of jaundice. [4] Others at King’s College Hospital, in London, England have suggested that FLF should be replaced by the term “acute liver failure” and subcategorized into three groups: hyperacute liver failure, in which the interval between jaundice and encephalopathy is 7 days or less; acute liver failure, for cases in which the interval is 7 to 28 days; and subacute liver failure, for cases in which the interval is 5 to 12 weeks. [5] Such a classification of FLF has the advantage that certain causes, complications, and prognoses are more common in the different subgroups. For example, hyperacute liver failure is most commonly seen after acetaminophen poisoning, and it has a high frequency of cerebral edema, but paradoxically it is associated with a relatively good prognosis.

A clinically relevant problem is how to define the concept of a pre-encephalopathy stage of FLF or subfulminant hepatic failure. Many more patients show clinical and biochemical evidence of severe liver injury but never develop hepatic encephalopathy. In these patients, who may not be managed by hepatologists, it is important to anticipate and monitor closely for the development of hepatic encephalopathy. The ability to predict which patients with severe liver injury will deteriorate clinically with the development of encephalopathy will allow earliest referral to a specialized liver center and will avoid the known dangers of transporting patients with encephalopathy. This pre-encephalopathy stage of FLF or subfulminant hepatic failure has been defined as “severe acute hepatic failure” and as “impending” or “incipient” FLF. [6] In France, this condition is diagnosed whenever the prothrombin ratio falls to less than 50% of normal during the course of an acute liver disease, and does not require the presence of clinical encephalopathy. [7] Even using widely accepted criteria in the United Kingdom for transfer of patients with acetaminophen poisoning to specialized liver centers, data from our own unit have shown that only 50% of these patients will subsequently develop hepatic encephalopathy.

Throughout this chapter we use the designation FLF, and for the purposes of discussion, we use the original definition of Trey and Davidson, namely, the development of hepatic encephalopathy within 8 weeks of the onset of symptoms in a patient without preexisting liver disease. The term *subacute hepatic failure* is used to define the syndrome whereby hepatic encephalopathy develops within 8 weeks to 6 months of the onset of symptoms. These definitions were used by Lucey and colleagues when discussing transplant listing and by Schiodt and colleagues in the Acute Liver Failure Study Group. [8], [9]

DIFFERENTIAL DIAGNOSIS

The constellation of clinical and biochemical features including hepatic encephalopathy, jaundice, transaminitis, and coagulopathy often makes the diagnosis of FLF. However, the distinction from decompensated chronic liver disease may be difficult, especially if there is a prolonged clinical course with the development of ascites. Careful review of all the patient’s medical records may reveal previous evidence of liver abnormality. The presence of the cutaneous stigmata of chronic liver disease, the clinical or radiologic detection of splenomegaly, and the endoscopic appearances of esophageal varices are more suggestive of chronic liver disease in patients who have only had jaundice for less than 2 weeks. Ultrasound often fails to differentiate between collapse and cirrhosis, but it may be useful in identifying uncommon causes of FLF such as Budd-Chiari syndrome and metastatic malignant disease. Occasionally, liver biopsy is required. Because of the coagulopathy, this is most safely performed by the transjugular route. At the same time, measurement of the hepatic venous pressure gradient may suggest the occurrence of portal hypertension, which is uncommon in patients with a short history of jaundice and encephalopathy. The liver biopsy, as well as excluding cirrhosis, may be helpful in providing some prognostic information. In one study, hepatic necrosis greater than 70% was associated with a poor prognosis. [10] /SUP>Certain other clinical situations may be confused with FLF. Some patients with severe intra-abdominal sepsis or pancreatitis may develop a syndrome very similar to FLF. Tropical diseases such as falciparum malaria and dengue fever may be confused with FLF.

INCIDENCE AND ETIOLOGY

Accurate data on the incidence of FLF in populations throughout the world is limited. It has been suggested that, in the United States, there are 2000 deaths from acute viral hepatitis annually. [11] Alternatively, using International Classification of Diseases codes on death certificates, approximately 5000 potential deaths from FLF were identified in the United States, between 1980 and 1988, with an incidence of 3.5 deaths per million population. [11] Examination of the National Hospital Discharge Survey between 1988 and 1990 gave an estimate of hospitalizations for FLF at 31.2 per

million population. [11] The distribution of causes of FLF is different in different countries throughout the world: In general, viral hepatitis is the most common cause of FLF in developing countries, and in the West, toxic drug reactions and acetaminophen poisoning are the more common causes (Table 48-1).

CAUSE	INVESTIGATION
Acetaminophen poisoning	Acidosis, early renal failure, very high transaminases (>5000), detectable acetaminophen
Idiosyncratic drug reactions	Positive serology
Budd-Chiari syndrome	Ultrasound, CT scan, MRI, hepatic venogram
Wilson disease	Slit-lamp examination, hemolytic anemia, relatively normal transaminases, ceruloplasmin, urinary and serum copper
Hepatic malignancy	Ultrasound scan, CT scan, MRI, transjugular biopsy
Autoimmune hepatitis	Immunoglobulins, antinuclear factor, anti–smooth muscle antibody
Viral Hepatitis	
Hepatitis A	IgM anti-HAV
Hepatitis B	IgM anti-HB core
Hepatitis D	HDV, RNA, IgM anti-HDV, HDV antigen

Note:
CT, computed tomography; HAV, hepatitis A virus; HB, hepatitis B; HDV, hepatitis D virus; IgM, immunoglobulin M; MRI, magnetic resonance imaging.

TABLE 48-1 Fulminant Liver Failure: Causes and Helpful Diagnostic Investigations

Acetaminophen Toxicity

Acetaminophen is the most common single cause of FLF in the United States. [9] The relative frequency has increased from 20% (1994 to 1996) to 36% (1998 to 1999), but it still does not reach the numbers seen in the United Kingdom (between 70% and 80%). Changes in the packaging of acetaminophen and restriction in availability may have reduced its relative frequency, but the early data are still contradictory, and acetaminophen remains the most common cause of FLF in the United Kingdom. [12], [13] Acetaminophen poisoning is less common in Australia and other European countries and is rarely encountered in India. [14], [15] In contrast to the United Kingdom, where more than 90% of cases are associated with attempted suicide, in the United States, most patients (64%) report accidental toxicity. [16], [17] Other reports have highlighted the potential fatal ingestion of therapeutic doses of acetaminophen, which may induce FLF in patients taking enzyme-inducing drugs (e.g., phenobarbitone or isoniazid) or in those who have been fasting or who consume excessive amounts of alcohol.

The diagnosis of acetaminophen-induced FLF is suggested by the presence of markedly elevated serum transaminases (>100 times normal), acute renal failure, metabolic acidosis, and hypophosphatemia. In some cases, acetaminophen may still be detectable within the blood because, as liver injury progresses, the plasma clearance of acetaminophen is reduced. As discussed later, the prognosis of patients with acetaminophen toxicity may be difficult to assess, especially in patients with staggered or accidental overdoses. However, the spontaneous rates of survival are higher in acetaminophen-induced FLF compared with other causes.

The hepatotoxic affects of acetaminophen are dependent on its metabolic activation by several members of the cytochrome P450 system producing the highly reactive intermediate, *N*-acetyl-*para*-benzoquinoneimine (NAPQI). NAPQI is normally conjugated with glutathione, but levels accumulate once cytoplasmic glutathione becomes depleted. However, the exact mechanism by which NAPQI leads to hepatocyte death is not clear. Interesting studies in animals have implicated a central role for Kupffer cells; depleting Kupffer cells with gadolinium chloride completely protects against the liver injury in vivo in the rat. [18] Other workers have suggested a role for Fas-mediated apoptosis. [19]

Acute Viral Hepatitis

Acute viral hepatitis causes 10% of cases of FLF in the United States. A similar frequency has been reported in the United Kingdom. [14] Viral hepatitis is the most common cause of FLF in France (50%) and is the cause of FLF in most cases in India. [15] Hepatitis B virus (HBV) is the most commonly isolated, and its relative frequency is determined by the carrier rate in a certain country. The reported frequency in the United States (5% of cases of FLF) fell slightly between 1994 to 1996 and 1998 to 1999, perhaps reflecting increasing vaccination rates. [14], [20] Approximately 1% of symptomatic patients with acute hepatitis B are at risk of developing FLF. [11] The risk is higher in women and after cytotoxic chemotherapy. [21] FLF associated with hepatitis B can occur during seroconversion to anti-HBe positivity and with coinfection or superinfection with hepatitis D virus (HDV). Superinfection with HDV is more likely to result in FLF because the antigen (HBsAg) essential for HDV replication is already present. The presence of IgM anti-HBc antibody at high titer is diagnostic. In up to 20% of patients, HBsAg is lacking, and HBV DNA is undetectable; these findings may be associated with improved prognosis. [21] In a few patients without any serologic markers of HBV infection, HBV DNA has been detected by the polymerase chain reaction in liver tissue. [22] The detection of HDV RNA, IgM anti-HDV, or HDV antigen suggests superinfection or coinfection with HDV. Patients surviving HDV-associated FLF become chronic carriers of both HDV and HBV. This situation is far more common after HDV superinfection and frequently leads to severe chronic hepatitis and cirrhosis. [23] The prognosis of HBV-associated FLF is generally good. [3]

Several factors are important in the development of FLF resulting from HBV or HDV infection. FLF is more common in chronic carriers of HBV after recent withdrawal of antineoplastic or immunosuppressive drugs and in those superinfected with HDV. The size of the viral inoculum is also important. There is some debate regarding the importance of infection with HBeAg-deficient mutants. [24], [25] HBV is not generally considered to be cytopathic, and with the early loss of HBsAg, it is generally accepted that FLF related to HBV is associated with a vigorous host immune response toward the virus.

