In 1991, Neuberger and colleagues reported staining of intact bile duct epithelial cells with antibodies to PDC-E2 in explanted PBC liver. [12] Similar aberrant staining was not seen in normal liver or liver disease controls. The events leading to this expression of PDC-E2-reactive material are still not understood. One hypothesis is that cholangiocytes are first injured by another process, allowing release of intracellular antigens that are then displayed on the cell surface. Another hypothesis is that mitochondrial antigens are carried to the surface complexed with immunoglobulin A (IgA) during the normal route of IgA excretion into bile. Alternatively, the abnormal surface staining could result from surface expression of an abnormal or partial-length PDC-E2, or a molecule that is cross-reactive with antibodies generated against PDC-E2. Reactivity to such a cross-reactive molecule could, in theory, originate from exposure to an infectious organism, since PDC enzymes are well conserved across species. In particular, the rough mutant of *Escherichia coli* expresses a PDC epitope that is recognized by PBC AMAs, [13] and these bacteria have been found in PBC urine and feces more frequently than in liver disease controls. [14], [15]

Clinically, AMAs appear years before other clinical signs of the disease, and thus may be present at the initiation of the disease process. However, there is no evidence that antibody and complement-dependent cytotoxicity is occurring near the small bile ducts in PBC liver. Deposits of C3d (derived from the terminal complex of complement) are not found near bile ducts [16] and immune complexes are not consistently identified in patients with PBC. [17] Furthermore, AMA titer does not correlate well with disease severity. Hence, many questions regarding the role of AMA in the pathogenesis of PBC remain unanswered.

T-lymphocyte–Mediated Destruction of Biliary Epithelial Cells

A rapidly growing body of evidence supports the hypothesis that bile duct destruction occurs through T-cell–mediated mechanisms in PBC. This is not surprising considering the abundance of T-lymphocytes in PBC portal tract infiltrates. [18] The mechanisms leading to T-cell activation are not well understood. Classically, T cells are activated after recognition of an antigen in the context of major histocompatibility complex (MHC) and costimulation by molecules on the surface of professional antigen-presenting cells. Indirect evidence suggests cholangiocytes may be able to serve as antigen presenting cells in PBC. The biliary epithelial cells of patients with PBC exhibit increased expression of HLA class I, HLA class II, and intracellular adhesion molecule 1 (ICAM-1), and have been noted to express the costimulatory molecule, B7, by some investigators. [4] Collectively, these cell surface markers create the appropriate environment in which T cells could make direct contact with cholangiocytes and recognize antigens. However, antigen presentation by cholangiocytes has not been demonstrated in vitro. [19]

Both $CD4^+$ and $CD8^+$ T cells have been implicated in the pathogenesis of PBC. In vitro, cytotoxic $CD8^+$ cells are the major lymphocyte subset that binds to cholangiocytes. [19] Aberrant staining for HLA class II on biliary epithelium, however, suggests that $CD4^+$ T-cell recognition of antigens on cholangiocytes may be important. Clinical studies examining HLA associations with PBC have reached a variety of contradictory conclusions. The most frequently observed association across studies is a weak link with HLA-DR8, with a recent study suggesting that HLA-DR8 is a risk factor for disease progression. [20] In North America and Europe, 11% to 36% of Caucasian females with PBC carry the HLA-DR8 antigen, as opposed to 4% to 9% of controls. In Japan, where HLA-DR8 is present in 23% of the normal population, HLA-DR8 is found in up to 79% of patients with PBC.

PDC-specific $CD4^+$ T cells have been demonstrated in the blood and liver of patients with PBC. About 55% of patients with PBC have circulating T cells reactive to the purified E2/X component of PDC, as compared to 1% to 13% of controls. [21], [22] Between 3% to 8% of liver-derived T-cell clones from patients with PBC are also specific for PDC. [22] In addition, T cells within PBC liver have been found to consist of oligoclonal populations, in agreement with the notion that they are antigen-specific T cells. [23] The identification of PDC-E2/X specific $CD4^+$ T cells in blood and liver of patients with PBC along with linkage of PBC to selected HLA-DR alleles supports a role for T-cell responses to mitochondrial antigens presented by cholangiocytes in the pathogenesis of PBC.

The Th1 cytokine interferon-? (IFN-?) has been found to be expressed at higher levels in PBC liver than in control livers from patients with autoimmune hepatitis or in normal liver tissue from transplant donors. [24], [25] Patients with PBC are also more likely to have an interleukin 1ß (IL-1ß) gene allele associated with high IL-1ß production. [26] It remains to be determined whether these cytokines play an important role in biliary cell death via macrophage or cytotoxic lymphocyte activation. Biliary cell death likely occurs primarily through induction of apoptosis. Fas antigen is present on biliary epithelium, and biliary epithelial cells from patients with PBC have been observed to undergo apoptosis more frequently than control biliary epithelial cells. [26]

CLINICAL MANIFESTATIONS

Clinical Presentation

The diagnosis of PBC is suspected when a patient presents with evidence of chronic cholestasis. In the early stages, this may be an asymptomatic elevation of serum alkaline phosphatase levels and/or ?-glutamyl transpeptidase. Over time, fatigue or clinical signs of chronic cholestasis such as pruritus or hypercholesterolemia may develop. Jaundice occurs late in the disease process and is a poor prognostic sign. Early reports of patients with PBC primarily described patients with jaundice and advanced disease. [27], [28] Over time, clinical case series have included a decreasing percentage of jaundiced patients and an increasing number of asymptomatic patients. [29] This phenomenon is attributed to increasing physician awareness of the disease as well as widespread use of serum alkaline phosphatase and specific autoantibody tests to help establish an early diagnosis. With earlier diagnosis, a long presymptomatic stage of PBC has become well recognized. In one study of 45 patients with PBC identified during this asymptomatic stage, 84% remained asymptomatic 5 years after the diagnosis had been originally suspected. [29] Patients with PBC may experience symptoms from associated conditions, such as sicca complex, thyroid disease, or arthritis before symptoms of the liver disease itself. [30] Eventually, however, the typical patient experiences the insidious onset of fatigue or pruritus. [31]

Signs/Symptoms

Fatigue is the most common complaint of patients with PBC. Its etiology is obscure, and its severity may be disproportionate to other disease manifestations. [31] No specific medical therapy is yet available, but lifestyle changes such as adequate rest and regular exercise may offer some benefit. [32] Concomitant depression or anxiety is not uncommon, and these co-morbidities may benefit from pharmacological therapy.

The generalized pruritus of PBC is characterized by periodic exacerbations and improvements. Pruritus is often more noticeable in the evenings, when distractions are minimal. Dry skin and decreased ultraviolet exposure during the winter months or intense heat and sweating during warm weather may intensify symptoms. Pruritus is more common in females than males, [33] and pregnancy or exogenous estrogens may precipitate or worsen the itching. The etiology of the pruritus is still obscure. The serendipitous discovery that bile acid sequestrants improve symptoms has led to the hypothesis that elevated bile acid levels are responsible. However, a poor correlation between serum or skin levels of bile acids and symptoms argues against this. [34] A centrally mediated mechanism of pruritus, potentially mediated by endogenous opioids, was proposed by Bergasa and colleagues, [35] who was able to elicit scratching in monkeys by injecting PBC plasma into their brains. Endogenous opioid levels are increased in cholestatic patients, and symptoms of pruritus are relieved by administration of opioid receptor antagonists. Interestingly, this intervention is often accompanied by symptoms of narcotic withdrawal. [34]

Right upper quadrant discomfort is present in about 17% of patients with PBC. [36] It may be present in the absence of hepatomegaly, and it has no correlation with levels of alkaline phosphatase, bilirubin, or aminotransferases, or with histological stage. It is typically nonspecific in character, is not progressive in nature, and, in fact, often disappears spontaneously.

Xanthomas and hyperpigmentation are the primary skin findings expressed in patients with PBC. [31] Xanthomas are most often seen around the eyes (xanthelasma), but may also develop over tendons and in palmar-digital creases. Hyperpigmentation, which results from increased melanin deposition, is most often found on the trunk and arms. Skin may also darken in areas that are repetitively scratched, which may result in a butterfly pattern of sparing in the middle of the back. Both xanthomas and hyperpigmentation are more often seen in patients with prolonged cholestasis but can also be seen before the onset of cirrhosis. [37]

Serologic Findings

The laboratory abnormalities seen in PBC reflect its cholestatic and immunologic nature. Elevated alkaline phosphatase and ?-glutamyl transpeptidase are the predominant feature, although aminotransferases may also be moderately elevated. Hyperbilirubinemia ensues in later stages of the disease. Prothrombin times may be prolonged due to either malabsorption of vitamin K or deteriorating hepatic synthetic function. Hypercholesterolemia often occurs as a consequence of reduced biliary excretion of sterols and impaired feedback regulation of retained bile acids. [38] In early stages of the disease, it primarily consists of high-density lipoprotein (HDL) particles. Elevated serum and hepatic copper levels also develop as a consequence of chronic cholestasis. Although impressive copper deposition can be seen in the liver, there is no evidence that this contributes to disease progression. [39] As with other etiologies of portal hypertension and cirrhosis, decreased albumin and platelet counts reflect underlying hepatic synthetic function and hypersplenism, respectively. Elevated erythrocyte sedimentation rates are not uncommon, but are not useful in following clinical status.

Almost 100% of patients with PBC have circulating autoantibodies (see Table 111-1). The most sensitive and specific autoantibodies are the AMAs, present in 90% to 95% of patients with PBC and rarely found in other conditions. [40] ANAs are not as sensitive or specific, but are also present in 25% to 70% of patients with PBC. The ANAs found in patients with PBC are comprised primarily of anti-Sp100, anti-Gp210, anticentromeres, and occasionally antilamins. Of note, some investigators have found antinuclear pore complex (anti-gp210, antilamin B receptor) or nuclear dot (anti-sp100, anti-PML) to be relatively specific markers for PBC, [41], [42] In addition, the anticentromere antibodies are specifically associated with patients that also have the CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia). [43] It is not uncommon to find other autoantibodies that are usually associated with other connective tissue diseases, but these autoantibodies are usually an isolated finding that is not accompanied by other clinical features of the connective tissue disease. Hyperglobulinemia is not as prominent as in autoimmune hepatitis, but selective elevations of the immunoglobulin M (IgM) fraction are found in 80% to 95% of patients with PBC. [2] IgM levels may also be increased in up to 20% of patients with common bile duct obstruction and 70% of patients with alcoholic cirrhosis, but in these diseases IgM elevations are usually accompanied by similar elevations in the IgA and IgG levels. [44]

A positive serum test for AMA is characteristic of patients with PBC. When present in higher titers (=1:80), it is the most specific laboratory abnormality of this disease. Using indirect immunofluorescence, approximately 90% to 97% of patients with PBC will be AMA-positive. [40] AMAs detected by immunofluorescence are rarely associated with diseases other than PBC, but have been reported in association with syphilis, myocarditis, tuberculosis, collagen vascular disease, and iproniazid therapy. [45] Low titer (=1:40) AMAs have also been reported in individuals with other liver diseases such as autoimmune hepatitis. [46] Low titer AMAs may also be found in PBC, and these are sometimes transient. [47] Therefore, repeat testing is warranted when the clinician suspects a diagnosis of PBC, but the AMA test is initially negative. AMAs that are identified in seemingly healthy individuals may represent subclinical PBC and deserve to be followed up. Most of these asymptomatic individuals will eventually develop an elevated alkaline phosphatase, histological findings compatible with PBC, and fatigue or pruritus. [48]

Histology

The hallmark histological finding of PBC is focal and segmental nonsuppurative cholangitis. Various authors have developed histological staging systems that group the histological abnormalities into four distinct stages [49], [50] (Fig. 111-1). As described by Ludwig and colleagues, [49] stage I is characterized by lymphocytes infiltrating the portal tracts. In stage II the degree of inflammation is greater, extending beyond the limiting plate. In all systems, stage III is defined by the presence of bridging fibrosis, and the presence of cirrhosis represents stage IV.

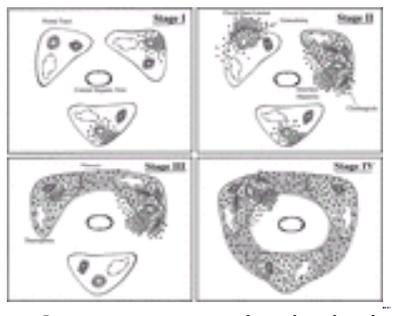

FIGURE 111-1. Histological progression of primary biliary cirrhosis (PBC) is categorized into four stages. Characteristic features of each stage are illustrated here, but the lesions are often patchy in nature. Stage I: mononuclear portal tract infiltrates, sometimes involving the bile duct. Stage II: intense mononuclear portal tract infiltrate with interface hepatitis, a florid duct lesion (granulomatous involvement of bile duct), and pseudoductular (cholangiolar) proliferation. Stage III: bridging fibrosis, mononuclear portal tract infiltrates with interface hepatitis, pseudoductular proliferation, and ductopenia. Stage IV: cirrhosis, mononuclear portal tract infiltrates with interface hepatitis, pseudoductular proliferation, and ductopenia.

In earlier stages, bile ducts may show evidence of damage, but are still present in adequate numbers. The most specific (although not pathognomonic) histological finding is the "florid duct lesion," in which the bile duct is surrounded by an intense lymphocytic or granulomatous infiltrate, and the basal integrity of the bile duct has been breached by individual lymphocytes. Granulomas in close proximity to the bile duct are also highly suggestive of PBC. Because of the patchy nature of bile duct involvement in PBC, many portal tracts remain normal or display a nonspecific pattern of mononuclear cell infiltration. The mononuclear infiltrate of PBC consists primarily of T cells, but plasma cells and eosinophils may be seen. The presence of a large number of polymorphonuclear cells, however, should prompt consideration of extrahepatic obstruction. Because interface hepatitis (piecemeal necrosis) and foci of lobular inflammation may be present in PBC, the presence of bile duct involvement is an important factor in distinguishing PBC from other forms of chronic inflammatory liver diseases such as autoimmune hepatitis. Bile staining and cholate stasis with feathery degeneration of hepatocytes is evident in some patients, and Mallory's hyaline may be found in the affected hepatocytes. Bile ductular proliferation (cholangioles or pseudo-ducts) is very common, particularly along the periphery of the portal tract, and is used as a defining characteristic of stage II PBC in the Scheuer staging system. [50] As the disease advances, ductopenia becomes evident. It is essential to have an adequate number of portal tracts on the biopsy to evaluate the presence of ductopenia. A minimum sample of 4 portal tracts (with all 4 portal tracts containing arterioles but no ducts) or ideally 20 portal tracts (with =10 portal tracts containing arterioles but no ducts) are needed to make a diagnosis of ductopenia. [51] Rhodamine and orcein stains for copper and copper binding protein are often positive in PBC liver. The intensity of staining correlates with disease severity, and copper retention may reach levels comparable to that seen in Wilson disease. [52]

Epidemiology

The prevalence of primary biliary cirrhosis in the United States and Europe is estimated to be 3.5 per 100,000 individuals (range 0.7–24) with a yearly incidence of 0.9 per 100,000. [3], [53] Some of the highest prevalences have been reported in England and Sweden, where interested researchers have conducted careful epidemiologic studies. PBC has been infrequently reported in native Africans [54] and Asians. [55] However, a higher incidence has been reported in persons from India and southern Asia who have migrated to Western countries. [56] In addition, the prevalence in Japan (5.4 per 100,000) appears to be comparable to that in many European countries. [57] Over the last two decades, the reported prevalence of PBC in North America and Europe has been increasing more rapidly than for any other autoimmune disease. [53] This increase began shortly after the discovery of the AMA and the widespread use of automated chemistry panels, suggesting that greater physician awareness and easier access to diagnostic tests is leading to an increase in the number of patients who are identified at an earlier, frequently asymptomatic phase. [29] Most patients are still identified during middle age, with a median age of presentation between 40 and 55 years of age.

Women are affected with PBC much more frequently than are men. The reported female:male ratio ranges from 3:1 to 22:1, with most studies reporting about 12:1. [3] The reason for such a strong female predilection is not known. One hypothesis is that estrogens play an important role in the development and/or clinical expression of PBC, as have been noted for other autoimmune diseases. The fact that PBC has not yet been reported in a prepubertal female also supports this hypothesis. Of note, while many autoimmune diseases improve during pregnancy, the symptoms of PBC may worsen due to an increase in cholestasis. While most features of PBC

in men are similar to those in women, men have been found to have less pruritus and fewer other autoimmune-associated conditions. [33]

The prevalence of PBC in family members of affected individuals reported from North America and Europe is near 4% (range 1%–6.4%), [3], [58] which translates into a prevalence rate nearly a thousand-fold higher than control rates. Of first-degree relatives with PBC, mother-daughter pairs are the most common. This familial clustering has been considered evidence for a genetic predisposition to PBC. A positive family history of other autoimmune disorders is quite common, and the prevalence of AMA in family members of probands with PBC is increased. [59]

Most epidemiologic studies have found neither evidence for geographic clustering nor associations with previous surgeries, pregnancies, infections, vaccinations, medications, or alcohol ingestion. [60] Only a very weak association with past smoking has been reported. Thus, the genetic and environmental factors that may be important in the development of PBC remain elusive.

Extrahepatic Conditions Reported to Be Associated With PBC

PBC is frequently accompanied by other extrahepatic conditions, many of which are also believed to be autoimmune in nature. Up to 84% of patients with PBC manifest features of other autoimmune diseases (Table 111-2).

EXTRAHEPATIC DISEASE	PREVALENCE (%)
Sjögren syndrome	30–58
Gallstones	30–50
Decreased pulmonary diffusion capacity	40–50
Renal tubular acidosis	20–33
Osteoporosis	15–40
Bacteriuria	11–35
Arthropathy	4–38
Rheumatoid arthritis	3–26
Hypothyroidism	11–32
Raynaud phenomenon	7–14
CREST* syndrome	3–6
Autoimmune thyroiditis	3–6
Autoimmune anemias	1–2
Psoriasis	1–13
Lichen planus	0.5–6
Ulcerative colitis	0.5–1

*CREST: syndrome of calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias.

TABLE 111-2 Extrahepatic Diseases Associated With Primary Biliary Cirrhosis

The most common symptomatic co-morbid condition by far is Sjögren syndrome, which occurs in 30% to 58% of patients with PBC. [2], [28], [61], [62] Xerostomia and xerophthalmia of sicca syndrome are the usual manifestations. Vasculitis, renal, pulmonary, or neurological involvement are rarely clinically significant problems. Evidence of renal tubular acidosis is also present in one third of patients with PBC, but this association appears to be independent of Sjögren syndrome. [63]

The CREST syndrome is present in about 5% of PBC patients. [2], [28], [33], [62], [64] The most common features seen are Raynaud syndrome and telangiectasias. Isolated Raynaud syndrome occurs in an additional 7% to 14%. Esophageal dysmotility usually presents as gastroesophageal reflux disease or symptomatic hiatal hernia, but frank dysphagia may be present and can be worsened by concomitant xerostomia from Sjögren syndrome. Progressive systemic sclerosis, with involvement of other internal organs such as kidney and heart, is actually rare in patients with PBC.

About 10% to 20% of patients with PBC complain of arthralgias, [2], [61], [65] which may be due to a variety of causes. Because PBC often occurs in older individuals, osteoarthritis is the most common reason for joint pains. Rheumatoid arthritis is, however, more common in patients with PBC than in the general population. One study found that 53% of patients with PBC had circulating rheumatoid factor, although only 7% met established criteria for the diagnosis of rheumatoid arthritis. [66] Radiologic surveys of patients with PBC demonstrate that erosive arthritis is common and may not always be accompanied by a positive rheumatoid factor. Hypercholesterolemic arthropathy and hypertrophic osteoarthropathy are also potential reasons for joint disease in this population. [67]

Thyroid disease is another frequent co-morbid condition, present in about 20% of patients with PBC. [2], [28], [33], [61], [68] Usually this manifests as hypothyroidism, but Hashimoto thyroiditis is also common. Fatigue is a frequent symptom of PBC. However, hypothyroidism should always be excluded before attributing the fatigue to PBC itself.

Osteoporosis is observed in up to 40% of patients with PBC referred for transplant. [69] The severity of bone disease correlates with the severity of the liver disease, and therefore patients with stage IV disease should be screened with bone densitometry at regular intervals. In an unselected group of stable patients with PBC, osteopenia (defined as T score of -1.5 to -2.5) was present in 45%, and osteoporosis (defined as T score <2.5) was present in 15%. [70] Osteoporosis in patients with PBC is due to both increased resorption and decreased formation of bone. [71] Vitamin D deficiency due to malabsorption in later stages of disease may also lead to osteomalacia.

Decreased pulmonary diffusion capacity is very common in PBC, but it is usually asymptomatic. It is disputed as to whether this finding is related to Sjögren syndrome, CREST syndrome, or the presence of cirrhosis. [72] Symptomatic pulmonary disease is present with a low frequency (<1%) and has been reported to be due to a variety of conditions, including sarcoidosis, [73] interstitial pulmonary fibrosis, [74] fibrosing alveolitis, [29] bronchiolitis obliterans with organizing pneumonia (BOOP), [75] primary pulmonary hypertension, and hepatopulmonary syndrome.

Urinary tract infections are frequent, recurrent, and often asymptomatic in female patients with PBC. Up to 61% of female patients with PBC report prior urinary tract infections. [71] Upon random screening, about 20% of female patients with PBC will have bacteriuria, as compared to about 7% of age-matched female patients with other liver diseases, 5% of healthy age-matched females, and 20% of age-matched female cirrhotics. [76] At least half of patients with PBC with bacteriuria are asymptomatic. When followed over time, an additional 10% will develop bacteriuria over a 3-month interval, and 65% will develop pyuria over a 12-month interval. Recurrent infections are often with a different organism, and treatment of asymptomatic infections does not decrease recurrence.

Despite the frequent occurrence of circulating immune complexes, immune complex disease has only occasionally been reported to occur in PBC. Systemic lupus erythematosus, [77] temporal arteritis, [78] and other vasculitis syndromes can be found in patients with PBC, but are not particularly increased in frequency. Several reports of membranous glomerular nephritis and leukocytoclastic vasculitis indicate that IgM complexes can be found in the kidney and skin, suggesting that the elevated IgM levels may play a role. [79] In addition, more than a dozen cases of polymyositis with PBC appear in the literature, many of which are in Asian patients. [80]

Numerous case reports testify that celiac sprue can occur in patients with PBC. A single study from Ireland found that 11% of patients with PBC had anti-endomysial antibodies, which were often accompanied by villous atrophy. [81] However, three larger studies examining prevalence of anti-endomysial antibodies in unselected patients with PBC have failed to find a valid association. [82]

Gallstones are found by radiologic imaging in 30% to 50% of patients with PBC, particularly in later stages of the disease when pigment stones are more likely to be formed. [83] Their presence often leads to confusion and delays in diagnosis of PBC, when the patient presents with cholestatic liver test abnormalities, right upper quadrant discomfort, and gallstones, and a presumptive diagnosis of extrahepatic biliary disease is made.

Autoimmune anemias are occasionally seen (1%–2%), and anemia can be due to pernicious anemia, celiac disease-related iron deficiency anemia, or autoimmune hemolytic anemia. The autoimmune hemolytic anemias can be warm, cold, or mixed.

Inflammatory bowel disease has been reported in several patients with PBC that have been carefully characterized. [84] The coexistence of PBC and ulcerative colitis is much less frequent than in primary sclerosing cholangitis, and Crohn’s disease has not been reported as frequently as ulcerative colitis.

Skin disorders that are considered autoimmune have been reported in association with PBC. The most common is psoriasis, [60] but also lichen planus, [2] pemphigoid, [85] dermatitis herpetiformis, and cutaneous sarcoid [86] have been reported. In large screening studies of patients with psoriasis or lichen planus, PBC is very rare or nonexistent, probably reflecting the differences in disease prevalence. [87] Some reports of lichen planus may have been attributable to penicillamine treatment.

The incidence of extrahepatic cancer in PBC has been studied because of numerous case reports of cancers found in patients with PBC, as well as reports from the 1980s that the relative risk of breast cancer was increased 4.4-fold compared to other individuals. [88] More recent population studies, however, have failed to find an increased risk of extrahepatic malignancies in PBC. [89], [90]

The clinical course of associated conditions is not altered by treatment of PBC. [61] The clinician must maintain a high index of suspicion for those conditions that are commonly encountered in patients with PBC so that these diseases may be recognized and managed appropriately.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a patient who presents with chronic cholestatic liver tests may initially include extrahepatic obstruction or intrahepatic cholestatic liver diseases, as well as granulomatous and infiltrative diseases of the liver.

Extrahepatic obstruction, from gallstones, tumors, or sclerosing diseases of the bile ducts should first be excluded with good sonographic imaging or cholangiography. Serologic testing for AMA will help to differentiate PBC from other intrahepatic cholestatic liver diseases. In patients who are AMA-negative, cholangiography is usually necessary. Liver biopsy is recommended for patients who are suspected to have PBC in order to confirm the suspected diagnosis, stage the patient, and rule out other etiologies of liver disease. In patients who are AMA-negative, liver biopsy is essential to demonstrate a nonsuppurative cholangiopathy and to exclude other disorders. [32]

A variety of diseases may resemble PBC clinically and/or histologically, but they do not lead to AMAs. Patients who have had prolonged extrahepatic obstruction may also develop a secondary biliary cirrhosis which histologically resembles primary biliary cirrhosis. A rare variant of primary sclerosing cholangitis affects only the small intrahepatic ducts. [91] However, these biliary lesions are characterized by an exuberant fibrotic reaction (“onion skinning”) and less lymphocytic infiltration. Sarcoidosis or idiopathic granulomatous hepatitis may mimic PBC with similar biochemical liver tests, right upper quadrant discomfort, hepatomegaly, and hepatic granulomas. Typically, the granulomas of sarcoidosis are larger, well-formed granulomas found in the liver parenchyma rather than involving the bile ducts. [92] It is possible to have both conditions concurrently; there are several well-documented cases of patients with AMA-positive PBC who also have multiorgan involvement with sarcoidosis. [73] A rare form of chronic hepatitis C that is cholestatic has also been reported, [93] and cirrhotic patients with hepatitis C may present with fatigue and pruritus. Because infection with the hepatitis C virus is so prevalent, viral infection with hepatitis C should be excluded in all patients with suspected PBC. It is also important to recognize that a variety of drugs have been implicated as causes of nonsuppurative cholangitis and ductopenia, which in some cases may progress to biliary cirrhosis. [94] Other rare causes of intrahepatic cholestasis, such as lymphoma and idiopathic ductopenia, are best excluded by examining liver tissue.

Differentiating primary biliary cirrhosis from autoimmune hepatitis (AIH) can be difficult because of occasional overlapping histological and serologic features. However, the distinction is essential in order to develop a safe and effective treatment program for each patient. A published scoring system by the International Autoimmune Hepatitis Group can be used to facilitate the distinction and is particularly helpful when the AMA test is negative. [95] ANAs detected by routine immunofluorescence are common in both diseases and their titer does not help to distinguish between AIH and PBC.

Autoimmune Cholangitis/AMA-Negative PBC

It is clear that a small number of patients have a clinical and histological picture similar to that of primary biliary cirrhosis, except they have atypical antibody profiles including the absence of AMAs, higher prevalence of ANAs (70% to 100%), and lower (although still elevated) total IgM levels. [96] This syndrome has been called “autoimmune cholangitis” or “AMA-negative PBC.” It is unclear whether the pathogenesis of this condition is distinct from that of AMA-positive PBC, or whether the serologic differences between the two syndromes merely reflect individual diversity of the humoral immune response. Large series of patients with autoimmune cholangitis have not been extensively examined because the frequency of this disorder is so low that few centers see more than a handful of cases. Interpretation of studies is further complicated by the lack of uniform diagnostic criteria. The limited studies that have been conducted suggest that the natural history and response to treatment of this disorder is quite similar to that of AMA-positive PBC. [97] Similar immunologic disturbances, including the presence of PDC-E2-reactive material on the surface of bile ducts and oligoclonality of T-cell populations, have been noted in both conditions. [98], [99] In fact, there is currently reluctance among many experts to embrace the hypothesis that this syndrome represents a distinct entity from the syndrome of AMA-positive PBC.

COURSE AND COMPLICATIONS

Clinical Course

PBC may exist for relatively long periods of time in an asymptomatic state. [31], [100] Indeed, data from a natural history study suggest that a fraction of asymptomatic patients will never develop symptoms during their natural life span. [100] However, most asymptomatic individuals eventually become symptomatic, and most individuals with established disease eventually progress to cirrhosis. Clinical progression is foretold by worsening of specific biochemical parameters, particularly serum bilirubin levels. The mean survival of patients with bilirubin values over 2 mg/dL is 4 years, and for those with bilirubin values over 6 mg/dL, mean survival drops to 2 years. [101] Development of variceal bleeding is not a good indicator of prognosis, since portal hypertension may develop before the onset of cirrhosis. In those cases, portal fibrosis, portal granulomas, or nodular regenerative hyperplasia are thought to cause pre-sinusoidal portal hypertension. [102] Several mathematical models exist that incorporate bilirubin and other parameters into formulas that are clinically useful to predict mortality and judge timing for transplant referral of individual patients. [103], [104] The most extensively validated and commonly used survival model is the Mayo Risk Score. [103] The Mayo Risk Score calculates an R score based on the following formula (adapted from original to use international normalized ratio [INR], personal communication with Dr. E.R. Dickson and Dr. Terry Therneau, Mayo Clinic, April, 2001):

$R = 0.871 \log_e(\text{bilirubin mg/dL}) + -2.53 \log_e(\text{albumin g/dL}) = 0.039 \text{ age (years)} = 0.881 \log_e(\text{INR}) = 5.92 = 0.859$ (edema score of 0, 0.5, or 1.0 for none, mild, or moderate edema).

The computed R score is then used to predict the fraction of patients expected to survive for:

- 1 year = 0.970 (R-5.07)
- 2 years = 0.941 (R-5.07)
- 3 years = 0.883 (R-5.07)
- 4 years = 0.833 (R-5.07)
- 5 years = 0.774 (R-5.07)
- 6 years = 0.721 (R-5.07)
- 7 years = 0.651 (R-5.07).

Of note, in all prognostic models, serum bilirubin values play a prominent role in predicting survival. Serum albumin, age, and time are found to be independent predictors of survival in some but not all prognostic models. The Mayo Risk Score has been demonstrated to be useful in judging the appropriate time for transplantation. However, in some populations, it has been found to overestimate mortality. [105] An updated version of the model, which evaluates interval changes in the patient’s condition to estimate short-term survival, is less likely to overestimate long-range mortality in patients with early disease. [106]

Complications

Once cirrhosis is established, the clinical complications of portal hypertension and deteriorating liver function are similar to those of patients with cirrhosis from other causes. The risk of hepatocellular carcinoma in patients with PBC is greatly increased compared to healthy individuals. [89] This risk is almost exclusively limited to cirrhotics, and is higher for men. In general, the reported risk of hepatocellular carcinoma in PBC is significantly less than the reported risk of hepatocellular carcinoma in other liver diseases such as hereditary hemochromatosis, hepatitis B, or chronic hepatitis C. One possible exception is the subgroup of men with advanced PBC in whom incidences as high as 20% have been reported. [90]

Pruritus is a common and often a vexing symptom of patients with PBC. Its severity often fluctuates and is not correlated with disease progression. However, in the terminal stages of the disease, pruritus often disappears. Its etiology is unknown, but elevated bile acid levels and endogenous opioid levels have been implicated. [107]

Decreased osteoblastic and increased osteoclastic activity contribute to accelerated osteoporosis in patients with primary biliary cirrhosis. [71] The risk increases with disease severity, and regular screening of bone density in cirrhotic patients facilitates treatment. Preserving bone mass is particularly important for patients who ultimately undergo liver transplantation, because bone mass decreases further in the immediate posttransplant period of heavy immunosuppression.

Like osteoporosis, deficiencies of the fat-soluble vitamins are common in patients with PBC, and correlate with disease severity. For this reason, asymptomatic cirrhotics should be screened. Poor bile salt excretion is the primary reason for deficiencies, which may be made worse by treatment with bile acid sequestrants or antibiotics. Vitamin A is frequently the first fat-soluble vitamin to become deficient, and patients may not complain of night blindness. Vitamin D deficiency may cause osteomalacia, and vitamin K deficiency may result in prolonged coagulation times. Vitamin E serum levels may be falsely elevated in patients with hyperlipidemia. A serum vitamin E to total lipid ratio of less than 0.8 mg/g is considered deficient.

TREATMENT

Therapy for PBC

Therapy with ursodeoxycholic acid (ursodiol), at a dose of 13 to 15 mg/kg/day has become the mainstay of therapy for PBC (Fig. 111-2). The medication may be administered in three divided doses or as a single evening dose. The potential mechanisms of ursodiol's beneficial effect on PBC are multiple. [108] Ursodiol is a bile acid that is less toxic to hepatocytes than other more hydrophobic bile acids. It is normally present in human bile at low concentrations (1%), but when ingested at a daily dose of 13 to 15 mg/kg, it replaces about 40% of the bile acid pool. It increases intracellular and canalicular transport of hydrophobic bile acids, thereby decreasing the potentially toxic effects of bile on the liver during cholestasis. Ursodiol stabilizes hepatocyte membranes, decreases rates of apoptosis of biliary epithelial cells, and has antioxidant properties such as the ability to inhibit nitric oxide synthetase. Ursodiol decreases expression of adhesion molecules (LFA-I, LFA-II, and ICAM-1), HLA class I and II expression in the liver, and T-cell reactivity and cytokine production.

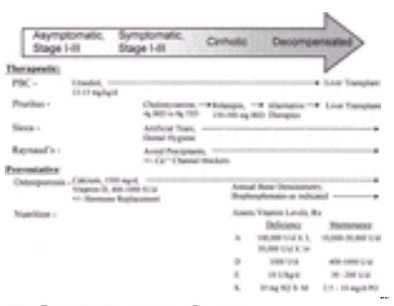

FIGURE 111-2. Management of PBC and associated conditions. (Adapted from Heathcote, J. AASLD practice guidelines: management of primary biliary cirrhosis. Hepatology 2000;31:1005.) Complications of portal hypertension (not shown) are managed in the same manner as in other forms of cirrhosis.