Hepatitis A virus (HAV) and hepatitis E virus (HEV) are both RNA viruses that are enterically transmitted and can cause occasional epidemics. HAV is distributed throughout the world and has a similar relative frequency in causing FLF in the United States compared with HBV. Acute hepatitis A causes FLF in up to 0.4% of symptomatic patients. [26] Approximately 100 deaths per year occur in the United States from HAV-associated FLF, and it is more common in patients who are infected when they are more than 40 years old and in patients with chronic liver disease, especially HCV infection. [27], [28] Detection of IgM antibody to HAV is diagnostic. The prognosis of FLF caused by HAV infection is relatively good. [3] HEV has a more restricted distribution compared with HAV. HEV infection is endemic in Asia, the Middle East, and North Africa. Cases of FLF associated with HEV infection reported from the developed countries of North America and Europe are usually in patients who have traveled to endemic areas within the previous 1 to 2 months. Rarely are cases reported in patients without a history of travel to endemic areas. Mortality from HEV infection is similar to that from HAV infection. However, the risk of FLF is particularly increased in pregnant women, especially those in the third trimester. [29] Mother-to-fetus intrauterine transmission has been reported to occur, and severe liver necrosis may affect the infant. [30] The finding of IgM anti-HEV antibody in serum is diagnostic of acute HEV infection. The pathogenic mechanisms leading to FLF in patients with HAV or HEV infection are poorly understood. Both viral and host immunologic factors are likely to be important.

The risk of developing FLF after infection with hepatitis C virus (HCV) is not clear. The occurrence of HCV RNA in patients with FLF is related to the geographic area, 45% in Taiwan and 50% in Japan, but 0% in France, the United Kingdom, and the United States. [31] It may be difficult to exclude an acute exacerbation of a hitherto unrecognized chronic hepatitis C infection. FLF has been reported in chronic carriers of HCV after coinfection or superinfection with HBV or after withdrawal of chemotherapy.

Several other viruses have been reported to cause FLF, including herpes simplex virus, varicella zoster, cytomegalovirus, Epstein-Barr viruses, human herpes virus 6, human parvovirus B19, and the RNA viruses responsible for viral hemorrhagic fevers. Severe liver injury and FLF may accompany adenoviral infection in immunocompromised persons and are major obstacles to the use of these viruses as vectors for the delivery of gene therapy.

Large proportions of patients in most reported series of FLF have no identifiable cause for developing FLF. Such patients are classified as having an indeterminate cause. However, many have a viral prodrome, and the term *non-A, non-B hepatitis* became popular. With the further recognition of HCV and HEV, such patients are more correctly now described as contracting *non- A–E hepatitis*. Intensive investigation over the years has led to the identification of several potential candidate viruses. The agent designated GBV-C or hepatitis G can be transmitted by blood transfusion, but it is not associated with FLF or any other form of liver disease. [32] The TT virus was characterized more recently from a patient with posttransfusion hepatitis. This DNA virus can infect the liver, but the degree of infection is not related to hepatic histological activity, and evidence of replication within the liver is lacking. Early studies suggested that TT virus may be associated with non-A–E FLF, but

subsequent studies did not confirm its pathogenic role. [33] Other potential candidates as causal agents in non-A–E hepatitis include SANBAN and SEN-V viruses; further studies of these agents are eagerly awaited.

Idiosyncratic Drug Reactions

Although severe hepatotoxicity is rare, many drugs have been reported to cause liver injury and occasionally FLF. Drug reactions as a cause of FLF vary in relative frequency from 2% in the United Kingdom to 16% to 17% in France and the United States. [20] A high index of suspicion is often required to make the association between drug ingestion and the development of FLF. However, certain drugs are more commonly associated with both hepatotoxicity and FLF. Antituberculosis therapy (isoniazid and especially pyrazinamide) is an important cause of FLF and may potentiate acetaminophen toxicity. [34] Halothane and its derivatives can induce immune-mediated liver injury and can potentially lead to FLF. Halothane hepatitis occurs up to 28 days after exposure and is more common in female patients and those who have received multiple halothane anesthetic administrations. [35] This condition has become a much less frequent cause with the advent of newer anesthetic agents. Sulfonamides, for example sulfasalazine, can cause FLF, which may recur with exposure to other sulfonamide-containing drugs. Nonsteroidal antiinflammatory drugs such as piroxicam and bromfenac have been reported to cause FLF. Other drugs implicated in causing FLF include fialuridine and 2,3-dideoxyinosine. These drugs may induce mitochondrial dysfunction and hepatotoxicity. Idiosyncratic drug reactions are associated with a poor prognosis. [3]

Reye syndrome is characterized by rapidly progressive hepatic encephalopathy associated with cerebral edema and hepatic steatosis. This syndrome is most common in children, but a few adult cases have been reported. [36] There is a strong association with the use of salicylates, and a reduction in consumption of these drugs has led to a fall in incidence of this disorder. [37] Mitochondrial toxicity has been implicated in the pathogenesis of Reye syndrome. The mortality rates are high in patients who develop coma, but early recognition of the syndrome and specialist management have led to a reduction in death rates. [38]

Several investigators have reported hepatotoxicity and FLF after ingestion of herbal remedies, available without prescription. The use of such agents is commonplace, and patients may not necessarily volunteer to their physicians that they have been consuming these remedies. Herbal remedies often contain multiple compounds, which do not remain constant, and therefore it may be difficult to isolate the responsible component. Wall germander is hepatotoxic, and FLF requiring emergency liver transplantation has been reported in some cases. [39] Pennyroyal oil causes dose-dependent acute hepatitis and occasionally FLF, which may be successfully treated with *N*-acetylcysteine. [40] Many other herbal remedies have been associated with acute hepatitis or FLF. FLF has also been reported after occupational or accidental ingestion of several industrial solvents such as carbon tetrachloride, trichloroethylene, and 2-nitropropane. Ingestion of food contaminated with aflatoxin and acute poisoning with yellow phosphorus can also lead to FLF.

Illicit drugs may cause severe hepatotoxicity and FLF. Several cases have been reported after ingestion of cocaine or ecstasy (3,4-methylenedioxymetamphetamine). FLF after ecstasy ingestion can occur either with or without an associated hyperpyrexia syndrome (rarely, exertional heat stroke can lead to FLF). The case fatality rate is high, and some survivors after emergency liver transplantation have been reported. [41]

Amanita mushroom consumption has been reported as a cause of FLF from continental Europe and the United States. About three medium-sized mushrooms can deliver a lethal dose of amanitoxins. FLF occurs late in the clinical course. Severe vomiting and diarrhea lasting 1 to 4 days follow an initial asymptomatic phase of up to 12 hours. After recovery from these symptoms, the liver injury becomes apparent, with massive elevation of the serum aminotransferases and the development of jaundice, coagulopathy, and hepatic encephalopathy. In the largest series published, the mortality rate was 22%, and it was especially high in patients with markedly prolonged prothrombin times. Emergency liver transplantation can be successful, but prognostication in such patients is exceedingly difficult.

Other Causes

Obstruction to the hepatic veins as occurs in Budd-Chiari syndrome can rarely lead to FLF. Abdominal pain and the early development of ascites (which is exudative in the early stages) are characteristic of Budd-Chiari syndrome, but the absence of these symptoms and signs does not exclude the diagnosis. Hepatic venous thrombosis is more common in female patients. [42] There is a high frequency of an associated coagulation abnormality, for example, lupus anticoagulant or a primary myeloproliferative disorder. Ultrasound, computed tomography, and hepatic venography are helpful in confirming the diagnosis. Early intervention with emergency mesocaval or mesoatrial shunt, transjugular intrahepatic portosystemic stent shunt placement, or emergency liver transplantation, followed by lifelong anticoagulation may be successful. Pyrrolizidine alkaloids present in some herbal remedies or teas can induce venoocclusive disease of the liver and can present with FLF. Antineoplastic chemotherapy, radiation, and graft versus host disease may result in venoocclusive disease.

Rarely, patients with Wilson disease present with FLF. Such a presentation may occur in patients newly diagnosed with Wilson disease or in those who have been taking D-penicillamine treatment for several years after interruption of therapy. Examination of the genetic variants occurring in this condition has failed to identify a specific genetic mutation in patients with FLF in Wilson disease. Coombs-negative hemolytic anemia accompanies the release of copper from damaged hepatocytes into the systemic circulation and contributes to the very high bilirubin levels seen in these patients. Occasionally, the serum transaminases are normal, but more often they are only modestly increased. Kayser-Fleischer rings and diminished serum ceruloplasmin may be absent in 50% and 10% of patients, respectively. The plasma copper (especially the free copper) and urinary copper levels are elevated, and the 24-hour urinary copper excretion is increased. [43] The prognosis of FLF secondary to Wilson disease is poor, and liver transplantation is often required. [3] A prognostic index derived from the serum aspartate aminotransferase, bilirubin, and prothrombin time may indicate those with a fatal outcome, who would be best treated with liver transplantation, compared with those who could survive with D-penicillamine treatment. [44]

FLF is a rare finding in patients with hepatic metastasis. Hepatomegaly and ascites are almost always found, and most commonly the primary tumor is breast carcinoma. Malignant melanoma and nasopharangeal carcinomas have also been reported to cause FLF. Infiltration of the liver by leukemia, Hodgkin's disease, or non-Hodgkin's lymphoma may present with FLF. [45] Hepatomegaly is a prominent feature, and marked increases in circulating lactate concentrations have been reported. Most often, the patient has a previous history of the tumor, and very rarely it is the first manifestation of the disease. In patients with acute leukemia or lymphoma, intensive chemotherapy may lead to regression of the FLF.

Occasionally, pregnancy may be associated with FLF. The two main syndromes leading to this clinical picture are acute fatty liver of pregnancy and hemolysis with elevated liver enzymes and low platelet (HELLP) syndrome. [46] Such syndromes are often associated with clinical features of preeclampsia including hypertension, peripheral edema, and proteinuria, and early symptoms of the liver disease include polydipsia, nausea, and vomiting. The delivery of the child results in the regression of the liver disease, although severe bleeding may occur after delivery.

In a small number of patients, hypoxic liver cell necrosis leads to FLF. [47] This is associated with a high mortality rate because the underlying precipitating cause is most commonly a cardiac arrhythmia or myocardial infarction. Other reported causes include pulmonary emboli and acute cardiac tamponade. Rarely, hypoxic liver cell necrosis follows severe and profound hypoxemia.

MANAGEMENT

The management of patients with FLF is mainly supportive, that is, avoiding complications and correcting abnormalities while allowing the greatest potential for recovery of liver function to take place. The only definitive treatment that alters the natural history of the disease is liver transplantation, as discussed later. *N*-acetylcysteine, used in the setting other than as an antidote to acetaminophen poisoning, may fall into the category of definitive (nonsupportive) therapy, but its effect is small and controversial (see later). Artificial liver support systems currently are of unproven benefit but clearly represent the most exciting treatment option for the future.

Early (Pre-ICU) Management

Cardiovascular Manifestations FLF is characterized by hyperdynamic circulation with tachycardia, hypotension, increased cardiac output, and low peripheral vascular resistance. This clinical picture resembles that seen in sepsis, and separation of these two syndromes may be difficult; the two often coexist. Use of inotropes to maintain the mean arterial pressure around 80 mm Hg or higher is generally thought desirable to maintain tissue, especially renal, perfusion, although some patients will maintain reasonable cardiovascular stability with judicious volume support alone. Traditionally, inotropes are reserved for use in the ICU and are discussed later. Early on, if adequate urine output is maintained, this can be used as a good clinical indicator of satisfactory tissue perfusion. However, because renal failure is common in FLF, particularly that caused by acetaminophen poisoning, poor urine output cannot be taken as indicating renal hypoperfusion. Placement of a line to monitor the central venous pressure is important to ensure adequate filling of the circulation. Peripheral vasoconstriction, which may be present earlier in the course of the disease, is usually a good indicator of volume requirement at this stage. Because the prothrombin time is such a useful marker of hepatic function, the administration of fresh frozen plasma before inserting lines is generally avoided. The internal jugular vein is usually the best site for cannulation because compression can be applied if bleeding occurs. Low-dose dopamine was shown to be ineffective in maintaining renal function in critically ill patients in a reasonably large randomized study, [48] and there is no evidence that it is beneficial in maintaining renal function in FLF. Terlipressin, which can be given by bolus

injection rather than by infusion, may be valuable as an inotrope, but experience is limited.

Metabolic Effects The most important metabolic abnormality to anticipate is hypoglycemia. Ten percent dextrose should be given through the central line to prevent this condition, and testing of blood glucose should be carried out every 2 hours, especially if the patient becomes drowsy. Acidosis is common, particularly in patients with acetaminophen poisoning, and it has prognostic significance. A pH of 7.3 or less in patients who have been fully resuscitated from a cardiovascular perspective is associated with a 90% mortality in acetaminophen poisoning and is one of the major factors in the King's College criteria for poor prognosis (Table 48-2). [3] Hypophosphatemia is common, but correction of this condition should be cautious in renal failure because levels may rise rapidly. Hypokalemia accompanying respiratory alkalosis may be marked and should be corrected.

Acetaminophen Poisoning
Arterial pH <7.3 (H^+ >50 nmol.l^{-1})
OR
Three of the following:
Prothrombin time >100 s
Serum creatinine >3.41 mg/L
Encephalopathy grade III/IV
Causes Other than Acetaminophen Poisoning
Prothrombin time >100sec
OR
Three of the following:
Unfavorable cause (e.g., drugs, non-A, non-B) jaundice for >7 d
before encephalopathy age <10 or >40 y
Prothrombin time >50 s
Serum bilirubin >300μmol/L

TABLE 48-2 Indicators of Poor Prognosis in Fulminant Hepatic Failure

Renal Effects Hepatorenal syndrome is common in FLF, particularly in acetaminophen poisoning, because acetaminophen is directly toxic to the kidney. Indeed, a few patients will develop renal failure alone after acetaminophen poisoning. Urine output should be closely monitored in patients with acute liver injury, which requires urinary catheterization. Renal function must be monitored by serum creatinine, rather than by urea, because urea is dependent on hepatic synthesis and values may be misleadingly low. Creatinine should be measured daily, and twice daily once it is more than 1.70 mg/L, because it may increase rapidly. A serum creatinine level of more than 3.41 μg/L is a marker of poor prognosis in acetaminophen-induced FLF (see Table 48-2).

Hematologic Manifestations One of the best markers of acute liver injury is the prothrombin time, and this should be measured daily and more frequently once it is longer than 50 seconds. Because the prothrombin time is a valuable marker of prognosis, clotting factors should not be given prophylactically but only if there is bleeding. If clotting factors have been given, the length of time it takes for the prothrombin time to revert to its untreated level is unpredictable. A prothrombin time longer than 50 seconds in non–acetaminophen-induced FLF and a prothrombin time more than 100 seconds in acetaminophen-induced FLF are indices used in the King's College criteria for poor prognosis. [3] An increase in the prothrombin time between day 3 and day 4 after the ingestion and a single prothrombin time greater than 180 seconds may also have some prognostic significance. These prognostic markers may be influenced by other drugs that induce acidosis (e.g., aspirin) and by not taking the acetaminophen as a single overdose. Staggered overdoses or paracetamol taken during a therapeutic misadventure will not conform to these prognostic indicators, and in these patients it is notoriously difficult to establish an accurate prognosis and to make the decision confidently to proceed to liver transplantation. To standardize prothrombin time reports among patients with FLF, the international normalized ratio (INR) has been advocated. However, others have suggested that the INR is not valid in patients with liver disease, especially those with FLF, and it is best to express the prothrombin time as an activity percentage. Gastrointestinal bleeding is reduced by the prophylactic use of H_2-antagonists or sucralfate. [49], [50] Thrombocytopenia is common in FLF, and the platelet count may decrease to less than 30 × 10^9/L. Platelets should be given only in patients with active bleeding because clotting factors in the platelet replacement packs will affect the prothrombin time.

Infection Sepsis is common in FLF, and the prophylactic administration of antibiotics such as ciprofloxacillin is recommended once encephalopathy develops. Blood cultures should be taken daily, and bacteremia should be treated appropriately and early. This is important, because sepsis is a contraindication to liver transplantation.

Neurological Features Encephalopathy is a cardinal feature of FLF and should be actively assessed and monitored because it may be subtle in the early stages and may progress rapidly. Traditionally, encephalopathy is divided into 4 grades: slow mentation (grade 1), agitation (grade 2), permanent somnolence (grade 3), and coma (grade 4). This grading is important because grades 3 and 4 have prognostic significance (see Table 48-2). Patients are generally transferred to ICU once grade 3 encephalopathy develops because assisted ventilation is often required. Raised intracranial pressure (ICP) and cerebral edema generally are complications of patients with grade 4 encephalopathy. The disadvantage of this classification of encephalopathy is that it is somewhat crude and not generally known by personnel in other medical disciplines who may be involved in the management of these patients, such as intensive care specialists and anesthesiologists. The Glasgow coma scale may be useful in discussing the neurological state of patients and should probably be more widely used.

***N*-Acetylcysteine** This agent has been known for years to be an effective antidote for acetaminophen poisoning if it is administered within 18 hours of the overdose. In the United Kingdom, it is generally given intravenously. Oral administration of this drug or methionine will reduce the risk of liver injury, but vomiting may complicate drug delivery. However, as well as the action of this drug as an antidote, it was reported by the King's College group that administration of this agent after this period improved outcome for both acetaminophen-induced and non–acetaminophen-induced FLF. [51] The mechanism of this possible benefit is unclear. Improved tissue oxygen delivery has been proposed as one mechanism, but this was based on a standard methodology that is now questioned, and further work demonstrated that oxygen consumption is unchanged by *N*-acetylcysteine administration. [52], [53] There is no universal agreement that late (>18 hours after the overdose) administration of *N*-acetylcysteine is beneficial in FLF, particularly in the non-acetaminophen group of patients. The drug is generally well tolerated, however, apart from occasional urticarial and allergic reactions, and many clinicians give the drug in the absence of alternative therapy. If given, it is generally administered until the patient is clearly recovering or dies.

Late (ICU) Management

Cardiovascular Manifestations By the time the patient with FLF requires to be transferred to ICU, usually because of deteriorating encephalopathy or for renal replacement therapy, hypotension is generally apparent, with a systolic blood pressure lower than 100 mm Hg and a mean arterial pressure lower than 70 mm Hg. Norepinephrine is the most commonly used inotrope, started at a dose of 0.05 $\mu g.kg^{-1}.min^{-1}$ and increasing to achieve a mean arterial blood pressure higher than 80 mm Hg. Adequate blood pressure is important to maintain satisfactory renal perfusion in these patients, who are frequently oliguric or anuric, and to maintain an adequate cerebral perfusion pressure. Peripheral perfusion may be compromised by norepinephrine administration, especially in the relatively hypovolemic patient. The insertion of a pulmonary artery catheter to monitor right-sided and left-sided cardiac pressures is valuable for optimizing fluid replacement.

Ventilation Pulmonary problems in FLF may include aspiration pneumonia, noncardiogenic pulmonary edema, and the adult respiratory distress syndrome as part of multiorgan failure. Artificial ventilation is generally initiated because of deepening encephalopathy, but oxygen requirements commonly increase because of an increased metabolic rate secondary to the hyperdynamic state and cytokine release.