Five large, randomized, double-blind controlled trials have demonstrated the beneficial effects of ursodeoxycholic acid therapy. [109], [110], [111], [112] and [113] Collectively, these studies randomized 890 individuals to either ursodiol or placebo and followed them for an average of 2 years. In all trials, ursodiol produced a rapid and impressive improvement in serum liver tests, primarily alkaline phosphatase, bilirubin, aminotransferases, and IgM levels. Biochemical improvement was usually noted within the first 1 to 2 months of therapy and continued to improve, with a maximal response seen by about 6 months. Effects on symptoms were unimpressive, although a small number of patients reported an improvement in itching. Four of the five trials reported beneficial effects on histology, primarily improvement in inflammatory features and less ductopenia in the treated groups. No effect on the development of cirrhosis or portal hypertension, or death/transplantation could be detected at 2 years in any of the individual trials. However, in follow-up of one of the study groups, ursodiol therapy was associated with a delay in the onset of varices. [114] In addition, a combined analysis of patients from three of the trials, which included patients that were switched from placebo to ursodiol after 2 years, reported an improvement in transplant-free survival after 4 to 6 years in patients originally randomized to ursodiol. [115] The conclusions from this combined study, however, have been disputed by a subsequent metaanalysis of 11 randomized trials that examined outcomes of both the initial randomized treatment periods and the follow-up periods. This metaanalysis failed to show any difference between ursodiol and placebo in the incidence of death or transplantation, or development of liver disease complications. [116] The difficulty in clearly demonstrating survival benefits of ursodiol is not surprising considering the slowly progressive course of PBC and the relatively short duration of the placebo phase in most randomized controlled trials. Importantly, ursodiol was extremely well tolerated and safe in all trials. Therefore, because of its excellent safety profile, proven ability to improve markers of cholestasis, and suggestion of long-term benefits, ursodiol is recommended as treatment for all stages of PBC.

Because the prevailing viewpoint is that bile duct destruction is immune-mediated, immunosuppressive and antiinflammatory drugs have historically been selected as potential medical treatments for PBC. Unfortunately, the results of clinical trials have been disappointing or inconclusive for almost all of them. In striking contrast to ursodiol therapy, the major problems encountered in the use of immunosuppressive therapy have been their serious side effects, which have an important cumulative impact on therapy of a slowly progressive, lifelong disease.

Chlorambucil was evaluated in a controlled trial of 24 patients followed for 4 years. [117] Modest improvements in bilirubin levels, IgM levels, and inflammatory scores were seen in the chlorambucil group. However, bone marrow depression, requiring cessation of treatment in 17% of patients, was a significant problem. It was thought that the potentially dangerous side effects of chlorambucil, combined with its modest effects on the disease, made it an impractical therapeutic choice.

D-Penicillamine has been tested in 3 large controlled clinical trials on 472 patients with long-term follow-up. [118], [119] and [120] Between 22% and 46% of patients experienced serious side effects necessitating discontinuation of the drug. Despite its antiinflammatory, immunosuppressive, antifibrotic, and copper-chelating properties, D-Penicillamine was found to have no therapeutic benefit in PBC.

Prednisolone was evaluated in a controlled trial of 36 patients followed for 3 years. [121] Significant improvements in alkaline phosphatase, aminotransferases, and immunoglobulin levels were seen. Improvements in fatigue, pruritus, and bilirubin levels were transient, and there was a trend toward an improvement in liver histology. These modest benefits were outweighed by the deleterious side effects of prednisolone, especially with respect to accelerated loss of bone density. Budesonide, a corticosteroid with a high first pass hepatic metabolism, has been tested as co-therapy with ursodeoxycholic acid and compared to ursodeoxycholic acid monotherapy in two controlled clinical trials in a total of 42 patients followed for 2 years. [122], [123] Divergent conclusions were reached in the two studies. The European study found significant improvement in liver histology, liver enzymes, and immunoglobulin levels with no significant increase in bone loss in the budesonide group. The American trial, which included a larger percentage of patients with advanced disease, found marginal improvements in liver tests and significant loss of bone mass in the budesonide group.

Cyclosporine was evaluated in a multicenter controlled trial in which 349 patients were followed for up to 6 years. [124] Significant improvements in bilirubin, alkaline phosphatase, albumin, aminotransferases, and pruritus were seen, but liver histology was not affected. Survival (time to death or transplant) was modestly prolonged

in the cyclosporine group, but complications such as hypertension and renal toxicity were severe enough to discourage cyclosporine from further consideration.

Azathioprine has been tested in two controlled clinical trials [125], [126] on a total of 293 patients followed for 2 to 3 years. Both trials failed to see a survival difference between those treated with azathioprine and those treated with placebo. However, both trials also included a large percentage of jaundiced patients with advanced disease. In the European trial, when patients with higher bilirubin levels were excluded from the analysis, a slight survival advantage was seen in the azathioprine group. Azathioprine was well tolerated by patients with PBC in both studies. Nevertheless, after these trials, azathioprine was largely abandoned as a therapy for PBC.

Colchicine has both antiinflammatory and antifibrotic properties, and thus has been seriously considered as a potential therapy for PBC. Three controlled trials have compared colchicine to placebo with similar results. [127], [128] and [129] Serum levels of bilirubin, albumin, alkaline phosphatase, cholesterol, and aminotransferases were modestly improved, but symptoms and histological progression were not affected. Colchicine was not associated with any severe side effects, although some patients discontinued the drug because of gastrointestinal complaints. In the trial by Kaplan and colleagues, [127] a trend toward decrease in liver mortality was seen at 4 years. However, larger studies with longer follow-up are needed to determine the true long-term effects of colchicine.

The use of methotrexate as a therapeutic agent is still under investigation. Small, uncontrolled trials have reported dramatic biochemical and histological responses to low-dose weekly methotrexate. [130] One controlled trial of 60 patients randomized to either methotrexate or placebo for 4 to 6 years noted improvements in alkaline phosphatase, aminotransferases, and immunoglobulin levels. [131] Trends toward a decrease in hepatic fibrosis were seen. The safety of long-term methotrexate in primary biliary cirrhosis is unknown and is a valid concern. Conflicting reports exist regarding the potential pulmonary toxicity and effect on hepatic fibrosis. [131], [132]

Thus, at present, ursodiol is the only approved recommended therapy for PBC. While it is hoped that ursodiol therapy will delay liver disease progression and prolong survival, it is clear that ursodiol does not obviate the need for liver transplantation. Patients with complicated cirrhosis or poor estimated survival (Mayo Risk Score =7) should be considered for transplant referral. Ursodiol therapy does not invalidate the use of serum bilirubin or Mayo Risk Score to estimate the appropriate timing for transplant referral. [32] In general, patients with PBC have excellent posttransplant outcomes, with a 75% 5-year survival and with 95% of survivors returning to work. AMAs frequently persist after transplant, although often at lower titers than pretransplant. Recurrence of PBC in the transplanted liver is difficult to distinguish histologically and biochemically from chronic rejection and effects of immunosuppressant drugs, but it has been reported to occur in a minority of patients. Fortunately, due to slow progression of recurrent disease, it is not a significant clinical problem.

Management of Complications

Managing the complications of cholestasis comprises a considerable portion of the clinician's treatment of the patient with PBC (see Fig. 111-2).

Bile acid sequestrants, such as cholestyramine and colestipol, are effective in controlling 80% of cholestatic pruritus. Because of their efficacy and safety profile, they are the first line of medical treatment for cholestatic pruritus. [32] Unfortunately, compliance with these drugs is sometimes impaired by dislike of the powdered drug delivery system or the difficulty in timing other medication doses so that the sequestrant does not inhibit drug absorption. (Manufacturers recommend that all other medicines be taken at least 1 hour before or 4 hours after taking the sequestrant.) Because the sequestrants are not absorbed, side effects are limited to the gastrointestinal tract. Rifampin has also been demonstrated to relieve cholestatic itching in small controlled trials. [133], [134] The mechanism is unknown but is postulated to be mediated via enhancement of the mixed function oxidase system leading to an increase in the rate of bile acid metabolism and excretion and/or competition for hepatic bile acid uptake. The latter may also lead to an increase in serum bilirubin levels in some patients, which may make monitoring of disease progression difficult. At a total dose of 300 to 600 mg/day given in divided doses, the mean time to relief is 2 days, and it is also effective long term. It has been demonstrated by one group to be superior to phenobarbital therapy. [135] Phenobarbital, however, is also more effective than placebo. The mechanism of action is likely related to hepatic enzyme induction and/or sedation. The drug dosage (15–180 mg/d) is titrated to balance efficacy and sedation, but usually much lower doses are required than for the treatment of epilepsy. Antihistamines are often used to treat itching in patients with PBC, but no controlled trials have demonstrated their efficacy. In fact, there is a lack of evidence that cholestatic pruritus is histamine-mediated. However, anecdotal success in patients with mild itching may be attributable to their sedating properties. Naloxone, naltrexone, and nalmefene, opioid receptor blockers, have been demonstrated to be superior to placebo in alleviating cholestatic pruritus. [136] Unfortunately, these drugs can elicit an opioid withdrawal syndrome, which can limit the tolerability of these drugs. Several small studies have investigated *ondansetron,* a serotonin 5HT3 receptor blocker, as a potential antipruritic agent in PBC, with results ranging from dramatic to marginal. [137] The potential mechanism of action is unknown, but may be related to crossing of the serotonergic and opioid pathways. Larger controlled trials are needed to assess its efficacy. Plasmapheresis has been attempted as a desperate measure to control difficult pruritus of cholestasis. In a very small number of patients, transient success has been reported lasting anywhere from 24 hours to several months. Phototherapy has also been anecdotally successful in ameliorating cholestatic pruritus, but its effectiveness has never been adequately tested in clinical trials. Finally, some patients have intractable itching, which has been an independent indication for liver transplantation. [32]

Accelerated osteoporosis can be a devastating complication of chronic cholestasis, and careful monitoring and preventive treatment is the best therapy. Calcium supplementation (1500 mg/day for postmenopausal women and 1000 mg/day for men and premenopausal women) is well tolerated and widely used. Estrogen replacement for postmenopausal women is also well tolerated. Estrogens inhibit canalicular transport of bilirubin and have the potential to worsen cholestasis. However, the majority of patients with PBC can benefit from transdermal or low-dose oral estrogen replacement without experiencing a clinically significant increase in cholestasis. [138] The ability of bisphosphonates to increase bone density has been demonstrated in patients with PBC, so these agents are indicated when bone density is already decreased. [32] Slow fluoride has also been demonstrated in one trial to increase bone density in patients with PBC. [32] However, less overall experience and increased side effects makes this drug a less attractive choice compared to bisphosphonates.

Deficiencies in fat-soluble vitamins should be replaced. Due to potential toxicity from overdoses, levels of vitamin A and D should be monitored in patients receiving supplements.

Serum cholesterol levels are typically elevated in patients with PBC, even in early stages of the disease. However, two retrospective studies indicate that this does not translate into increased mortality from cardiovascular events. [139], [140] Potential reasons for this include:

- onset of disease during middle age rather than childhood resulting in less time for plaque formation
- a favorable HDL/total cholesterol ratio during early stages of the disease
- a favorable lipoprotein profile including the presence of lipoprotein X and low lipoprotein A levels.

Therefore, the decision to intervene medically should be based upon factors such as unfavorable lipoprotein profiles, significant personal or family cardiac history, or the presence of painful xanthomas. Patients with PBC are often resistant to dietary management of hypercholesterolemia, and they may respond paradoxically to clofibrate therapy. [141] Almost all controlled trials of ursodiol have shown significant decreases in serum cholesterol levels with ursodiol therapy. Case reports have claimed efficacy with HMG-coenzyme A reductase inhibitor, [142] or low-density lipoprotein (LDL) apheresis, [143] but no large randomized clinical trials have been published.

Many patients with PBC have sicca syndrome and are troubled by xerophthalmia nd xerostomia. Saline moisturizers (artificial tears) may be used to relieve irritation of the cornea and help prevent ulceration. Xerostomia may be relieved with adequate access to fluids, use of sugar-free hard candies, and prescription moisturizers when necessary. It is important to have regular evaluation by a dental professional, since decreased saliva secretion leads to decreased clearance of food particles and increased dental caries.

Treatment of Autoimmune Cholangitis/AMA-Negative PBC

In autoimmune cholangitis, ursodiol is effective at improving liver biochemistries, and 3-year clinical outcome is similar to that of AMA-positive PBC. [97] However, the ability of ursodiol to improve transplant-free survival in autoimmune cholangitis has not been specifically investigated. Steroid therapy may modestly improve liver biochemistries in autoimmune cholangitis, as it does in AMA-positive PBC, [144] but steroids have been associated with accelerated bone density loss and other undesirable side effects in cholestatic patients. Thus, ursodiol appears to be better tolerated as a long-term therapy than corticosteroids. Rarely, some individuals will have overlapping features of both autoimmune hepatitis and autoimmune cholangitis. Some of these patients who meet criteria for possible or probable autoimmune

hepatitis and who do not respond well to an initial trial of ursodiol may respond to corticosteroids. [144] Thus, clinical judgment must be used to determine the predominant syndrome and initiate therapy accordingly.

CHAPTER 112

Paul C. Adams

HEMOCHROMATOSIS

Hemochromatosis is the most common genetic disease in populations of European ancestry. Despite estimates in different countries ranging from 1 in 100 to 1 in 300, many physicians consider hemochromatosis to be a rare disease. The diagnosis can be elusive because of the nonspecific nature of the symptoms. With the discovery of the hemochromatosis gene (*HFE*) in 1996, [1] new insights into the pathogenesis of the disease and new diagnostic strategies have come forth.

A fundamental issue has arisen since the discovery of the *HFE* gene. This issue concerns whether the disease “hemochromatosis” should be defined strictly on phenotypic criteria, such as the degree of iron overload (transferrin saturation, ferritin, liver biopsy, hepatic iron concentration, iron removed by venesection therapy), or whether it should be defined as a familial disease in Europeans most commonly associated with the C282Y mutation of the *HFE* gene and varying degrees of iron overload. Since the genetic test has been widely used as a diagnostic tool, most studies now use a combination of phenotypic and genotypic criteria for the diagnosis of hemochromatosis. It is important to realize that there are many causes of iron overload other than hemochromatosis (Table 112-1).

HFE-related hemochromatosis
C282Y homozygotes (95%)
C282Y/H63D compound heterozygotes (4%)
H63D homozygotes (1%)
Non-HFE related hemochromatosis
Transferrin receptor-2 mutation
Ferroportin mutation
Non-familial (may be a heterogeneous collection of conditions resulting in iron overload)
Juvenile hemochromatosis (young adults with cardiac and endocrine dysfunction)
Neonatal hemochromatosis
Miscellaneous iron overload
African-American iron overload
African iron overload
Polynesian iron overload
Transfusional iron overload
Insulin resistance–related iron overload
Aceruloplasminemia
Alcoholic siderosis
Iron overload secondary to end-stage cirrhosis
Porphyria cutanea tarda
Post-porta caval shunt

TABLE 112-1 Differential Diagnosis of Iron Overload

IRON ABSORPTION AND PATHOGENESIS OF HEMOCHROMATOSIS

In a normal human, most dietary iron is absorbed from the proximal duodenum. Both ionic iron and heme iron are absorbed across the enterocyte at the tip of the intestinal villi. Iron transport proteins at the brush border include DMT1 (divalent metal transport protein 1) and Dcytb. Iron transport within the enterocyte has not been well defined, but a number of iron-related proteins including transferrin, transferrin receptor, ferritin, iron regulatory peptide, and hepcidin have been described. The transfer of iron from the enterocyte into the portal circulation involves another series of transport proteins including hephaestin and ferroportin (IREG1).

The *HFE* gene produces a major histocompatibility complex (MHC) class 1 protein that is expressed in many cells but has a high concentration in the duodenal crypts. It interacts with transferrin receptor to facilitate iron uptake into cells. In hemochromatosis, patients have a mutated HFE protein resulting in a conformational change in the protein and this interaction is impaired. A current hypothesis is that the duodenal crypt cells develop a relative iron deficiency and when they migrate to the tip of the villi another gene is stimulated (DMT1) which increases iron absorption (Fig. 112-1). The data on HFE function and DMT1 expression have not built a conclusive case for the pathogenesis of hemochromatosis. Other iron-related genes and proteins are being investigated and it is likely that a cascade of events follows the mutation in HFE protein resulting in iron overload. [2], [3]

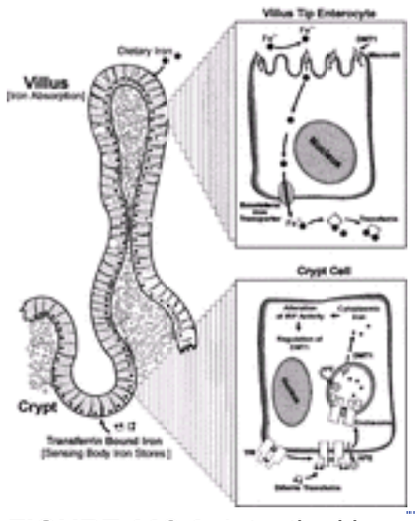

FIGURE 112-1. Intestinal iron absorption in hemochromatosis. (From Bacon BR, Powell LW, Adams PC, et al. Molecular medicine and hemochromatosis: at the crossroads. Gastroenterology 1999;116:197.)

CLINICAL FEATURES

Liver Disease

Although hemochromatosis is often classified as a liver disease, it should be emphasized that it is a systemic genetic disease with multisystem involvement. The liver has been central both in the diagnosis and prognosis in hemochromatosis. Hepatic iron deposition is common in hemochromatosis because it is the first stop on the pathway after enhanced intestinal iron absorption. The liver has a great capacity to accumulate iron within hepatocytes initially without any obvious sequelae both in terms of clinical symptoms or abnormal liver biochemistry. Since hepatic iron presumably accumulates from birth in this genetic disease a relationship between iron and age seems predictable. However, this may only apply serially within an individual patient since the correlation coefficient between age and hepatic iron concentration was not significant in the 410 homozygotes ($r = 0.07$, $p = 0.12$). [4] Hepatomegaly remains one of the more common physical signs in hemochromatosis but may not be present in the young asymptomatic homozygote. In older studies in which patients presented with clinical features of chronic liver disease in the 5th or 6th decade, cirrhosis was invariably present. As patients are detected as young adults through pedigree studies or population screening studies, the prevalence of cirrhosis is much lower. In a study of 410 homozygotes from Canada and France, 22% had cirrhosis of the liver at the time of diagnosis. The mean aspartate aminotransferase (AST) and alanine aminotransferase (ALT) were within the normal range within these 410 patients. Cirrhotic patients and patients with concomitant alcohol abuse were more likely to have abnormal liver enzymes. [5] A study of the critical hepatic iron concentration associated with cirrhosis in C282Y homozygotes using receiver operating characteristic curve analysis suggested that the critical iron concentration was 283 µmol/g (normal 0–35). [6] However, there were many patients with much higher liver iron concentrations who did not have cirrhosis. Liver damage at lower iron concentrations was usually associated with other risk factors such as alcohol abuse or chronic viral hepatitis. Therefore, it seems likely that there are factors other than iron overload that contribute to cirrhosis in hemochromatosis. It should also be emphasized that women can have significant liver involvement in hemochromatosis. In a study of 176 women, matched with men for year of birth, there was no difference in the hepatic iron concentration. [7] Many of these studies are subject to referral bias with only the sickest patients being sent for medical evaluation. Population screening studies have rarely identified patients with cirrhosis but large studies are in progress to resolve this issue. In fact, a large screening study suggested that the prevalence of symptoms in screened C282Y homozygotes does not differ from a control population. [5] Another approach has been to study hemochromatosis in relatives of the proband case. A large study from Utah demonstrated that 38% of men and 10% of women relatives had at least one hemochromatosis-related condition. [8]

Hepatocellular carcinoma has been described in 18.5% of cirrhotic patients with hemochromatosis. [9] It has rarely been described in noncirrhotic hemochromatosis patients. The relative risk is approximately 200-fold, which is similar to cirrhotic patients with chronic viral hepatitis. The effect of iron-depletion therapy has usually been stabilization of the liver disease. This may account for the relatively small number of C282Y homozygotes that have required liver transplantation. Reversal of cirrhosis has rarely been described with iron depletion. This has been previously questioned on the basis of sampling errors but evidence is increasing in other liver diseases (treatment of chronic viral hepatitis) that cirrhosis can be reversed. Posttreatment liver biopsies have been uncommonly reported; [10] they are not recommended.

Diabetes

The presence of diabetes in hemochromatosis is directly related to the presence of liver disease. [4] Many patients with cirrhosis of any etiology have glucose intolerance or diabetes and this is true for hemochromatosis as well. Earlier morphologic studies of iron deposition in the pancreas suggested pancreatic damage as the cause of diabetes. However subsequent studies have demonstrated that high-circulating insulin levels (insulin resistance secondary to liver disease) are more common than low-circulating insulin levels related to islet cell damage. Metabolic studies of insulin and glucose have not clearly demonstrated a reversal of these changes with iron depletion. This is consistent with the clinical observation that diabetes rarely resolves with therapy. [11], [12] Insulin resistance in obese patients has also been associated with iron overload in patients without the typical genetic profile for hemochromatosis. [13] Most of these cases have a moderate elevation in serum ferritin with a normal transferrin saturation.

Cardiac Disease

Cardiac disease in hemochromatosis includes both cardiomyopathy and arrhythmias. In a series of 410 patients, cardiac disease was only present in 10% of probands and 3% of discovered cases. [4] Dyspnea is the most common symptom associated with the cardiomyopathy. The cardiac iron concentration is significantly lower than the liver iron concentration. Transvenous cardiac biopsies have occasionally missed the diagnosis of hemochromatosis and should not be considered to have excluded the diagnosis. Uncommon cases of young adults presenting with life-threatening cardiac disease have been reported. These cases have been called “juvenile hemochromatosis” and preliminary studies would suggest that they are not homozygous for the *HFE* gene. [14] The putative gene for juvenile hemochromatosis has been localized to chromosome 1 in several Italian pedigrees but the gene has not yet been identified. [15] These patients can also have life-threatening ventricular arrhythmias requiring implantable defibrillators or potentially hepatotoxic medications such as amiodarone.

Arthropathy

Arthralgias are perhaps the most common symptom of hemochromatosis. Joint complaints have been found in 32% of probands and 21% of discovered cases. [4] The classic description is in the proximal interphalangeal joints of the hands but wrist, shoulder, knees, and feet are commonly affected. The features of the arthropathy are more similar to osteoarthritis and less commonly chondrocalcinosis. Radiologic features are often nonspecific but, on occasion, the diagnosis is suggested by an astute radiologist. Joint complaints are particularly common in women with hemochromatosis. Arthritis has been demonstrated to be the major factor affecting quality of life in hemochromatosis. [16] Since arthritis is common, it has been difficult to attribute the arthritis to hemochromatosis in an aging population. [17] This relationship between the background prevalence of arthritis in the female population is illustrated in Figure 112-2.

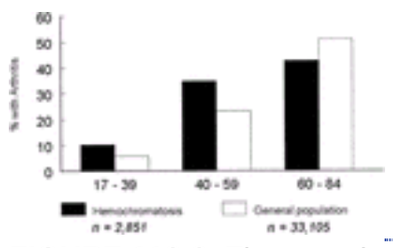

FIGURE 112-2. The prevalence of arthritis in hemochromatosis is compared to the general population in women in various age ranges. (Adapted from a survey of 2851 hemochromatosis patients and 33,105 patients in the general population. [17])

DIAGNOSIS

A paradox of genetic hemochromatosis is the observation that the disease is underdiagnosed in the general population and overdiagnosed in patients with secondary iron overload.

Underdiagnosis

Preliminary population studies using genetic testing have demonstrated a prevalence of homozygotes of 1 in 200 in patients of Northern European ancestry. The fact that many physicians consider hemochromatosis to be rare implies either a lack of penetrance of the gene (nonexpressing homozygote) or a large number of patients who remain undiagnosed in the community. Until larger genetic population studies allow us to estimate the percentage of homozygotes without iron overload, it is assumed that both of these factors are contributory.

A major problem in the diagnosis of hemochromatosis is the lack of symptoms and the nonspecific nature of symptoms. An elderly patient who presents with joint symptoms and diabetes is not often considered to have genetic hemochromatosis. Many patients assume that the routine blood tests done frequently at ambulatory clinics would have tested their iron status but this is uncommonly done unless iron deficiency is suspected. The presenting features vary depending on age and gender but fatigue is the most common complaint. Women are more likely to have fatigue, arthralgia, and pigmentation rather than liver disease. [7]

Diagnostic Tests for Hemochromatosis

A number of diagnostic algorithms based on laboratory tests have been proposed for the diagnosis of hemochromatosis. [18] These should be used as guidelines for the clinician and do not replace clinical judgment based on history and physical examination, imaging studies, pathology, and pedigree studies.

Transferrin Saturation The transferrin saturation is often elevated in patients with hemochromatosis. It is a two-step test that is widely available. It can be calculated by using the serum iron and one of the following: total iron binding capacity, unsaturated iron binding capacity, or transferrin. The transferrin saturation has been reported to have a sensitivity of greater than 90% for hemochromatosis. However, this has previously been part of the diagnostic criteria. The sensitivity of transferrin saturation is lower in population screening studies designed to detect C282Y homozygotes. A fasting value has even greater predictive value but may not always be practical. The fasting transferrin saturation is most useful in excluding false-positive cases. The transferrin saturation is often elevated in young adults with hemochromatosis before the development of iron overload and a rising ferritin. The threshold to pursue further diagnostic studies has varied from 45% to 62% in previous studies. A lower threshold picks up more patients with hemochromatosis but also leads to more investigations in patients without hemochromatosis. A higher threshold leads to fewer investigations overall with a greater possibility of missing some patients. A common threshold used in screening studies is more than 45% in women and more than 50% in men.
Unsaturated Iron Binding Capacity The unsaturated iron binding capacity (UIBC) is a one-step colorimetric assay that has been used in many reference laboratories to calculate the transferrin saturation. It is an inexpensive test compared to transferrin saturation and has been demonstrated to be a promising initial screening test for hemochromatosis. [19], [20] A UIBC less than 27 µmol/L has been proposed as a screening threshold for hemochromatosis. [21]
Serum Ferritin The relationship between serum ferritin and total body iron stores has been clearly established by strong correlations with hepatic iron concentration and amount of iron removed by venesection. [22] However, ferritin can be elevated secondary to chronic inflammation and histiocytic neoplasms. A major diagnostic dilemma in the past was whether the serum ferritin is related to hemochromatosis or another underlying liver disease such as alcoholic liver disease, chronic viral hepatitis, or nonalcoholic steatohepatitis (with or without insulin resistance). It is likely that some of these difficult cases will now be resolved by genetic testing.
Liver Biopsy Liver biopsy has previously been the gold standard diagnostic test for hemochromatosis. Liver biopsy has shifted from a major diagnostic tool to a method of estimating prognosis and concomitant disease. The need for liver biopsy seems less clear now in the young asymptomatic C282Y homozygote where there is a low clinical suspicion of cirrhosis based on history, physical examination, and liver biochemistry. A large study conducted in France and Canada suggested that C282Y homozygotes with a serum ferritin of less than 1000 µg/L, a normal AST, and without hepatomegaly have a very low risk of cirrhosis. In this multivariate model, it was more difficult to predict the presence of cirrhosis rather than the absence of cirrhosis. [23] Patients with cirrhosis have a 5.5-fold relative risk of death compared to noncirrhotic hemochromatosis patients. [10], [24] Liver biopsy is considered in typical C282Y homozygotes with liver dysfunction, and in iron-overloaded patients without the typical C282Y mutation. Simple C282Y heterozygotes, compound heterozygotes (C282Y/H63D), and patients with other risk factors (alcohol abuse, chronic viral hepatitis) with moderate to severe iron overload (ferritin more than 1000 µg/L) may be considered for liver biopsy.
Hepatic Iron Concentration and Hepatic Iron Index The traditional method of assessing iron status by liver biopsy uses the semiquantitative staining method of Perls. This is adequate when there is no iron staining or massive parenchymal iron overload. However, when moderate iron overload is present, the degree of iron overload can be difficult to interpret. Iron concentration can be measured using atomic absorption spectrophotometry. The normal reference range for hepatic iron concentration is 0 to 35 µmol/g (<2000 µg/g). The hepatic iron concentration (µmol/g) divided by age (years) is the hepatic iron index. This was demonstrated by Bassett and colleagues [25] to be a useful test in differentiating the patient with genetic hemochromatosis from the patient with alcoholic siderosis. The index remains a useful test in this clinical setting but has been extrapolated to be a diagnostic criterion for hemochromatosis. The hepatic iron index will become less useful with the advent of genetic testing. It will remain a tool to aid the clinician in clinical judgment about an individual case. It may be most useful in the unusual hemochromatosis patient that is negative by conventional genetic testing but clinically seems to have genetic hemochromatosis.

Imaging Studies of the Liver

Magnetic resonance imaging (MRI) can demonstrate moderate to severe iron overload of the liver. The technology is advancing and it is possible that eventually it may be as precise as hepatic iron determination.

Genetic Testing for Hemochromatosis

A major advance that stems from the discovery of the hemochromatosis gene is the use of a diagnostic genetic test. The original publication reported that 83% of a group of patients with suspected hemochromatosis had the characteristic C282Y mutation of the *HFE* gene. A more detailed analysis of the non-C282Y cases revealed other explanations for the iron overload in some cases resulting in more than 90% of the typical hemochromatosis patients being C282Y homozygotes. In the original report, the gene was called *HLA-H* but this name was later changed to *HFE*. [1] The C282Y mutation is also reported as 845A in some laboratories reflecting the base pair change rather than the amino acid change. Subsequent studies in well-defined hemochromatosis pedigrees reported that 90% to 100% of typical hemochromatosis patients had the C282Y mutation. [26], [27], [28], [29] and [30] The presence of a single mutation in most patients is in marked contrast to other genetic diseases in which multiple mutations were discovered (cystic fibrosis, Wilson disease, a1-antitrypsin deficiency). A second minor mutation, H63D, was also described in the original report. [1] This mutation does not cause the same intracellular trafficking defect of the *HFE* protein. Compound heterozygotes (C282Y/H63D) and less commonly H63D homozygotes [31] may resemble C282Y homozygotes with mild to moderate iron overload (Fig. 112-3A and Fig. 112-3B). These genotypes are much more common than C282Y homozygotes in the general population yet are not commonly reported in large series of typical hemochromatosis patients. This suggests that most compound heterozygotes and H63D homozygotes have normal iron studies. A polymorphism on intron 4 of the *HFE* gene (5569A) was independently reported by several laboratories to lead to false-positive genetic testing in which a C282Y heterozygote appears to be a homozygote. [32], [33] This should be considered during the evaluation of a “nonexpressing” C282Y homozygote. The correct diagnosis can be confirmed by direct DNA sequencing. Pedigrees with iron overload have been described with mutations in the transferrin receptor 2 gene and the ferroportin gene. [34], [35] and [36] It is likely that more mutations will be found but they will only be relevant to a minority of patients. The interpretation of the test in several settings is shown in Table 112-2.

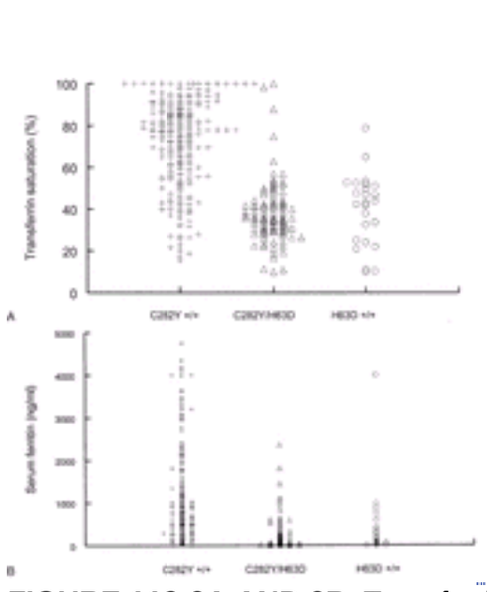

FIGURE 112-3A AND 3B. Transferrin saturation and serum ferritin in referred C282Y homozygotes, compound heterozygotes (C282Y/H63D), and H63D homozygotes. Iron studies in screening studies are usually normal in compound heterozygotes and H63D homozygotes.

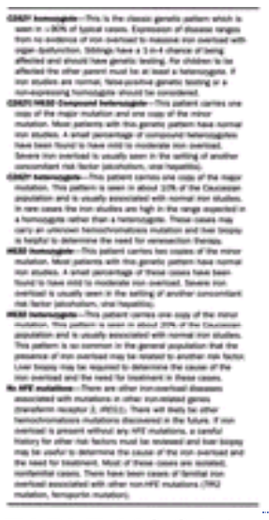

TABLE 112-2 Interpretation of Genetic Testing for Hemochromatosis

The genetic test can also be done on DNA extracted from buccal smears or from paraffin-embedded tissue such as liver explants. Studies of explanted livers have demonstrated that many liver transplant patients classified as hemochromatosis are negative for the C282Y mutation. [37] This suggests that those patients may have had iron overload secondary to chronic liver disease rather than hemochromatosis. Therefore any interpretation of iron reaccumulation after liver transplant for hemochromatosis must be cautious.

Genetic discrimination is a major concern with the widespread use of genetic testing. A positive genetic test even without iron overload could disqualify a patient for health or life insurance. [38] In the case of hemochromatosis, the advantages of early diagnosis of a treatable disease outweigh the disadvantages of genetic discrimination.

If we define the presence of homozygosity for the C282Y mutation as the new gold standard for hemochromatosis, it provides for the first time a benchmark for the assessment of the phenotypic diagnostic tools that have been used for decades. The transferrin saturation and serum ferritin with 3 HFE genotypes are shown in Figure 112-3.

Nonexpressing Homozygotes As genetic testing has become more widespread an increasing number of persons have been found with the hemochromatosis gene without iron overload. This includes siblings within well- defined hemochromatosis pedigrees. [29] The prevalence of these nonexpressing homozygotes is not yet determined from population studies but this may explain the wide discrepancy between the gene frequency and the clinician's perception that this is an uncommon disease. Pooled estimates from 14 studies have suggested that 50% of C282Y homozygotes may not have iron overload. [39] Patients who are homozygous for the C282Y mutation should be considered at risk of developing iron overload. If there are no abnormalities in transferrin saturation or ferritin in adulthood however, it seems more likely that these individuals are nonexpressing homozygotes rather than patients who will develop iron overload later in life. It seems appropriate to repeat the serum ferritin and transferrin saturation every 5 years in non–iron-loaded C282Y homozygotes to understand more about their natural history. It is important to exclude a false-positive genetic test result as previously described. In most nonexpressing homozygotes, there has been no evidence of chronic blood loss or reduced dietary intake of iron. The study of the nonexpressing homozygote may provide additional information about new genes that counteract the effect of the hemochromatosis gene.