Intracranial Pressure Raised ICP leading to cerebral edema is a common cause of death in FLF. Recognition of raised ICP by such clinical features as pupillary dilation, elevated blood pressure, bradycardia, and opisthotonos are insensitive and delayed features, and many clinicians believe that insertion of an ICP monitor is indicated despite the recognized risks of insertion in a patient with coagulopathy and thrombocytopenia. Most clinicians prefer to treat deranged coagulation before insertion of an ICP transducer, and it is desirable to wait until a prothrombin time of more than 100 seconds in acetaminophen poisoning and more than 50 seconds in non-acetaminophen cases is exceeded, so clotting factor replacement does not interfere with critical decision-making steps, particularly listing for liver transplantation. Once these prothrombin levels have been exceeded, clotting factor and platelet replacement therapy may allow safer insertion of an ICP monitor. With such monitoring, the management of raised ICP is greatly facilitated. An ICP greater than 20 mm Hg for more than 10 minutes is associated with cerebral edema and should be treated. The choice of intracranial monitoring system is debatable; epidural, subdural, and parenchymal systems are available. All are associated with some risk of intracranial bleeding. The risk of hemorrhage may be lower with epidural devices, but most centers use fiberoptic catheter systems placed subdurally for greater accuracy and ease of bedside insertion. Other noninvasive methods for detecting cerebral edema such as computed tomography are insensitive in this setting, only provide a snapshot at one moment in time, and require moving the patient from the ICU setting, which is undesirable and possibly dangerous. Management of the ICP is valuable, but the cerebral perfusion pressure is probably a more useful parameter. It is derived from the mean arterial pressure minus the ICP and ideally should be higher than 60 mm Hg. A value lower than 40 mm Hg is likely to lead to cerebral damage, and many clinicians believe that a cerebral perfusion pressure of less than 40 mm Hg for more than 60 minutes is a contraindication to liver transplantation. [54] A further useful measurement in monitoring the neurological status in these patients is to record cerebral oxygen consumption. This may be achieved by measurement of cerebral blood flow together with arterial and jugular bulb oxygen contents, but simply using a jugular bulb catheter to measure jugular venous oxygen saturation provides a reasonable guide to whether luxury perfusion or cerebral ischemia is associated with raised ICP and helps therapy to be appropriately targeted. Mannitol therapy has been shown to be effective in controlling ICP in this setting and is the treatment of choice. [55] However, repeated administration may be required, and efficacy reduces with time. Hyperosmolality may occur, and plasma osmolality should be measured. The response to mannitol administration should be monitored, and further treatments or second-line therapies should be used if necessary. Second-line therapy with thiopentone is less commonly used in patients with head injury, and evidence of efficacy in FLF is limited. More recently, work from our unit has shown that moderate hypothermia is effective in controlling ICP. [56] Animal data support this clinical observation, but more work is needed to establish whether this finding is translated into improved survival. A further important neurological complication of FLF is epileptic seizures. These may be masked by sedation and are easily overlooked. One study in which prophylactic phenytoin therapy was administered suggested that this was of benefit in reducing the prevalence of cerebral edema. [57] Continuous electroencephalographic monitoring for epileptiform activity should be routine.

Renal Effects Renal failure is common in FLF, and most patients will require renal replacement therapy at some time during their illness. Continuous venovenous hemofiltration is preferable to intermittent filtration or dialysis, which may lead to an increase in ICP. Because of coagulopathy, prostacyclin is often used in preference to heparin as the anticoagulant in the hemofiltration system, although in some cases no anticoagulant is necessary. Filtration against bicarbonate buffer may be used in place of lactate buffer, but with continuous hemofiltration, extrahepatic lactate clearance is sufficient to avoid a significant increase in plasma lactate. Correction of acidosis, rather than lactate decrease, is the criterion of effectiveness. After recovery of hepatic unction or liver transplantation, renal support may need to be continued for weeks as the hepatorenal failure or acute tubular necrosis recovers. The eventual renal recovery is almost invariably complete.

Infection By the time patients with FLF are admitted to the ICU, prophylactic antibiotics should have been started. The most common infections are with gut- or skin-derived organisms, and antibiotics should be broad-spectrum agents such as cefotaxime and amoxicillin-clavulinic acid combinations. Daily blood cultures and culture of urine and sputum should be performed. Sepsis may be difficult to identify because of the similarity between the cardiovascular changes of FLF and sepsis, and a low threshold of suspicion must be maintained. Suspected infection in patients receiving antibiotics, especially after 5 days in an ICU, should lead to the empiric introduction of antifungal therapy. Many clinicians administer prophylactic fluconazole from the time of admission to the ICU.

Liver Transplantation It is generally in ICU that liver function deteriorates to the level at which prognosis can be determined (see Table 48-2). Patients in whom the poor prognosis criteria are not met will generally survive with full supportive therapy, but 80% to 90% of those who reach these criteria will die without liver transplantation. As well as the King's College and the coagulation criteria discussed earlier, Apache II and III scores have been assessed to identify patients with acetaminophen-induced acute liver failure with a poor prognosis. An Apache II score greater than 15 soon after admission may be useful in the early identification of patients with a poor prognosis and has an advantage over the King's College criteria in that intensive care specialists are familiar with its use. Overall, however, the predictive power of the two scoring systems is similar. [58] These poor prognosis scores are generally taken as the transplantation criteria as long as other medical or psychiatric contraindications are not present. Because patients may deteriorate very rapidly once the criteria are met, listing for liver transplantation should not be delayed. Other important testing required for urgent listing for liver transplantation such as human immunodeficiency virus status should therefore be carried out before the criteria are met to avoid unnecessary delay. Matching between donor and recipient with regard to size is not so important as before because of the ability to reduce graft size. However, transplantation across blood groups, with the exception of blood group AB recipients, has generally been abandoned because of poor results. Overall, the results of liver transplantation for FLF are not as good as for chronic liver disease. Most centers achieve 12-month survival figures of around 60% compared with 80% for patients who undergo liver transplantation for cirrhosis. One of the main reasons for this probably is that patients go to the operating room while they are critically ill, and anything that can be done to stabilize their clinical condition while they wait for a donor to become available is likely to affect results beneficially. Interventions aimed at improving the patient's condition, albeit temporarily, have been promoted as a bridge to transplantation. These include high-volume plasmapheresis, moderate hypothermia, hepatectomy, and use of a molecular adsorbent recirculating system. This last intervention is currently under study in numerous centers, and benefit has been reported in both acute and chronic liver failure. However, results of randomized studies will be needed to evaluate its role properly. The most promising therapeutic approach as a bridge to transplantation is probably the use of bioartificial liver support devices.

Liver Support Devices Treatment strategies using liver support devices designed to help patients with FLF have either been those aimed at detoxifying the blood or those aimed at providing liver-derived factors. The former includes hemofiltration, charcoal hemoperfusion, and plasmapheresis. None of these has proven to be of value in clinical practice. The latter measures require liver cells, and although extracorporeal hepatic perfusion has been attempted, incorporation of hepatocytes into a filtering system that contains a framework to support the cells (a bioreactor) physically as a bioartificial liver support device is the most attractive. This approach still requires much research and must be subjected to clinical trials before it can be advocated in clinical practice. At present, the choice of hepatocyte represents the major problem. Ideally, the liver cell should be human, highly differentiated, and readily available in large numbers. The critical functions necessary for a hepatocyte to work well in a bioartificial liver remain to be discovered. If bioartificial liver support devices do prove to be effective in clinical practice, it is hoped that, as well as being a bridge to transplantation, they may allow some patients to recover sufficient native liver function to survive without liver transplantation.

OVERVIEW

FLF is an uncommon medical emergency with many possible causes. Reliable criteria have been established that predict prognosis, and patients in the poor prognosis group are unlikely to survive without definitive intervention. At present, the only treatment shown to prolong survival is liver transplantation, but it is to be hoped that liver support devices and, in particular, bioartificial liver systems may in the near future prolong survival, both by allowing more patients to survive to liver transplantation or by bridging the period of acute liver failure until native liver function returns.

CHAPTER 49

Michelle L. Bennett, Joseph L. Jorizzo, and Elizabeth F. Sherertz

SKIN LESIONS ASSOCIATED WITH GASTROINTESTINAL AND LIVER DISEASES

Many diseases can involve both the skin and gastrointestinal tract. Primary disorders of the gut such as inflammatory bowel disease can initially manifest in the skin, and primary skin disorders such as pemphigus vulgaris may present with mucosal lesions. It is important that specialists in both disciplines be aware of how cutaneous lesions may be reflective of gastrointestinal diseases. This chapter reviews the skin lesions that may be associated with specific gastrointestinal complaints or known pathological processes. If a dermatologic lesion or diagnosis is suspected, dermatologic consultation is suggested to assist in diagnosis and management.

INFLAMMATORY BOWEL DISEASE

Chronic nonspecific ulcerative colitis and Crohn's disease are associated with a host of immunologic abnormalities. Although the role of circulating immune complexes in producing extraintestinal manifestations has been debated (see Chapter 7, Chapter 83, and Chapter 129), it is not surprising that numerous reactive inflammatory vascular dermatoses occur in patients with these diseases.

Erythema: Generalized, Localized, and Annular

Reactive inflammatory vascular dermatoses comprise a spectrum of inflammatory blood vessel reactions that occur in association with internal disease. [1] These range from generalized or local erythema, (macular blanchable lesions characterized histologically by simple vasodilation and mild inflammation) to urticarial lesions, erythema multiforme, and vasculitis characterized by palpable purpuric lesions with histological leukocytoclasis and fibrinoid necrosis of blood vessel walls. Table 49-1 summarizes the various types of vessel-based inflammatory lesions that may occur in patients with gastrointestinal disease.

TABLE 49-1 Erythematous Vessel-Based Eruptions in Patients with Gastrointestinal Disease

Urticaria and Angioedema

Urticaria is a raised, peau d'orange cutaneous vascular reaction characterized by dermal edema and erythema in which, by definition, individual lesions resolve within 24 hours. [1] Similar lesions occurring in a deep dermal or subcutaneous location are called *angioedema.* Urticaria is a common condition, affecting up to 20% of people at least once in their lifetime, often in young adulthood. In patients with inflammatory bowel disease, [2] urticaria is usually drug induced or results from some cause other than bowel disease. Hereditary or acquired C1 esterase deficiency is associated more with angioedema than urticaria; abdominal pain caused by mucosal edema may occur. Chronic urticaria affects primarily middle-aged women and is characterized by the occurrence of daily hives (individual lesions still resolve within 24 hours) for longer than 6 weeks. Two specific conditions, urticarial vasculitis and a syndrome of urticarial lesions occurring in the setting of a serum sickness–like illness lasting longer than 24 hours, are not, by definition, true urticaria. A skin biopsy should be performed on urticarial lesions that last longer than 24 hours, to exclude vasculitis. The cause of chronic urticaria in an individual patient may be difficult to establish. Several practical approaches have been published. [3] Treatment of urticaria consists of an attempt to eliminate the cause and to relieve signs and symptoms with around-the-clock antihistamine therapy.

Erythema Multiforme

Erythema multiforme is an acute, self-limited, mucocutaneous syndrome characterized by targetoid cutaneous lesions that may be accompanied by serum sickness–like signs and symptoms (e.g., fever, arthralgias). [4] *Erythema multiforme minor* refers to a form of the syndrome in which patients have a finite number of acrally located typical target lesions and, in general, lack mucosal lesions and other symptoms. *Erythema multiforme major* represents a more severe disease, and it is termed *Stevens-Johnson syndrome* if the patient has significant mucosal involvement. [4] Patients with *toxic epidermal necrolysis,* which may overlap with severe Stevens-Johnson syndrome, have a burnlike appearance. Toxic epidermal necrolysis is usually drug induced and may be associated with a 30% rate of mortality.

Well-documented causes of acute erythema multiforme include drugs (e.g., sulfonamides, phenytoin, penicillin), herpes simplex, *Mycoplasma* infections, and other infections (e.g., tuberculosis), as well as a host of underlying diseases. [4] Typical erythema multiforme has been described in patients with inflammatory bowel disease. [2] Complications of erythema multiforme major may affect the gastrointestinal tract and may be severe in toxic epidermal necrolysis. Esophagitis and esophageal stricture have been reported. There is considerable evidence that most cases of recurrent erythema multiforme minor are induced by recurrent herpes simplex infections. [4]

Therapy for erythema multiforme has not been assessed in a double-blind trial. Systemic corticosteroids are often prescribed for adults with erythema multiforme major in whom infection has been excluded. Ophthalmologic consultation for eye involvement and aggressive topical care are required to prevent secondary infection.

Erythema Nodosum

Erythema nodosum is characterized by the occurrence of tender, nonulcerative nodules, most often on the legs, resulting from inflammation in the subcutaneous fat (Fig. 49-1; see Color Fig. 49-1). Usually, these nodules last from 3 to 6 weeks and affect the anterior lower legs in a symmetric distribution. Patients may have associated signs and symptoms, including fever, malaise, arthritis, and arthralgias. [5]

FIGURE 49-1. (See Color Fig. 49-1.) The tender nodules of erythema nodosum occurred in association with ulcerative colitis.

Erythema nodosum has been well established as an extraintestinal manifestation of ulcerative colitis, Crohn's disease, and infectious colitis, such as that caused by *Yersinia enterocolitica.* [1] The incidence of erythema nodosum in patients with ulcerative colitis was 7% in one large series, but the incidence in Crohn's disease is lower. [5] Other well-documented conditions associated with erythema nodosum include drugs (e.g., estrogen, sulfonamides), infections (e.g., by bacteria, viruses, fungi, chlamydia, acid-fast bacteria, spirochetes), malignant diseases, and other diseases, including Behçet disease and sarcoidosis. [5] An immune complex–mediated mechanism affecting vessels in the septal panniculus has been proposed, although the exact pathogenesis of erythema nodosum remains unknown.

Treatment of erythema nodosum in patients with inflammatory bowel disease is directed at the underlying disease. Nonsteroidal antiinflammatory drugs or even acetaminophen may alleviate the systemic symptoms.

Vasculitis

The term *leukocytoclastic vasculitis* has been used to refer to a form of vasculitis affecting postcapillary venules with the histopathological findings of endothelial swelling, neutrophilic invasion of blood vessel walls, leukocytoclasis (karyorrhexis of nuclei of neutrophils), extravasation of erythrocytes, and fibrinoid necrosis of blood vessel walls. [6] It presents as palpable purpura and may go by other names such as small vessel venulitis, Henoch-Schönlein purpura (which is actually a subgroup with IgA-containing immune complexes), allergic angiitis, and hypersensitivity vasculitis. Larger vessel involvement characterizes polyarteritis nodosa, granulomatous vasculitis (e.g., Wegener syndrome, Churg-Strauss syndrome), and giant cell arteritis.

Small vessel vasculitis has been proposed as a cutaneous model for circulating immune complex–mediated vessel damage. [6] The central and peripheral nervous system, synovium, pleura, pericardium, gastrointestinal tract, and kidney may act as filters for complexes with the similar end result of necrotizing lesions. [6]

From 39% to 61% of patients with necrotizing venulitis do not have a precipitating cause that can be identified. Drugs, infections (e.g., hepatitis B, streptococcal infection), and diseases associated with immune complexes (e.g., collagen vascular diseases, cancers, chronic active hepatitis) account for most of the identified associations. Crohn's disease [7] and ulcerative colitis [8] have both been clearly described in association with necrotizing venulitis and occasionally with granulomatous vasculitis. [9]

Prognosis in all forms of vasculitis depends on the internal organ involvement. Treatment should be directed at the underlying disease. Severe vasculitis may require acute therapy with plasmapheresis or high-dose therapy with systemic corticosteroids, or both. Low-dose weekly methotrexate, azathioprine, or, for larger vessel vasculitis, cyclophosphamide may be important adjuvant therapies. Oral colchicine or sulfone drugs (e.g., dapsone) may be used for primarily cutaneous vasculitis. [6]

Erythema Elevatum Diutinum

Erythema elevatum diutinum is a chronic fibrosing dermatosis characterized by juxtaarticular, persistent, symmetric, firm, tender, red to yellow-brown papules and plaques on the extensor surfaces of extremities (Fig. 49-2; see Color Fig. 49-2). It is believed to be caused by immune complexes. Early histological features include leukocytoclastic vasculitis, subepidermal fibrin deposition, and dermal papillary edema. A storiform proliferation of dermal spindle cells with fibrosis and foci of neutrophils or neutrophilic vasculitis characterize older lesions. Besides inflammatory bowel disease and celiac disease, it has been associated with rheumatoid arthritis, pyoderma gangrenosum, diabetes mellitus, paraproteinemias, and dermatitis herpetiformis, as well as chronic infections including streptococcal, mycobacterial, and human immunodeficiency virus infections. [10] Oral dapsone therapy is the treatment of choice.

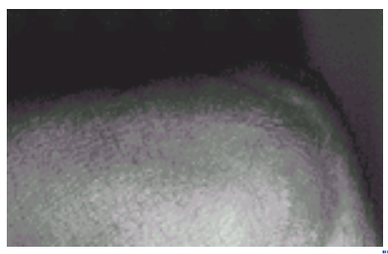

FIGURE 49-2. (See Color Fig. 49-2.) Typical lesions over joints in a patient with erythema elevatum diutinum.

Pyoderma Gangrenosum

Pyoderma gangrenosum is a misleading designation for an idiopathic ulcerating cutaneous disease. Theories range from a forme fruste of vasculitis to a cell-mediated reactive process. [6] Typically, fully evolved lesions have a dusky purple, undermined border and heal with cribriform scarring (Fig. 49-3; see Color Fig. 49-3). [6] Lesions may demonstrate the *pathergy phenomenon:* the rapid extension of the lesion after trauma such as from surgical debridement. Controversy exists about the exact histology of pyoderma gangrenosum, perhaps because older or partially treated lesions are often examined by biopsy. [6]

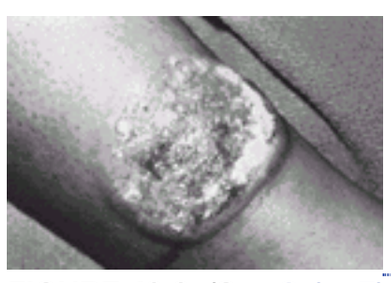

FIGURE 49-3. (See Color Fig. 49-3.) Pyoderma gangrenosum in a patient with Crohn's disease.

The diagnosis of pyoderma gangrenosum is a clinical diagnosis of exclusion. Bacterial, fungal, mycobacterial, and other infections, as well as vasculitis, squamous cell carcinoma, iododerma, bromoderma, and factitial disease, must be excluded histologically with appropriate special stains and cultures from biopsy specimens. More than 50% of patients with typical pyoderma gangrenosum do not have an associated disease. The association with inflammatory bowel disease, however, is one of the best known and should be considered and excluded in every patient with pyoderma gangrenosum. [11] Other associated conditions include chronic active and chronic persistent hepatitis, polyarthritis including rheumatoid arthritis, and myeloproliferative disorders.

Aggressive therapy is often required because the disease can spread rapidly and can predispose patients to sepsis or inanition and even death. Systemic corticosteroids in high doses, immunosuppressive agents, and sulfones are the mainstays of treatment. Anti–tumor necrosis factor antibody therapy may be useful.

Sweet Syndrome

Sweet syndrome, also known as acute febrile neutrophilic dermatosis, is characterized by the abrupt onset of tender cutaneous erythematous papules and plaques (Fig. 49-4; see Color Fig. 49-4). [15] Fever and peripheral blood neutrophilia also may occur. Disease onset frequently follows a nonspecific infection of the respiratory or gastrointestinal tract and is believed to represent a hypersensitivity reaction. Sweet syndrome has been reported in association with acute infections, myelodysplastic and other malignant diseases, and inflammatory bowel disease. [16] Histological specimens show a neutrophil vascular reaction with dermal inflammatory neutrophilic infiltrates and leukocytoclasia with no fibrinoid change in vessel walls.