Family Studies in Hemochromatosis Once the proband case is identified and confirmed with the genetic test for the C282Y mutation, family testing is imperative. Siblings have the highest chance of carrying the gene and should be screened with the genetic test (C282Y and H63D mutation), transferrin saturation, and serum ferritin. [40] Phenotypic expression can vary widely between siblings and I have identified identical twins with hemochromatosis with a marked difference in iron loading which suggests that environmental factors are contributory. Patients are usually very concerned about their children and may have difficulty with the concept of autosomal recessive transmission. The risk to a child is dependent on the prevalence of heterozygotes in the community and is probably greater than 1 in 20 and much lower if the spouse is non-Caucasian. A cost-effective strategy now possible with the genetic test is to test the spouse for the C282Y mutation to assess the risk in the children. [41] If the spouse is not a C282Y heterozygote or homozygote, the children will be obligate heterozygotes. This assumes paternity and excludes another gene or mutation causing hemochromatosis. This strategy is particularly advantageous when the children are geographically separated or may be under a different health care system than the parents. Genetic testing in general raises many ethical questions such as premarital testing, in utero testing, and paternity issues which have not been tested yet in hemochromatosis. Preliminary studies at our center have demonstrated that genetic testing is well accepted by patients and does not lead to an increase in anxiety. [42] If an isolated heterozygote is detected by genetic testing, it is recommended to test siblings. Extended family studies are less revealing than a family study with a homozygote but more likely to uncover a homozygote than random population screening.

DIAGNOSIS OF NON-*HFE* HEMOCHROMATOSIS AND SECONDARY IRON OVERLOAD

It is important to remember that there will be patients with a clinical picture indistinguishable from genetic hemochromatosis that will be negative for the C282Y mutation. Most of these patients will be isolated cases although a few cases of familial iron overload have been reported with negative C282Y testing. [34], [43] In non-Caucasians, iron overload is not commonly associated with HFE mutations. Therefore, the role of screening for *HFE* mutations in African Americans and Asians has not been clinically useful. Hispanic populations have been found to have HFE mutations, which is likely related to their Spanish heritage. Iron overload has been described in African Americans [44] but many of these cases had other risk factors for iron overload and pedigree studies have not been commonly reported. The iron overload described in sub-Saharan Africans may be related to another iron-loading gene [45] and a linkage to iron overload in African Americans is an intriguing hypothesis that awaits the identification of that gene.

A negative C282Y test should alert the physician to question the diagnosis of genetic hemochromatosis and reconsider secondary iron overload related to cirrhosis, alcohol, viral hepatitis, or iron-loading anemias. If no other risk factors are found, the patient should begin venesection treatment similar to any other patient with hemochromatosis. The decision to classify this group of patients as non-HFE hemochromatosis or idiopathic iron overload is a matter of semantics and ideology surrounding case definition. Quantification of iron burden by hepatic iron concentration or quantitative phlebotomy will be important to further characterize this group of patients.

In most cases of secondary iron overload, the patient has anemia with iron overload from increased iron absorption or multiple transfusions. These patients will not tolerate venesections and will require parenteral chelation therapy. Oral iron chelators such as deferiprone have been controversial because of potential hepatotoxicity.

Some patients with hepatitis C or alcoholic liver disease will be misdiagnosed as hemochromatosis. An elevated serum ferritin is common in these conditions but the hepatic iron concentration is often within normal limits. Venesection therapy of these conditions has been studied and is not recommended in patients with a normal hepatic iron concentration.

TREATMENT

The treatment for hemochromatosis continues to rely on the medieval therapy of periodic bleeding. At the University of Western Ontario, patients attend an ambulatory care facility and the venesections are performed by a nurse using a kit containing a 16-gauge straight needle and collection bag (Blood Pack MR6102, Baxter, Deerfield, IL). The patient lies in the reclining position for 15 to 30 minutes while blood is removed. A hemoglobin test is done at the time of each venesection. If the hemoglobin decreased to less than 10 g/dL the venesection schedule is modified to 500 mL every other week. Venesections are continued until the serum ferritin is approximately 50 g/L. The concomitant administration of a salt-containing sport beverage (e.g., Gatorade) is a simple method of maintaining plasma volume during the venesection. Maintenance venesections after iron depletion of three to four venesections per year are done in most patients although the rate of iron reaccumulation is highly variable. [46] The transferrin saturation will remain elevated in many treated patients and will not normalize unless the patient becomes iron-deficient. The prognosis of hemochromatosis is primarily dependent on the presence of cirrhosis at the time of diagnosis (Fig. 112-4). In some cases (particularly non-HFE related iron overload), a component of the serum ferritin elevation is related to inflammation rather than iron overload, so the ferritin does not decrease with

treatment and the patient becomes anemic. In these cases, a careful review of the liver biopsy including hepatic iron concentration may be helpful in deciding to discontinue treatment or decrease the frequency of phlebotomies.

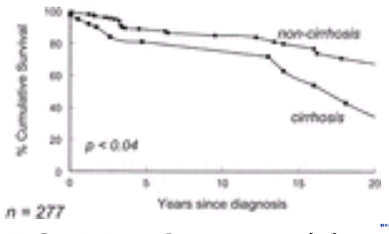

FIGURE 112-4. Actuarial survival of treated C282Y homozygotes in cirrhotic and noncirrhotic patients.

Chelation therapy with desferrioxamine is not recommended for hemochromatosis. The therapy is expensive, inefficient, cumbersome, and potentially toxic. Oral chelators such as deferiprone have side effects such as agranulocytosis and possible hepatotoxicity. Erythrocytophoresis has been used but is more expensive than simple phlebotomy therapy. Patients are advised to avoid oral iron therapy and alcohol abuse but there are no dietary restrictions. Patient support groups are discouraged by the practice of iron fortification of foods, but much of this iron is in an inexpensive form with poor bioavailability.

POPULATION SCREENING

Identification of persons at risk of developing the sequelae of hemochromatosis is preferred. The plan is to screen a population of asymptomatic individuals, with no personal or family history to suggest that they are at higher risk of the disease than the rest of the population. It aims to detect disease in presymptomatic individuals in order to provide more effective treatment in the early stages of disease. [47] Since screening programs are initially associated with increased health care costs, it is imperative that planning of screening protocols consider all the risks and benefits, and the diagnostic strategy relevant to the disease being considered prior to implementation. Population screening for hemochromatosis meets most of the criteria established by the World Health Organization for screening for medical disease.

Target Populations

It is inadequate to wait for the onset of symptoms to diagnose hemochromatosis. Many of the symptoms are unrecognized and organ damage is usually present at the time of clinical presentation. [48] In our database, 43% of referred male probands had cirrhosis of the liver (irreversible complication) at the time of diagnosis. In contrast, among the asymptomatic siblings that were then investigated, cirrhosis was present in only 6%. The ideal patient to screen is the young adult with Northern European ancestry.

Phenotypic Screening

Sporadic screening studies have been performed to establish the use of various tests and the prevalence of hemochromatosis in a target population. Target populations have included blood donors, hospital inpatients, outpatients, employees, diabetics, and military recruits. Initial testing and test thresholds also varied and have included serum iron, UIBC, transferrin saturation, ferritin and combinations of these tests. All of these studies have used phenotypic screening rather than genotypic screening. The prevalence of hemochromatosis in most of these studies is similar to studies using genetic testing which suggests that most cases will show biochemical expression of the disease.

Genetic Population Screening

A large study was conducted on 2375 Australian neonates. A prevalence of 1 in 150 were homozygous for the C282Y mutation. [49] A population study in Western Australia demonstrated a frequency in adults of 1 in 189. [50] In this study, inhabitants of Busselton, Western Australia had annual examinations and blood tests as part of a long-term epidemiologic project. When 12 C282Y homozygotes were discovered in the screening study, it was possible to determine the serum ferritin drawn 4 years previously. This is a fascinating glimpse into the natural history of untreated hemochromatosis detected at an early stage in the asymptomatic population. The serum ferritin in these homozygotes is shown in Figure 112-5. It is apparent that most but not all of these homozygotes are accumulating iron over the observation period. Another large study screened 5211 Canadian blood donors and directly compared transferrin saturation, UIBC, and C282Y genotyping. In this study, the UIBC detected more homozygotes than the transferrin saturation at a lower cost and with fewer false-positive cases. [19] A screening study of 41,038 adults attending a health appraisal clinic in San Diego, demonstrated a prevalence of C282Y homozygotes of 1 in 271. The transferrin saturation was more than 50% in only 75% of male and 40% of female C282Y homozygotes. An elevated ferritin was present in approximately 76% of male and 54% of female C282Y homozygotes. Patients were asymptomatic with a low iron burden. [5]

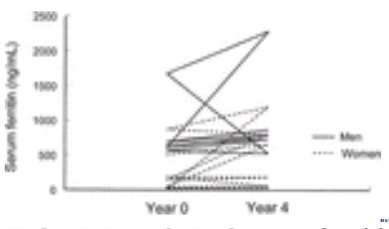

FIGURE 112-5. Serum ferritin in untreated C282Y homozygotes observed over a 4-year period. (Adapted from a population survey screening for hemochromatosis in Busselton, Australia. [50])

Since many patients have now been described homozygous for the C282Y mutation without iron overload, the role of the genetic test as the initial screening test will greatly depend on the prevalence of the nonexpressing homozygote in the general population. The preferred approach for screening at the present time is initial screening for iron overload with transferrin saturation or UIBC, with C282Y genotyping as the second line test in those with abnormal iron tests. An example of this approach is a study in 65,238 Norwegians attending a health appraisal clinic. [51] Genetic testing was only done in cases with an elevated transferrin saturation. Cirrhosis of the liver was detected in 3.7% of men and none of the women. This approach allows for the genetic testing to be focused on those with iron abnormalities. In general, the screening studies to date have demonstrated high prevalence but low morbidity. [52], [53] The natural history of untreated disease remains unknown. If untreated cases would never develop significant morbidity the use of population screening is greatly decreased.

A strong case for initial screening with the genetic test can be made in countries with a high prevalence of disease, low cost of the genetic test, and a lower risk of genetic discrimination (e.g., Ireland).

Periodic health examination in asymptomatic people has been discouraged by many health care systems. Screening in diabetic and arthritis clinics has also been studied. By the time that diabetes is present, organ damage is also evident and arthritis is a common cause of an elevation in serum ferritin which will increase the number of false-positive patients that will go on to have invasive testing. The use of genetic testing within an arthritis clinic would likely improve the screening algorithm.

It seems that population screening studies will continue using combinations of phenotypic and genotypic testing. The challenge for the future will be to devise an optimal method of sampling the population and financial support from health care systems. Physicians and third party payers need to be convinced about the

morbidity of hemochromatosis before accepting mass screening.

SUMMARY

Hemochromatosis is a common and often underdiagnosed disease. Early diagnosis and treatment results in an excellent long-term prognosis. The development of a diagnostic genetic test has improved the feasibility of the goal of prevention of morbidity and mortality from hemochromatosis.

CHAPTER 113

Ronald J. Sokol

METABOLIC DISEASES OF THE LIVER

Hepatic involvement is a common feature in inborn errors of metabolism that are manifest in childhood and in adult life. In these disorders, it is frequent that a gene controlling a single enzyme in an important metabolic pathway or coding for a transport protein has been mutated, causing a significant block in the metabolism or transport of the substrate. Both deficiencies of important products of the enzyme and accumulation of toxic precursors lead to the disease phenotypes. In many of the genetic disorders affecting the liver, an environmental exposure to the specific substrate or toxin (galactose, fructose, copper, protein load) are important modifiers of the onset and severity of the disease phenotype. Many prior cryptogenic acute and chronic liver diseases have now been attributed to specific metabolic defects, and there are certainly many more to be discovered. It has become apparent that modifier genes most certainly play a major role in determining the clinical phenotype, severity of disease, and onset of illness for many metabolic and genetic liver diseases that were previously thought to be caused by single gene mutations.

Metabolic liver disease may present in children in a variety of clinical phenotypes, including the appearance of acute hepatitis, bacterial sepsis, metabolic coma, or as an ingestion of a toxin or drug overdose. A high index of suspicion is necessary in order to perform the correct metabolic testing and establish the diagnosis of a metabolic disorder. Some of the clinical features suggesting a metabolic liver disease include:

- hepatomegaly or splenomegaly
- cirrhosis
- hepatic steatosis
- acute fulminant liver failure
- the presence of neuromuscular or cardiac findings
- hypoglycemia, hyperammonemia
- organic acidemia
- hepatic synthetic functional failure
- mildly elevated aminotransferases
- episodes of recurrent vomiting or severe gastroesophageal reflux
- developmental delays
- failure to thrive
- chronic diarrhea
- cataracts
- abnormalities of skin or hair
- family history of similarly affected infants or children, or of consanguinity.

Most metabolic liver diseases are inherited in an autosomal recessive manner; however, several segregate into autosomal dominant and x-linked inheritance patterns. Diseases with maternal inheritance (mitochondrial DNA [mtDNA] diseases) also commonly involve the liver.

Metabolic liver diseases that present during childhood follow three patterns. A number of diseases present as a neonatal cholestasis syndrome (Table 113-1) which requires rapid diagnostic evaluation so that effective therapy can be instituted to avert permanent injury to the liver or other organs. A second mode of presentation is that of chronic liver disease with progressive hepatic fibrosis, portal hypertension, and eventually cirrhosis, with or without splenomegaly. Finally, metabolic liver diseases may present as a “metabolic syndrome,” including hypoglycemia, encephalopathy, metabolic acidosis, variable ketonemia, or lactic acidosis and/or hyperammonemia. A complete categorization of all metabolic liver diseases affecting children and adults is beyond the scope of this chapter. The reader is referred to textbooks on liver disease in children for more complete coverage of this topic. [1] This chapter will focus on five major areas of metabolic disease: Wilson disease, a1-antitrypsin deficiency, Reye syndrome, porphyria, and a group of important metabolic liver diseases presenting in early childhood.

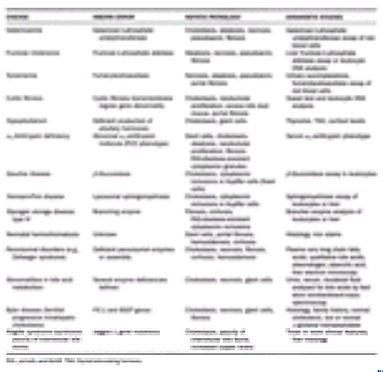

TABLE 113-1 Metabolic and Genetic Causes of Neonatal Cholestasis

WILSON DISEASE

Clinical Features

Wilson disease is caused by mutations in *ATP7B* gene which lead to progressive accumulation of copper in the liver followed by copper deposition in other organs, leading to the varying clinical features of Wilson disease. Although copper accumulates from birth, clinical symptoms are rarely apparent prior to 4 to 5 years of age. [2] Copper deposition in the liver initially causes asymptomatic biochemical abnormalities. The youngest reported patient presenting with hepatic clinical symptoms was 4 years old. [3] After the storage capacity of the liver is exceeded, circulating nonceruloplasmin-bound copper levels increase, distributing copper systemically. This redistribution of copper to other organs parallels the development of clinical manifestations of Wilson disease. Prior to 10 years of age, 80% of patients present with hepatic and 17% with neuropsychiatric manifestations. Between 10 and 18 years of age approximately 50% of patients present with either hepatic or neuropsychiatric symptoms. After 18 years of age, only 25% present with hepatic symptoms, with 75% having neuropsychiatric symptoms. [4] After hepatic saturation with copper, copper may also accumulate in the ocular cornea, leading to the characteristic Kayser-Fleischer (K-F) ring, a greenish-brown pigment at the periphery of the cornea on its posterior surface in Descemet membrane. [5] A less common ophthalmologic feature of Wilson disease is the “sunflower cataract” caused by deposits of copper in the anterior and posterior lens capsule. Wilson disease may also lead to a variety of renal disturbances including proteinuria, glucosuria, phosphaturia, generalized amino aciduria, and microscopic hematuria. Kidney stones are also common in Wilson disease, [6] and patients with the fulminant presentation of Wilson disease present with acute renal failure. Intravascular hemolysis is frequent and may be the presenting abnormality in approximately 15% of patients. Cardiac involvement has been recognized in Wilson disease with echocardiographic abnormalities present in up to one third of adults, [7] as well as arrhythmias, orthostatic hypotension, and histological changes in the heart. [7] Skeletal manifestations of Wilson disease include bone demineralization, rickets, spontaneous fractures, osteochondritis desiccants, chondromalacia patellae, and degenerative arthritis. [8] Skin pigmentation may be increased, particularly on the anterior aspect of the lower legs. [9] Various endocrinologic abnormalities have also been reported. [10], [11]

The liver is both the site of the Wilson disease biochemical defect in copper metabolism that leads to systemic disease, as well as the initial target of copper toxicity. Hepatic involvement in Wilson disease can present in one of four clinical subtypes: acute hepatitis, fulminant hepatic failure, chronic active hepatitis, and cirrhosis. Occasionally elevated aminotransferase levels are detected in asymptomatic patients for whom a chemistry panel is drawn, or in siblings of a patient with Wilson disease. It is essential that the clinician investigate children and young adults for Wilson disease if aminotransferase levels remain elevated and more common diseases are excluded.

Acute hepatitis is the mode of presentation for approximately 25% of patients with Wilson disease, with typical findings of jaundice, anorexia, nausea, malaise, pale stools, and dark urine, mimicking the features of infectious hepatitis. Laboratory tests show typically elevated aminotransferases, a normal serum albumin, and prothrombin time, with conjugated hyperbilirubinemia. However, if serologic testing for viral hepatitis is negative, Wilson disease needs to be considered. A mild hemolytic anemia or a depressed serum uric acid level (due to renal tubular losses) may be key features to alert the clinician to this diagnosis. However, the patients generally recover from this presentation, and the diagnosis may be missed.

Fulminant hepatic failure is a much more dramatic presentation of Wilson disease, although less common. It typically occurs in the adolescent or young adult who develops an acute icteric hepatitis that rapidly evolves to liver failure in a few days to several weeks with extreme jaundice, fatigue, hepatic coma, severe coagulopathy, ascites, renal failure, and invariably death, if liver transplantation is not performed. A Coombs-negative hemolytic anemia is caused by the rapid release of massive amounts of copper from the necrosing liver, and is the single most important diagnostic feature suggesting Wilson disease in this clinical setting. Interestingly, serum aminotransferase levels are not as high as in other patients with acute liver failure, alkaline phosphatase is generally very low for the age of the patient, and serum aspartate aminotransferase (AST) is significantly more elevated than the alanine aminotransferase (ALT). [12] Serum copper levels are actually elevated above normal in this presentation of Wilson disease because of the massive release of copper from the liver. K-F rings are present in no more than half of patients with this presentation, so their absence does not exclude the presence of Wilson disease. Prompt referral of patients with this presentation to a center that can perform liver transplantation is essential in order to save the patient’s life. A similar presentation of acute fulminant liver failure and death has been described in patients with Wilson disease who had been successfully chelated with medications, but who unadvisedly discontinued therapy or became noncompliant for as little as 8 months.

Chronic active hepatitis is a presentation of Wilson disease in up to 30% of patients, generally occurring during adolescence or young adulthood. Cirrhosis is common at the time of diagnosis. Typical findings of malaise, anorexia, fatigue, abdominal pain, nausea, and weight loss may precede the onset of jaundice in this scenario. Amenorrhea, delayed onset of puberty, edema, polyarthralgia, ascites, and clubbing may also indicate the chronic nature of this hepatitis. Physical examination invariably reveals hepatomegaly and usually splenomegaly. Liver biopsy shows characteristic findings of chronic active hepatitis with variable degrees of fibrosis. The histology can mimic autoimmune or chronic viral hepatitis, so a high suspicion for Wilson disease is necessary to establish this diagnosis. Importantly, histochemical stains for copper-associated proteins in the liver may be negative in patients with Wilson disease, and should never be used as the diagnostic criteria for copper overload. K-F rings are present 50% of the time, but their absence does not exclude Wilson disease. For this reason, it is imperative that biochemical screening for Wilson disease be undertaken in all patients with chronic active hepatitis who present younger than age 40 to 45 years.

Cirrhosis and its complications are relatively common features of Wilson disease in childhood and during adulthood. Virtually all adults with the neuropsychiatric presentation of Wilson disease have underlying compensated cirrhosis. Patients with cirrhosis may have an insidious presentation with cutaneous signs of chronic liver disease, splenomegaly, or onset of ascites as the initial clinical abnormalities. Other than the findings of a mild hemolytic anemia, a K-F ring if sought, positive family history, or neuropsychiatric symptoms, there is little to clinically distinguish this cause of cirrhosis from others.

Cholelithiasis is relatively common in adolescents with Wilson disease because of ongoing hemolysis and the presence of cirrhosis. Interestingly, hepatocellular carcinoma has been quite unusual in patients with Wilson disease, even those with advanced cirrhosis.

Neuropsychiatric Presentation

The onset of neurological or psychiatric symptoms is the first indication of illness in approximately 40% to 50% of patients with Wilson disease. Neurological onset has been recorded in children as young as 6 years, and in adults as old as 52 years of age. [13] Neurological symptoms generally involve the motor system presenting as manifestations of extrapyramidal or cerebellar dysfunction. [14], [15] Symptoms may be broken down into those of “pseudoparkinsonism,” pseudosclerosis, and dyskinesia, each of which correlates with specific magnetic resonance imaging features of the brain. [16] Common extrapyramidal symptoms include facial grimaces, drooling, a fixed grin, dysphasia, and contractures of the jaw and extremities. Bradykinesia, cognitive impairment, cogwheel rigidity, and an organic mood syndrome characterize the pseudoparkinsonism features. Ataxia, tremor, and reduced functional capacity are present in patients with the pseudosclerosis presentation. Because intelligence is unaffected, patients generally become frustrated and depressed with the neurological presentations of Wilson disease. The neurological basis for these abnormalities is the dysfunction of the basal ganglia and cerebellum, although corticospinal and corticobulbar pathways are also affected.

It is well appreciated that patients with Wilson disease can have a primary psychiatric presentation, including organic dementia, neurotic behavior, bipolar disorder, schizophrenic psychosis, or antisocial behavior. In children and adolescents, there may be a major change in affect or personality that impairs socialization skills and school performance. Psychiatrists must maintain a high index of suspicion for Wilson disease and measure the plasma ceruloplasmin and obtain an eye examination

for a K-F ring in all young patients with psychiatric disorders. K-F rings are present in over 90% of patients with the neuropsychiatric presentation of Wilson disease.

Hepatic Histology

Early histological findings in asymptomatic children with Wilson disease include periportal glycogen-filled, swollen nuclei [17] and hepatic microvesicular and macrovesicular steatosis. [18] In adolescents and young adults, the macrovesicular steatosis may be confused with alcoholic liver disease or nonalcoholic steatohepatitis. As the disease progresses, mononuclear cell infiltrates of the portal tracts become evident with increasing periportal fibrosis over time. Focal hepatocyte necrosis with interface hepatitis may be present in the chronic active hepatitis form of the disease. Eventually, mixed micro- and macronodular cirrhosis develops. The fulminant hepatitis lesions are characterized by microvesicular fat, coagulative cell necrosis, pigment laden Kupffer cells, collapse of stroma, and drop out of hepatocytes, with underlying well established cirrhosis. Histochemical stains for copper or copper-associated proteins may be negative despite massive accumulation of copper in the liver, and thus may be misleading. There is no correlation between histochemical staining of copper and quantitative copper measurements of liver biopsy samples in Wilson disease.

Electron microscopy may be helpful in Wilson disease because of characteristic ultrastructural lesions. In the early stage of Wilson disease, hepatocellular mitochondria are pleomorphic and large, and show widened intracristal spaces, increased matrix density, large granules, and sometimes crystalline, vacuolated, or dense inclusions in the mitochondrial matrix. There is usually microvesicular steatosis present at the same time. These mitochondrial changes diminish with progression of the lesion toward cirrhosis.

Genetics

In 1993, *ATP7B* was identified by three groups as the gene affected in Wilson disease. [19], [20], [21] and [22] By 2000, over 170 mutations in this gene have been identified from patients with Wilson disease, most being small deletions or missense mutations. FONT size=-1> [23] , [24] Unfortunately, there are no dominant mutations, although specific mutations appear to be more common among certain ethnic groups. [23] Thus, the most common mutation (*His1069Glu*) may be present in as many as 40% of cases in specific ethnic populations. Consequently, genotyping of suspected patients is a tedious task and is performed primarily in research laboratories. Haplotype analysis (microsatellite markers) may be particularly helpful in evaluating relatives of a known case in which microsatellite markers are informative. [25] *ATP7B* is located on the long arm of chromosome 13.

Pathogenesis and Biochemistry

The *ATP7B* gene is highly expressed in the liver and kidney, with lower expression in the lung, placenta, and other tissues. The encoded protein is a P-type cation-transporting ATPase, and includes domains for copper binding sites and ATP binding. *ATP7B* is located in the trans-Golgi compartment of the hepatocyte and appears necessary for the transport of copper into vesicles bound for lysosomes and eventual excretion in the bile canaliculus. *ATP7B* also makes copper available for synthesis of ceruloplasmin. When *ATP7B* is mutated in Wilson disease, both copper secretion into bile and copper incorporation into ceruloplasmin are impaired, resulting in accumulation of toxic levels of copper within the hepatocyte. The function of the hepatic copper chaperone proteins that deliver copper into intracellular targets appear to be normal in Wilson disease. Ceruloplasmin is the primary carrier by which copper is secreted from the liver into the systemic circulation. Ceruloplasmin functions to mobilize iron from tissues by oxidizing ferrous iron for transfer into transferrin. Although ceruloplasmin levels in plasma are very low in Wilson disease, the ceruloplasmin gene is unaffected.

More than 80% of absorbed copper from the diet each day is excreted in bile. Therefore, impaired biliary excretion of copper in Wilson disease leads to accumulation of this toxic metal in the liver. Copper also accumulates in the liver in other conditions that cause cholestasis; however it is primarily lysosomal-bound in those conditions and may not necessarily be hepatotoxic. In Wilson disease, the copper appears to be free to enter other compartments, such as the mitochondria. The precise intracellular target for the toxic action of copper is not known; however, recent data suggest that mitochondrial oxidative injury caused by copper overload may be one of the primary pathogenetic events in Wilson disease. [26], [27] and [28] Several studies suggest that hepatocyte apoptosis may be the primary mode of cell death in copper toxicity. [29], [30]

Diagnosis

The diagnostic criteria for Wilson disease are dependent on the clinical presentation. In patients presenting with neurological or psychiatric symptoms, the absence of a K-F ring, and a normal ceruloplasmin level virtually exclude the diagnosis of Wilson disease. However, in one series, 2 of 20 patients with neurological symptoms did not have K-F rings. [31] In the presence of normal neurological or psychiatric function, the absence of a K-F ring does not exclude Wilson disease. The common biochemical tests used for diagnosis of Wilson disease are plasma ceruloplasmin, hepatic copper concentration, and 24-hour urine copper excretion (basal and after penicillamine challenge) (Table 113-2). For patients presenting with liver dysfunction, ceruloplasmin is generally less than 20 mg/dL, 24-hour urine copper is greater than 100 µg, and hepatic copper concentration is more than 250 µg/g dry weight. Other conditions that can give rise to increased hepatic copper concentration (see Table 113-2) must be excluded with appropriate testing. Two studies [32], [33] demonstrated excellent discrimination between Wilson disease and other liver disorders when a 24-hour urine copper analysis was measured after a penicillamine challenge (500 mg given orally immediately before and repeated 12 hours into the urine collection). Values above 1575 µg of copper in this 24-hour urine collection indicated Wilson disease. Liver biopsy samples must be obtained in copper-free stainless steel needles. Quantitative hepatic copper determination is essential, with normal copper content <50 µg/g dry weight, [34] and in Wilson disease, it is virtually always above 250 µg/g dry weight, [2] if not considerably higher.

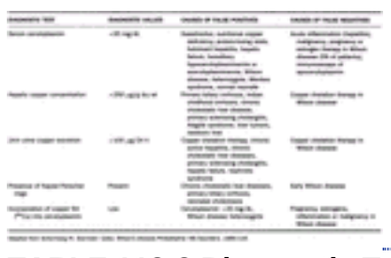

TABLE 113-2 Diagnostic Tests for Wilson Disease

Unfortunately, the assays used to analyze serum for ceruloplasmin have changed over recent years to the immunologic technique, which is in common use. Apo-ceruloplasmin is recognized by this assay, resulting in higher values than those previously measured by oxidase techniques. Therefore, a ceruloplasmin level between 20 and 30 mg/dL cannot be used on its own to definitively exclude Wilson disease. If there is a high suspicion of Wilson disease, the 24-urine copper excretion, slit-lamp examination, and perhaps liver biopsy should be performed despite a low normal level of ceruloplasmin. If a sibling has Wilson disease, microsatellite (haplotype) analysis may be another potential means to diagnose Wilson disease. In the past, incorporation of copper 64 (^{64}Cu) into ceruloplasmin could be determined; however, it is now difficult to obtain this radiolabeled copper. Finally, it may be possible to obtain genotyping of *ATP7B* from one of the research laboratories performing this analysis. If the diagnosis still remains in doubt, genotype and phenotype approaches to diagnosing Wilson disease have been published. [4]

In patients with fulminant hepatic failure, specimens to establish the diagnosis of Wilson disease may be difficult to obtain. Standard liver biopsy may be contraindicated because of coagulopathy, and the patient may be in acute renal failure, so a collection of 24-hour urine copper concentrations may not be possible. However, the diagnostic features of a severe hemolytic anemia, extremely high bilirubin, elevated serum copper values, acute renal failure, low serum alkaline phosphatase, and inappropriately mild elevations of aminotransferase levels are consistent with this diagnosis. Because these patients will either succumb to their illness or undergo a liver transplant, the explanted or autopsied liver should be evaluated for histology and for copper content.

Treatment

Wilson disease is uniformly fatal without effective therapy. Therefore the hallmark of medical management is the reduction (or chelation) of the accumulated burden of copper and preventing reaccumulation of copper. For symptomatic patients, most authorities recommend copper chelating agents and a low copper diet. For maintenance therapy, copper chelators or oral zinc therapy may be effective.

When the diagnosis of Wilson disease is established in a symptomatic patient, treatment should begin with either triethylenetetramine dihydrochloride (trientine) or D-penicillamine. In recent years it has become evident that trientine is probably better tolerated in most patients than D-penicillamine. The dose of trientine in adults and adolescents is approximately 1 to 2 g daily in 3 divided doses 1 hour prior to meals. The dose of penicillamine is also 1 to 2 g/day, given at least 30 minutes before or 2 hours after meals. [2] In young children, the dose for each of these drugs is approximately 20 mg/kg/day rounded to the nearest multiple of 250 mg given in divided doses over 24 hours. After stabilization, the dose of trientine or D-penicillamine can be divided into 2 or 3 daily doses, and reduced to approximately 1 g/day in adults. D-penicillamine may have an antipyridoxine effect, [2] thus all patients should also receive 25 mg of pyridoxine daily. It is recommended that D-penicillamine or trientine be started at one fourth to one half the desired dose and increased gradually over 1 to 2 weeks' time. Within the initial month of therapy the patient should be monitored for signs of acute allergic reactions or other toxicity. Thus a complete blood count, urinalysis, and renal and liver tests should be obtained weekly for the first month. If the patient responds appropriately, monitoring is then performed each 1 to 3 months for the first year, and then every 6 to 12 months thereafter. Some experts recommend following 24-hour urine excretion of copper to monitor chelation therapy, obtained several times in the first 6 months and then yearly thereafter. Several grams of copper should initially be excreted over 24 hours, but after several years of chelation, as little as 300 µg of copper should be excreted per day. [2] If urinary copper excretion is very low or very high, it suggests poor compliance with copper chelators. If the K-F rings had initially been present, then serial ophthalmologic examinations yearly should be performed to be certain that these lesions disappear with time. The failure of disappearance again suggests poor compliance. Many authorities recommend lifelong chelation therapy with trientine or D-penicillamine in patients who responded well to therapy. A sudden discontinuation of chelation therapy can result in fulminant liver failure which is usually fatal. [35]

It has been demonstrated that up to 30% of patients [36] will have some worsening of neurological symptoms when treated with D-penicillamine. The cause of this neurological worsening has been proposed to be a transient increase in blood copper, and then brain copper exposure as the penicillamine mobilizes hepatic copper stores; [37], [38] or alternatively, that penicillamine may form a complex of intracellular copper that is more toxic. [38] Neurological exacerbation has also been reported following initiation of treatment with trientine, [39] thiomolybdates, [40] and zinc; [41] however the frequency seems to be lower than with D-penicillamine. For these reasons, Brewer and colleagues [42] propose the use of ammonium tetrathiomolybdate for initial therapy in neurologically affected patients. This remains an investigational compound which complexes with dietary copper, thus preventing its absorption, and when absorbed complexes with copper and albumin in blood preventing cellular uptake and decreased intracellular copper stores. Concerns have been raised regarding bone marrow suppression and other toxicities of ammonium tetrathiomolybdate; this drug is under investigation.

D-penicillamine may produce both allergic and toxic effects in up to 20% of patients. Trientine appears to be associated with a lower frequency of side effects, and therefore is recommended by some authorities as a safer initial chelator for Wilson disease. Side effects of penicillamine include fever, skin rash, lymphadenopathy, pancytopenia, proteinuria, nephrotic syndrome, drug-associated systemic lupus erythematosus, Goodpasture syndrome, optic neuritis, and bone marrow suppression. Long-term therapy with D-penicillamine may cause a dermatopathy. [43], [44]

Patients who present with fulminant hepatic failure caused by Wilson disease rarely, if ever, survive unless orthotopic liver transplantation is performed. These patients require critical care therapy in a liver transplantation center fully equipped to use hemodialysis, plasmapheresis, and other means of sustaining the patient until liver transplantation.

In recent years the use of zinc has been proposed as maintenance or adjunctive [45] therapy for Wilson disease. Zinc inhibits intestinal absorption of copper by increasing metallothionein binding of copper in intestinal epithelia, which are sloughed in the gut. Some authorities recommend starting zinc acetate 50 mg of elemental zinc 3 times a day [46] or zinc sulfate 150 to 220 mg 3 times a day. [46] The zinc must be given between meals, and compliance may limit the effectiveness of this therapy. Zinc therapy is generally not used as initial therapy of symptomatic patients because of its slower onset of action. It may play a role in presymptomatic patients or siblings (especially young children) who are diagnosed with Wilson disease. Iron status needs to be monitored on patients who are undergoing chronic zinc therapy.

Finally, the use of antioxidants as adjunctive therapy in Wilson disease has not been fully explored. Because copper induces oxidative damage to the hepatocyte, [27], [47] and because a-tocopherol levels may be low during copper overload, [27], [47] it has been proposed that a-tocopherol might be an adjunctive therapy in symptomatic patients with Wilson disease. [4]

The role of orthotopic liver transplantation is well established in patients with fulminant liver failure caused by Wilson disease. In addition, patients with end-stage liver disease caused by Wilsonian cirrhosis should be considered for liver transplantation, as would other patients with cirrhosis. Long-term survival is excellent following liver transplantation. Neurological features generally improve following liver transplantation, however this currently is not recommended to treat the sole neurological presentation of Wilson disease.