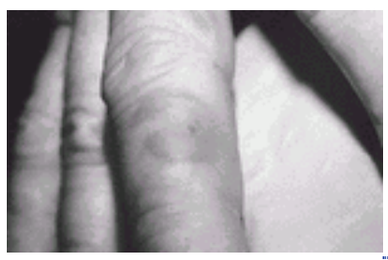

FIGURE 49-4. (See Color Fig. 49-4.) Tender erythematous papules and plaques on the upper extremities in a patient with Sweet syndrome.

Cutaneous lesions are typically located on the upper extremities, head, and neck. They may ulcerate, become purulent, and resemble lesions of pyoderma gangrenosum. Many dermatologists view Sweet syndrome and pyoderma gangrenosum as representing a continuum along a spectrum of disease, and considerable overlap between these two diseases occurs. [15] Like pyoderma gangrenosum, the disease responds to therapy with prednisone or other immunosuppressive agents, although often therapy with oral dapsone alone is adequate.

Oral Manifestations

As many as 30% of patients with ulcerative colitis have oral lesions, including aphthae and angular stomatitis, [2] whereas specific lesions (i.e., granulomas) of Crohn's disease affect the mouth and lips more rarely. Granulomatous lip lesions of Crohn's disease may be confused with Melkersson-Rosenthal syndrome, a condition in which granulomatous cheilitis occurs in association with facial nerve palsy. Granulomatous oral lesions may be nodular or show a cobblestone pattern. [12] *Aphthae* (canker sores) are nonspecific mucosal lesions that may be the most common oral lesions in patients with inflammatory bowel disease (Fig. 49-5; see Color Fig. 49-5). Simple aphthae occur in up to 25% of healthy persons. Patients with numerous, almost constant, oral aphthae (complex aphthosis) should be evaluated to exclude inflammatory bowel disease [13] and Behçet disease.

FIGURE 49-5. (See Color Fig. 49-5.) Aphthous ulcer involving the tongue in a patient with Behçet disease.

Angular cheilitis (perléche and angular stomatitis) may occur as a manifestation of nutritional deficiency or, more commonly, as a manifestation of oral candidiasis. *Pyostomatitis vegetans* is a papular eruption of the oral mucosa that produces a cobblestone and eroded appearance. This distinctive oral disease is associated with Crohn's disease or ulcerative colitis in most patients. [14]

Miscellaneous Skin Lesions

Although certain reactive dermatoses occur more commonly in patients with inflammatory bowel disease, many reports exist of single-case associations of a given dermatosis with Crohn's disease or ulcerative colitis. Metastatic Crohn's disease, which is the occurrence of noncaseating granulomas remote from the gastrointestinal tract in patients with Crohn's disease, has been well described at a host of cutaneous sites. [17] Lesions are usually ulcers, papules, or nodules. Pustular vasculitis, which can occur with inflammatory bowel bypass syndrome, is discussed later (see section " Bowel-Associated Dermatosis-Arthritis Syndrome"). Details of other less common associations can be sought in review articles, [2], [7] as well as in classical reports of large patient population surveys. [18], [19] Table 49-2 provides an overview.

Erythemas (including annular erythemas)
Urticaria
Erythema nodosum
Necrotizing venulitis
Larger vessel necrotizing vasculitis
Pustular vasculitis
Pyoderma gangrenosum
Oral lesions
Specific granulomas (Crohn's disease only)
Aphthosis
Angular cheilitis
Pyostomatitis vegetans
Metastatic Crohn's disease
Finger clubbing
Acquired acrodermatitis enteropathica (zinc deficiency)
Striae
Epidermolysis bullosa acquisita
Psoriasis
Exfoliative erythroderma
Vitiligo
Lichen nitidus
Lichen planus

TABLE 49-2 Some Cutaneous Associations of Crohn's Disease and Ulcerative Colitis

RHEUMATOLOGIC DISEASES

Rheumatoid Arthritis and Systemic Lupus Erythematosus

A review of skin manifestations of rheumatoid arthritis and systemic lupus erythematosus is beyond the scope of this review. Gastrointestinal involvement is usually related to vasculitis and is similar to that described earlier. Chapter 128 describes the gastrointestinal manifestations of rheumatic diseases.

Dermatomyositis

Dermatomyositis is an idiopathic inflammatory disorder that affects primarily skin and muscle and may manifest gastrointestinal symptoms (see Chapter 128). The cutaneous lesions are a violaceous poikiloderma (i.e., hyperpigmentation and hypopigmentation, telangiectasia, and epidermal atrophy) that occurs over the eyes (heliotrope sign), knuckles (Gottron sign), and extensor surfaces. There is a photosensitivity component to the eruption. Periungual telangiectasia and cuticular dystrophy are also typical. As many as 25% of patients with primary idiopathic polymyositis, and a smaller percentage of those with dermatomyositis, have dysphagia caused by involvement of striated muscles of the pharynx and esophagus. [20] Dermatomyositis or polymyositis may occur as a paraneoplastic syndrome in adults; therefore, the adult patient with dermatomyositis or polymyositis should be evaluated for occult malignant disease. Studies should include a complete history, physical examination, chest radiograph, and screening laboratory tests, as well as a breast and pelvic examination, Papanicolaou smear, and mammography in women and a prostate examination in men. [21] Because gastrointestinal tumors may be a cause, the rectum, colon, pancreas, and stomach may need evaluation as well.

Scleroderma

Scleroderma is a cutaneous or multisystem disease of unknown origin. A localized cutaneous form (morphea) is characterized by plaque, gyrate, generalized, or linear dermal sclerosis. The systemic form may be considered as a continuum of disease severity, the extremes of which are the milder CREST variant (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) and a more severe, progressive systemic sclerosis. [22] Most patients with systemic scleroderma have the CREST variant. Although patients with CREST can become critically ill with any of the varied manifestations of systemic scleroderma, they generally are middle-aged or older women who have a chronic course and die with, not of, their disease. Esophageal reflux should be treated to reduce esophageal fibrosis. Sclerosis occurs acrally and periorally and can affect the trunk. A salt-and-pepper postinflammatory pigment change is particularly noticeable over sclerotic areas in darker-skinned patients. Telangiectasias are described as being boxlike or matlike and occur on the hands, face, oral mucosa, and other sites. [23] The progressive systemic sclerosis type of systemic scleroderma occurs with an explosive onset. The dermal sclerosis is dramatic, but CREST features are often absent or are present to a lesser degree. The systemic and gastrointestinal features of scleroderma are discussed in Chapter 59, Chapter 73, and Chapter 128.

Behçet Disease

Behçet disease is a complex multisystem disease first described by and named after a Turkish dermatologist. [6] Because there is no pathognomonic laboratory test for the diagnosis, several sets of diagnostic criteria have been proposed. The O'Duffy criteria require that patients without inflammatory bowel disease or collagen vascular disease must have oral aphthosis (canker sores) plus at least two of the following: genital aphthae, synovitis, posterior uveitis, cutaneous pustular vasculitis, and meningoencephalitis. [24] The exclusion of patients with inflammatory bowel disease is crucial because patients with bowel disease may have recurrent aphthosis and (especially those with HLA-B27 antigen) are best considered as having the Reiter disease/HLA-B27 spectrum of diseases rather than Behçet disease. [25]

The oral lesions in Behçet disease are aphthae and can easily be distinguished from the psoriasiform oral lesions of Reiter disease. [25] Genital aphthae resemble oral aphthae (Fig. 49-6; see Color Fig. 49-6). Recurrent herpes simplex must be excluded by culture or by immunoperoxidase study of biopsy material. Cutaneous pustular vasculitis lesions show either leukocytoclastic vasculitis or a neutrophilic vascular reaction histologically. [26] Other lesions have been described that are similar to those seen in erythema nodosum, Sweet syndrome, or pyoderma gangrenosum.

FIGURE 49-6. (See Color Fig. 49-6.) Early genital aphtha showing features of pustular vasculitis in a patient with Behçet disease.

Certain ocular changes have been described in these patients, although posterior uveitis (i.e., retinal vasculitis) is the most important manifestation. The synovitis produces an asymmetric, migratory, nonerosive oligoarthritis. Many neurological manifestations have been reported. Vascular involvement such as aneurysms, arterial occlusions, venous occlusions, and varices may occur, and they can prove fatal. The principal gastrointestinal manifestations are aphthae, which can occur at any gastrointestinal site. Changes similar to those in inflammatory bowel disease have been described, but, as has been discussed, these may occur in HLA-B27–positive patients with a Reiter-like illness and aphthae.

Bowel-Associated Dermatosis-Arthritis Syndrome

Approximately 20% of patients in one report developed a characteristic syndrome after jejunoileal bypass surgery [27] that included pustular vasculitic cutaneous lesions, arthritis, and serum sickness–like features. Clinically and histopathologically, the skin lesions resembled the pustular vasculitis lesions seen in Behçet disease. This operation has essentially been abandoned; however, we expanded the concept to include patients who have not had bypass surgery but who have either inflammatory bowel disease or the occurrence of a blind loop after Billroth II surgery. [28]

The cutaneous lesions occur in crops, with each episode lasting 1 to 2 weeks and occurring at intervals of 1 month to several months (Fig. 49-7; see Color Fig. 49-7). Lesions similar to those seen in erythema nodosum may occur. Fever, myalgias, chills, flulike symptoms, gastrointestinal upset, and arthralgias or nonerosive arthritis are often associated. Circulating immune complexes have been postulated to mediate this syndrome, [27] and serum enhancement of neutrophil migration may mediate the cutaneous lesions. [29]

FIGURE 49-7. (See Color Fig. 49-7.) Bowel-associated dermatosis-arthritis syndrome. Pustular vasculitis lesions occurred in a patient with a blind loop after Billroth II surgery.

The bowel bypass syndrome can be cured by restoration of normal bowel anatomy (see Chapter 79). Treatment of the underlying disease is necessary to control the syndrome in patients with inflammatory bowel disease. Systemic antibiotic therapy with metronidazole, tetracycline, or erythromycin has proved beneficial in controlling cutaneous and systemic manifestations of this syndrome. Systemic corticosteroid therapy and oral dapsone are also effective therapies. [6]

Amyloidosis

Amyloidosis is a group of syndromes characterized by the extracellular deposition of an abnormal protein with certain staining properties and electron microscope features. Primary amyloidosis, also called light-chain–related systemic amyloidosis, [30] often occurs in patients with multiple myeloma. Macroglossia, cutaneous papules, plaques, and nodules occur with pinch purpura (Fig. 49-8; see Color Fig. 49-8). Patients with primary amyloidosis have frequent gastrointestinal, cardiac, renal, and other multisystem involvement. Skin biopsy of a cutaneous lesion in primary amyloid is virtually diagnostic of the disease.

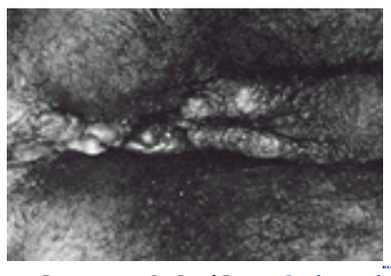

FIGURE 49-8. (See Color Fig. 49-8.) Amyloidosis. Note the perirectal amyloid nodules in this patient with multiple myeloma.

Patients with secondary (AA) amyloidosis do not have cutaneous involvement. [31] This pattern is associated with underlying disease, such as chronic inflammatory bowel disease, tuberculosis, leprosy, chronic osteomyelitis, or familial Mediterranean fever. Biopsy of normal skin reveals amyloid deposits in fewer than one third of patients, whereas small bowel or colonic mucosal biopsy samples are positive in more than 75% to 85% of patients.

SKIN DISEASE AND GASTROINTESTINAL BLEEDING

Vascular Abnormalities

Osler-Weber-Rendu Disease (Hereditary Hemorrhagic Telangiectasia) This autosomal dominant trait is characterized by telangiectasis, aneurysms, and arteriovenous malformations that can affect mucocutaneous areas as well as internal organs. [32] The mucocutaneous hallmark for the syndrome is 1- to 3-mm telangiectatic mats resembling those seen in patients with scleroderma (Fig. 49-9; see Color Fig. 49-9). These lesions can affect the lips, tongue, face, hands, chest, and feet [32] (see Chapter 130).

FIGURE 49-9. (See Color Fig. 49-9.) Typical telangiectasia of Osler-Weber-Rendu disease.

Blue Rubber Bleb Nevus Syndrome *Blue rubber bleb nevus syndrome* is a rare autosomal dominant condition with blue, subcutaneous, rubbery, compressible, sometimes painful nodular vascular malformations that are up to 10 cm in diameter. [33] These vascular malformations are not true hemangiomas. They occur in the small intestine or colon but also have been observed in the oropharynx, nasopharynx, esophagus, stomach, peritoneal cavity, mesentery, liver, lung, glans penis, eye, and central nervous system. [34] Gastrointestinal bleeding and intussusception may occur (see Chapter 130).

Kaposi Sarcoma Most publications since the early 1980s regarding *Kaposi sarcoma* have focused on the epidemic form of the disease, associated with the acquired immunodeficiency syndrome (AIDS) [35] (see Chapter 51). An endemic form has long been recognized in Africa, and the third variant is the classic type, which occurs primarily in persons of Mediterranean ancestry. The tumor in all groups is derived from proliferating endothelial cells. The cutaneous lesions vary from reddish-purple macules to large vascular tumors. In the slowly progressive classic form of the disease, lesions begin on the feet or lower legs of affected patients (who are typically elderly men) and extend proximally, becoming associated with severe peripheral edema. The most common site of internal involvement, but usually not a prominent feature, is the gastrointestinal tract. Sites affected, in order of decreasing frequency of involvement, are the small intestine, stomach, esophagus, and colon. [36] Extensive hemorrhage or partial bowel obstruction can occur. Other organs that may be affected include lymph nodes, larynx, spleen, liver, and lungs. Most patients with the classic form of Kaposi sarcoma die with, and not of, their disease. In contrast, the Kaposi sarcoma associated with AIDS is far more aggressive clinically (see Chapter 51).

Malignant Atrophic Papulosis (Degos Disease) *Malignant atrophic papulosis* (Degos disease) is a rare, idiopathic, usually lethal disease with characteristic lesions that affect the skin, gastrointestinal tract, and central nervous system. [37] The cutaneous lesions are discrete, painless papules with umbilicated porcelain-white centers surrounded by telangiectatic rims. Histologically, these lesions reveal an atrophic epidermis with a wedge-shaped dermal scar that is broader at the top than at the bottom. [38] Gastrointestinal involvement may lead to massive gastrointestinal bleeding and to death (see Chapter 130). Current evidence is against an immunopathogenesis in this disease. [38] There is no effective therapy, and visceral involvement may be fatal.

Diseases of Connective Tissue

Pseudoxanthoma Elasticum *Pseudoxanthoma elasticum* is a genetic disorder characterized by cutaneous and visceral manifestations that result from alterations to elastic fibers. Four genetic subtypes have been described, including both autosomal recessive and dominant inheritance patterns. [39] These types have a variety of ocular, cardiovascular, and gastrointestinal manifestations. The cutaneous lesions consist of yellow papules and plaques that resemble chicken skin (Fig. 49-10; see Color Fig. 49-10). These lesions begin early in life and may progress to affect the buccal mucosa, neck, axillae, and other flexures. Histologically, lesions show calcification of middermal elastic fibers. Angioid streaks are the characteristic retinal finding in patients affected with pseudoxanthoma elasticum but are not specific. The entire cardiovascular system is at risk for vascular calcification.

FIGURE 49-10. (See Color Fig. 49-10.) Pseudoxanthoma elasticum. Note the chicken skin–like appearance of the axillary skin.

Gastrointestinal involvement may present with recurrent upper or lower gastrointestinal hemorrhage (see Chapter 130). Endoscopy reveals the characteristic yellow cobblestone changes in the bowel. The pathogenesis remains unknown. The treatment is aimed at complications, but no therapy exists to alter the connective tissue abnormality. Prognosis depends on the subtype of disease.

Ehlers-Danlos Syndrome *Ehlers-Danlos syndrome* is a heterogenous group of genetically inherited syndromes characterized by defective collagen. More than 10 distinct subtypes exist, with various autosomal or X-linked inheritance patterns and with diverse abnormalities of collagen production. [40] The skin may be both hyperextensible and fragile. Wound healing is delayed and may produce cigarette burn–like scars or "fishmouth" scars as well as pseudotumors over joints. Purpura caused by easy bruising and hyperextensibility of joints are prominent features of Ehlers-Danlos syndrome. Visceral involvement is varied. Ocular and dental abnormalities are common. Large arteries may be affected by abnormal collagen, and rupture may occur, especially during pregnancy. Gastrointestinal perforation is prevalent in patients with type IV Ehlers-Danlos syndrome who have defective type III collagen and translucent skin with numerous ecchymoses. In addition to bowel perforation and gastrointestinal bleeding, these patients have a predisposition toward rupture of blood vessels; therefore, the prognosis is particularly grave [41] (see Chapter 130).

Cutis Laxa (Generalized Elastolysis) *Cutis laxa* is a heterogeneous group of autosomal and X-linked disorders characterized primarily by abnormalities of elastic fibers. [42] The skin appears to be too large for the body. It sags and has a wrinkled, aged appearance. Gastrointestinal diverticula and hernias occur. [42] The genitourinary tract also may be affected. Typical corkscrew-shaped blood vessels are seen on arteriography. Progressive pulmonary involvement may lead to chronic obstructive pulmonary disease, cor pulmonale, and premature death.

Neurofibromatosis (Von Recklinghausen Disease) *Neurofibromatosis* is inherited in an autosomal dominant fashion. Cutaneous features such as café au lait macules, axillary freckles, and cutaneous neurofibromas are hallmarks of this disease. Neurofibromas may occur throughout the gastrointestinal tract in 25% of patients. [43] The tongue, gallbladder, stomach, and jejunum are more commonly affected than the esophagus or colon. Ulceration, bleeding, volvulus, obstruction, perforation, and intussusception may occur. Malignant transformation of neurofibromas in the gut is not common, but it is well reported. Surgery is often required for symptomatic gastrointestinal involvement.

SYNDROMES ASSOCIATED WITH GASTROINTESTINAL POLYPS

Gardner Syndrome (Familial Adenomatous Polyposis)

In 1953, Gardner refined his description of a dominantly inherited triad of osteomas, epidermoid cysts, and colorectal polyposis that predisposed to colonic adenocarcinoma. [44] *Gardner syndrome* occurs as part of a spectrum that includes familial polyposis coli (no extracolonic lesions) and Turcot syndrome (features of Gardner syndrome plus central nervous system neoplasms) [45] (see Chapter 90).

Patients with Gardner syndrome develop multiple epidermoid cysts in their early teenage years. These cysts occur in a generalized distribution, especially on the scalp, face, and extremities [46] (Fig. 49-11; see Color Fig. 49-11). Desmoid tumors, which represent locally aggressive but nonmetastasizing tumors of fibrous tissue,

often affect the mesentery or the abdominal wall.

FIGURE 49-11. (See Color Fig. 49-11.) Typical epidermal inclusion cyst of Gardner syndrome. This patient had many other cystic nodules, particularly on the scalp.

Peutz-Jeghers Syndrome

Peutz and, later, Jeghers described a condition with an autosomal dominant inheritance pattern characterized by small intestinal hamartomatous polyps and hyperpigmented macules of the lips. [47] Although most polyps occur in the jejunum, they also occur in the ileum, stomach, duodenum, and colon (see Chapter 90). Polyps are present in childhood and may predispose to intussusception or to gastrointestinal bleeding.