REYE SYNDROME

In the 1960s and 1970s, reports of children developing an apparently new disease called encephalopathy with fatty liver appeared in Australia, the United States, and Europe. Mortality was 40% to 70%, and the disease tended to occur in epidemics linked to influenza B, varicella infection, and other viral infections. The incidence of Reye syndrome peaked in the early 1980s, rapidly falling during the late 1980s and 1990s following the restriction of aspirin use in children. [48] The decline in incidence was also associated with the discovery and identification of numerous inherited metabolic defects of fatty acid transport and mitochondrial fatty acid oxidation, which harbor similar clinical features to Reye syndrome. Therefore, it is not completely clear whether the near disappearance of Reye syndrome was the result of reduction of aspirin use or the reclassification of many patients into newly discovered inborn errors of metabolism.

Clinical Features

Reye syndrome is characterized by a prodromal febrile illness, usually a viral respiratory illness, followed by the abrupt onset of protracted vomiting after it appears that the child was in a recovery phase from the viral illness. Although cases have most often been linked to epidemics of influenza A and B and varicella infections, Reye syndrome has been reported in association with almost every viral illness. The vomiting occurs within 3 to 7 days of the onset of the viral illness, and leads to dehydration and hyperpnea. Patients then rapidly pass through graded stages of encephalopathy, progressing to seizures, cerebral edema, coma, and possibly death. In over 90% of cases in the United States, a history of aspirin use for the treatment of the initial viral illness is obtained. Physical examination reveals an anicteric state with mild to moderate hepatomegaly, neurological dysfunction, overly brisk deep tendon reflexes, and varying degrees of dehydration. Biochemical testing reveals elevated AST and ALT from several 100's to several 1000's, a normal serum bilirubin and albumin, elevated prothrombin time and international normalized ratio (INR), hyperammonemia, and hypoglycemia, particularly in young children. The Centers for Disease Control case definition of Reye syndrome includes:

- the presence of acute, noninflammatory encephalopathy with a normal cerebral spinal fluid cell count and protein
- liver involvement characterized by microvesicular steatosis, AST/ALT elevation of threefold or greater, or hyperammonemia
- no other known explanation for the patient's illness.

During epidemics, patients with Reye syndrome were generally school-age to teenage children who were previously healthy, however a subgroup of children presented within the first few years of life, frequently with underlying failure to thrive and hypoglycemia in the presentation. Interestingly, respiratory alkalosis was present, lactic acidosis was rare, but dicarboxylic organic aciduria was common.

Hepatic Histology

Reye syndrome causes extensive hepatic panlobular microvesicular steatosis, characterized by foaminess of hepatocytes with centrally placed nuclei, which may

require special fat stains to identify the microvesicular steatosis. Cholestasis is absent, and inflammation is unusual. Electron microscopic examination of the liver shows striking mitochondrial morphologic abnormalities. Variable degrees of mitochondrial swelling, pleomorphism, loss of dense bodies, and matrix edema are present, correlating with the severity of the disease. Striking microvesicular steatosis is present early in the course, progressing to macrovesicular steatosis during the recovery phase. Hepatocytes do not undergo necrosis, but rather suffer from temporary metabolic (mitochondrial) failure. The central nervous system shows marked cerebral edema, particularly in fatal cases, with changes in neuronal mitochondria resembling those in the liver. Kidney lesions also show lipidosis and mitochondrial abnormalities. Thus, Reye syndrome is believed to be caused by generalized mitochondrial dysfunction, and was one of the first well-described mitochondrial hepatopathies.

Genetics

Reye syndrome occurs in children generally between the ages of 4 and 12 years, with only very rare cases being reported in adults. Occasional cases of recurrent Reye syndrome were reported in very young children, now believed to have been caused by fatty acid oxidation defects and other metabolic disorders that were not identified at the time. Familial cases of Reye syndrome were also reported, most likely caused by autosomal recessively inherited inborn errors of metabolism.

Pathogenesis and Biochemistry

Generalized acute mitochondrial dysfunction underlies the biochemical and clinical abnormalities observed in patients with Reye syndrome. [49] The etiology of the mitochondrial lesions is most likely a combination of viral-induced, cytokine-mediated cellular injury, the effect of aspirin on mitochondrial oxidative phosphorylation in, perhaps, genetically predisposed individuals. Because Reye syndrome has been reported in patients with collagen vascular disorders receiving large doses of aspirin who did not have apparent viral infections, isolated cases may have been purely caused by the effects of aspirin. The similar clinical presentation of fatty acid oxidation defects suggests that many cases of Reye syndrome were undiagnosed defects in this important pathway for cellular energy metabolism.

The epidemiologic association between aspirin intake and Reye syndrome was established in the United States in the late 1970s. [50], [51] Subsequently, in 1982, the U.S. surgeon general advised against the use of salicylates in children with febrile illnesses, and warning labels were placed on all aspirin products. A dramatic reduction in the use of aspirin in children followed over the next several years, with a coincident decline in the number of reported cases of Reye syndrome. However, in other countries in the world, such as Australia and Asian countries, aspirin use was not associated with Reye syndrome, yet there was dramatic reduction in the number of cases. Thus, it has been proposed by some [52] that the discovery of new metabolic diseases (such as fatty acid oxidation defects) and closer examination of cases resulted in a clinical reclassification of cases that would have previously been called Reye syndrome. Others claim that the effects of salicylates on mitochondrial oxidative phosphorylation may have brought to clinical recognition cases of subclinical metabolic liver disease.

Diagnosis

The diagnosis of Reye syndrome is made clinically, based on a prodromal viral illness, an intake of aspirin products, acute onset of vomiting with progressive encephalopathy, and cerebral edema. [53] Hyperammonemia, elevated AST and ALT, prolongation of prothrombin time, and normal or only slightly elevated bilirubin are characteristic. A normal cerebral spinal fluid excludes infectious or other causes of similar illnesses. Toxin ingestions need to be excluded, as do fatty acid oxidation defects, organic acidopathies, adrenal insufficiency, urea cycle enzymopathies, and intracranial lesions resulting from brain tumors, nonaccidental trauma, and so forth. The finding of microvesicular steatosis in a noninflamed liver with characteristic mitochondrial changes on electron microscopy is consistent with the diagnosis, but may be seen in other inborn errors of metabolism as well. [54]

Treatment

Management of Reye syndrome requires early diagnosis and a high index of suspicion for the disease. Initial treatment includes controlled rehydration for the vomiting, and administration of 6 to 8 mg/kg/min of concentrated solutions of dextrose plus electrolytes, to maintain blood sugars well above 100 mg/dL. Excessive sedation is avoided and the treatment of hyperammonemia varies among institutions. Intracranial pressure monitoring is necessary for patients who reach the encephalopathy stage of delirium and combativeness, with treatment aimed at carefully reducing intracranial pressure to maintain a cerebral perfusion pressure above 45 to 50 mm Hg (intravenous mannitol, pentobarbital coma, hypothermia, etc.). [55] Complications such as pancreatitis, acute renal failure, sepsis, pulmonary hemorrhage, or cerebral hemorrhage increase the risk of mortality. Unfortunately, most contemporary cases of Reye syndrome present in stage 3 to 4 coma, and do not have acceptable control of intracranial pressure resulting in sub-optimal nervous system outcome, despite survival. It should be pointed out that the metabolic liver failure in Reye syndrome undergoes spontaneous recovery (consistent with the effects of a toxin) during the first 2 to 3 weeks of illness, except for continued steatosis.

ALPHA-1 ANTITRYPSIN DEFICIENCY

a1-Antitrypsin deficiency affects 1 in 600 to 1 in 2000 live births. The PiZZ homozygous phenotype is an autosomal recessive disorder in which there is defective secretion of a1-antitrypsin from the liver, resulting in serum levels of only 10% to 20% of normal. The mutant a1-antitrypsin Z protein is trapped in the endoplasmic reticulum of the hepatocyte, causing liver injury in 10% to 20% of affected individuals. [56] The protein is in the family of circulating serine protease inhibitors called *serpins,* and is an approximately 55-kd secreted glycoprotein which inhibits neutrophil proteases and elastases. For reasons that are not clear, only 10% to 20% of PiZZ affected individuals develop clinically significant liver disease during the first 20 years of life. In adults, emphysema is common in affected homozygotes, particularly in association with cigarette smoking. a1-antitrypsin deficiency is the most common genetic cause of liver disease in children that leads to cirrhosis, and hence, is the leading genetic indication for orthotopic liver transplantation.

Clinical Features

Persistent neonatal cholestatic jaundice is the most common childhood presentation of a1-antitrypsin deficiency. Some infants occasionally present with acholic stools and may mimic the clinical appearance of biliary atresia. Affected infants tend to have been small for gestational age at birth. Serum aminotransferase levels, alkaline phosphatase, and ?-glutamyl transpeptidase may all be elevated. Hepatomegaly associated with progressive hepatic fibrosis may or may not be present on physical examination. Occasionally patients present with a secondary vitamin K deficiency coagulopathy causing bleeding in the first several months of life. Other affected infants and young children will present abruptly with symptoms of portal hypertension, such as esophageal variceal bleeding or hypersplenism. A very small number of patients present in acute fulminant liver failure during infancy. In adults, a1-antitrypsin deficiency may cause chronic hepatitis, cirrhosis, portal hypertension, or present as hepatocellular carcinoma. [57] There is also a slight increase in the risk of cryptogenic cirrhosis in adults who are PiMZ heterozygotes.

Sveger [58] conducted a prospective study, examining a1- antitrypsin phenotype in 200,000 newborn infants in Sweden. Of those 200,000 infants, 127 PiZZ infants were detected, 14 of which had cholestatic jaundice in infancy, 9 that had severe liver disease. Approximately 50% of the PiZZ individuals had abnormal aminotransferase levels without any other indication of liver involvement. Through childhood, more than 85% of the 127 patients had normalization and persistently normal aminotransferase levels with no evidence of liver disease or liver dysfunction. This prospective study in Swedish children suggests that only 5% to 10% of all PiZZ children will develop significant liver disease. However, it is well appreciated that subclinical hepatic fibrosis and even cirrhosis can occur in this disease without elevated liver blood tests.

Several other alleles of a-1 antitrypsin have been associated with liver disease. Children who are phenotype PiSZ appear to develop liver disease in a similar manner to PiZZ affected children. PiSS affected children do not develop liver disease. Other rare forms of a1-antitrypsin deficiency have occasionally been associated with liver disease. [59], [60]

It is rare for emphysema or any significant pulmonary involvement to affect children with a1-antitrypsin deficiency. In one study there were no significant differences between pulmonary function of PiZZ children and that of an age-matched control group between 13 and 17 years of age. [61] In adults over the age of 25 years, approximately 60% to 70% with a1-antitrypsin deficiency may develop variable degrees of emphysema, generally in the 4th or 5th decade.

Hepatic Histology

Liver histology in PiZZ homozygotes ranges from a benign-appearing, almost normal liver to one of extensive cirrhosis. The classic hallmarks of this deficiency are the

periodic acid-Schiff–positive (PAS), diastase-resistant globules that appear in periportal hepatocytes. These globules represent retained a1-antitrypsin material in the endoplasmic reticulum of hepatocytes. Globules may not be easily recognized in PiZZ infants until up to 6 months of age. [62] In the neonate, a giant cell hepatitis with multinucleated giant cells, lobular disarray, cellular, and canalicular cholestasis is commonly observed in affected infants. Occasionally, bile duct proliferation suggests biliary atresia. As the child becomes older, a more benign appearance of bridging hepatic fibrosis with minimal or no giant cell transformation is observed. The liver can also have the appearance of a chronic active hepatitis, or show increased iron deposition. Approximately 10% to 30% of infants with cholestatic jaundice evolve into a mixed macro- and micronodular cirrhosis. Bile ducts are generally normal; however, in 5% to 10% of children who present with neonatal cholestasis, paucity of interlobular bile ducts will develop, causing a chronic cholestatic disease.

Genetics

a1-Antitrypsin is encoded by a 12.2-kb gene located on human chromosome 14 q31-32. [2], [63], [64] Structural variances of the a1-antitrypsin protein are classified by the protease inhibitor phenotype system defined by agarose electrophoresis or isoelectric focusing of plasma. [64] A letter is assigned to variants according to the position of migration of a1-antitrypsin in these gel systems. The more common normal variant migrates in an intermediate isoelectric point. It has been designated M. The most severe deficiency form migrates to a high isoelectric point, and has been designated as Z. More than 100 allelic variants of a1- antitrypsin have been reported, all inherited in an autosomal recessive fashion. With some variants there is no a1-antitrypsin detectable in serum, the so-called null variants. The variants that have been associated with low serum concentrations of a1- antitrypsin are known as deficiency variants. Not all of these are associated with clinical disease, such as the S variant; emphysema and liver disease have been associated with the PiSZ, PiZZ, M $_{malton}$, and M $_{duarte}$ variants. The heterozygote state does not confer disease susceptibility, except for the small possibility that the PiMZ heterozygote state increases risk for cryptogenic cirrhosis in adults.

Pathogenesis and Biochemistry

The pathogenesis of liver injury in a1-antitrypsin deficiency has not been completely defined. It is clear that the accumulation of mutant a1-antitrypsin protein in the endoplasmic reticulum of liver cells is involved in its pathogenesis. In fact, transgenic mice carrying the mutant Z allele of the human a1-antitrypsin gene developed PAS-positive, diastase-resistant globules in the liver as well as liver injury. [65], [66] It is difficult, therefore, to understand why only 10% to 15% of patients develop significant disease, since all PiZZ affected individuals have globules present in their liver. Perlmutter and colleagues have demonstrated delay of degradation of mutant a1-antitrypsin Z protein in fibroblasts from PiZZ individuals with liver disease as compared to those without liver disease, [67] providing evidence that other factors affecting the fate of mutant a1-antitrypsin molecules may play a role in determining the genetic susceptibility to liver disease. This important role for a modifier gene may help explain the 10% to 15% incidence of significant liver disease in this and other single gene mutation metabolic disorders. [68]

Diagnosis

Diagnosis is established by isoelectric focusing or agarose electrophoresis of a patient's serum a1-antitrypsin. Generally, total serum levels of a1-antitrypsin are found to be 10% to 20% of the normal values with the PiZZ phenotype. Establishing the exact phenotype assists in determining the risk of the patient for liver disease. For example, the PiSS phenotype elicits no risk for liver disease, whereas PiSZ and PiZZ do pose this risk. All infants with neonatal cholestatic jaundice require a1-antitrypsin testing, inasmuch as it may be very difficult to clinically or histologically identify this disease at that time. Infants with a1-antitrypsin deficiency may mimic the presentation of biliary atresia, including acholic stools, failure of biliary excretion on nuclear scintigraphy, and liver biopsy findings that are similar. It is said that a1-antitrypsin concentrations may increase during the acute phase response, however serum concentrations never exceed 50 to 60 mg/dL in patients with the PiZZ phenotype, allowing one to use serum concentrations as a screen for deficiency. The finding of PAS-positive, diastase-resistant globules on liver biopsy should never in itself be used to either diagnose or exclude the diagnosis of a1-antitrypsin deficiency.

Treatment

There is no specific therapy for a1-antitrypsin deficiency–associated liver disease; however, several measures are taken in infants with the cholestatic presentation. Fat-soluble vitamin supplementation and an infant formula containing medium chain triglyceride oil are administered until the cholestasis resolves. In addition, ursodeoxycholic acid is frequently given to increase bile flow and reduce liver injury from cholestasis, as in other neonatal cholestatic diseases. Although early studies suggested that breast feeding might be beneficial, [69] subsequent data from the Swedish Nationwide Screening Study did not support this contention. [70] Approximately 10% to 30% of infants diagnosed with a1-antitrypsin deficiency who have neonatal cholestasis progress within the first 5 years to cirrhosis and end-stage liver disease. The remaining 70% to 90% of patients either show complete recovery from liver injury, or have variable degrees of chronic elevated aminotransferases and progressive hepatic fibrosis.

Complications of portal hypertension are treated as they are in other childhood liver diseases. Orthotopic liver transplantation is required for children with end-stage liver disease, in whom hepatic synthetic functional failure or severe complications do not respond to standard therapy.

Patients with emphysema caused by a1-antitrypsin deficiency are now treated with replacement therapy with purified or recombinant plasma a1-antitrypsin, either by intratracheal aerosol administration or by intravenous administration. [71] Improvement in serum concentrations of a1-antitrypsin without significant side effects results from these therapies. One nonrandomized trial suggested that there was slower decline in forced expiratory volume in 1 second in patients on replacement therapy. [72] Lung transplantation has been performed in a number of patients with severe emphysema. Actuarial survival is approximately 50% at 5 years. [73] a1-antitrypsin is certainly a disease that could benefit from successful gene replacement therapy: continued investigation in this arena will take place over the next decade.

Finally, siblings of all affected patients with the PiZZ phenotype should be screened by isoelectric focusing or agarose gel electrophoresis to determine their phenotype. If identified as a homozygote, strict avoidance of cigarette smoke and other air pollutants may help prevent the onset of emphysema later on in life.

PORPHYRIA

Inherited deficiencies or toxic inhibition of the enzymes involved in the heme synthesis pathway leads to eight disorders called the porphyrias. Each of these porphyrias is characterized by the accumulation of specific substrates or precursors of heme that provide characteristic biochemical footprints in blood, urine, and feces, which allow for differentiation of the type of porphyria. The varied accumulated compounds, rather than the decrease in synthesis of heme, are responsible for the cutaneous, hepatic, neuropsychiatric, and hematologic manifestations of the porphyrias. Three of the porphyrias are inherited in autosomal recessive fashion, and five by autosomal dominant inheritance. Most patients present during or after puberty; however, onset in infancy or early childhood has been reported. [74], [75], [76], [77], [78], [79] and [80] Five of the porphyrias are expressed exclusively in the liver, two in both liver and erythroid cells, and one type has only erythroid expression. [74], [75], [76] and [77] Porphyrias are generally classified into the acute porphyrias and the cutaneous porphyrias. In the acute porphyrias, aminolevulinic acid (ALA) is increased. In the cutaneous porphyrias, porphyrins rather than ALA accumulate. Diagnostic studies and clinical features of the major porphyrias are outlined in Table 113-3.

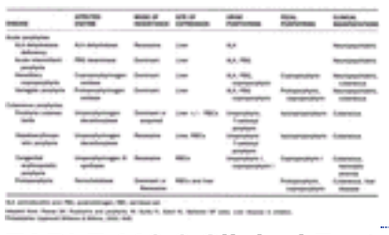

TABLE 113-3 Clinical Features of Human Porphyrias

Acute Porphyrias

Four hepatic porphyrias present with acute attacks of potentially life-threatening neurological dysfunction. These attacks generally begin around puberty, and may

diminish after the 5th decade of life. The most common symptoms include abdominal pain, constipation, and vomiting, presumably caused by autonomic nervous system dysfunction of the gastrointestinal tract. The peripheral neuropathy may develop into a flaccid quadriplegia with respiratory compromise in severe cases. Psychiatric symptoms may include depression, psychosis, and hysterical behavior. [74], [75] and [76], [81], [82], [83], [84], [85], [86] and [87] The pathogenesis of neurological symptoms is related to the ALA blood levels, although the exact mechanism by which the ALA functions as a neurotoxin has not been determined. Drugs and toxins that increase cytochrome P450 activity may precipitate acute attacks; relative iron deficiency and cyclical progesterone excretion in menstruating females may be responsible for the higher frequency of acute attacks in women compared to men.

Hepatic abnormalities in the acute porphyrias are characterized by mild AST and ALT elevations during attacks. Histological examination of the liver reveals steatosis and increased iron deposition. Intramitochondrial crystalline inclusions have also been described. [81], [82], [88], [89], [90], [91] and [92] A disturbing high incidence of hepatocellular carcinoma has been described in patients with inducible porphyrias. [93]

Acute Intermittent Porphyria

The most common form of acute porphyria is acute intermittent porphyria (AIP). The defective enzyme is porphobilinogen (PBG) deaminase and the disease is of autosomal dominant inheritance. The prevalence of the disorder is approximately 1 in 1000 to 2000. [81], [94] Diagnosis is established by the determination of large amounts of ALA and PBG in the urine during acute attacks, with PBG excretion above that of ALA. A characteristic of AIP is a black or red color of a patient's urine after exposure to light or air. In asymptomatic patients, there is no increase in PBG or ALA excretion in the urine. A diagnosis is then established by enzyme analysis in liver tissue, red blood cell lysates, or genetic analysis of leukocyte DNA. [82], [95]

Treatment of mild AIP attacks includes management of fluids and electrolytes, avoidance of drugs that may precipitate symptoms, and observation. Severe neurological symptoms are treated with hematin, which inhibits hepatic ALA-synthetase activity, yielding lower circulating levels of ALA. [96], [97] Liver transplantation has been used in very unusual circumstances for severe, unremitting symptoms. [98]

Other Acute Porphyrias

Hereditary coproporphyria (HCP), variegate porphyria (VP), and ALA dehydratase deficiency comprise the other acute porphyrias. HCP and VP are autosomal dominant. The urine co-proporphyrin excretion is elevated in these two disorders, with fecal protoporphyrin being present in VP. Cutaneous manifestations predominate over neurological symptoms in these conditions. The accumulation of porphyrins in the skin is responsible for the cutaneous lesions. Neurological symptoms can resemble those of AIP. ALA dehydratase deficiency is a very rare autosomal recessive disorder, yielding exclusive excretion of ALA in the urine. The disease is characterized by severe acute neuropsychiatric porphyria episodes that are poorly responsive to medical treatment. [99] Treatment of neurological attacks in all of these conditions follows the protocol for the treatment of AIP attacks.

Cutaneous Porphyrias

Cutaneous lesions without neurological or psychiatric involvement characterize four of the porphyrias. However, significant hepatic involvement may be observed. These diseases include porphyria cutanea tarda (PCT), hepatoerythropoietic porphyria (HEP), congenital erythropoietic porphyria (CEP), and protoporphyria. Two types of skin photosensitivity develop in the cutaneous porphyrias. Skin lesions appear to be the result of photoexcitation of porphyrins located in the upper levels of the epidermis or walls of dermal blood vessels with resulting reactive oxygen species generation leading to tissue injury by a variety of proposed mechanisms. [100], [101], [102], [103], [104] and [105] Patients with PCT, HEP, and CEP show increased skin fragility in light exposed areas, manifested by the formation of bullous lesions, secondary scarring, and hypertrichosis. Patients with protoporphyria show immediate photosensitivity with itching, burning, and erythema soon after light exposure. Although they do not develop bullae, chronic skin changes evolve into leathery, hyperkeratotic skin in light exposed areas.

Porphyria Cutanea Tarda

PCT is the most common form of porphyria in North America and Europe, inherited as an autosomal dominant disorder or acquired during chronic hepatitis C and other infectious diseases. PCT may also be associated with toxins, particularly halogenated hydrocarbons. The genetic form of PCT is caused by deficiency of uroporphyrinogen decarboxylase. Urine and fecal uroporphyrins are elevated (see Table 113-3), however PBG levels are normal. Most patients with PCT present in adulthood, with photosensitivity skin reactions, scarring, infection, and lichenification of the skin. Because many individuals with the identical enzyme deficiency remain asymptomatic, others have sought coexisting abnormalities that must be present in order to develop overt disease. These include iron overload, a mutated allele in the *HFE* (hereditary hemochromatosis) gene, the presence of hepatitis C viral infection, or Alagille syndrome. Ingestion of ethanol, toxins, and estrogens may also be involved in the development of sporadic cases of PCT.

Liver involvement is a frequent finding in PCT, manifested by hepatomegaly, focal inflammation, granuloma formation, and hepatic hemosiderosis. Progression to cirrhosis is not uncommon. [106], [107] and [108] It remains controversial whether there is an increased risk for hepatocellular carcinoma in patients with PCT. [109], [110]

Therapy for PCT includes phlebotomy or chelation therapy to reduce the iron burden. Chloroquine has been used to form complexes with uroporphyrin to enhance removal of these deposits from skin. These treatments may be combined in patients with significant liver disease, however their efficacy is still unclear. [76], [79], [106], [111]

Protoporphyria

Erythropoietic protoporphyria is one of the most common forms of porphyria in North America, caused by a defect in ferrochelatase. The enzyme can be measured in liver and bone marrow cells, being less than 50% of normal in almost all cases. Affected patients have elevated levels of erythrocyte, plasma, and fecal protoporphyrin. [112], [113] and [114] The primary clinical manifestation of protoporphyria is photosensitivity, which generally appears in childhood as burning, pruritus, erythema, and edema in light exposed areas. Scarring and lichenification of the skin develop with time. Avoidance of light, use of sunscreens, and oral administration of carotenoids appear to be the most efficacious treatment for the skin lesions. Approximately 5% to 10% of affected patients develop significant hepatic involvement, with reports in children as young as 10 years of age. Jaundice is generally the first indication of hepatic dysfunction, however rapid progression of decompensated cirrhosis may lead to liver failure within several years of clinical presentation. [115], [116], [117], [118] and [119] The liver is black in color, enlarged, and exhibits fibrosis and macronodular cirrhosis. Dark brown pigment, which represents protoporphyrin deposits, is found in hepatocytes, Kupffer cells, and small biliary ducts. Soluble protoporphyrin appears to plug small bile ducts interrupting bile flow and may initiate oxidative injury to hepatocytes. It is unclear why only 5% to 10% of patients develop progressive liver disease, but other gene modifiers or environmental factors must be involved. Other manifestations of protoporphyria include hemolysis, neurological dysfunction, and gallstones.

Treatment of individuals with liver disease is aimed at reduction of protoporphyrin levels in the liver. Iron supplementation and blood transfusions have been used in the past to diminish erythropoiesis, thereby reducing protoporphyrin production. Hematin has similarly been shown to decrease plasma protoporphyrin in several patients. [120] Interestingly, administration of chenodeoxycholic acid has been demonstrated to increase protoporphyrin excretion into bile. [76], [77], [78] and [79], [111] Cholestyramine and activated charcoal both bind protoporphyrin, interrupting the enterohepatic circulation and increasing fecal excretion. [82], [121] These modalities do decrease circulating levels of protoporphyrin, however they have not been shown to conclusively affect the course of the liver disease. Although orthotopic liver transplantation has been performed in several patients with end-stage liver disease, protoporphyrin production continues in the bone marrow, depositing protoporphyrins in the newly transplanted allograft. [122], [123] In addition, skin lesions and neurological symptoms may continue, complicating the postoperative course.

Congenital Erythropoietic Porphyria

CEP is an autosomal recessive disorder caused by a deficiency of uroporphyrinogen III co-synthase. It is quite rare with fewer than 100 patients reported. The major manifestation is photosensitivity, hypertrichosis, and hemolysis. Liver disease is present and may progress to cirrhosis, with iron overload playing a significant role. [76], [79], [111], [124] Treatment includes limiting light exposure, sunscreens, and beta carotene. Hematin or blood transfusions to decrease erythropoiesis have also been attempted in patients with liver disease.

METABOLIC DISEASES OF THE NEONATE AND OF CHILDHOOD

Hepatic involvement may be the presenting symptom of a variety of metabolic disorders occurring primarily or exclusively in infancy and childhood. Because effective treatments for many of these diseases have been identified over the past decades, patients are now surviving into adulthood. Disorders of amino acid, carbohydrate, lipid, ammonia, and mitochondrial metabolism may all have hepatic involvement as the primary clinical manifestation. It is beyond the scope of this chapter to describe in detail all childhood metabolic liver diseases, and the reader is referred to other sources for further details. [1] This chapter will focus on several of the most common metabolic liver diseases presenting in infancy and early childhood.

Hereditary Tyrosinemia

Hereditary tyrosinemia is caused by a deficiency of the enzyme fumarylacetoacetate hydrolase (FAH), the terminal enzyme in the pathway of phenylalanine and tyrosine degradation. Although the gene for the enzyme has been cloned, there are no definite genotype-to-phenotype correlations in severity of the disease. A number of metabolites of tyrosine accumulate proximal to the FAH block, including tyrosine and succinylacetone. [125], [126] Succinylacetone and succinylacetoacetate inhibit enzymes such as porphobilinogen synthase, which causes the build-up of ALA and symptoms similar to that of acute intermittent porphyria. [127], [128] It is unclear how accumulated toxic compounds initiate liver injury in tyrosinemia.

Tyrosinemia may present in infancy as acute hepatic failure, neonatal cholestasis, rickets, failure to thrive, or as compensated or decompensated cirrhosis later in childhood. There is also a very high incidence of hepatocellular carcinoma in affected children. Episodes of acute peripheral neuropathy may lead to pain, respiratory depression, and death. [129] Children who present during infancy have decreased survival compared to those with a later presentation in childhood. [130]

Liver histology is characterized by macrovesicular steatosis, pseudo-acinar formation of hepatocyte rosettes, hemosiderosis, and varying degrees of hepatocyte necrosis and apoptosis. A fine diffuse fibrosis develops, eventually progressing into a micronodular cirrhosis. Regenerative nodules are frequently present, and frank hepatocellular carcinoma may occur in patients as early as 2 years of age. The incidence of tyrosinemia is approximately 1 in 100,000; however, there are pockets of high frequency secondary to a founder effect, such as 1:1800 live births which occurs in the Saguenay-Lac Saint Jean region of Quebec, Canada. [131]

Hereditary tyrosinemia diagnosis is suggested by features of metabolic liver disease in infants or older children, including diminished hepatic synthetic function (hypoglycemia, coagulopathy, hypoalbuminemia) in the face of only mildly elevated aminotransferases. Bilirubin may be elevated or normal, and hypophosphatemic rickets may be present. Renal tubular dysfunction may cause glycosuria, proteinuria, amino aciduria, and hyperphosphaturia. Serum a-fetoprotein levels are usually extremely high for age. The diagnosis of tyrosinemia is established by the finding of succinylacetone in the urine. In some research laboratories, FAH activity can be measured in red blood cells. Genetic diagnosis is generally not necessary, however in Quebec, 100% of patients have a single mutation of the FAH gene. [132] Hypertyrosinemia is a nonspecific finding and is not used to establish this diagnosis. Neonatal screening is being carried out in high incidence regions, such as Quebec.

Treatment of hereditary tyrosinemia involves a diet restricted in phenylalanine and tyrosine, although this diet does not prevent liver disease but may have beneficial effects on kidneys. Orthotopic liver transplantation reverses the metabolic abnormalities and reduces the risk for hepatocellular carcinoma, prevents neurological disease, and is usually associated with stabilization of kidney disease. This generally had been considered the preferred option for children with tyrosinemia over the age of 1 to 2 years. However, a recent metabolic inhibitor, NTBC [2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione] has been shown to be effective in many cases with tyrosinemia. This compound inhibits 4-hydroxyphenyl-pyruvate dioxygenase, the second enzyme involved in tyrosine degradation, which, when inhibited, prevents the production of succinylacetone. Therefore, toxic precursors do not accumulate, liver disease improves dramatically, patients exhibit reduction of a-fetoprotein levels, liver synthetic function improves, and renal tubular damage may resolve. To date, well over 150 patients have been treated with NTBC in an ongoing investigation of its long-term effectiveness. The major concern is that mice who were homozygous for the FAH gene mutation, and who develop tyrosinemia, respond to NTBC but still develop hepatocellular carcinoma. [133] Whether or not treatment with NTBC will reduce the high risk for development of hepatocellular carcinoma in children with tyrosinemia is unknown. The current recommendation is for continued surveillance for hepatic masses in children under long-term NTBC therapy. Neurological symptoms are treated with intravenous dextrose, pain control, NTBC, or hematin.

Galactosemia

Classic galactosemia is an autosomal recessive disorder resulting from a deficiency of the enzyme galactose 1-phosphate uridyltransferase. Patients develop chronic cholestatic liver disease, failure to thrive, mental retardation, and cataracts. Two other conditions result in elevated plasma galactose concentrations, however, without observable liver disease. These include uridine diphosphate 4-epimerase deficiency and galactokinase deficiency, the latter causing only juvenile cataracts. Classic galactosemia is a disease in which toxicity of the liver results from ingested dietary galactose and its failure to be converted to glucose. Most cases are now detected by newborn screening programs, such that it is an unusual patient who presents with neonatal liver disease.

The classic presentation of galactosemia is that of vomiting, diarrhea, and failure to thrive following the institution of lactose-containing infant feedings—either breast milk or lactose-containing infant formula. Within weeks to months of birth, hepatomegaly, cholestatic jaundice, and cataracts develop in the affected infant. If left completely untreated, mental retardation as well as cirrhosis of the liver will develop. Another classic presentation is that of *Escherichia coli* urinary tract infections and bacteremia, sometimes with a fatal course. Affected females may show ovarian failure due to in utero injury from the galactose toxic products. Laboratory findings include elevated serum aminotransferase levels, prolonged prothrombin time, conjugated hyperbilirubinemia, and hypoalbuminemia. Hemolytic anemia occurs frequently. Renal tubular dysfunction is characterized by generalized amino aciduria in combination with proteinuria and galactosuria.

Pathogenesis Galactose-1-phosphate accumulates in classic galactosemia, causing injury to the affected organs. Galactose may also be reduced to galactitol, which causes cataracts when it accumulates in the lens of the eye. It appears that galactose-1-phosphate or galactosamine accumulation is responsible for the renal, ovarian, hepatic, and brain abnormalities. Galactose-1-phosphate may also interfere with phosphoglucomutase, an enzyme that allows the release of glucose from glycogen. Liver biopsy reveals macrovesicular steatosis in the first months of life, with pseudoacinar transformation of hepatocytes, but giant cell transformation is generally absent. If left untreated over the first several months of life, portal fibrosis and the development of cirrhosis accompany bile duct proliferation. The diagnosis of galactosemia is suggested by the detection of reducing substances in the urine with a negative glucose-oxidase paper test on the urine. Since vomiting or poor intake of lactose-containing formula or breast milk may limit galactose excretion in the urine, false-negative results of urine reducing substance tests may occur in galactosemia. More specific diagnosis is based on measurements of erythrocyte galactose 1-phosphate uridyltransferase. If an infant with galactosemia has received a red blood cell transfusion, the red cell enzyme level may be raised into the normal range and the diagnosis missed. Newborn screening programs have been established across the United States and in many areas of the world. Measurement of enzyme activity for galactose compounds is the analysis performed on newborn blood spots.