The melanotic macules of Peutz-Jeghers syndrome begin in infancy. They affect the lips most commonly, but they also may affect the palms, soles, digits, periorbital skin, anus, and buccal mucosa. They histologically resemble ephelides (freckles). All except the buccal lesions fade with age. [48]

Cronkhite-Canada Syndrome

The *Cronkhite-Canada syndrome* is a sporadically occurring disorder of adults defined by the tetrad of cutaneous hyperpigmentation, alopecia, onychodystrophy, and intestinal polyposis. [49] The gastrointestinal signs and symptoms (e.g., diarrhea, abdominal pain, weight loss, anorexia) often precede the onset of the hair, nail, and cutaneous manifestations by several months (see Chapter 90).

The predominant cutaneous lesions are macular hyperpigmented macules that coalesce to form plaques that are distributed primarily on the upper extremities but may occur on most cutaneous sites. [50] Vitiligo occasionally may occur. Onycholysis, onychoschizia, or onychomadesis may affect all 20 nails. Widespread alopecia is nonscarring and may resemble alopecia areata. [50] The tongue may be fissured.

Cowden Disease

Cowden disease, also called multiple hamartoma syndrome, is inherited in an autosomal dominant fashion. Mucocutaneous markers for the syndrome include facial and oral mucosal papules that histologically represent tricholemmomas (benign hair-derived tumors). [51] The oral lesions produce a cobblestone appearance. A scrotal tongue is often associated. Acral keratoses resemble acrokeratosis verruciformis. [50] Patients also may have lipomas, hemangiomas, neuromas, and café au lait macules.

Gastrointestinal hamartomatous polyps occur throughout the gastrointestinal tract, with the majority affecting the rectum and sigmoid colon. The polyps are not premalignant; however, up to one third of patients with Cowden disease develop a malignant disease, usually of the breast or thyroid. [51]

Muir-Torre Syndrome

Muir and Torre each reported the association of sebaceous neoplasms and multiple visceral carcinomas. [52], [53] The inheritance pattern is autosomal dominant. Cutaneous markers for the syndrome include sebaceous neoplasms (hyperplasia, adenoma, epithelioma, and carcinoma), basal cell carcinomas, and keratoacanthomas. [50]

Adenomatous colonic polyps are not a universal feature of the syndrome, but one half or more of these patients do have polyps, and some develop colonic adenocarcinomas. Urogenital, hematologic, breast, and other malignant diseases may occur. [54] Patients should be screened frequently for colonic polyps, colonic carcinoma, and other malignant diseases.

Acrochordons and Colonic Polyps

In 1982, Klein and associates reported an increased incidence of *acrochordons* (skin tags) in patients with acromegaly observed for colonic polyps [55] and suggested that patients with more than six acrochordons could reasonably be targeted for evaluation for colonic polyps. [56] Several subsequent studies confirmed the correlation between acrochordons and colonic polyps, [57] although this was refuted in an autopsy study. [58] Most agree that the association is of no prognostic significance (see Chapter 91).

CUTANEOUS SIGNS OF GASTROINTESTINAL MALIGNANCY

Metastases and Direct Extension

Metastatic nodules of gastrointestinal adenocarcinoma are usually firm, pink, dermal to subcutaneous masses most likely to occur on the abdomen or pelvic area. The primary lesion has usually already been diagnosed by the time metastases develop. Biopsy of such a lesion helps to diagnose the primary site in fewer than 50% of patients. [59] An indurated nodule of the umbilicus (the Sister Mary Joseph nodule) may be the initial clinical presentation of an underlying (usually advanced) abdominal malignant disease, most commonly adenocarcinoma of the stomach or large bowel. Rarely, direct involvement of the lymphatics in the abdominal or thigh region draining a primary site can lead to extensive dermal infiltration, presenting as a sclerotic plaque. Occasionally, such a plaque can be quite erythematous and can mimic cellulitis (carcinoma erysipeloides).

Cutaneous Lesions that Should Raise Suspicion of Possible Gastrointestinal Malignancy

Extramammary Paget disease is considered to be a cutaneous adenocarcinoma, probably of apocrine gland origin. [60] It presents insidiously as an erythematous scaling or lichenified patch, often with surface erosion or crusting. Typically, the site has been treated with topical corticosteroids or antifungals without response, and the diagnosis is made by clinical suspicion and skin biopsy. If it occurs in the perianal area, it should raise suspicion of a possible underlying rectal or cloacogenic carcinoma [61] (see Chapter 91 and Chapter 92). The frequency of underlying visceral carcinoma has been reported at up to 86%, although a more recent review showed that only 25% of patients with perianal Paget's disease had a concurrent carcinoma of rectal origin. [61] Treatment of Paget's disease is usually by surgery (Mohs micrographic or wide excision) or radiation therapy, but the lesion frequently recurs.

Acanthosis nigricans presents as a smooth, thickened, and dark appearance to the skin in body fold areas, most often in the axilla and around the neck (Fig. 49-12; see Color Fig. 49-12). If extensive, it may lead to a striking appearance, with thickening of the palms and soles and oral lesions of hyperkeratosis. Acrochordons (or skin tags) also may occur in affected sites. This clinical presentation is most often seen without malignant disease in obese patients, in certain insulin-resistant diabetes syndromes, as a familial trait, and with certain medications.

FIGURE 49-12. (See Color Fig. 49-12.) Acanthosis nigricans in a nonobese adult patient.

Suspicion for malignancy-associated acanthosis nigricans should arise if the condition occurs with recent onset in a nonobese patient who does not have diabetes. Biopsy of the skin is not helpful. Attention should be focused on the possibility of gastric adenocarcinoma, although other intra-abdominal and pelvic sites also should be evaluated for possible malignant disease. [62], [63] The malignant disease appears concomitantly in 61% of patients, but in almost 20%, the acanthosis nigricans may precede the diagnosable tumor by years. In these patients, frequent surveillance is necessary. In a patient known to have had an abdominal adenocarcinoma who then develops acanthosis nigricans, a vigorous search for recurrence or metastatic disease should be undertaken. The mechanism of malignant acanthosis nigricans is thought to be related to peptide growth factors released by the tumor. [64] Remission of the skin lesions occurs with removal of the tumor. There is no good dermatologic or cosmetic treatment for acanthosis nigricans.

Keratoderma of the palms and soles (tylosis) is a nonspecific presentation of diffuse or punctate yellow hyperkeratosis of the palmar and plantar surfaces. There are multiple causes, and it is only in patients with long-standing skin lesions and a family history of cancer that the question of gastrointestinal malignant disease should be raised. The strongest association has been with esophageal squamous cell carcinoma, and in the Howel-Evans syndrome it may occur in an autosomal dominant pattern, with up to 95% of family members developing esophageal carcinoma by 65 years of age [65] (see Chapter 62). In such kindreds, regular evaluations with barium swallow and esophagoscopy are warranted. [66] Other kindreds have been described with punctate keratodermas and carcinoma of the colon or pancreas. There are individual case reports of tylosis occurring in association with esophageal or bronchial carcinoma without a family history. In most of those cases, the palmar-plantar thickening was of recent onset without any other skin disease. The diagnosis of malignant disease was usually apparent at the time of initial presentation and evaluation.

Generalized erythroderma is a nonspecific cutaneous reaction pattern with a large differential diagnosis of possible causes, including primary skin diseases, adverse drug reaction, and internal malignant disease (especially lymphoma). The possibility of esophageal or other occult carcinoma should be raised in an erythrodermic patient with compatible symptoms. [68]

Hypertrichosis lanuginosa acquisita refers to the sudden development of diffuse, fine, downy hair on the face and trunk. It is extremely rare but is strongly associated with internal malignant disease. It has been seen most often with carcinoma of the lung or colon and, less commonly, of the pancreas and gallbladder. [68]

Patients with the *Paterson-Brown-Kelly (Plummer-Vinson) syndrome* present with mucocutaneous findings of brittle, spoon-shaped nails (koilonychia), atrophic tongue, and angular stomatitis (see Chapter 31 and Chapter 58). Dysphagia and iron deficiency complete the syndrome. Carcinoma of the postcricoid area of the esophagus occasionally occurs in long-standing cases. [69]

Flushing episodes may be the presenting sign of *carcinoid syndrome,* which has been seen primarily with carcinoid tumors of the small intestine with liver metastases. The flushing is a bright red color on the face and upper chest, occasionally involving the entire trunk and extremities, lasting from 10 to 30 minutes. After repeated episodes, permanent, rosacea-like telangiectasia and edema develop. Episodes may be provoked by food intake, alcohol, and emotional stress. The mechanism of the flushing is related to contributions by various vasoactive and neuropeptides, as discussed in more detail in Chapter 80. The best current treatment for carcinoid flush is octreotide, which is effective in up to 90% of cases. [70] Similar flushing episodes can occur in patients with multiple endocrine neoplasia. Pellagra-like skin lesions and cutaneous metastases have rarely been reported in patients with carcinoid tumors.

Necrolytic migratory erythema is the specific descriptive term for the cutaneous lesions of the glucagonoma syndrome, which occurs with a glucagon-secreting islet cell tumor of the pancreas (see Chapter 97). The cutaneous eruption typically affects perioral, lower abdominal, and perineal sites with a configurative erythema, erosions, and superficial necrosis and scale. Clinically, the condition resembles zinc deficiency. Patients often have angular cheilitis and a red, swollen tongue. The clinical presentation consisting of glucose intolerance, weight loss, psychological changes, and anemia is more important than skin biopsy in making the diagnosis. [71] Skin lesions may respond to intravenous amino acid supplementation, to octreotide or its analog, or to treatment of the underlying tumor. [72], [73] Necrolytic migratory erythema has occasionally been reported in the absence of a pancreatic tumor, but a vigorous search for a tumor is needed whenever typical skin lesions occur in a patient with other suggestive symptoms.

BULLOUS DISEASES OF THE SKIN THAT CAN DIRECTLY AFFECT THE GASTROINTESTINAL TRACT

Epidermolysis Bullosa