Treatment Treatment of galactosemia is based on the complete elimination of dietary galactose. Infant lactose and galactose-free formulas have been marketed around the world and are instituted as soon as the diagnosis is made. As the child becomes older, a complete lactose and galactose-free diet must be maintained. [134], [135] In recent years, it has been suggested that endogenous production of some galactose may be the mechanism that underlies some of the delayed toxicity present in children maintained on a lactose and galactose-free diet. [136] Follow-up studies have revealed that some patients treated from infancy still suffer poor growth, learning disabilities, and primary ovarian failure in females. [136]

Hereditary Fructose Intolerance

Hereditary fructose intolerance is an autosomal recessive disorder caused by deficiency of the fructose-1-phosphate aldolase B enzyme activity in the liver. Symptoms occur when fructose is added to the infant's diet, usually in the form of fruit juices or infant formulas that contain sucrose. [137], [138] Infants develop vomiting, irritability, hypoglycemia, and even convulsions following the ingestion of fructose. If fructose is not removed from the diet, hepatomegaly, failure to thrive, chronic diarrhea, conjugated hyperbilirubinemia, and metabolic dysfunction ensue, including proximal renal tubular abnormalities. [139] Older children may have a self-aversion to sweets, knowing that these tend to make the child feel ill. Growth delay, consequences of repeated episodes of hypoglycemia on brain development, and metabolic acidosis eventually complicate the clinical picture.

Liver histology is characterized by diffuse macrovesicular steatosis, scattered hepatocellular necrosis, bile duct proliferation, and periportal fibrosis. Cirrhosis has also been described with complications of portal hypertension. The toxic moiety leading to liver injury is accumulated fructose-1-phosphate. Both hypoglycemia and ATP

depletion in hepatocytes are caused by the accumulation of this compound. [139]

Diagnosis of hereditary fructose intolerance is suggested by the onset of hypoglycemia, a profound hypophosphatemia, and hyperuricemia following fructose ingestion with detection of fructose in the urine by chromatography. Several common mutations in the gene for this enzyme allow for genetic diagnosis in most cases. [140] The incidence of the disease is approximately 1 in 20,000 newborns. [141], [142] Because the enzyme is also present in jejunum, it has been suggested that jejunal biopsies can be used for enzyme analysis to establish the diagnosis.

Treatment of hereditary fructose intolerance is based on the complete and lifelong elimination of fructose, sucrose, and sorbitol-containing foods, juices, medications, or other compounds from the diet. [137], [143], [144] Low levels of chronic fructose ingestion may lead to growth failure [143] and persistent hepatic steatohepatitis.

Glycogen Storage Diseases

Excessive accumulation of glycogen or abnormal synthesis of glycogen in the liver or muscle tissue is the underlying basis for a group of diseases called the glycogen storage diseases (GSD). Seven of the glycogen storage diseases primarily involve the liver causing a variety of hepatic manifestations. Types Ia, Ib, Ic, and III lead to hypoglycemia and characteristic metabolic derangements; types III, IV, and IX are associated with periportal fibrosis; and types VI and IX are associated with benign hepatomegaly. Understanding the underlying enzymatic defects in each of these disorders has led to a better understanding of the pathophysiology and the development of treatment modalities (Table 113-4). The hepatic glycogen storage diseases will be discussed in the remainder of this chapter.

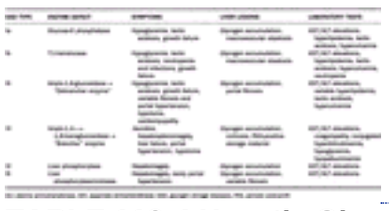

TABLE 113-4 Hepatic Glycogen Storage Diseases

GSD Type I There are three forms of GSD type I involving the glucose-6-phosphatase enzyme system. Glucose-6-phosphatase catalyzes the last step in the enzymatic degradation of glycogen with release of glucose into the blood. Failure of proper function of glucose-6-phosphatase leads to profound hypoglycemia during the fasting state. GSD type Ia involves deficiency of the glucose-6-phosphatase enzyme, GSD type Ib involves abnormalities in the translocase responsible for movement of glucose-6-phosphate across microsomal membranes to the site of action of glucose-6-phosphatase. GSD type Ic has been reported with a deficiency of the phosphate-pyrophosphate translocase. [145] GSD type Ia (von Gierke disease) is characterized by recurrent episodes of profound and severe hypoglycemia, lactic acidemia, hyperuricemia, hypertriglyceridemia, and hypercholesterolemia. The hypoglycemic events frequently start during infancy, when the interval between feedings becomes prolonged beyond 2 to 3 hours, or when the child starts sleeping for longer durations at night. The child generally suffers from growth failure and short stature, extreme hepatomegaly without splenomegaly, bleeding episodes caused by platelet dysfunction, renomegaly, and a cherubic appearance secondary to the deposition of “baby fat” in the face and trunk. The abdomen is protuberant, and arms and legs are frequently thin. Impaired glucose production through glycogenolysis leads to overproduction of glucose-6-phosphate which is shunted into pathways for synthesis of lactate, triglycerides, cholesterol, and uric acid. [146] As a result, glucagon levels are high and insulin levels are low. Patients suffer from growth failure if untreated or poorly treated, and eventually multiple hepatic adenomas, which may develop into hepatocellular carcinoma. As glucose-6-phosphatase is also expressed in the kidney, enlarged kidneys are common, and nephrocalcinosis or glomerulosclerosis may also develop over time. [147] Hyperuricemia may contribute to chronic renal disease as well as to gouty arthritis. [148] Progressive hepatic fibrosis and portal hypertension virtually never occur in this disorder, however hepatomegaly is extremely prominent. The diagnosis is established by demonstrating elevated hepatic glycogen content and low activity of glucose-6-phosphatase on frozen liver tissue. Liver histology shows markedly enlarged hepatocytes with pale cytoplasm causing a “mosaic” appearance histologically. There is also macrovesicular steatosis and an accumulation of glycogen in both cytoplasm and nucleus under electron microscopy. There is no hepatic fibrosis, cirrhosis, or chronic inflammation. Treatment of GSD-1a is directed at providing a continuous source of exogenous glucose to prevent hypoglycemia and the resultant hormonal and metabolic changes. Frequent daytime high starch meals along with uncooked cornstarch supplements are provided. Cornstarch is given in doses of 1.5 to 3 g/kg every 3 to 6 hours as needed. In order to maintain blood sugar at night, constant drip feedings of a high glucose elemental formula are provided through either a nasogastric tube or a gastrostomy tube. The aim is to maintain blood sugars of at least 70 mg/dL. As children become older, many opt to discontinue constant drip feedings at night, and ingest uncooked cornstarch at bedtime, awakening every 4 hours at night to drink a dose of cornstarch. Either of these techniques can effectively maintain blood sugar, reverse metabolic abnormalities, and provide adequate growth. [149], [150], [151], [152], [153], [154] and [155] However blood sugars need to be monitored periodically. It should be pointed that the hypoglycemia is better tolerated when the children are hyperlipidemic and acidotic than when they are adequately treated with cornstarch or constant drip feedings. However, once the patients are well controlled with these modalities, the children may react severely to episodes of hypoglycemia, with neurological depression, convulsions, and even death. For patients who cannot be controlled with these therapeutic modalities, and for patients with multiple hepatic adenomas, liver transplantation has been advocated. [156] However, the vast majority of patients can maintain a high quality of life with their native liver.

GSD Type Ib GSD-Ib presents in a similar manner as GSD-Ia, however patients also have neutrophil dysfunction and frequently are neutropenic. Therefore, they have a propensity toward recurrent bacterial infections, inflammatory bowel disease-like lesions, and oral ulcerations. [157], [158], [159], [160] and [161] The diagnosis of GSD-Ib is suggested by the finding of neutropenia in a patient who appears to have all of the other classic features of GSD type Ia (hypoglycemia upon fasting, lactic acidosis, elevated AST, ALT, hypertriglyceridemia, hyperuric acidemia, hepatomegaly, growth failure). This disorder is diagnosed by measurements of liver glucose-6-phosphatase activity. In GSD type Ib, which involves the glucose-6-phosphate T_1 translocase enzyme, fresh liver homogenate will yield defective activity, whereas frozen liver homogenate will have normal glucose-6-phosphate activity. The reason for this finding is that freezing disrupts the microsomal enzyme barrier, allowing access of the substrate to glucose-6-phosphatase, thereby bypassing the need for the translocase enzyme. In fresh homogenate tissue, the microsomes are intact, thus necessitating the requirement for the translocase enzyme. This disease is treated similarly to GSD type 1a, with the addition of granulocyte colony stimulating factor to elevate neutrophil counts.

GSD Type III GSD type III is due to the deficiency of debrancher enzyme activity, [146] also known as amylo-1,6-glucosidase. This enzyme degrades the 1,6 branch points of the glycogen molecule after hepatic phosphorylase has hydrolyzed the outer branches. Patients with GSD type III have either liver and muscle involvement (type IIIa), or liver involvement alone (type IIIb), the latter being the minority of patients. The patients may present in identical manner to GSD type Ia, with hepatomegaly, hypoglycemia, hyperlipidemia, hyperuricemia, growth retardation, and similar biochemical features. However, blood lactate and uric acid levels may be normal in GSD type III, with moderate elevations of serum AST and ALT. Patients have the potential to develop progressive portal fibrosis, leading to cirrhosis and complications of portal hypertension. [162] Myopathic weakness may worsen as the patient ages into adulthood. Cardiomyopathy with ventricular hypertrophy may also occur in type III patients. GSD type III is inherited in an autosomal recessive manner, the human gene being an 85-kb gene composed of 35 exons located on chromosome 1p21. Mutations in this gene have been described in both types IIIa and IIIb GSD. Liver histology in GSD type III resembles that found in type Ia, however, there is less steatosis, and periportal fibrosis progressing to cirrhosis may be present. [163] Treatment of type III GSD depends upon the symptomatology. In patients with hypoglycemia, acidosis, and hypertriglyceridemia, treatment is similar to that in type Ia GSD. However, many patients with GSD type III can be managed on a high starch diet, without the need for cornstarch therapy. There is one report of a high protein diet and continuous nocturnal infusion of a high protein formula improving muscle strength in a patient with myopathy. There is no other effective treatment for the progressive myopathy or cardiomyopathy.

GSD Type IV GSD type IV is caused by a deficiency of the brancher enzyme, amylo-1,4,6-transglucosidase, present in leukocytes and in liver. An abnormal glycogen is formed that contains few branch points, which appears to be toxic to hepatocytes. [164] Inheritance is autosomal recessive. The human gene coding for this enzyme is on chromosome 3p12. There appears to be a phenotype-genotype correlation which may explain clinical variability. [165] Patients may present with three clinical scenarios:

1. Progressive liver injury and cirrhosis, leading to liver failure and death during the first 5 years of life
2. Chronic liver disease without progressive fibrosis
3. Abnormal neuromuscular development with hypotonia, muscle atrophy, and absent deep tendon reflexes.

Cardiomyopathy may also develop because of deposition of amylopectin in myocardial cells. Adults with milder symptoms, but with similar muscle histology have been described. [165] Children with early onset liver failure present with failure to thrive, hepatosplenomegaly, cholestatic jaundice, and occasionally hypotonia. Complications of cirrhosis such as ascites and liver synthetic dysfunction prevail and death usually occurs by the 2nd to 4th year of life. [166] Diagnosis is established by finding the

characteristic abnormal structure of glycogen on electron microscopy in muscle, cultured fibroblasts, or liver. Verification of deficient branching enzyme activity is determined in muscle, leukocytes, cultured fibroblasts, or liver. Liver histology reveals micronodular cirrhosis and hepatocytes that appear to contain excessive glycogen, which is PAS-positive and diastase-resistant. [167] Electron microscopy shows large irregular areas of glycogen fibrils, and finely granular material. [167] Liver transplantation appears to be the only effective therapy for children with progressive liver failure and cirrhosis. [168], [169] Although many patients have done well following liver transplantation without cardiac or muscle involvement, a single report suggests that cardiac disease may be a posttransplantation issue. [170]

GSD Type VI and IX GSD type VI and IX involve deficiencies of the phosphorylase system, which stimulates degradation of hepatic glycogen. Deficiency of hepatic phosphorylase causes GSD type VI, of which there are many subtypes. Patients generally present with asymptomatic hepatomegaly, elevated aminotransferases, variably with hypoglycemia or hyperlipidemia. Growth retardation occasionally occurs, but many children are found to be normal in stature. Lactic acidosis is rare and the prognosis is generally very good. Hepatomegaly improves as the patient reaches adulthood, and growth also is generally normal by adulthood. Liver biopsy findings include glycogen-filled hepatocytes, but generally the absence of inflammation, cell injury, and fibrosis. GSD type IX is caused by phosphorylase b kinase deficiency. This disorder is characterized by asymptomatic hepatomegaly, mild elevation of aminotransferases, glycogen-filled hepatocytes on liver biopsy, and variable degrees of hepatic fibrosis. Slow progression to cirrhosis has been reported in several cases with the development of portal hypertension. Diagnosis is established through enzyme analysis of liver and erythrocytes. [171], [172] Phosphorylase b kinase deficiency is more common than the true phosphorylase deficiency. Rarely, patients with type IX GSD develop biochemical features of type I or type III GSD. Treatment is generally not necessary for GSD type IX.

CHAPTER 114

David W. Crabb and Lawrence Lumeng

ALCOHOLIC LIVER DISEASES

EPIDEMIOLOGY

Alcoholic liver disease (ALD) continues to be a major cause of cirrhosis and death around the world. In the United States, there are at least 14 million problem drinkers and alcoholics, [1] and alcohol abuse is one of the most important causes of chronic liver disease. Cirrhosis accounts for the majority of all medical deaths among alcoholics. In the past, ALD was attributed to malnutrition (hence the term *Laënnec nutritional cirrhosis*). However, alcoholic cirrhosis occurs in well-nourished persons, and cirrhosis does not occur in patients with simple malnutrition. In fact, there is some evidence that the rate of ALD has increased in Japan despite significant increases in the fat and caloric content of the diet. [2] Epidemiologic studies have shown a direct correlation between national per capita consumption of alcohol and prevalence of ALD, and between individual alcohol consumption and the risk of alcoholic hepatitis or cirrhosis. [3], [4] and [5] Historically, a dramatic decrease in ALD was associated with diminished alcohol intake during war rationing and prohibition. Both the amount of ethanol ingested and duration of heavy drinking are important factors in the induction of ALD. Alcohol intake is best quantified in terms of grams of ethanol per day, and interestingly, each common unit of drinking contains about 10 to 15 g of ethanol: one ounce or shot of distilled spirits, a 12-oz bottle of beer, or a 4-oz glass of wine. There is no difference in risk of ALD associated with use of any of these forms of beverage alcohol or with the pattern of drinking, with the exception that drinking alcohol at times other than at meals is associated with increased risk of liver injury. [6] The amount of ethanol that can be safely consumed is estimated to be up to 20 g (two drinks) per day for men and up to 10 g (one drink) for women, and in fact this amount of alcohol consumption is associated with reduced risk of myocardial infarction. [7] A daily intake of ethanol as low as 40 g in men or 20 g in women over more than 10 years results in a significant increase in the incidence of cirrhosis. The peak incidence of ALD is in the age range of 40 to 55 in men, but a decade earlier in women. Not only do women develop liver disease more rapidly, they do so with a lower daily alcohol intake, and thus lower cumulative exposure to ethanol, [8], [9], [10] and [11] and there is evidence that a larger percentage of women progress to more advanced liver disease. [12], [13] and [14] The male-to-female ratio of alcoholism is about 10:1, but for alcoholic liver injury it is about 3:1. This strongly supports the clinical impression of an increased susceptibility of women to ALD, and emphasizes the need to help women control abusive drinking at a younger age. It remains an unsolved question why only a subset of alcoholics develops serious liver injury (no more than 35% of heavy drinkers develop alcoholic hepatitis and only 20% develop cirrhosis). Indeed, even in the alcohol-fed baboon model, only a fraction of the animals developed cirrhosis. A better understanding of this phenomenon could lead to identification or modification of risk factors. Some clues have been gained from studies of the pathogenesis of this disease.

PATHOGENESIS

It may be argued that the ultimate treatment for ALD is the prevention or treatment of alcohol abuse. However, a better understanding of the hepatotoxicity of alcohol may lead to treatments of fatty liver and alcoholic hepatitis, and thus prevention or delay of occurrence of cirrhosis. It may also foster an understanding of the adverse interaction between alcohol consumption and hepatitis C virus (HCV) infection. Furthermore, insights gained from studying alcoholic liver injury may extrapolate to nonalcoholic fatty liver and steatohepatitis.

Metabolism of Ethanol

Ethanol is rapidly absorbed from the gastrointestinal tract and most of it is metabolized in the liver. When moderate amounts (e.g., 10–30 g) of ethanol are consumed by normal adult men in the fed state, a sizeable first pass metabolism of ethanol can be easily detected. That is, the increase in blood alcohol level is less when alcohol is taken orally than when the same dose is given intravenously. Whether the stomach or liver or both is responsible for this phenomenon is debated. In favor of gastric metabolism are the facts that gastric mucosa contains alcohol dehydrogenases and peak blood alcohol levels are higher in individuals with decreased gastric alcohol dehydrogenase activity (e.g., women and patients with a gastrectomy, chronic gastritis, or who are taking cimetidine). [15], [16], [17], [18], [19], [20] and [21] However, the total ethanol oxidizing capacity of the stomach is rather low, suggesting a hepatic contribution. [22], [23] It has been suggested that the observed alterations in first pass metabolism seen with the various stomach conditions reflect concomitant changes in rates of alcohol absorption and delivery to the liver. [24] First pass metabolism is most evident when low doses of alcohol are ingested with or soon after a meal.

After absorption, ethanol is distributed in the body water space, and is largely metabolized in liver to acetaldehyde by alcohol dehydrogenase (ADH) in the cytosol and the cytochrome P450IIE1 (CYP2E1) in microsomes (Fig. 114-1). ADH is responsible for the bulk of ethanol oxidation. The ADH reaction rate is controlled by the amount of ADH, the acetaldehyde level, and the free reduced nicotinamide adenine dinucleotide/nicotinamide adenine dinucleotide $^{+}$ (NADH/ NAD $^{+}$) ratio in the cytosol. [25] The amount of ADH in the liver is not induced by chronic drinking; however, with fasting, protein malnutrition and liver disease, ADH activity and the ethanol elimination rate are decreased. [26] Humans have seven ADH gene loci, two of which are polymorphic (Table 114-1). People of different racial groups inherit different sets of ADH isoenzymes. The kinetic properties of the various ADH isoenzymes differ widely in vitro, [26] but the effects of inheriting different ADH isoenzymes on

alcohol pharmacokinetics are relatively small. African Americans who carry a copy of the *ADH2 * 3* gene, encoding an enzyme with high maximum velocity, have a somewhat faster rate of alcohol metabolism. [27]

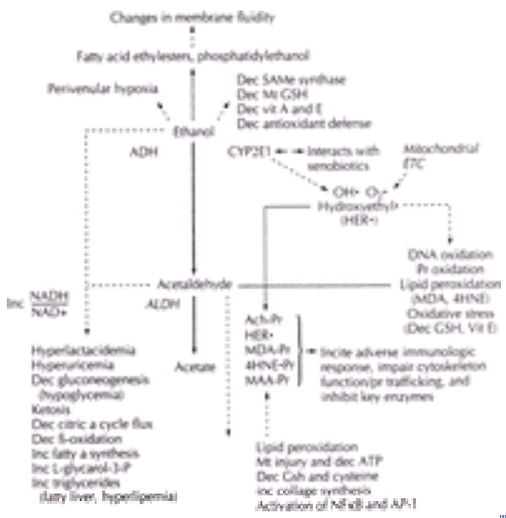

FIGURE 114-1. Pathway of alcohol metabolism and its effect on metabolism of hepatocytes. Alcohol is metabolized by alcohol dehydrogenase (ADH) or cytochrome P4502E1 (CYP2E1) to acetaldehyde. Acetaldehyde is then oxidized by aldehyde dehydrogenase (ALDH). The ADH and ALDH reactions generate free reduced nicotinamide adenine dinucleotide (NADH) more rapidly than it can be reoxidized by the mitochondria. The increased reduced nicotinamide adenine dinucleotide/nicotinamide adenine dinucleotide $^{+}$ (NADH/NAD $^{+}$) ratio modifies many intermediary metabolism pathways, indicated in the lower left, and contributes to formation of reactive O_2 species by the mitochondrial electron transfer chain (ETC). CYP2E1 contributes to the formation of reactive O_2 species and hydroxyethyl radical (HER·), which promote oxidation and peroxidation of DNA, proteins, and lipids. Acetaldehyde (*Ach*) and aldehyde products of lipid peroxidation (*4HNE,* 4-hydroxynonenal; *MDA,* malondialdehyde) participate in the formation of various aldehyde-protein adducts (*MAA,* malondialdehyde-acetaldehyde adducts; *Pr,* protein). Other effects include changes in membrane fluidity and depletion of antioxidants (including *SAMe,* S-adenosylmethionine). These effects are important mechanisms that lead to liver cell injury and cell death. Other abbreviations: *Dec,* decrease; *Fe,* iron; *Inc,* increase; *Mt,* mitochondrial. (From Lumeng L, Crabb DW. Alcoholic liver disease. Curr Opin Gastroenterol 2001;17:211, with permission.)

Aldehyde dehydrogenase 1	Cytosolic	None known

TABLE 114-1 Ethanol Metabolizing Enzymes in Humans

CYP2E1 is associated with reduced nicotinamide adenine dinucleotide phosphate (NADPH)-cytochrome P450 reductase in the microsomal membrane (this complex was originally designated the microsomal ethanol oxidizing system [MEOS]), and reduces molecular oxygen to water as ethanol is oxidized to acetaldehyde. [28] CYP2E1 is inducible by chronic drinking, [29] especially in the perivenular zone, [30], [31] and it may contribute to the increased rates of alcohol elimination in heavy drinkers. CYP2E1 can also be induced in fasting and diabetes and by a diet high in fat. [29] CYP2E1 has a high K_m for ethanol and may assume a greater role in ethanol metabolism at high blood levels. CYP2E1 is unusually “leaky” and generates reactive oxygen species (ROS) including hydroxyl radical (OH·), superoxide anion (O_2), hydrogen peroxide (H_2O_2), and hydroxy ethyl radical (H_2). Thus, CYP2E1 is a major source of oxidative stress. [32], [33] This P450 enzyme also has capacity to activate many xenobiotics to toxic metabolites, most notably acetaminophen. [34] In addition to CYP2E1, other P450 enzymes such as CYP1A2 and 3A4 may also play a role in ethanol oxidation. [29]

Acetaldehyde is converted by aldehyde dehydrogenases (ALDH) to acetate, which is released from the liver and metabolized by heart and muscle. [35] The most important ALDH isozyme in acetaldehyde metabolism is the mitochondrial form, designated ALDH2 (Table 114-1). ALDH2 is inhibited by disulfiram (Antabuse). Consumption of alcohol while taking disulfiram or one of a number of other drugs (metronidazole, and some sulfonylureas and cephalosporins) results in the accumulation of acetaldehyde, producing vasodilation, facial flushing, tachycardia, nausea, and vomiting. [36], [37] and [38] This reaction is also observed in about half of Asians when they drink. [39] It is the result of inheriting an ALDH2 allele (*ALDH2 *2*) that contains a point mutation at position 487. This allele acts as a dominant negative, resulting in markedly reduced activity of ALDH2 in heterozygotes. [40]

A minor pathway of alcohol metabolism is the formation of fatty acid ethyl esters. [41], [42], [43] and [44] During the hydrolysis of triglyceride or phospholipid, ethanol can substitute for water, forming the ethyl ester. This metabolite can form in tissues that do not otherwise participate in ethanol oxidation, such as heart and pancreas. It is suggested that these lipids disturb membrane function, and may thus contribute to organ dysfunction.

Nutritional Aspects of ALD

It is important to emphasize that ethanol itself, rather than a nutritional deficiency in the alcoholic patient, can cause ALD. Baboons chronically given large amounts of ethanol, despite a nutritionally complete diet, developed fatty liver and significant fibrosis. [45] About 30% of the baboons developed cirrhosis after 1 to 5 years. Rats fed by constant intragastric infusion of a nutritionally adequate liquid diet containing ethanol comprising 50% of total calories developed fatty liver, necrosis, and fibrosis. However, there are interactions between diet and alcohol in the development of liver injury. The most obvious is that severe liver injury in the rat model (in particular activation of stellate cells and fibrosis) required a high content of polyunsaturated fatty acids (PUFA) in the diet; [46] fatty liver and injury are in fact prevented by substituting saturated fat or medium chain triglycerides for the PUFA. [47] This has been suggested to be due to increased susceptibility of the PUFA to oxidative damage. It is interesting that there appears to be an inverse relationship between saturated fat and cholesterol intake, and risk of ALD. [48] Administration of ethanol in a liquid diet that is very low in carbohydrate also causes liver inflammation and severe fatty liver in rats. [49] Lastly, obesity has been found to be a risk factor for the development of cirrhosis in humans. [50]

Genetic Predisposition to Alcoholism and ALD

Twin, adoption, and high-risk familial clustering studies have all proven genetic predisposition to alcoholism (see Chapter 55). The strongest genetic associations identified to date are those between risk of alcoholism and genes encoding alcohol-metabolizing enzymes. In particular, individuals having the genes encoding high activity ADH (ß2 ADH encoded by *ADH2 *2*) or the dominant negative allele for ALDH2 found in Asians (*ALDH2 *2*) are at reduced risk of alcoholism. [51], [52] This finding is quite robust, having been replicated by a number of groups. *ADH2 *2* is very common in Asians, and it has also been identified in about 20% of Israelis. This gene locus also appears to reduce the risk of alcohol abuse in Israelis. [53] The effect of these variants can best be explained by either increased rates of formation (high activity ADH) or decreased rates of clearance of acetaldehyde (ALDH2 deficiency), which can cause aversive reactions to drinking. However to date, high circulating levels of acetaldehyde have not been documented in the patients with *ADH2 *2*. An additional polymorphism in the promoter of the *ALDH2* gene has been reported. [54], [55] The polymorphic site, either an A or G, is adjacent to an element bound by transcription factors belonging to the steroid receptor family. The A allele, which is less active in vitro, was less common in a group of Japanese alcoholics with active ALDH2. [54] This would be consistent with the notion that a less active promoter results in synthesis of less ALDH2 enzyme and reduced ability to remove acetaldehyde. This variant was found in all ethnic groups examined. [55] It will be

very interesting to see if the observations on the association of the A allele with protection from alcoholism can be extended to Caucasians and Africans.

The evidence for genetic risk factors for ALD is less strong than that for alcoholism. The largest existing study is the U.S. Veterans Administration Twin Panel Study. Analysis of the dataset in 1981 showed a substantially higher concordance for cirrhosis in monozygotic twins than in dizygotic twins, indicating the presence of a genetic component to the risk. [56] This database was reanalyzed in 1994. The analysis again supported the notion that concordance for cirrhosis was higher in the monozygotic twins, but found that most, but not all, of the genetic liability for cirrhosis was the result of shared risk for alcoholism. [57] This study is limited by lack of information on the prevalence of hepatitis C in the cohort. No specific candidate genes that confer risk or protection against ALD have been firmly established. Specifically, none of the ADH polymorphisms have been clearly identified as predisposing to the development of ALD. Polymorphisms in CYP2E1 have been sought as a clue to predisposition to ALD, since this enzyme may contribute to the oxidative stress of ethanol metabolism. An initial report suggested a significant association of the c2 allele (one that lacks the Rsa I restriction site) with ALD. This promoter variant is known to increase the rate of transcription (compared to the wild type c1 allele) when this 5'-regulatory construct was coupled to a reporter gene in an in vitro expression system. [58] Although this initial report drew much attention, most subsequent studies have refuted any relationship between the c2 allele and the risk of ALD. [59] Case-control studies have indicated the possibility of increased genetic risk for ALD through inheritance of *ALDH2 *2,* and polymorphisms of the tumor necrosis factor-a (TNFa) and interleukin-10 (IL-10) promoters, as well as glutathione S-transferase, [60], [61], [62] and [63] but these require confirmation.

Genesis and Consequences of Fatty Liver

Fatty liver has long been recognized as the earliest response of the liver to chronic alcohol consumption. This was attributed to the effect of increased levels of cytosolic and mitochondrial NADH, which inhibits oxidation of fatty acids and stimulates their synthesis (see Fig. 114-1). Increased levels of L-glycerol-3-phosphate and fatty acids, as well as induction of a number of enzymes involved in de novo fatty acid synthesis, result in accelerated synthesis of triglycerides. The liver secretes some of this fat as very-low-density lipoprotein (VLDL), which can result in hyperlipidemia. The rate of secretion of VLDL apparently does not keep pace with the increased rate of synthesis of triglycerides, so the liver cells become filled with fat. Because the high periportal to low perivenous oxygen gradient normally present within the liver acinus is made steeper by chronic alcohol ingestion, perivenous hepatocytes become much more hypoxic. [64] As a result, the effect of alcohol metabolism on the redox state and on fat accumulation is most severe in perivenous cells. Fat accumulation does not continue indefinitely because the redox-state changes are attenuated with continuing chronic alcohol use. [65]

Additional support for this model comes from cell model studies. Cell lines expressing high levels of ADH metabolize alcohol and experience a more reduced redox potential in the cytosol, as reflected by an increase in the lactate/pyruvate ratio in the medium. Coincident with this, the cells accumulate large amounts of triglyceride and free fatty acids. As in perfused liver or isolated hepatocytes, this was associated with inhibition of fatty acid oxidation and an increased rate of fatty acid synthesis. [66] Addition of tocopherol to the medium did not prevent fat accumulation, arguing that oxidative stress was not involved. On the other hand, methylene blue lowered the lactate/ pyruvate ratio and attenuated the accumulation of fat in the cells. These results argue that a high NADH/NAD $^{+}$ ratio alone is sufficient to initiate the accumulation of fat and the development of fatty liver.

In addition to these effects of ethanol, another mechanism has been suggested. The levels of fatty acids in the liver appear to be sensed by the peroxisome proliferator-activated receptor (PPARa). [67], [68] This receptor forms heterodimers with retinoid X receptor, binds consensus response elements, and activates gene transcription. Many genes involved in fatty acid binding (fatty acid binding protein), fatty acid oxidation (peroxisomal fatty acyl-coenzyme A [CoA] oxidase, mitochondrial medium chain fatty acyl-CoA dehydrogenase, microsomal lauryl hydroxylase), and lipoprotein synthesis (apo CIII and AI) appear to be regulated by PPARa. Mice in which the genes for PPARa or fatty acyl-CoA oxidase are disrupted develop steatohepatitis. [69], [70] PPARa mRNA was also reported to be decreased in the liver of rats fed ethanol chronically, [71] and certain PPARa-regulated genes (fatty acid binding protein, malic enzyme, and acyl-CoA oxidase) were repressed by alcohol feeding of mice. [72] Moreover, alcohol metabolism by hepatoma cells impairs the function of transfected PPARa. [73] Further work will be required to understand the role of this interesting receptor in the development of fatty liver.

An interesting variant of fatty liver is alcoholic foamy degeneration. Pathologically, there is microvesicular steatosis, especially prominent in the perivenous zone of the liver. Microvesicular fatty change typically suggests damage to mitochondria, and indeed, this lesion has been associated with deletions in the mitochondrial genome. [74] This may be related to the oxidative stress on the mitochondrion discussed subsequently.

Fatty liver is not as benign as once considered. Some patients with alcoholic fatty liver may develop fibrosis or cirrhosis without ever experiencing an attack of alcoholic hepatitis, as may some with nonalcoholic fatty liver. Animals with fatty liver are exquisitely sensitive to lipopolysaccharide (LPS), [75] and LPS has an important role in the pathogenesis of experimental ALD, as discussed in more detail later in the chapter. Thus, prevention or reversal of fatty liver may reduce the hepatotoxicity of ethanol.

Roles of Oxidant Stress

The redox hypothesis of alcoholic fatty liver has been challenged by studies in which antioxidants prevented development of fatty liver in animals receiving large, single doses or chronic feeding of alcohol. In addition, with chronic alcohol feeding of baboons, the redox shift in the liver becomes less severe, but the fat accumulation persists. This suggests that over time, the redox state is no longer the primary cause of alcoholic fatty liver. [65] A candidate for the perpetuation of fatty liver at this stage is oxidative stress. There are two primary ways by which chronic alcohol use can induce oxidative stress: induction of CYP2E1 and reductive pressure on the mitochondrial electron transfer system (see Fig. 114-1). In either case, increased rates of single electron transfers (at the sites of flavin coenzymes in the cytochrome catalytic cycle or the electron transfer system) facilitate the transfer of electrons to oxygen. CYP2E1 is induced by chronic alcohol use and is “leaky,” in that electrons transferred to it from CYP450 reductase can be transferred to molecular oxygen in the absence of substrate, forming superoxide. [76] The preferential expression of CYP2E1 in the central zone of the liver coincides with the prominence of alcohol-induced injury to this zone. Exposure of CYP2E1-expressing HepG2 cells to high concentrations of ethanol produced morphologic changes and DNA fragmentation, activation of caspases 1 and 3, and apoptosis. [77] These changes were not observed in control HepG2 cells, and could be prevented by an inhibitor of CYP2E1, by antioxidant compounds, or by inhibition of the caspases. Thus, oxidative stress mediated by CYP2E1 can injure cells via activation of caspases and apoptosis. The situation is less clear in vivo; CYP2E1 inhibitors attenuated liver injury in alcohol-fed rats; [78] however, mice with the CYP2E1 gene knocked out were still sensitive to ethanol hepatotoxicity. [79] It is possible that other ethanol-metabolizing CYPs are important in the CYP2E1 knockout animals.

Other groups have shown that ethanol metabolism is capable of causing acute oxidative stress (as demonstrated by dichlorofluorescein fluorescence) in perfused liver and isolated hepatocytes. [80], [81] The mitochondrion appears to be important in this phenomenon, and it is well known that chronic alcohol use causes abnormalities of mitochondrial morphology and function. Among, the most prominent antioxidant defenses in the mitochondrion is the presence of glutathione and glutathione peroxidase. It is noteworthy that mitochondrial glutathione is preferentially depleted in the alcohol-fed baboon or rat. [82] Alcohol use also adversely affects antioxidant defense in hepatocytes by decreasing the activity of S-adenosylmethionine synthase and depleting the stores of vitamins A and E. [83]

An end result of oxidative stress is lipid peroxidation, a chain reaction of lipid radical formation that follows from the removal of an electron from PUFA. The lipid free radical undergoes addition of oxygen to form a lipid hydroperoxide, and then decomposes. This leads to production of reactive aldehydes such as malondialdehyde (MDA) and 4-hydroxynonenal (4-HNE). Lipid peroxidation has been demonstrated in experimental animals exposed to alcohol. [84] In humans, ethanol use increases the formation of lipid peroxides and is associated with reduced levels of vitamin E, the chief antioxidant in membranes systems [85] and increased exhalation of pentane (a product of lipid peroxidation) has been reported in ALD. [86] However, a trial of vitamin E supplementation in alcoholic cirrhosis did not show beneficial effects on mortality or hospitalization rate. [87]

Role of Protein Adduct Formation

Protein adducts are covalent linkages formed between the amino acid side chains (typically lysine) of a number of liver proteins and a low-molecular-weight reactive chemical such as acetaldehyde, hydroxyethyl radical (HER $^{\cdot}$), and peroxidative aldehydes like 4-HNE and MDA [88] (see Fig. 114-1). Adducts are more likely to form when the level of the reactive aldehydes are increased. Acetaldehyde levels are higher in alcoholics than in social drinkers due to the adaptive increase in ethanol oxidation and reduction in the ability of mitochondria to oxidize acetaldehyde after heavy use of alcohol. [89] HER $^{\cdot}$ forms when ethanol itself accepts an electron and forms a free radical. [90] The peroxidative aldehydes form during lipid peroxidation. The modified proteins identified to date include tubulin, [91] ? [4] -3-ketosteroid

5ß-reductase (initially identified as the 37-kd protein), [92] low-density lipoproteins, [93] cytochrome C, [94] CYP2E1, [95] and various liver cell membrane proteins. In the hepatic stellate cell, Jun N-terminal kinase has been shown to form adducts with 4-HNE. [96] Undoubtedly there are other as yet undiscovered adducts. There are two important biologic consequences and one practical consequence of adduct formation. First, the adducts are recognized as neo-antigens. Antibodies directed against membrane and soluble proteins of the hepatocyte modified by acetaldehyde and by HER [-·] are detected in alcoholics and they constitute a possible immune component to liver injury. [97] Among the most provocative studies are those that showed increased sensitivity of the liver to ethanol in animals immunized with protein-acetaldehyde adducts, then fed ethanol. The immunized, alcohol-fed animals developed hepatic inflammation and fibrosis, while animals that were only immunized or only fed alcohol did not. [98] Second, the adducted protein maybe dysfunctional. For example, tubulin adducts are abnormal in terms of protein trafficking and this probably contributes to protein retention and swelling of the liver cells. A practical ramification is that the detection of adducts may ultimately be used as a test for alcohol abuse and to monitor for abstinence.

Cytoskeletal Changes in ALD

The accumulation of fat in the liver is accompanied by induction of microsomal proteins and fatty acid binding protein, and by retention of secretory proteins (due to impaired cytoskeleton function and protein trafficking pathways caused by formation of acetaldehyde-protein adducts) and water. [99] In addition, continuous intragastric infusion of ethanol caused a striking decrease in alkaline protease activity in liver as well as a decline in sodium dodecyl sulfate (SDS)-activated 20S proteasome proteases (i.e., chymotrypsin-like (ChT-L) and peptidylglutamyl peptide hydrolase activities). [100] The inhibition of proteolysis under this condition was abrogated by administration of an inhibitor of CYP2E1, suggesting that oxidative stress caused this inhibition. Western blot studies also demonstrated a marked reduction of ubiquitin and ubiquitin conjugates, and levels of ubiquitin mRNA, in rats given ethanol. [101] Ubiquitin is necessary for the targeting of cytosolic proteins for degradation in the proteasome, and deficiency of ubiquitin could contribute to the accumulation of cytosolic proteins. This causes the hepatocytes to swell and is called balloon or hydropic degeneration. The sheer size of the cells may increase portal pressure and interferes with blood flow to the perivenous zone. [102] There is also increased oxygen consumption in the liver of rats after prolonged alcohol consumption. Increased oxygen consumption coupled with decreased blood flow may induce perivenular hypoxia; this may be a signal for apoptosis or necrosis and fibrosis in the perivenous zone. Ethanol may also affect the interactions of hepatocytes with extracellular matrix. Tuma and colleagues [103] reported that alcohol-feeding preferentially impaired cellular attachment and spreading of perivenous hepatocytes but spared the periportal counterparts.

The Role of Lipopolysaccharide and the Kupffer Cell

There is a growing appreciation that portal vein lipopolysaccharide (LPS) and activation of the Kupffer cells are important in alcoholic liver injury (Fig. 114-2). Studies show that alcohol feeding increases LPS levels in the portal vein, that chronic ethanol feeding induces the expression of the LPS binding protein and its receptor present on the Kupffer cell (CD14), and that inactivation of Kupffer cells by gadolinium chloride ameliorates the injury seen with chronic ethanol administration in the Tsukamoto-French model. [104] Kupffer cells can also be activated by ethanol oxidation by CYP2E1, [105] which appears to act via the oxidative stress-sensitive nuclear transcription factor, NF-?B. This factor coordinately increases the expression of a wide range of genes, including those for cytokines and chemokines. Among these are:

- TNFa, which is a cause of hepatocyte apoptosis and oxidative stress
- transforming growth factor-ß1 (TGFß1), the most important stimulus for collagen synthesis by stellate cells
- IL-8, which attracts neutrophils to the liver (plasma IL-8 levels are markedly increased in patients with alcoholic hepatitis on admission and decreased thereafter with recovery)
- IL-1 and IL-6, which elicit an acute phase response
- eicosanoids, which are implicated in the increased rate of hepatocyte oxygen consumption during ethanol metabolism
- chemokines that stimulate migration of leukocytes into the liver
- platelet-derived growth factor (PDGF), a major stimulator of hepatic stellate cell (HSC) proliferation [106] (discussed later in the chapter).

FIGURE 114-2. Effects of alcohol ingestion on endotoxin levels, the activation of Kupffer cells (KC). Ethanol consumption increases the absorption of lipopolysaccharide (endotoxin) from the gut, and induces expression of CD14, the endotoxin receptor, on KC. This action is more pronounced in females, due to effects of estrogen. Antibiotics and medium chain triglycerides (*MCT*) may reduce endotoxin absorption and action. Binding of endotoxin to the CD14 molecule leads to activation of nuclear factor ?B (NF?B), which in turn activates numerous inflammation-related genes, including those for tumor necrosis factor-a (*TNF*a), interleukin 6 (*IL-6*), and transforming growth factor-ß (*TGFß-1*). These in turn have effects on the hepatocytes (HC), such as synthesis of acute phase proteins (*APP*) and generation of reactive oxygen species (*ROS*), endothelial cells (*EC*), such as expression of intercellular adhesion molecule-1 (*ICAM-1*), and hepatic stellate cells (*HSC*), leading to proliferation and collagen synthesis. Formation of ROS may independently activate NF?B. KC contain calcium channels that are involved in activation; calcium channel blockers reduce the activation of these cells in experimental models. Other abbreviations: *I?B,* inhibitor of NF?B *Fe,* iron. (From Lumeng L, Crabb DW. Alcoholic liver disease. Curr Opin Gastroenterol 2001;17:211, used with permission.)

TNFa appears to play a particularly important role in ALD. Knock-out mice, which lack the TNF type 1 receptor, [107] and rats given antibody against TNFa [108] are protected against liver injury in the Tsukamoto-French model. This cytokine may contribute to liver injury by stimulating the formation of superoxide in the mitochondria, [109] particularly when mitochondrial glutathione is depleted. It is also interesting to note that the mere presence of fatty liver (even without ethanol consumption) increases the sensitivity of the liver to the effects of LPS. [75] Two reviews by Diehl [110] and McClain and colleagues [111] summarized the role of cytokines in the pathogenesis of ALD.

The relationship between pathological liver injury, endotoxemia, diet, lipid peroxidation, and NF?B activation and imbalance of the expression of pro- and antiinflammatory cytokines has been examined in rats. [112] The animals were given ethanol in a diet containing medium-chain triglycerides, palm oil, corn oil, or fish oil by chronic intragastric infusion. Electrophoretic mobility shift assay was used to evaluate NF?B activation and mRNA assays were performed for proinflammatory cytokines (TNFa, IL-1ß, interferon-? [IFN-?], and IL-12), C-C chemokines (MCP-1, MIP-1, and RANTES), C-X-C chemokines (CINC-1, MIP-2, IL-10, and ENA-78) and antiinflammatory cytokines (IL-10, IL-4, and IL-13). The greatest necroinflammatory injury was observed in rats fed fish oil or corn oil plus ethanol. These animals had activation of NF?B, increased expression of proinflammatory C-C and C-X-C chemokines, and also the highest levels of LPS and lipid peroxidation. IL-10 and IL-4 mRNA levels were decreased in these two groups of alcohol-fed rats that exhibited the most extensive necroinflammation.

Pathways of Hepatic Stellate Cell Activation

The final element in alcoholic liver injury is activation of the hepatic stellate cell (HSC) and production of collagen. [106], [113] This fibrogenic process requires the interaction of Kupffer cell-derived cytokines with the HSC (Fig. 114-2 and Fig. 114-3). An area of great interest is the control of the earliest stage of HSC activation. One of the very earliest events is the activation of NF-?B in the HSC, but the signal responsible for this is as yet unknown. [114] This might relate to changes in the matrix which these cells contact in the liver (e.g., by modification by acetaldehyde), formation of protein adducts in the HSC, or oxidative stress originating in the hepatocytes or within the stellate cells themselves (HSC are known to express ADH and ALDH, but not CYP2E1). [115], [116] Acetaldehyde, MDA, and 4-HNE can also

induce stellate cells to express collagen genes. [117], [118] The ? isoform of PPAR may participate in the control of HSC differentiation. Expression of this receptor falls during HSC activation, and treatment of the cells with PPAR? ligands retards the activation of the cells. [119]

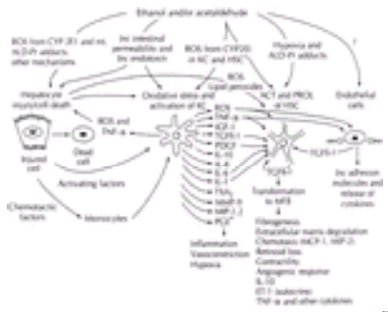

FIGURE 114-3. Effects of hepatocyte injury, endotoxin, and ethanol- or acetaldehyde-induced changes (including hypoxia and oxidative stress) on autocrine and paracrine pathways of activated Kupffer cells (*KCs*), hepatic stellate cells (*HSCs*), and endothelial cells. Although not shown, other cell types in liver (e.g., bile duct epithelium, lymphocytes, and platelets) are also involved. Fibrogenesis includes synthesis of matrix proteins (e.g., type 1 and 3 collagens, proteoglycans, hyaluronate, and several specialized glycoproteins including fibronectin), release of metalloproteinases and secretion of tissue inhibitors of metalloproteinases (*TIMPs*). Abbreviations: *ALD-Pr,* aldehyde-protein; *ROS,* reactive oxygen species; *TNFa,* tumor necrosis factor-alpha; *IGF-1,* insulin growth factor-1; *TGFß-1,* transforming growth factor beta-1; *PDGF,* platelet-derived growth factor; *IL,* interleukin; *TXA* $_2$, thromboxane A $_2$; *MMP,* matrix metalloproteinase; *MIP,* macrophage inflammatory protein; *MCP,* monocyte chemotactic protein; *ET,* endothelin; *PGE,* prostaglandin E; *MFB,* myofibroblast. *ACT,* activation; *PROL,* proliferation; *mt,* mitochondria; *Inc,* increased. (From Lumeng L, Crabb DW. Alcoholic liver disease. Curr Opin Gastroenterol 2001;17:211, with permission.)

Once NF-?B is activated, the stellate cells express receptors for and can be stimulated to divide by PDGF. They also can be stimulated to secrete collagen by TGFß1 and possibly IL-1. [106] With time, this activation may become irreversible, leading to progressive fibrosis and cirrhosis. The irreversible activation may be driven by the changes the cells make in the extracellular matrix, such as deposition of type I collagen, production of TGFß1 by the HSC themselves (resulting in a positive feedback loop), and depletion of retinyl ester stores in the HSC. In addition, the HSC also make intercellular adhesion molecule-1 (ICAM-1), macrophage inflammatory protein-2 (MIP-2), platelet-activating factor (PAF), stem cell factor (SCF-1), and monocyte chemotactic factor (MCP-2), chemokines and adhesion molecules that may be important in the migration of leukocytes into the liver. [106] All of these factors may lead to progressive liver damage, even if the patient stops drinking.

Gender Differences in the Response to Alcohol

Given the new knowledge about the pathogenesis of ALD, it is worth revisiting the differences in responses to alcohol between men and women. [120] Studies using volume estimates by computed tomography (CT) scan have shown that men and women have livers that are similar in size. This results in a larger liver mass/body mass ratio for women. When the rate of alcohol metabolism is normalized to liver mass, men and women have similar metabolic rates. [121] However, blood alcohol levels after comparable doses of alcohol will usually be higher in women than in men because of the women's smaller body mass and lean body mass, resulting in a lower volume of distribution in women. It has also been found that female rats are more susceptible to alcohol-induced liver injury in the Tsukamoto-French model. [122] This is likely due to more pronounced accumulation of fat in their livers, lower levels of fatty acid binding protein (and thus higher concentrations of unbound free fatty acids), high levels of plasma LPS, more striking expression of the LPS receptor (CD14) in Kupffer cells and LPS binding protein, [123] more pronounced central hypoxia, and more marked activation of NF-?B in the HSC. [124] Female rats fed ethanol showed a significantly higher level of CINC-1 mRNA (the rat equivalent of IL-8, the major neutrophil chemokine) in the liver than male counterparts in response to LPS. Oophorectomy abolished the gender difference in CINC-1 mRNA expression. Estrogens also modulate the oxidative stress of ethanol metabolism. [125] Thus, many mechanisms may conspire to make women alcoholics more prone to develop alcoholic hepatitis and cirrhosis.

Apoptosis in ALD

Cell death in ALD can occur by either apoptosis or necrosis. Traditionally, these processes are distinguished by the lack of inflammation in the former. However, recent concepts dispute this distinction (i.e., massive cell death via apoptosis can overwhelm phagocytic clearance and can incite inflammation including chemotaxis for neutrophils). While there is no doubt that hepatocyte necrosis takes place due to alcohol-induced liver injury, data indicate that apoptosis is also important. Because apoptosis is a rapid process (varying from minutes to a few hours), hematoxylin and eosin staining for apoptotic bodies underestimates the extent of apoptosis; thus, the TUNEL assay and immunohistological methods are needed to evaluate apoptosis. With these latter methods, the apoptotic index was found to correlate with Maddrey discriminant function [126] and histological severity. [127]

There are two major pathways in apoptosis that ultimately activate effector caspases and cell death. One involves the death ligands and death receptors (e.g., ligand-receptor binding involving TNFa and FAS-ligand) and the other involves opening of mitochondrial membrane transition pores and release of cytochrome C. [128] The release of TNFa from Kupffer cells has been mentioned; ROS are also able to induce apoptosis. Apoptosis in ALD has important consequences. Activation of Fas induces IL-8, probably a key factor in the neutrophilic infiltration of the liver in alcoholic hepatitis. Moreover, apoptosis, followed by phagocytosis of the dead cell, can present intracellular neoantigens, such as aldehyde-protein adducts, to the immune system, with the formation of cytotoxic T cells directed toward these epitopes. Thus, it may be possible to formulate therapeutic modalities that modulate the toxicity of ethanol by altering either the pro-apoptotic signals or the anti-apoptotic defenses of the liver cells.

CLINICAL MANIFESTATIONS

The spectrum of ALD ranges from asymptomatic hepatomegaly to hepatocellular failure from alcoholic hepatitis or end-stage cirrhosis. Increasingly, patients are referred for evaluation of abnormal laboratory tests or radiographs. For example, macrocytosis is common in alcoholics and its presence in an otherwise healthy person suggests occult alcohol abuse. [129] This may be due to either thick macrocytes caused by folate deficiency or thin, target cell macrocytes due to a toxic effect of alcohol on the bone marrow, or changes in the lipid composition of the red cell membrane in cirrhosis or cholestasis. These thin target macrocytes disappear very slowly with improvement in liver function. On the other hand, spur cell anemia is seen in patients with severe ALD. The red cells of these patients have increased free cholesterol, form multiple irregular projections, and are cleared from the circulation by the spleen. Thus, the patient presents with hemolytic anemia. [130] It carries a poor prognosis. Abdominal ultrasound examinations may detect unsuspected alcoholic fatty liver exhibiting increased echogenicity.

Clinical diagnosis of the three major stages of alcoholic liver injury is difficult in that these stages may occur in any combination in the same patient, emphasizing the importance of liver biopsy. For purposes of instruction, it is useful to divide ALD into its three major types: alcoholic fatty liver, alcoholic hepatitis, and cirrhosis, and discuss clinical, laboratory, and pathological features of each. A number of less common variants are listed in Table 114-2 and discussed within the following sections.

1. Alcoholic fatty liver with perivenular fibrosis
2. Alcoholic foamy degeneration (alcoholic microvesicular steatosis)
3. Sclerosing hyaline necrosis
4. Alcoholic cirrhosis with chronic hepatitis*
5. Cholestasis
6. Hepatic iron overload
7. Lipogranuloma
8. Massive hepatic necrosis (due to acetaminophen ingestion)
9. Focal fatty liver or focal fat sparing

*A significant portion of these patients likely have concomitant hepatitis B or C infection.

TABLE 114-2 Less Common Pathological Features of Alcoholic Liver Disease

Alcoholic Fatty Liver

Consumption of ethanol in sufficient quantities (in the range of 120–150 g/d for 2 to 3 weeks) will result in fatty liver. Abstinence for 4 weeks leads to resolution. [131], [132] The development of fatty liver occurs despite consumption of an otherwise adequate diet. Stigmata of alcoholism (e.g., Dupuytren contractures, testicular atrophy, loss of the male pattern of body hair, palmar erythema, spider angiomata, and gynecomastia) may also be present. Evidence of hypogonadism and feminization are evident in alcoholic males before the onset of liver disease. It results from toxic effects of ethanol on Leydig cells leading to decreased testosterone production; impairment of hypothalamic-pituitary function resulting in low luteinizing hormone levels; induction of aromatase in adipose tissue and increased conversion of androgens to estrogens; and ingestion of nonsteroidal estrogens derived from plants (called phytoestrogens) in alcoholic beverages which then can lead to increased estrogenic effect. [133], [134] and [135]

Some cases of biopsy-proven alcoholic fatty liver are associated with constitutional symptoms of weakness, cachexia, fever, anorexia, nausea, vomiting, jaundice, hepatic tenderness, splenomegaly, or ascites. Most likely, such cases represent a combination of fatty liver and alcoholic hepatitis, since the classic lesions of alcoholic hepatitis are difficult to find in livers with panlobular fat, or may be missed because of sampling error. Another clinical variant is alcoholic foamy degeneration. [136] It has been noted in about 2% of a series of over 300 patients in Spain. [137] These patients typically present with hepatomegaly, an increased international normalized ratio (INR), jaundice, and often hyperlipemia. Encephalopathy and leukocytosis are uncommon. A transient sharp increase in transaminases followed by more prolonged evidence of cholestasis is described. This may be the explanation for cases of apparent alcoholic fatty liver that is complicated by cholestasis and hepatic failure. [138]

Laboratory abnormalities are generally mild. Bilirubin is elevated in about one fourth of cases but is usually less than 5 mg/dL. As in all stages of ALD, serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are usually less than 300 IU/L (with the exception of foamy degeneration). The AST is usually higher than serum ALT (with the AST:ALT ratio =2 in 80% of the cases) in ALD, while the ALT is usually higher than AST in viral and toxic hepatitis and nonalcoholic steatohepatitis (NASH). Alkaline phosphatase (AP) is usually no more than 300 IU/dL. The ratio of ?-glutamyltranspeptidase (GGT) to AP activity is at times greater than 5, as a result of disproportionate induction of GGT by alcohol abuse per se. This ratio is more specific than sensitive provided that the patient is not on drugs that also induce GGT (e.g., anticonvulsants). In alcoholic fatty liver, serum albumin and globulin levels are expected to be normal in the absence of coincidental medical conditions, including malnutrition.

The fatty liver is enlarged, firm, and may be pale yellow. Microscopically, there is great variation in the number of cells affected, with a tendency for fat accumulation in the perivenous and midzones of the liver lobule. Occasionally, hepatocytes rupture to form a fatty cyst, and then a lipogranuloma. Generally, there is sparse cell necrosis or inflammation. Intrahepatic cholestasis and mild cholangiolitis may be seen in the absence of extrahepatic biliary obstruction. [139] Perivenular fibrosis may be present and has been shown to be a precursor of cirrhosis. Alcoholic foamy degeneration is characterized by perivenous hepatocytes filled with foamy, microvesicular fat, and focal cell necrosis, but no inflammation. [136], [137] There are yet other variants of fatty liver diagnosed radiographically as focal fatty liver and focal fat sparing. As these names imply, the former is due to focal accumulation of fat while the rest of the liver is not steatotic. The latter indicates the reverse. These lesions may be confused with mass lesions on ultrasound or abdominal CT scan. In the past, these conditions could be diagnosed by liver spleen scan. [140], [141] Magnetic resonance imaging (MRI) will provide definitive diagnosis of these conditions and will distinguish them from mass lesions.

Alcoholic Hepatitis

Patients with alcoholic hepatitis are usually symptomatic with anorexia, nausea, malaise, weakness, abdominal pain, icterus, weight loss, and fever. Most also show obvious evidence of protein-calorie malnutrition. [142], [143] The most severe cases are those with deep jaundice, ascites (often infected), azotemia, and hepatic encephalopathy, and may progress rapidly to death. Once set into motion, alcoholic hepatitis seems to progress despite stopping drinking. The importance of LPS in animal models of alcoholic liver injury suggests that infection, with endotoxinemia, may precipitate an attack of alcoholic hepatitis, and thus infection should be sought and treated in patients presenting with alcoholic hepatitis. Physical examination reveals the findings summarized in Table 114-3. Laboratory abnormalities are more severe in alcoholic hepatitis than in alcoholic fatty liver. [144] Anemia occurs in 50% to 70% of patients, secondary to toxic effects of ethanol on the bone marrow, impaired pyridoxine metabolism, folic acid deficiency, iron deficiency from blood loss, or hypersplenism. Leukocytosis is observed in many, and may assume leukemoid proportions, probably driven by increased levels of IL-8. Leukopenia and thrombocytopenia are present in 10% to 15% and may reflect folate deficiency, alcohol-induced marrow suppression, or hypersplenism. Serum AST and ALT are elevated in all cases of alcoholic hepatitis and AP is elevated in 80% of cases. If AST levels exceed 300 IU/L, sclerosing hyaline necrosis (discussed subsequently), coincidental viral hepatitis, or acetaminophen overdose should be suspected. An elevation of the AST:ALT ratio greater than 2 is characteristic of, but certainly not diagnostic of, alcoholic liver injury. [145], [146] Bilirubin is usually increased, while albumin is usually decreased and the prothrombin time (PT) is often prolonged. Electrolyte abnormalities are frequent in alcoholic hepatitis, and include hyponatremia, hyperchloremia due to renal tubular acidosis, hypokalemia from poor dietary intake, vomiting or diarrhea, hypomagnesemia from increased urinary loss, and respiratory alkalosis.

FINDING	FREQUENCY (%)
Hepatomegaly	95
Hepatic tenderness	50–70
Signs of portal hypertension (splenomegaly, prominent abdominal veins and ascites)	40–70
Stigmata of chronic parenchymal liver disease and alcoholism (bruising, leukonychia, palmar erythema, spider angiomata, edema, parotid gland enlargement, gynecomastia, and testicular atrophy)	30–60
Jaundice	55
Fever	50
Upper gastrointestinal bleeding	30
Hepatic encephalopathy	20

TABLE 114-3 Frequency of Clinical Findings in Alcoholic Hepatitis

In alcoholic hepatitis there is ballooning degeneration, focal hepatocyte necrosis, and a neutrophilic inflammatory infiltrate. The latter two are considered absolute criteria for the diagnosis of alcoholic hepatitis. More than 30% of patients develop alcoholic hyaline (i.e., Mallory bodies, aggregates of perinuclear, eosinophilic, amorphous material that are composed of intermediate filaments). Although highly suggestive of ALD, hyaline is also seen in many other liver diseases (Table 114-4). Other pathological findings in alcoholic hepatitis include steatosis and fibrosis or cirrhosis. [139], [147] On a case-by-case basis, it is difficult to distinguish alcoholic hepatitis from NASH on biopsy; however, periportal fibrosis, bile duct proliferation, and cirrhosis are more frequently seen in alcoholic steatohepatitis. Pericellular and perisinusoidal fibrosis are seen in both alcoholic steatohepatitis and NASH and give rise to a characteristic “chicken-wire” appearance, and perivenular sclerosis leads to deposition of a collar of collagen in the wall of the central vein. [148], [149], [150] and [151] Clinically, patients with alcoholic hepatitis are much sicker than those with NASH. In a few cases of alcoholic hepatitis, there is sclerosing hyaline necrosis (i.e., severe, irregular, confluent, centrilobular necrosis with obliteration of the central vein by collagen). [151] Some type of venoocclusive lesions are commonly seen in patients with alcoholic hepatitis and alcoholic liver cirrhosis. [152] Ninety-three percent of 15 patients with severe alcoholic hepatitis and 87% of 15 patients with alcoholic cirrhosis exhibited mild focal stenosis to severe stenosis or obstruction. Severe venoocclusive lesions were associated with recalcitrant ascites and variceal bleeding, and portended a high mortality.

Alcoholic cirrhosis (especially with continued drinking)*
Steatohepatitis
Alcoholic steatohepatitis*
Nonalcoholic steatohepatitis*
Chronic hepatitis C
Parenteral nutrition-induced liver disease
Drug-induced liver disease (e.g., griseofulvin, nifedipine, nicardipine, didanosine, diethylstilbestrol, tamoxifen, tetracycline, valproic acid, vitamin A, diltiazem, glucocorticoids, methotrexate, or amiodarone)
Chronic cholestatic disorders
Primary biliary cirrhosis*
Primary sclerosing cholangitis
Chronic biliary obstruction
Extrahepatic biliary atresia
Copper overload conditions
Wilson disease*
Indian childhood cirrhosis*
Congenital hepatic fibrosis
Copper-associated liver disease of childhood
Hepatocellular neoplasms/masses
Hepatocellular carcinoma
Hepatic adenoma
Dysplastic hepatocellular nodule
Focal nodular hyperplasia
Adenomatous hyperplasia
Weber-Christian disease
Inherited diseases of metabolism:
Abetalipoproteinemia
Alpha$_1$-antitrypsin deficiency
Glycogen storage disease, type IV*
Bloom syndrome
Postinfantile giant cell hepatitis
Juvenile Parkinson's disease

*Indicates that Mallory bodies are found occasionally to commonly; in the other conditions, they are rare. For more information, see ref. 221.

TABLE 114-4 Differential Diagnosis of Liver Diseases Exhibiting Mallory's Hyaline

Alcoholic Cirrhosis

Alcoholic cirrhosis may be asymptomatic in 10% to 20% of patients but commonly presents with the complications of chronic liver disease and the usual stigmata. The stigmata related to hypogonadism and feminization, such as spider nevi, are most prominent in patients with ALD and hereditary hemochromatosis. Complications of alcoholic cirrhosis include cachexia, coagulopathy, anasarca, spontaneous bacterial peritonitis, hepatorenal syndrome, hepatic encephalopathy, hepatocellular carcinoma, and gastrointestinal bleeding from esophageal and gastric varices. Other less frequent causes of bleeding are ectopic varices and portal hypertensive gastropathy.

The liver test abnormalities in alcoholic cirrhosis are less pronounced than those in alcoholic hepatitis. In fact, in compensated cirrhosis, many of the liver tests are nearly normal. Laboratory abnormalities may include mild increases in AST, ALT, and AP, depression of serum albumin, polyclonal elevation of serum globulins (greater than 4 g/dL), prolongation of PT, leukopenia, thrombocytopenia, and anemia. In fact, thrombocytopenia is an excellent clue to the presence of large varices (and therefore cirrhosis) in patients evaluated for abnormal liver tests. [153] Hypersplenism by itself rarely leads to platelet counts lower than 40,000/µL and splenectomy or splenic embolization is almost never indicated.

The pathological end-stage of ALD is of course cirrhosis, characterized by fibrous bands connecting portal triads with central veins, and by regenerative nodules. The nodules are typically small (1–3 mm) and uniform in size. [147] Although fibrosis may be reversible, regression is impossible when significant nodular regeneration occurs. Ethanol is known to suppress hepatic regeneration; [154] thus, with prolonged abstinence, nodular regeneration becomes more vigorous and may result in mixed micro/macronodular or macronodular cirrhosis. Superimposed fatty change and alcoholic hepatitis are often seen with cirrhosis. There may also be increased stainable iron in biopsy samples. Iron overload in alcoholic cirrhosis can be differentiated from hereditary hemochromatosis by genetic analysis for *HFE* mutations or by quantitative iron analysis. In hereditary hemochromatosis, the hepatic iron index (hepatic iron content expressed as µmol/g dry weight divided by the patient's age) in the cirrhotic liver is more than 1.9 while that in the cirrhotic liver of alcoholics is less than 1.9. In some patients with alcoholic cirrhosis, there is portal inflammation with piecemeal necrosis. This feature may reflect an autoimmune component of ALD, unsuspected Wilson disease (particularly in young patients), or most commonly, coexistent chronic viral hepatitis (particularly HCV infection).

DIFFERENTIAL DIAGNOSIS

There are numerous pitfalls in the diagnosis of ALD, among them failing to consider ALD in patients not fitting the stereotype of the skid-row alcoholic (such individuals account for only a minority of alcoholics), and assuming that abnormal liver tests in an alcoholic patient are due to ALD. It should be noted that more than 50% of patients with alcohol abuse develop liver disease because of HCV or HBV infection. Alcoholism should be considered in any patient with liver disease, and a careful drinking history should be obtained from the patient and a reliable third party such as a family member. The history should be augmented by the simple CAGE questionnaire. [155], [156] The CAGE test employs the following questions: Have you felt the need to *Cut down* on drinking? Are you *Annoyed* by references to your drinking? Do you feel *Guilty* about your drinking? Do you ever need an *Eye-opener* (i.e., do you drink in the morning to relieve withdrawal symptoms)? The phrase "eye-opener" is no longer widely used, and the concept usually needs to be explained to the patient. A positive response to two or more of these questions, however, strongly suggests alcohol abuse and should prompt a more thorough history investigating consequences of alcohol use. These include problems with the law, loss of jobs, family disruption, and injury while drinking, as well as the better known medical complications such as withdrawal syndromes. The central feature of alcoholism is that drinking takes precedence over other activities in the patient's life. The sensitivity of the CAGE test for alcohol abuse is 70% to 96%, the specificity is 91% to 99%, and the positive predictive value is about 80%. The history should also include an estimate of the grams of ethanol consumed daily and the duration of drinking.

A liver biopsy is necessary to differentiate fatty liver, alcoholic hepatitis, and cirrhosis reliably and to distinguish ALD from other causes of liver disease. Since more than 50% of patients with presumed ALD are infected with HCV or HBV, these infections must be excluded in any alcoholic. Prior to the discovery of HCV, it was reported that up to 20% of liver biopsies done on alcoholic patients showed nonalcoholic (and sometimes treatable) liver diseases. This percentage is likely lower now, but the biopsy continues to provide information about the presence of fibrosis and cirrhosis that cannot otherwise be obtained. Appropriate blood tests and biopsy should be performed to exclude nonalcoholic causes of liver disease and to define the severity of disease. However, tense ascites, severe thrombocytopenia (<80,000/µL) or prolonged PT (INR >1.4), may preclude percutaneous needle biopsy. A safer but more expensive alternative is a transjugular liver biopsy.

Alcoholic Fatty Liver

As outlined in Table 114-5, fatty liver can result from many processes, and of course the patient may have more than one cause. When one encounters massive hepatomegaly (the liver span exceeds 13 cm in the midclavicular line), the differential diagnosis includes fatty liver, right heart failure, constrictive pericarditis, Budd-Chiari syndrome, infiltrative processes (e.g., amyloidosis, myeloproliferative disorders, reticuloendotheliosis, and lipid storage diseases), and neoplasms. In evaluating the cause of hepatomegaly, a helical CT scan with dual contrast and arterial/venous phases should be performed to exclude neoplasms, as this is more sensitive in detecting focal hepatic masses than either CT scan done only in the venous phase, ultrasound, or sulfur colloid scan.

Macrovesicular fat
Alcoholic steatohepatitis
Nonalcoholic steatohepatitis
Hepatitis C
Toxins and drugs: methotrexate, halogenated hydrocarbons, niacin, HIV protease inhibitors, glucocorticoids, heavy alcohol use
Nutritional disorders: obesity, diabetes, choline deficiency, systemic carnitine deficiency, celiac disease, kwashiorkor, parenteral nutrition
Inherited metabolic disorders:
Lipodystrophy
Wilson disease
Abetalipoproteinemia
Inflammatory bowel disease
Weber-Christian disease
Q fever
Microvesicular fat*
Reye syndrome
Parenteral alimentation
Yellow fever
Heat stroke
Alpers disease
Toxins and drugs: valproic acid, intravenous tetracycline, toxic shock syndromes, salicylate overdosage in children, Jamaican vomiting disease, FIAU, nucleoside reverse transcriptase inhibitors, mycotoxins
Metabolic diseases: cholesterol ester storage disease, galactosemia, Wolman disease, long chain 3-hydroxyacyl-CoA dehydrogenase deficiency, medium chain acyl-CoA deficiency
Complications of pregnancy: acute fatty liver of pregnancy, eclampsia, HELLP syndrome

CoA, coenzyme A; FIAU, fialuridine; HELLP, hemolysis, elevated liver enzymes, and low platelet syndrome; HIV, human immunodeficiency virus.

*Microvesicular fatty liver is usually the result of mitochondrial damage and defects in lipid oxidation pathways; however, there is significant overlap with many disorders occasionally producing microvesicular fatty liver. See ref. 221 for a more detailed discussion.

TABLE 114-5 Differential Diagnosis of Fatty Liver

Alcoholic Hepatitis

The distinctive histological appearance of alcoholic hepatitis usually establishes the diagnosis. However, NASH can mimic it. Clinically, patients with alcoholic steatohepatitis are usually much sicker than those with NASH. In one study, [147] patients with NASH had a mean AST:ALT of 0.9 (range 0.3–2.8) and patients with alcoholic hepatitis had a mean ratio of 2.6 (range 1.1–11.2). Thus, the AST:ALT ratio is a useful but not foolproof parameter to distinguish NASH from ALD. Since fever, leukocytosis, right upper quadrant pain, jaundice, and cholestasis can occur in alcoholic hepatitis, and patients with cirrhosis have an increased risk of cholelithiasis, imaging of the liver and biliary tree by ultrasound or CT may be necessary to exclude extrahepatic cholestasis. These noninvasive tests are more specific (85%–100%) than sensitive (50%–95%) in detecting extrahepatic biliary obstruction. Therefore, magnetic resonance cholangiography (which depends on a strong T2 signal from stationary fluid and thus cannot be done in the presence of ascites), endoscopic retrograde cholangiopancreatography (ERCP), or percutaneous transhepatic cholangiography (PTC) may be required to exclude obstruction.

Alcoholic Cirrhosis

Alcoholic cirrhosis is usually micronodular but it can be macronodular. Thus, the differential diagnosis of alcoholic cirrhosis includes posthepatitic cirrhosis (whether due to chronic viral infection, drugs, metabolic disorders, or autoimmune hepatitis), the cirrhotic stage of primary or secondary biliary cirrhosis, Wilson disease, hemochromatosis, and cirrhosis caused by NASH. As with NASH, the degree of fatty infiltration of the liver may decrease as cirrhosis develops. These diagnoses require a careful history of drug use (including herbs and over the counter medications) and exposure to hepatitis viruses. They also require tests for hepatitis B surface antigen, hepatitis C antibody, autoantibodies (antinuclear, anti-DNA, antimitochondrial, and anti-smooth muscle antibodies), serum ceruloplasmin, a1-antitrypsin level, copper and iron studies, and the measurement of the metal content of the liver biopsy. Alcoholic cirrhosis with features of chronic active hepatitis may reflect superimposed hepatitis B or C or an autoimmune process incited by alcoholic injury. Disease processes that mimic cirrhosis (e.g., constrictive pericarditis, Budd-Chiari syndrome, venoocclusive disease, idiopathic portal hypertension, portal vein thrombosis, and myeloid metaplasia) should be considered.

Special Considerations

HCV and ALD Soon after the introduction of serologic tests for HCV antibodies, it became apparent that HCV infection was common among alcoholics with liver disease (which would previously have been considered “pure” ALD). The prevalence of HCV markers in alcoholic patients without liver disease ranges from 0 to 14%; in alcoholic patients as a whole (with and without liver disease) the prevalence ranges from 11% to 35%; and in alcoholic patients with chronic liver disease the prevalence ranges from 18% to as high as 51%. [157], [158] This increased prevalence may reflect an increased likelihood of experimenting with injection drugs among alcoholics, but other factors cannot be excluded. The liver injury caused by alcohol plus HCV is more than additive—likely it is synergistic—in promoting the progression of fibrosis and the incidence of hepatocellular carcinoma. [159] Alcohol abuse may increase HCV viral load, [159] but this is controversial. [160] Alcohol use is believed to lead to a significant decrease in response of HCV to interferon therapy. [161] The mechanism for this interaction remains poorly understood but has been attributed to ethanol’s effect on hepatic iron content, hepatic regeneration, impairment of the immune system, and activation of stellate cells. It has been reported that alcoholic patients exhibited significantly greater quasispecies complexity than nonalcoholic controls. It has been suggested that the higher quasispecies complexity in alcoholic patients explains the poor response to interferon therapy. [162]

Hepatic Iron Stores and ALD Excessive deposition of iron in the liver is seen in at least one third of alcoholic patients. The mechanisms involved in this phenomenon remain largely unknown. [163] It is widely believed that iron overload can lead to hepatic damage in ALD and hereditary hemochromatosis by facilitating generation of reactive oxygen species, as ferrous iron can transfer electrons to oxygen, or catalyze the formation of hydroxyl radical from hydrogen peroxide. As a reflection of this, protein adducts with MDA or 4-HNE were much more prominent in ALD and hemochromatosis than in other forms of liver disease. [164] The protein-adducts were found predominantly in zone 3 in ALD and in zone 1 in patients with hemochromatosis. The role of HFE (the product of the gene that is mutated in hemochromatosis) mutations in ALD with iron overload has been investigated by groups in Japan and the United Kingdom. In Japanese, in whom the HFE C282Y and H63D mutations are uncommon, alcoholic patients still develop iron overload, and those with iron overload do not carry the mutations. [165] The British study [166] included 257 patients with ALD and 117 matched healthy volunteers. About 15% of fibrotic/cirrhotic patients were C282Y heterozygotes compared with approximately 14% of controls. Of the patients without the C282Y mutation, 15% carried the H63D mutation as compared with 17% of the controls. Thus, the cause of iron overload in ALD is unrelated to the mutations causing hemochromatosis.

COURSE AND COMPLICATIONS

Alcoholic Fatty Liver

Alcoholic fatty liver is thought to be benign unless accompanied by perivenular fibrosis or foamy degeneration. Patients with these conditions have a high risk of developing hepatic failure or cirrhosis. However, in animals, fatty livers are highly susceptible to toxicity from LPS, and it is well known that donor livers that are fatty may fail when transplanted; thus, fatty liver may be less benign than previously thought. Furthermore, obesity is a risk factor for the development of cirrhosis. Treatment includes abstinence from alcohol and correction of nutritional deficits. Bed rest has no proven value. Under this regimen, fatty liver should be expected to regress in 3 to 6 weeks.

Alcoholic Hepatitis

The early mortality rates for alcoholic hepatitis vary from 19% to 78% (mean 49%) within 2 months. In the subset of patients with severe disease and spontaneous hepatic encephalopathy, the early mortality rate was higher (59%). Not surprisingly, the worst prognosis has been observed in patients with severe jaundice, encephalopathy, renal failure, ascites, and variceal bleeding. [167], [168] Several laboratory tests are prognostic indicators: PT of more than 4 seconds above control despite vitamin K treatment, total bilirubin greater than 5 mg/dL, and serum creatinine that increases more than 0.6 mg/dL during the first 10 days of hospitalization. The severity of fibrosis or cirrhosis found on liver biopsy is also a prognostic indicator (i.e., with little fibrosis, the 5-year survival was 72% but with severe fibrosis, it was less than 50%). However, many patients are too ill for conventional liver biopsy. Patients with alcoholic hepatitis who continue to drink have a very high risk of persistent hepatitis or progression to cirrhosis, and a 5-year survival of only 50%. Among those able to stop drinking, 70% reverted to normal, and the remainder either had persistent alcoholic hepatitis or cirrhosis. As expected, their mortality rate decreased to 24%. Unfortunately, it appears that women are less likely to have a complete recovery from an attack of alcoholic hepatitis. [13]

For the planning of therapy, it is of value to stratify patients with alcoholic hepatitis according to severity and prognosis. Several scoring systems have been evaluated, including the Child-Turcot-Pugh system, the combined clinical laboratory index of the University of Toronto, [167] and Maddrey discriminant function, [169] for their ability to predict 30-day mortality of patients with alcoholic hepatitis. The simple Maddrey discriminant function (4.6 × [PT (sec) - control] + bilirubin (mg/dL)) exhibits the highest predictive value. A discriminant function of more than 32 predicted a less than 50% 30-day survival. The test suffers from the fact that it was developed and validated before the standardization of the PT as the INR. The presence of hepatic encephalopathy is also a poor prognostic indicator.

Alcoholic Cirrhosis

The prognosis of alcoholic cirrhosis depends upon drinking history, the presence of alcoholic hepatitis, and the severity of the disease. [170], [171], [172] and [173] Older literature (pre-liver transplant) indicated that the 5-year survival was nearly 85% for abstainers without jaundice, ascites, or gastrointestinal bleeding. Continued drinking lowered survival to 60%. The presence of jaundice or ascites reduced the survival to 50% in abstainers and to 30% in drinkers. Gastrointestinal bleeding carried the worst prognosis, with a 5-year survival of 35% in abstainers and 20% in drinkers. Therefore, it is prudent to urge complete abstinence for patients with any form of ALD. There are many therapies for cirrhotic patients that have become established since these data were analyzed (preventive treatment for varices and spontaneous bacterial peritonitis, endoscopic and transjugular intrahepatic porto-systemic shunt (TIPSS) treatment for varices, screening for hepatocellular carcinoma). However, for many of these therapies it has been difficult to demonstrate improvement in long-term survival.

Complications of Alcoholism and ALD

Metabolic Disorders The interaction between induced activity of CYP2E1 in alcoholics and acetaminophen is clinically very important. [174] Although therapeutic doses of acetaminophen are harmless when consumed by alcohol-naive individuals, in alcoholics such doses can produce serious liver disease with extremely high aminotransferase levels, massive perivenular hepatic necrosis, pancreatitis, and renal failure. Thus, heavy drinkers should be warned to avoid acetaminophen, and in

particular to read medication labels of over-the-counter medications to be sure they do not inadvertently consume more than 2 g per day. On the other hand, small doses of acetaminophen are safer in cirrhotic patients than nonsteroidal antiinflammatory drugs (NSAIDs), which have adverse effects on platelet and renal function. Cyclooxygensae-2 (COX-2) inhibitors have less effect on platelet function than traditional NSAIDS, but probably offer no benefit with regard to the risk of renal complications. Two problems unique to alcoholic patients are alcoholic ketoacidosis and hypoglycemia. Oxidation of ethanol is coupled to the production of NADH. The high NADH concentration inhibits fatty acid oxidation in the mitochondria. Alcoholics who are fasting while drinking heavily exhibit very high free fatty acid levels, low insulin levels, and high levels of glucagon and catecholamines. When they reduce their drinking (e.g., as a result of intercurrent illness), fatty acid oxidation is unrestrained, and there is accelerated ketogenesis with the concentration of ß-hydroxybutyrate (not detected by urine dipsticks) characteristically exceeding that of acetoacetate. [175] By administering glucose and fluids to these patients, insulin levels rise, lipolysis is curtailed, and the ketosis abates. The high NADH concentration also favors the formation of reduced metabolites (e.g., conversion of pyruvate to lactate, and dihydroxyacetone-phosphate to L-glycerol-3-phosphate). Increased lactate formation results in mild hyperlacticemia and contributes to hyperuricemia due to impaired renal excretion of urate. The reduction in pyruvate and dihydroxyacetone phosphate concentrations, two major carbon sources for glucose synthesis, inhibits gluconeogenesis, and may result in hypoglycemia. Alcoholic hypoglycemia occurs during fasting, when blood glucose levels are maintained by gluconeogenesis. [176] Hypoglycemic cerebral symptoms may be confused with alcohol intoxication. Alcoholic hypoglycemia is also readily reversible by administration of fluids and glucose, and subsequent resumption of eating. Most patients are phosphate- and magnesium-deficient as well and need to have these electrolytes replaced.

Infections Alcoholics are more prone to infections than other liver patients as a result of malnutrition, impaired phagocyte function and other immune defects, [177] and impaired sensorium (with its risk of aspiration). The most severe infections may be heralded by only a deterioration in mental status, hypotension, acute renal failure with features of prerenal azotemia or hepatorenal syndrome, or nonspecific symptoms, and frequently are not accompanied by fever. Bacteremia and spontaneous bacterial peritonitis (SBP) are common in cirrhotics. Other infections include pneumonia and lung abscess, bacterial meningitis, and urinary tract infections. [178] Patients with cirrhosis are also at increased risk of sepsis from opportunistic fungal infections, *Listeria monocytogenes,* or vibrios (especially *Vibrio vulnificus* when they consume raw seafood such as oysters [179]). Patients with possible infections should have a chest radiograph, urinalysis, surveillance blood cultures, and perhaps lumbar puncture. A sample of ascites, if present, should be analyzed for serum ascites-albumin gradient, cell count, differential, and cultured in blood culture bottles at the bedside. An absolute neutrophil count over 250/µL indicates infection. [180] Direct inoculation of ascitic fluid into blood culture bottles at the bedside substantially improves the chances of culturing an organism, as the concentration of bacteria in the fluid is quite low. [181] The presence of *Bacteroides* species or multiple organisms strongly suggests the possibility of a perforated viscus. Metaanalysis of many studies now supports the prophylactic use of antibiotics active against gram-negative rods for all cirrhotics with gastrointestinal bleeding, whether variceal or not. [182], [183], [184] and [185]

Altered Neurological Status It is difficult to evaluate sick, intoxicated alcoholic patients. The major differential diagnoses are stroke; head trauma; chronic or acute subdural hematoma; meningitis; hypoglycemia; hyponatremia; postictal state; drug, ethylene glycol, or methanol ingestion; Wernicke-Korsakoff syndrome; hepatic encephalopathy; and alcohol or drug withdrawal syndromes. [186] In most patients with impaired consciousness, a noncontrasted head CT will be performed early to exclude hematomas, tumor, and other mass lesions. Head CT is highly desirable before performing lumbar puncture, unless the clinical suspicion of meningitis is high, in which case lumbar puncture should be done promptly and antibacterial therapy initiated. Alcoholic patients often abuse drugs other than alcohol and they may ingest toxic substances by mistake. Depressant drugs, including narcotics, and phenothiazines can be detected by rapid blood and urine tests. Methanol or ethylene glycol poisoning is suggested by an anion gap metabolic acidosis (often with an osmolar gap) in the absence of ketosis. Because the requirement for thiamine is increased by carbohydrate, alcoholic patients should be given thiamine upon admission to the hospital before receiving dextrose solutions. Supplementation of other water-soluble vitamins, especially pyridoxine and folate, is advisable. Vitamin K should be given if the PT is prolonged. Hepatic encephalopathy may be difficult to diagnose. [187] Generally, there is physical evidence of chronic liver disease. The presence of fetor hepaticus (the odor of methionine catabolites) is distinctive, but not a sensitive diagnostic test. Venous or arterial blood levels of ammonia are usually elevated. Asterixis is an indicator of metabolic encephalopathy but is not specific or sensitive, and it disappears with deep coma. An electroencephalogram may help to distinguish hepatic encephalopathy from alcohol withdrawal. When hepatic encephalopathy is diagnosed, a careful search must be made for the factors that precipitated it (e.g., gastrointestinal bleeding; electrolyte and acid-base imbalance; high protein intake; severe constipation; noncompliance with medications; drug use, including acetaminophen, sedatives, and narcotic analgesics; infection; renal failure; and hepatoma). The use of centrally acting sedating drugs does not cause hepatic encephalopathy; rather the patients appear to have increased sensitivity to the sedating effects. Drug therapy of patients with liver disease must take into consideration alterations of pharmacodynamics and pharmacokinetics, [188], [189] as outlined in Table 114-6.

INCREASED DRUG METABOLISM	INCREASED DRUG/ CHEMICAL TOXICITY	INCREASED DRUG TOLERANCE
Pentobarbital	Acetaminophen	Anesthetics
Meprobamate	Vitamin A	Barbiturates
Warfarin	Isoniazid	Meprobamate
Tolbutamide (and other sulfonylureas)	Phenylbutazone	Benzodiazepines
Phenytoin	Halothane	
Cocaine	Enflurane	
Rifampin	Carbon tetrachloride	
Aminopyrine	Benzene	
Methadone	Nitrosamines	
	Cocaine	
INCREASED PHARMACODYNAMIC EFFECT		**ANTABUSE-LIKE REACTIONS**
H_1 antihistamines		Tolbutamide
Barbiturates		Metronidazole
Benzodiazepines		Griseofulvin
Chloral hydrate		Quinacrine
Meprobamate		Pargyline
Narcotics		Reserpine
Phenothiazines		Phenylbutazone
Phenytoin		Moxalactam, and several other second- and third-generation cephalosporins

TABLE 114-6 Interactions Between Chronic Alcohol Abuse and Drug Actions and Metabolism

Renal Dysfunction Patients with ALD may have renal dysfunction at the time of admission, or more likely, it may develop during hospitalization. If the patient has advanced, chronic liver disease with tense ascites or has been treated vigorously with diuretics, the hepatorenal syndrome (HRS) should be considered, [190] but other causes of renal failure should be excluded. Urine studies will allow one to distinguish acute tubular necrosis from either prerenal azotemia or hepatorenal syndrome. Typically in the latter, the urine sodium is low (<10 mEq/L), the fractional excretion of sodium (FE_{Na}) is less than 1%, the urine:serum creatinine ratio is over 30, and the urine osmolality is high (urine osmolality more than 100 mOsm/L greater than serum osmolality), with no proteinuria or casts, and an acellular urinary sediment. In order to distinguish prerenal azotemia (intravascular volume depletion) from HRS, careful physical examination and monitoring of chest radiographs must be employed as one judiciously infuses crystalloid and colloid. Ultimately, measurement of pulmonary artery pressure might be needed to ensure that the intravascular volume is adequately expanded. Other potentially reversible renal disease must also be considered (e.g., urinary tract obstruction, a drug side effect, radiocontrast-induced nephropathy, sepsis, rhabdomyolysis, hepatitis B- or C-associated cryoglobulinemia, and toxicity from inhalants such as toluene). The therapy for suspected HRS should include paracentesis, careful crystalloid and colloid administration, and continuous venovenous hemofiltration (preferred over hemodialysis). Ultimately orthotopic liver transplantation is the only definitive therapy for HRS and end-stage liver disease. Peritoneovenous shunts have not been shown to improve survival in HRS, [191] and have fallen out of favor because of the high rate of shunt occlusion. The role of TIPSS in the treatment of HRS is being assessed, [192], [193] but is not likely beneficial. The use of liver support systems is experimental.

Worsening Liver Disease Alcoholic patients may have historical or physical findings that suggest that previously diagnosed liver disease has worsened. Of course, it cannot be assumed that the abnormalities are all due to alcohol abuse. The patient may have superimposed viral hepatitis, drug toxicity, hepatoma, or biliary obstruction (up to 30% of patients with ALD have gallstones, usually bilirubin pigment stones [194]). The patient should be closely questioned about ingestion of drugs, toxins, herbal medications and OTC medicines, and exposure to viruses (e.g., by sexual contact, blood and blood product transfusions, or intravenous or nasal drug use). The physical examination should be directed toward finding new evidence of congestive heart failure or pericardial constriction, changes in liver size, abnormal masses, hepatic bruits, visible or palpable gallbladder, abdominal tenderness, Murphy's sign, and so on. Hepatomegaly suggests fat, tumor, mass, or infiltrative lesions, but is also common in uncomplicated cirrhosis. The liver tests may help with the diagnosis (transient high transaminases with abdominal pain suggests passage of a common duct stone; very high transaminases and new jaundice suggests a drug toxicity such as acetaminophen or viral hepatitis), and lead to evaluation for parenchymal liver diseases (hepatitis serology, autoimmune markers, markers of iron and copper overload). Predominant elevation of the alkaline phosphatases indicates cholestasis, but does not differentiate intrahepatic from extrahepatic causes. Radiologic imaging by CT or ultrasound should be performed to look for dilated ducts or intrahepatic masses. Magnetic resonance cholangiograms are usually not useful in patients with end-stage liver disease because ascites interferes with this imaging method. Masses usually require radiologically guided biopsy, but alternatively, selective intraarterial injection of an oily contrast material known as lipiodol may provide the diagnosis of malignancy. If the ducts are dilated, a cholangiogram should be obtained to find the site and possibly the cause of the obstruction. If the patient has symptoms suggestive of intermittent obstruction (attacks of pain or symptoms of biliary infection) but no dilation of the ducts, a cholangiogram should also be performed. If neither biliary obstruction nor masses are present, primary biliary cirrhosis and infiltrative diseases should be considered and the liver should be biopsied.

TREATMENT

The treatment of ALD should be divided into treatment of the underlying alcoholism, and measures to address the three major stages of ALD. The latter includes attempts to prevent or slow fibrosis, to control the inflammation of alcoholic hepatitis, and finally the treatment of complications that are common to other forms of end-stage liver disease.

Treatment of Alcoholism

The success of therapies for alcohol abuse varies from 30% to 90%. Results are improved when the abuse is detected at an early stage when the patient still has support from family and employers. Patients are first detoxified, usually as outpatients, then enter a phase of maintenance of sobriety. Current methods for monitoring alcohol consumption in patients who are under treatment are not satisfactory, despite the availability of the carbohydrate-deficient transferrin (CDT) test for well over a decade. [195], [196] and [197] This form of transferrin lacks the normal number of sialic acid moieties due to effects of ethanol on its posttranslation modification in the Golgi apparatus, and on its rate of removal from the plasma. Abstinence is sought through cognitive therapy and behavior modification counseling, augmented by pharmacological therapy. There is evidence from animal and clinical studies that opioid antagonists can improve the results of alcoholism treatment, and naltrexone has been approved for use in treatment of alcoholism, in conjunction with behavioral or psychological therapy. Additional medications to reduce craving, such as acamprosate and ondansetron, have shown promise in clinical trials. For most patients, optimal success will entail a combination of behavior modification, regular involvement in support groups such as Alcoholics Anonymous, and pharmacological therapy. Co-morbid psychiatric problems such as depression also need to be addressed. Alcohol abuse and its treatment are discussed in more detail in Chapter 55.

Treatment of ALD

McCullough and colleagues [198] have published a set of practice guidelines on the management of ALD. They summarized that treatment remains limited to the following:

- abstinence is crucial in the therapy for ALD
- there is general consensus to use corticosteroids to treat only those patients with severe alcoholic hepatitis
- there is good scientific basis to maintain good nutritional status at all stages of ALD
- liver transplantation should be considered in chronic ALD
- management of complications of chronic liver disease (e.g., ascites, portal hypertension-associated bleeding, hepatic encephalopathy, and hepatocellular carcinoma) is the same as for other causes of cirrhosis.

Alcoholic fatty liver responds well to abstinence and is not thought to cause lasting sequelae, thus it will not be discussed further. In addition to the therapies discussed in the following paragraphs, patients should be vaccinated against hepatitis A and B to prevent the often disastrous consequences of hepatitis superimposed on ALD, and should receive the polyvalent pneumococcal vaccine.

Alcoholic Hepatitis

Cessation of alcohol drinking is paramount in the treatment of alcoholic hepatitis, and is best accomplished by the usual measures discussed previously. Protein-calorie malnutrition is a common finding in patients with ALD. [142] In the VA Cooperative Study on Alcoholic Hepatitis, more than 75% of patients with severe liver disease exhibited signs of kwashiorkor, marasmus or both and malnutrition worsened the prognosis of alcoholic hepatitis. Several small controlled trials have tested the effect of enteral or parenteral amino acid therapy in alcoholic hepatitis. [199], [200], [201] and [202] These trials have shown faster improvement in serum bilirubin, serum albumin, and ascites, and no deterioration in hepatic encephalopathy in the patients provided amino acids. Only one of the controlled trials has demonstrated improved mortality rate, but most have been limited in this regard by insufficient statistical power. Certainly, most patients with alcoholic hepatitis are malnourished and this should be addressed either enterally or parenterally. [203] For these patients, the “routine” prescription for a 2-g sodium, 40- to 60-g protein diet is inappropriate. Although marketed aggressively, amino acid mixtures enriched in branched-chain amino acids are recommended only for patients who have not responded to conventional nutritional therapy. [204]

Corticosteroids modulate the immune system (including the production of the cytokines involved in liver injury) and inhibit the activation of HSC and fibrogenesis. The use of corticosteroids (prednisone, prednisolone, or 5-methylprednisolone in the dose range of 35 to 80 mg/d for 4 to 6 weeks) in the treatment of alcoholic hepatitis has been extensively studied in numerous randomized control trials and several metaanalyses. [205], [206], [207], [208] and [209] They demonstrated that:

1. Only patients with hepatic encephalopathy or Maddrey score of more than 32 should be treated.
2. Treatment should exclude patients with gastrointestinal bleeding, active infection, renal failure, or acute pancreatitis. The problem of unrecognized infection, or infection that occurs during the course of therapy, is of major concern.
3. Corticosteroids will reduce mortality risk by 25%.
4. One has to treat seven patients in order to avoid one death.

Overall, it appears that corticosteroid therapy benefits some patients with severe alcoholic hepatitis in the absence of contraindications, but this still remains controversial.

A randomized controlled trial [210] compared the therapeutic efficacies of corticosteroid therapy (40 mg/d) versus enteral nutrition (2000 kcal/d). Outcomes were assessed at 28 days (the end of therapy) and 1 year later or until death. Sixty-two percent of patients treated by enteral nutrition and 39% of patients treated with corticosteroids were alive at the end of 1-year follow-up. The difference was not statistically significant. Mortality during the 28 days of therapy occurred earlier with enteral nutrition but mortality beyond the first 28 days was higher with corticosteroid therapy, largely due to infections. Perhaps by deploying both therapies in combination the respective shortfalls of corticosteroid and enteral nutrition therapies can be offset.

Anabolic-androgenic steroids such as oxandrolone have been tested in an attempt to enhance recovery (i.e., to increase the removal of hepatic fat, to stimulate protein synthesis, and to accelerate cell repair and hepatic regeneration). Oxandrolone was tested in a VA cooperative study in a 30-day trial in patients with moderate to severe alcoholic hepatitis. Oxandrolone appeared to be most beneficial in patients with moderate malnutrition, particularly in those who ingested sufficient calories during the trial. [211] This emphasizes the importance of attention to the patients’ nutrition and the difficulty of performing such studies. Oxandrolone has not been widely used despite this trial; additional data on subsets of patients who will benefit most would probably increase physicians’ interest in this drug.

Propylthiouracil (PTU) has been used to treat alcoholic hepatitis, possibly by decreasing the hypermetabolic state induced by alcohol and protecting perivenous cells from hypoxic injury. [212], [213] It also inhibits neutrophil myeloperoxidase and may thereby reduce oxidative stress from hypochlorous acid made in the neutrophils. In one study, PTU improved symptoms and laboratory tests; [214] but in another series of more severely ill patients, PTU was not effective. [215] In the largest controlled trial, 310 patients with ALD were randomized to either PTU or placebo and followed for up to 2 years. PTU therapy resulted in a cumulative mortality rate that was half that of the placebo group among moderately ill patients, and in a subgroup of severely ill patients. [216] Thus, PTU therapy may benefit patients with moderate to severe alcoholic hepatitis. Other inhibitors that block myeloperoxidase but do not interfere with thyroxine production may ultimately be of value. Pentoxifylline has been reported to improve outcomes in alcoholic hepatitis, in particular it reduced the frequency of HRS. [217] The absolute risk reduction of HRS in this trial was an impressive 40%. This may be due to inhibition of the actions of TNFa and other cytokines and chemokines.

Alcoholic Cirrhosis

Alcoholic cirrhosis has been treated with corticosteroids without effect on survival. Colchicine (1 mg/d, 5 d/wk) improved survival in one study with a 14-year follow-up. [218] Oddly, much of the mortality in the placebo-treated group was not due to liver disease. The actions of colchicine are being studied further in an ongoing VA cooperative study.

Several other agents including polyunsaturated lecithin and S-adenosylmethionine (SAM) are being tested in multicenter trials. Lieber [219] has reviewed the actions of

polyunsaturated lecithin in the treatment of liver fibrosis and determined:

- it protects alcohol-fed baboons against alcohol-induced fibrosis and cirrhosis and prevented the depletion of hepatic dilinoleoylphosphatidylcholine
- it attenuates the transformation of HSCs into myofibroblasts
- it augments the defenses against oxidative stress, reduces the levels of CYPE21, and normalizes 4-HNE, F2-isoprostanes (an index of lipid peroxidation), and glutathione (GSH) levels
- it stimulates collagenase production in HSCs, thereby decreasing collagen accumulation in the liver.

A randomized double-blind multicenter trial that includes 800 patients with ALD with or without HCV infection is still ongoing.

SAM administration has been shown to be useful in experimental animals by replenishing this transmethylating agent, enhancing the synthesis of polyamines, and providing cysteine for glutathione synthesis. [220] The results of a large clinical trial were recently published. [221] SAM may reduce mortality or need for transplantation in cirrhosis, especially in those with less advanced liver disease. Future therapies may be suggested based on the mechanisms of injury discussed previously. These include better antioxidants, inhibitors of CYP2E1, inhibitors of NF-?B activation or of eicosanoid production by Kupffer cells, antagonists or antibodies against PDGF, TNFa, and TGFß, and inhibitors of apoptosis in hepatocytes.

Patients with advanced (Child's B or C) alcoholic cirrhosis can be treated by liver transplantation provided that they do not have other alcohol-related co-morbid disorders, they have undergone intensive outpatient treatment and rehabilitation, and have at least a 6-month period of documented abstinence. [222], [223] and [224] It has been of interest to use the CDT to test for abstinence in this population. However, CDT has only recently been evaluated in patients before and after liver transplantation. [225] Elevated CDT was found in a number of abstinent patients who had long-term, solid evidence of abstinence proven by negative biochemical short-term tests and negative psychological evaluations. After liver transplantation, patients with both ALD and non-ALD had significantly lower CDT values than before transplantation. The results suggest that CDT is not useful in evaluating patients before transplantation but may be useful in posttransplant settings.

Guidelines for treatment for alcoholism prior to transplantation vary from center to center, but the 2-year survival of carefully selected patients compares quite well with those transplanted for other indications. Additionally, the quality of life of these transplanted patients is excellent with many patients returning to part-time or full-time employment. The rates of return to drinking after transplantation vary between 10% to 30% depending on candidate selection process and criteria for relapse. ALD now accounts for approximately 25% of adult liver transplantations in the United States.

CHAPTER 115

Oliver F. W. James

NONALCOHOLIC FATTY LIVER DISEASE

As Maher has stated “NASH [nonalcoholic steatohepatitis] has become a household word in hepatology.” [1] The clinical and pathological features of nonalcoholic fatty liver disease have been recognized for 40 years. [2], [3] It was not until 1980 however that Ludwig and colleagues coined the term *nonalcoholic steatohepatitis (NASH)* to describe “the pathological and clinical features of non-alcoholic disease of the liver associated with the pathological features commonly seen in alcoholic liver disease itself.” [4] While the acronym NASH has been useful in drawing attention to this important liver disease the term *steatohepatitis* excluded the appearance of fat alone in the liver, yet pure fatty liver is part of the spectrum of nonalcoholic fatty liver disease as a whole and pure fatty liver is probably the precursor of steatohepatitis and fibrosis. [5] In 1999 McCullough and colleagues coined the term *nonalcoholic fatty liver disease (NAFLD)* to describe the whole spectrum of disease from simple fat through steatohepatitis and fibrosis to cirrhosis. This account refers to the whole spectrum of this disease as NAFLD and confines the term NASH to steatohepatitis with or without fibrosis or cirrhosis.

It is becoming clear that NAFLD is an important part of the insulin resistance, obesity, hyperlipidemia, hypertension, constellation known as syndrome X (the metabolic syndrome) and like the other features is rapidly becoming more common in overnourished, underexercised Western society. [6]

EPIDEMIOLOGY

There are no epidemiologic studies of the exact incidence or prevalence of NASH but there are a number of clues from several countries that suggest that it is becoming one of the commonest liver diseases in Western countries. In a study of Canadian office hepatology practices NASH was the second most common liver disease encountered (after hepatitis C). [7] In N-HANES-3 (USA) cryptogenic elevation in serum ALT [alanine aminotransferase] was seen in 2.6% of the population after exclusion of other possible causes. This was independently associated with increased waist: hip ratio and indices of insulin resistance (summarized in ref. [6]). In an ultrasound-based study in northern Italy 75% of obese individuals were found to have fatty liver; furthermore, 16% of nonobese, nonheavy drinking (by Italian standards) individuals were also found to have fatty liver on ultrasound. [8] While significant obesity and type 2 diabetes are becoming more common in adults, possibly more importantly, this is also occurring alarmingly in children. For example, in children in the United Kingdom between 1984 and 1994, obesity more than doubled. Almost 20% of Scottish girls between 9 and 11 were overweight in 1994, twice the prevalence of 10 years earlier. [9]

How many individuals who have fatty liver alone will go on to develop steatohepatitis and what proportion of these may develop cirrhosis is still quite unclear, but it may be a significant proportion.

PATHOGENESIS

Since fatty liver appears to be a necessary but not sufficient condition for the subsequent development of steatohepatitis and fibrosis, it has been suggested that the development of fatty liver is the first hit in a “two-hit” model of the pathogenesis of NASH. [10] Over 50% of obese individuals have fatty liver, and the more obese the more likely the fatty liver. Furthermore, central obesity is more closely related to fatty liver. [11] It is suggested that free fatty acids (FFAs) are mobilized more readily from visceral than from subcutaneous fat and visceral fat drains this increased load of FFAs directly into the liver, thus supplying increased hepatic triglyceride. [12]

Insulin Resistance and NAFLD

As well as increased delivery of FFA to the liver, insulin resistance appears to be necessary for the development of fatty liver. Of 46 NALFD (diagnosed by ultrasound), nondiabetic individuals, Marchesini and colleagues [13] found that 100% all had insulin resistance.

In careful studies, Sanyal and colleagues [14] used a two-step hyperinsulinemia euglycemic clamp to examine insulin resistance in patients with NASH, those with fatty liver alone, and controls. Patients with known diabetes or with cirrhosis were excluded. Both patients with NASH and fatty liver demonstrated insulin resistance. Using steady state enrichment of [6,6- $_2$H] glucose hepatic output was assessed before and during clamping by measuring differences between total enrichment and glucose infusion rate. This showed marked suppression of hepatic glucose output in both fatty liver and NASH subjects during insulin infusion. The Sanyal group thus demonstrated hepatic as well as peripheral insulin resistance. [14] Combined peripheral and hepatic insulin resistance in both pure fatty liver subjects and patients with NASH was confirmed by Marchesini and colleagues, [15] who found glucose disposal in patients with NAFLD was similar to well-controlled type 2 diabetics. Interestingly, among the NAFLD patients there was no difference in glucose disposal between patients with body mass index (BMI) less than 25 kg/m ^{2} and those with BMI over 25 kg/m ^{2}. This again points to the necessity of insulin resistance rather than mere generalized obesity in the pathogenesis of nonalcoholic fatty liver.

Development of Steatohepatitis

Two main pathways have been implicated in the development of steatohepatitis—these are oxidative stress caused by lipid peroxidation and release of reactive oxygen species (ROS) on the one hand, and the release of the endotoxin-cytokine proinflammatory cascade on the other. As we will see the two are by no means mutually exclusive and FFAs are important in both. FFAs are endogenous ligands for peroxisomal proliferator activated receptors a (PPARa) and ? (PPAR?). The severity of NASH has been shown to correlate with levels of serum FFAs (KD Lindor, personal communication, October 2000). Because as we have seen there may be hepatic as well as peripheral insulin resistance there is not only an increased supply of FFAs to the liver but increased mitochondrial ß-oxidation which itself generates reactive oxygen species.

Oxidative Stress In mammalian cells peroxisomes oxidize long chain and very long chain FFAs. Mice lacking the gene encoding fatty acyl-coenzyme A oxidase (AOX), the initial enzyme of the inducible peroxisomal ß-oxidation system, developed severe microvesicular NASH [16]— suggesting that an excess of long chain and very long chain acyl-coenzymes A (CoAs) can lead to the lesion. In contrast AOX -/-mice which also lack PPARa develop only mild steatosis suggesting first that the

long chain and very long chain acyl-CoAs can function as endogenous PPARa ligand and second that PPARa-induced genes must play a part in development of steatonecrosis/hepatitis. [17] PPARa regulates the transcription of some CYP450 enzymes involved in long chain FFA oxidation, including AOX and CYP4A family members. This metabolism via these extra mitochondrial pathways generates ROS—either hydrogen peroxide in the case of peroxisomal ß-oxidation or superoxide in the case of CYP4A catalyzed w-oxidation. Metabolism of long chain FFA by CYP4A also generates dicarboxylic fatty acids that are toxic to mitochondria leading to apoptosis and necrosis. [18] In the lipid-rich methionine-choline deficient (MCD) diet in the mouse, expression of two major CYP4A proteins (4A10 and 4A14) is greatly increased, hence, potentially increasing the generation of dicarboxylic fatty acids toxic to mitochondria and increasing apoptosis and necrosis. [19] Just as ethanol induces CYP2E1 so fatty acids are both substrate for and inducers of CYP2E1, and CYP2E1 activity is induced in diabetes. Microsomal CYP2E1 is an important microsomal catalyst of lipid peroxidation in the MCD mouse model and in patients with NASH. Studies have demonstrated marked induction of hepatic CYP2E1 correlated with measures of lipid peroxidation. [20], [21]

Endotoxin Cytokine-Mediated Injury

The human “model” of accelerated NASH provided by the series of patients given jejunoileal bypass (JIB) surgery for obesity was the initial clue to a second putative mechanism for steatonecrosis. [22] This “blind loop” provided an ideal source of bacterial endotoxin to be absorbed into the already fatty liver. Interestingly, early studies showed that this could be prevented or reversed in some patients by the antibiotic metronidazole. [22] A few patients have been described with bacterial contamination of the small bowel associated with NASH and it has been suggested that up to 50% of patients with NASH may have small intestinal bacterial overgrowth and raised serum tumor necrosis factor-a (TNFa); [23] these observations, however, need to be confirmed. In the mouse model it has been demonstrated that obesity increases sensitivity to endotoxin-induced liver injury and that there are altered hepatic lymphocyte subpopulations in obesity-related murine fatty liver. [24], [25] In addition FFAs are ligands for PPARa and these ligands inhibit macrophage function.

Fibrosis

Oxidative stress and the proinflammatory cascade lead to necroinflammation but independently excess fat has been shown to activate stellate cells leading to fibrosis. The greater the degree of fatty change in human fatty liver biopsies, the greater the number of activated stellate cells. [26] Since hypertension (part of the metabolic syndrome) is probably associated with NAFLD the finding that angiotensin II enhanced the production of transforming growth factor-ß1 (TGF-ß1) which contributes to stellate cell activation offers another putative mechanism for enhanced fibrosis. [27], [28] Very recently, leptin resistance, associated with insulin resistance, has also been implicated in fibrogenesis (AASLD Consensus, Atlanta, Sept. 2002).

In summary, the pathogenesis of NASH is complex. It offers obvious parallels with the pathogenesis of alcoholic steatohepatitis. In NASH insulin resistance and increased supply of FFA appear to be essential. The varying roles of oxidative stress, the endotoxin cytokine-mediated proinflammatory response and, more specifically, fibrotic stimuli probably determine which individuals develop NASH/cirrhosis and which merely retain a fatty liver.

Genetic Determinants

The mechanisms described for the development of NASH give clear indications of where we should look for genetic determinants both of the development of fatty liver and of NASH although these will be extraordinarily complex. Familial tendency to NASH and insulin resistance is now being described. [29] What is known, or rather what is not known, has been summarized by Day and Daly. [30] It has been shown that over-expression of the enzyme 11ß-hydroxysteroid dehydrogenase type 1 (11ß-HSD-1), which controls glucocorticoid activation in adipose tissue, leads to a phenotype of central obesity—at least in the mouse. [31] This may offer an important clue to the causation of central obesity in humans and hence, if variations of expression of 11ß-HSD-1 are confirmed, a clue to genetic susceptibility to NASH. This is speculative but indicative of current research thinking.

CLINICAL MANIFESTATIONS

Most patients with NASH have few symptoms or signs suggestive of chronic liver disease. Because case series are heterogeneous in their derivation—some being derived from groups of obese individuals for example—it is difficult to give precise figures. However, up to 30% of patients complain of persistent fatigue and lethargy, up to 30% have persistent right upper abdominal discomfort in the absence of gallstones, and probably about 50% of all patients are asymptomatic. Older series suggested that over 75% of patients were female and markedly obese but more recently the proportion of men reported with NAFLD or NASH has increased, many without marked obesity. [32] It is clear that increasing levels of obesity are, not surprisingly, accompanied by increasing likelihood of more severe histological change. Clinical examination is almost always unremarkable. The liver may be palpable but there are no other signs to suggest liver disease until the complications of cirrhosis develop. The most important features of examination of a patient with putative NAFLD are to measure patients’ weight and height—hence BMI and, if practiced, measure waist:hip ratio as an assessment of central obesity.

History

Paramount in history taking for NASH is careful documentation of alcohol consumption, including events in the medical or social history of the patient that might suggest previous heavy alcohol use. A history or the presence of other diseases associated with the metabolic syndrome—type 2 diabetes (noninsulin-dependent diabetes mellitus, NIDDM), hyperlipidemia, and hypertension should be recorded. A history of previous obesity and its duration, together with recurrent weight-reducing diets may also be important.

Although NAFLD has thus far only been discussed in the context of the metabolic syndrome, there are a number of other important rare potential causes of NAFLD (Table 115-1).

Surgical procedures for obesity
Jejunoileal bypass (JIB)
Gastroplasy
Biliopancreatic diversion
Surgery leading to major weight loss
e.g., massive intestinal resection
Total parenteral nutrition (adults)
more likely after intestinal resection
Weight cycling/bulimia
Bacterial contamination of small bowel
e.g., Jejunal diverticula
Medications
Amiodarone
Perhexiline
(Coralgil)
?? Calcium channel blockers
Tamoxifen
Environmental
? Dimethylformamide
? Toxic oil syndrome
Syndromes of severe insulin resistance
Lipodystrophies (complete or partial)
Insulin receptor mutations

TABLE 115-1 Causal Associations With Nonalcoholic Steatohepatitis

Previous Weight-Reducing Surgery Ten percent or more of patients undergoing JIB developed steatohepatitis, liver fibrosis, and, not infrequently, hepatocellular failure or the complications of cirrhosis—usually within 1 or 2 years but occasionally many years postoperatively. [33] More modern weight reduction surgery—for example gastroplasty—is now the surgical treatment of choice for morbid obesity. NASH has been shown to be present in up to a one fourth of these patients at surgery, although very severe deterioration or complications postoperatively are now much rarer than with JIB. [34]
Weight Cycling Occasionally individuals have been described who have made rapid weight reduction with “crash diets” only to regain weight again. At least one patient died of hepatic decompensation and cirrhosis in these circumstances. [35]
Total Parenteral Nutrition Total parenteral nutrition (TPN), particularly following small bowel resection, is followed by NASH in perhaps 15% of adult patients.

Occasionally this leads to cirrhosis. Presumably this may be related to weight loss with associated increased delivery of FFAs, possibly accompanied by small bowel bacterial contamination leading to release of endotoxin-TNFa, but this is speculative. [36]

Drugs A number of drugs have been implicated in the development of NASH. All of these reactions are rare and associated with other manifestations of drug hepatotoxicity. The most well re- cognized of these among currently used drugs is with amiodarone where “pseudo-alcoholic” liver disease has been detected in up to 1% patients receiving amiodorone, almost all taking the drug for over a year. This was in addition to more familiar iodine deposition and phospholipidosis. [37] More recently the estrogen-receptor ligand tamoxifen has been implicated in the development of not only fatty liver but NASH as well. However, a number of the reports of this apparent association have been among obese women so that the relationship between tamoxifen and true NASH is still rather unclear (summarized in ref. [20]). A recent report from Brazil suggests a relationship between exposure at work to petrochemicals in the environment and development of NASH; in some of these individuals liver function and histology improved following removal from the environment. [38] In general, however, the relationship between industrial or environmental exposure to, for example, petrochemicals, and development of NASH, is highly speculative.

Familial Lipodystrophy Severe insulin resistance is present in patients with complete or partial lipodystrophy. A number of these individuals, including some children, develop steatohepatitis with Mallory bodies and liver cell degeneration. [39] Very rare insulin receptor mutations are also associated with steatohepatitis.

Ethanol While it is vital to emphasize exclusion of excessive alcohol ingestion when making the diagnosis of NAFLD the relationship between ethanol consumption and NAFLD is interesting. While “excess” ethanol ingestion is almost certainly synergistic with other risk factors for fatty liver and steatohepatitis—obesity and insulin resistance—the exact meaning of “excess” is still unclear. Certainly, excess weight is perceived as a risk factor for the development of severe alcoholic liver disease. [40] Dixon and colleagues, however, have suggested that mild (probably less than 20 g/d) ethanol consumption among obese individuals reduced the risk of development of NASH, possibly by increasing insulin sensitivity but this is highly speculative. [27] It is recommended that patients with NASH, or steatohepatitis in which obesity/insulin resistance and higher ethanol consumption may each contribute to the liver disease should consume less than 20 g (2 U) ethanol/d.

DIAGNOSIS

The diagnosis of NAFLD/NASH is based upon the demonstration of a fatty liver ± steatohepatitis and fibrosis, rigorous exclusion of significant ethanol consumption, and exclusion of other conditions in which fatty liver can occur—for example hepatitis C. Patients with NAFLD often present with “cryptogenic” persistent elevation of ALT.

Laboratory

The standard range of liver function tests and other blood tests used in assessment of patients with liver disease are employed in evaluation of patients with possible NASH. There are a few features of these tests that help to distinguish NASH from ALD although none is really specific. These are shown in Table 115-2A. In mild NASH the aspartate aminotransferase:alanine aminotransferase (AST:ALT) ratio is often less than 1 whereas in alcoholic liver disease the reverse is true. In more severe NASH however AST is often higher than ALT. Note that ?-glutamyltranspeptidase (?GT) is elevated in both NASH and alcoholic liver disease. Very few patients with NASH have elevated red cell mean corpuscular volume (MCV) whereas macrocytosis is a common indicator of excess alcohol consumption.

TEST	NAFLD	ALCOHOLIC
AST/ALT	Often <1 (if mild)	>1
Bili	Normal	May be ↑ or ↑↑
Alk Phos	Usually normal until late	May be ↑
Albumin	Normal until late	Often ↓ or ↓↓
PT	Normal until late	Often ↑ or ↑↑
Gamma GT	↑	↑ or ↑↑
MCV*	Normal	↑ or ↑↑
Blood ethanol	Absent	Often present
Lipids	May be ↑ or ↑↑	May be ↑ or ↑↑
Ferritin	May be ↑ (slight)	May be ↑ or ↑↑

Alk Phos, alkaline phosphate; AST/ALT, aspartate aminotransferase/alanine aminotransferase; GT, glutamyl transpeptidase; MCV, mean corpuscular volume.

*Personal look back has shown 0/35 nonalcoholic steatohepatitis (NASH) patients with raised MCV. Ratziu et al.[42] had raised MCV in 0/93 NAFLD patients.

TABLE 115-2A Nonalcoholic Fatty Liver Disease (NAFLD) Laboratory Investigations

Other liver diseases are excluded by conventional means (see Table 115-2B). The presence of anti-hepatitis C virus (HCV) excludes a diagnosis of NASH alone. While the appearance of fatty liver in patients with genotype 3HCV may be virally induced, fatty liver and HCV may coexist in other genotypes and should not be regarded as mutually exclusive. Fat on biopsy in patients with HCV suggests the possibility of accelerated progression of fibrosis in these individuals. [41] An autoimmune profile should be checked although a few NASH patients have been described with low titers of anti-smooth muscle antibody by Bacon and colleagues [42] and Teli and colleagues. [43] The subject of iron markers is slightly confused since some groups believe that excess liver iron may be one of the factors promoting liver inflammation and fibrosis, through oxidative stress, in patients who have fatty change. [44] While some patients with NASH do have slightly raised serum ferritin this is probably a reflection of inflammatory change in the liver rather than of increased iron stores in most cases. HFE genotype now allows definitive diagnosis or exclusion of hemochromatosis where any doubt exists.

HBV and HCV markers	Negative[†]
Iron saturation	Normal and *HFE* gene wild type
Autoimmune profile	Normal[*]

HBV, hepatitis B virus; HCV, hepatitis C virus.

*Note a few NAFLD patients described with low titer smooth muscle antibody.

†Note HCV and NAFLD may coexist.

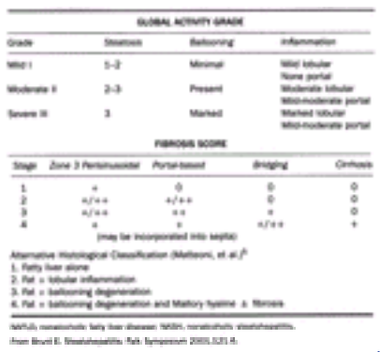
TABLE 115-2B Nonalcoholic Fatty Liver Disease (NAFLD) Laboratory Investigation: Exclusions

Liver Imaging

The most inexpensive, quickest, and probably still the most effective mode of liver imaging in patients with suspected fatty liver is with ultrasound. This confirms the presence of fat. Importantly, while ultrasound can demonstrate the likelihood of cirrhosis by gross changes in liver outline and signs of portal hypertension, liver fibrosis and steatosis can have similar sonographic appearances which can be indistinguishable. [45] Thus NASH cannot be “staged” by ultrasound or any other imaging modality. Small areas of focal fat within the liver should not be regarded as suggestive of NASH.

Liver Biopsy

Liver biopsy is essential to determine the presence and severity of steatohepatitis and extent of fibrosis-cirrhosis, and to give the best idea of likely prognosis. [46] It is also mandatory for the conduct of good clinical trials. Histopathologists may argue about the grading and staging of liver disease, but the suggestion of Brunt and colleagues to provide a global activity grade and a fibrosis stage seems sensible and its reproducibility appears reliable (AD Burt, personal communication, April 2002). This system, or something like it will probably be widely adopted [47] (Table 115-3). As implied in the original definition of NASH by Ludwig and colleagues, [4] there are really no distinguishing histological features between alcoholic and nonalcoholic steatohepatitis.



GLOBAL ACTIVITY GRADE			
Grade	Steatosis	Ballooning	Inflammation
Mild I	1–2	Minimal	Mild lobular None portal
Moderate II	2–3	Present	Moderate lobular Mild-moderate portal
Severe III	3	Marked	Marked lobular Mild-moderate portal

FIBROSIS SCORE				
Stage	Zone 3 Perisinusoidal	Portal-based	Bridging	Cirrhosis
1	+	0	0	0
2	+/++	+/++	0	0
3	+/++	++	+	0
4	+	+	+/++	+

(may be incorporated into septa)

Alternative Histological Classification (Matteoni, et al.)[3]
1. Fatty liver alone
2. Fat + lobular inflammation
3. Fat + ballooning degeneration
4. Fat + ballooning degeneration and Mallory hyaline ± fibrosis

NAFLD, nonalcoholic fatty liver disease; NASH, nonalcoholic steatohepatitis.
From Brunt E. Nonalcoholic fatty liver disease. NASH. nonalcoholic steatohepatitis.

TABLE 115-3 Histology: Grading and Staging NASH/NAFLD

In the context of a younger patient with no overt clinical liver disease, with ultrasound appearances diagnostic of fatty liver and persistent isolated elevation of ALT, it may be argued that outside the setting of a clinical trial liver biopsy is unnecessary. In view of lessons from the natural history of the disease (discussed subsequently) this author's current recommendation would be that unless there are clinical indications to the contrary, liver biopsy is unnecessary under the age of 40 to confirm a diagnosis of NASH. Under the age of 40, biopsy is unlikely to yield important prognostic information. In view of lessons from the natural history and of the inability of ultrasound to distinguish fat from inflammation/fibrosis, the author's present practice is to recommend liver biopsy in all patients over age 50 for information on grading and staging, which will inform physician and patient of prognosis.

COURSE AND COMPLICATIONS

Our knowledge of the natural history of NASH was, until a few years ago, based upon case series (summarized in ref. [48]). Three large cross-sectional studies and one quasi-longitudinal study, however, have allowed us to begin to understand the natural of history of NASH in adults. Pediatric NASH, the most common cause of abnormal liver function tests (LFTs) in adolescents, is outside the scope of this chapter. A cross-sectional study from the Mayo Clinic examined 144 patients in whom liver biopsy had been carried out and a diagnosis of NAFLD had been made after conventional exclusions of other liver disease. The diseases the patients had ranged from simple fatty liver to severe cirrhosis. A range of clinical and laboratory parameters were examined as predictors of severity of histological change. In these patients age was the most significant predictor of degree of fibrosis ($p < 0.001$). Only 4% of patients under age 45 (1 individual) had marked fibrosis, no nonobese, nondiabetic patient under age 45 had severe fibrosis. [49] Ratziu and colleagues [50] examined 93 obese patients with abnormal LFTs who had received liver biopsy and were found to have varying degrees of NAFLD. They found that age over 50 correlated independently with septal fibrosis (odds ratio 14:1 age over 50 vs. age under 50). They also found that if BMI was less than 30, age less than 50, and ALT elevated less than twofold then no patient had septal fibrosis or cirrhosis. They did find that 10 patients (12%) had cirrhosis on biopsy that had not been clinically evident in any way. In a series of 105 consecutive very obese (BMI > 35 kg/m ^{2}) patients having laparoscopic gastric banding, mean age 41, mean BMI 47 kg/m ^{2}, many of whom had normal LFTs, Dixon and associates [27] found 19% had steatohepatitis, 10 had advanced fibrosis, 1 had cirrhosis. Seventy-five individuals had steatosis ± nonspecific inflammation alone. The mean age of this group was 41. Of importance, the presence of NASH correlated with the presence of hypertension and measures of central obesity most closely. The longitudinal study from the Cleveland Clinic underlined the importance of the presence or absence of NIDDM. Whereas 25% of 44 patients with diabetes in this series developed cirrhosis (with a mean follow up of 9 years) only 10% of 88 patients without type 2 diabetes had cirrhosis on an initial biopsy or developed it at follow-up. [5]

At the "fat alone" end of the NAFLD spectrum Teli and colleagues [43] followed up 40 patients with simple fatty liver, most around the age of 40, in whom alcohol had been rigorously excluded. None developed significant clinical liver disease over an 11-year follow-up. In the Cleveland Clinic study only one patient out of 25 (4%) with simple fatty change went on to develop cirrhosis. Thus, simple fat with no evidence of necroinflammation, ballooning degeneration, or fibrosis, appears to have an excellent prognosis particularly in younger individuals, and for at least 10 years.

Cryptogenic Cirrhosis

At the other end of the spectrum of NAFLD there is now increasing intriguing evidence that NASH may be the most common precursor of cryptogenic cirrhosis. Two studies have shown that 70% of patients with cryptogenic cirrhosis, mean age just over 60, had one or more of the following: previous obesity, NIDDM, or hyperlipidemia, and may well, therefore, have had "burnt-out" NASH. This was in contrast to around 30% of patients of comparative age with other forms of cirrhosis. [51], [52] The reasons why most patients with cryptogenic cirrhosis do not demonstrate much fat in the liver may be because of the undernutrition of cirrhosis and because of portosystemic shunting of lipids "avoiding" delivery to the liver in the portal blood. To add some support to this concept, it is now reported that following transplantation for cryptogenic cirrhosis, a proportion of individuals, most with returning obesity or with NIDDM, developed fatty liver and classic histological features of NASH (J Ong, personal communication, Nov. 2000). The clinical course of patients with cryptogenic cirrhosis associated with obesity has been compared with that of HCV-related cirrhosis. [53] In this study patients with cryptogenic cirrhosis all over age 60, severe (Child-Tureot-Pugh grade B and C) cirrhosis was as frequent in cryptogenic as in HCV patients and survival of these cryptogenic obese patients was lower than in untreated age- and sex-matched HCV cirrhotic "controls" at 30 months ($p < 0.02$). Finally, hepatocellular cancer (HCC) was detected in 8 out of 27 (27%) of these patients. A second study has confirmed the relationship between cryptogenic cirrhosis, associated with previous features of the metabolic syndrome and development of HCC. [54] Median age for development of HCC was around 70 years.

We can now see a picture of the natural history of NAFLD (Fig. 115-1) in which obese individuals or those with insulin resistance develop fatty liver. At some stage over age 40, presumably particularly in individuals with genetic susceptibility, factors promoting oxidative stress, the proinflammatory cascade, and fibrosis are brought to bear and in this unknown proportion of initially "fat-alone" patients progressive liver disease develops. It appears that in patients with absolutely no histological features of necroinflammation, ballooning degeneration, or fibrosis, the prognosis is good—presumably these individuals have "good" genes and are less susceptible to insult by oxidative stress and so forth. At the other end of the spectrum, once cirrhosis has developed a proportion of patients lose the glycogen vacuoles and are left with "burnt-out" cirrhosis, typically around age 60. A proportion of these patients subsequently go on to develop HCC—like most other cirrhotic conditions.

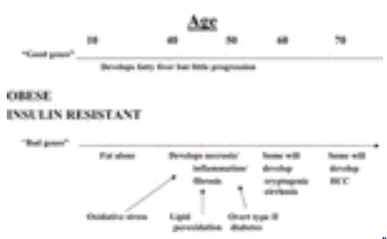


FIGURE 115-1. The fatty liver continuum.

TREATMENT

This consideration of treatment will focus on "classic" NAFLD associated with insulin resistance and obesity. Clearly, where there is an association between NASH and a rare causative factor, such as a medication, then treatment will be aimed at removing the underlying precipitating putative cause. Although the clinical course of NAFLD is variable and, at present, unpredictable, treatment should be aimed at stopping disease progression, certainly preventing development of cirrhosis, and if possible, returning hepatic architecture to normal. [55] Almost no biopsy- confirmed controlled trials of treatment for NAFLD have been reported.

We may consider treatment in two parts—reversal of the underlying metabolic defects—hence reduction of hepatic fat and reversal of insulin resistance, and intervention against such "attack" mechanisms as oxidative stress, proinflammatory cascade, and fibrosis itself.

Weight Loss and Exercise

There is probably nothing more difficult than long-term change of an individuals lifestyle; nonetheless, a number of uncontrolled pilot studies or case reports have suggested that weight reduction, restricted animal fat diet, and exercise do improve or normalize LFTs in patients with NASH. [56], [57] A number of control trials with liver biopsies are currently underway in respect of lifestyle modification.

In view of the importance of insulin resistance in genesis of fatty liver, drugs that improve insulin sensitivity are obvious candidates for use in treatments of NASH. Metformin reverses fatty liver disease in obese, leptin-deficient mice. [58] A pilot study of metformin in 20 patients with NASH showed reduction in transaminases (returning to normal values in half) and reduction in liver volume over 4 months. [59] Interestingly, the Ob/Ob grossly obese mice developed gross hepatic steatosis and steatohepatitis but not fibrosis suggesting that leptin may modulate development of fibrosis. The thiazolidinedione troglitazone was subjected to a pilot study in NASH treatment with liver biopsies before its withdrawal for other toxic side effects. Interestingly, there was little improvement in steatohepatitis. [60] Other PPAR? ligands (other thiazolidinediones) significantly increased severity of steatosis in diabetic mice. [61] Nonetheless, the use of newer thiazolidinediones may prove effective not only for their role in improving insulin resistance but because they may also reduce central obesity. [31]

Lipid lowering agents have been the subjects of pilot studies. In one of the very few control trials in which before and after biopsies were carried out, Laurin and colleagues [62] found no benefit either to LFTs or liver biopsies after 1-year treatment with clofibrate. A short pilot study of gemfibrozil showed improvement in LFTs but no biopsy evidence. [63]

Antiinflammatory/Antifibrotic

Because of its possible membrane-stabilizing and cytoprotective effects ursodeoxycholic acid (UDCA) was also subjected to a pilot, biopsy-proven, control trial evaluation. [62] There were improvements in LFTs but little real improvement was seen in liver biopsies. This treatment is now subject to a larger multicenter control trial whose results are awaited.

A variety of putative antioxidants—betaine, N-acetyl-cysteine (NAC), vitamin E, and silymarin have all been or are currently under pilot assessment (summarized in ref. [55]).

Because of the possibility that there is hypertension-associated increased angiotensin II activity leading to TGFß1 stimulation of stellate cells, and hence fibrosis in patients with NASH, a trial of angiotensin-converting enzyme inhibitors (e.g., captopril), conceivably in conjunction with one or more of the other treatments outlined previously, might be reasonable.

One can summarize by saying there is no proven treatment for NAFLD/NASH. End-stage cirrhosis is, of course, treated as for all other chronic liver disease. In individual patients outside the context of a controlled trial, gradual weight loss, return to an American Heart Association recommended dietary balance, modest regular exercise, and possibly an antioxidant would seem sensible. In those with frank NIDDM, metformin may be the treatment of choice if there are no other contraindications. In patients with known hyperlipidemia, treatment with a statin would seem reasonable. The results of control trials throughout the world are awaited eagerly.

CHAPTER 116

Michel Mendler, John Donovan, and Andres Blei

CENTRAL NERVOUS SYSTEM AND PULMONARY COMPLICATIONS OF END-STAGE LIVER DISEASES

Portal hypertension, after a critical level of portal pressure is reached, results in portal-to-systemic shunting of splanchnic blood. Substances present in portal blood gain access to the systemic circulation as the consequence of both portosystemic shunting and an impaired metabolism by the cirrhotic liver. An imbalance of humoral mediators is implicated in the pathogenesis of complications of cirrhosis and portal hypertension. Among these pathologies are hepatic encephalopathy, hepatopulmonary syndrome, and portopulmonary hypertension. These complications of the portal hypertensive state and, as discussed elsewhere, variceal bleeding, ascites, and hepatorenal syndrome represent the major manifestations of end-stage liver disease.

Hepatic encephalopathy, hepatopulmonary syndrome, and portopulmonary hypertension can be the cause of significant morbidity and poor quality of life. In patients with cirrhosis and portal hypertension, medical therapies may often attenuate the severity of symptoms associated with each of these conditions but are not considered curative. Liver transplantation, if not otherwise contraindicated, may be indicated as the treatment of choice in the selected patient.

HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy (HE) is a multifaceted neuropsychiatric syndrome observed in the setting of hepatic insufficiency or portosystemic shunting. Central nervous system (CNS) abnormalities in patients with liver failure were recognized by Hippocrates (quoted in refs. [1] and 237): “those who are mad on account of phlegm are quiet, but those on account of bile are vociferous, vicious, and do not keep quiet.” A graphic description of what is recognized today as HE was made by Frerichs in the late 19th century. [3], [4] The first assessment of HE in the era of modern medicine was made by Sherlock in 1954. [5] The onset of HE is a sign of poor prognosis both in acute or chronic liver disease. The diagnosis of HE relies on clinical indices in most instances, made in the setting of a confusional syndrome in a patient with liver failure or portosystemic shunting. *Minimal hepatic encephalopathy* (MHE) is a more recent concept of unrecognized, subtle abnormalities diagnosed by neuropsychiatric testing and identified by sophisticated imaging modalities. Multiple definitions and grading schemes for HE have been proposed, leading to confusion among clinicians when staging HE and to difficult interpretation of clinical data by researchers. In an attempt to remedy this lack of consensus, a team of experts recently elaborated guidelines for the nomenclature of HE and the performance of clinical trials. [6] The pathophysiology of HE is still incompletely understood. A clear requisite is the decreased hepatic clearance of potential neurotoxins, especially ammonia; as a result, neurotransmission abnormalities arise in the brain. Astrocyte swelling may also have an important pathogenic role. The factors involved in HE fluctuate over time, especially in the setting of cirrhosis; thus, it is common to observe precipitating factors and rapid regression of symptoms after treatment. Acute HE in the setting of acute hepatic failure (AHF), however, signals a grave prognosis requiring liver transplantation in selected cases.

Definition

HE can be defined by the presence of a wide range of neuropsychiatric disturbances secondary to either chronic liver disease (cirrhosis) or acute injury (fulminant hepatic failure [FHF]), or in a patient with either intrahepatic or extrahepatic portosystemic shunting (congenital, acquired, or iatrogenic). *Portosystemic encephalopathy* is the preferred term of some authors. HE is a diagnosis of exclusion with multiple differential diagnoses: metabolic encephalopathies, intracranial structural disorders, psychosis, Wernicke encephalopathy, drug- or toxin-induced alterations of mental status, seizure disorders, infectious diseases of the CNS. A clinical episode of HE can be overt and often easily diagnosed. HE can also be subclinical (MHE). Finally, HE can be episodic or persistent (Table 116-1).

A: Encephalopathy associated with acute liver failure.
B: Encephalopathy associated with Portosystemic bypass and no intrinsic liver disease.
C: Encephalopathy associated with cirrhosis and portal hypertension

1. *Episodic*
   a. Precipitated
   b. Spontaneous
   c. Recurrent
2. *Persistent*
   a. Mild
   b. Severe
   c. Treatment dependent
3. Minimal (formerly subclinical)

TABLE 116-1 Classification of Hepatic Encephalopathy

Pathophysiology

The pathophysiology of HE is complex and still incompletely understood despite extensive research in animal models and in humans. [7], [8], [9], [10], [11], [12] and [13] The mechanisms involve neurochemical alterations and changes in the functional status of cerebral neurotransmitter systems. Permanent structural disorders of the brain are not present. The pathogenic models developed to date attempt to explain the functional nature of HE, its reversible nature, and its precipitation by a host of clinical factors (see later). Current views support a role for multiple mechanisms participating together to different degrees in the production of neurological symptoms. The following is a summary of current hypotheses.

Role of Gut-Derived Neurotoxins The principal toxin implicated is ammonia. In the absence of liver disease, about 40% of ammonia is derived by colonic bacteria acting on lumenal contents; 60% is produced from catabolism of dietary protein, metabolism of glutamine, and deamination and transamination pathways of amino acids. Constant low levels of circulating ammonia are maintained by the production of urea (liver) and the production of glutamine from glutamate by glutamine synthetase (liver, muscle, and brain). In the brain, only astrocytes contain glutamine synthetase. In patients with cirrhosis or acute liver failure, reduction in hepatocellular function is thought to explain the observed elevations of blood ammonia. Portosystemic shunting increases ammonia levels by bypassing hepatic

metabolism. The deleterious effect of ammonia cannot be construed from the venous or arterial levels, which correlate poorly with symptoms of HE. The facilitated passage of ammonia across the blood–brain barrier (BBB) complicates the interpretation of blood levels. [14], [15] In animal models, coma stages of HE are achieved at brain ammonia concentrations of 1 to 5 mmol/L, as compared with normal blood levels of 0.05 to 0.1 mmol/L. The neurotoxicity of ammonia involves multiple mechanisms leading to the development of Alzheimer type II astrocytosis, regarded as the cardinal pathological CNS change associated with HE. These cells are recognized by their large pale nuclei, prominent nucleoli, abundant mitochondria, rough endoplasmic reticulum, and cytoplasmic vacuolation. [16] At low levels, ammonia suppresses inhibitory postsynaptic potential formation and depolarizes neurons. At high concentrations, ammonia increases the resting membrane potential and inhibits axonal conductance and excitatory postsynaptic potential formation, thereby depressing CNS function. These abnormalities involve the inhibition of cellular chloride channels by ammonia. Other mechanisms whereby ammonia may play a role in HE include a reduction in brain glucose and oxygen consumption, an increase in brain glutamine, a rise in serotonin by increased cerebral tryptophan uptake, and an alteration in glutamatergic neurotransmission [10] (Table 116-2). Oral therapies for HE, such as lactulose or antibiotics that lower gut-derived ammonia, support the ammonia hypothesis. However, the lack of a strong correlation between arterial levels and the severity of HE, along with the paradoxic excitatory effects of ammonia on the CNS in contrast to the state of neurodepression observed in HE, suggests that ammonia is not the sole player in HE. Other neurotoxins may act synergistically with ammonia. Methanethiol, a mercaptan derived by gut bacterial metabolism, may exert adverse effects on neuronal function by synergism with ammonia and short-chain fatty acids. [17] Decreased elimination of phenols derived from bacterial metabolism of tyrosine and phenylalanine in the gut may also act synergistically with ammonia.

TABLE 116-2 Changes in Brain and Cerebrospinal Fluid (CSF) Metabolites in Ammonia-Precipitated Encephalopathy in Chronic Liver Disease

Role of Altered Neurotransmitters Alteration in excitatory (glutamatergic-mediated) and inhibitory (?-aminobutyric acid [GABA]-mediated) neurotransmitters may underlie the pathogenesis of HE. In recent years, the GABA-ergic neurotransmission hypothesis received considerable attention. This hypothesis involves the interplay of GABA, so-called endogenous or natural benzodiazepines (BZ), and the diazepam-binding receptor. Normally, GABA acts as the primary inhibitory CNS neurotransmitter, counterbalancing excitatory glutamatergic tone by binding to $GABA_A$ receptors, triggering increased chloride currents into the neuron and neuroinhibition by hyperpolarization of the postsynaptic membrane. In animal models of HE, visual-evoked responses typical of HE can be induced by drugs that potentiate GABA-mediated neurotransmission, drugs that normally induce seizures by decreasing GABA-ergic tone are ineffective, and $GABA_A$-receptor complex antagonists reverse electrophysiologic and neurological aspects of HE. These phenomena in HE could be explained by an up-regulation and increase in number of $GABA_A$ receptors. There is little evidence, however, supporting the role of gut-derived GABA, decreased hepatic metabolism of GABA, or increased uptake of GABA through the BBB. [18] Rather, there is evidence suggesting that natural BZ receptor agonists may be elevated in HE and are responsible for the GABA-mediated responses observed experimentally. [8], [19], [20] Many of these compounds are classic 1,4-BZs, such as diazepam and *N*-desmethlydiazepam, but many others are yet to be characterized. The source of these compounds and their relation to cirrhosis or portosystemic shunting is still unclear. Hypothetical sources include dietary sources (wheat, potatoes, soy, milk, beans, rice, and mushrooms) and bacterial conversion of BZ precursors in the gut or by the diseased liver after absorption. Indirect evidence for the role of natural BZ in HE is the reversal, albeit incomplete, of HE by BZ receptor antagonists in animal models and in humans. [21], [22] Despite supporting evidence for the natural BZ hypothesis in HE, many issues remain unresolved (Table 116-3). Finally, peripheral benzodiazepine receptors (PBRs) located in glial mitochondria, [23] distinct from $GABA_A$ receptors, may play a role in HE. An increase in cerebral ammonia is thought to increase the density of these PBRs. Activation of these receptors in turn induces the synthesis of neurosteroids (tetrahydroprogesterone and tetrahydrodeoxycorticosterone), which are potent agonists of $GABA_A$ receptors, enhancing GABA-ergic neurotransmission. [24] Indirect evidence for the involvement of PBRs in HE is the effect in animal models of pregnenolone and dehydroepiandrosterone, endogenous neurosteroid antagonists. [25], [26]

Evidence Supporting the Concept
Studies in animal models
BZ receptor antagonist (BZRA)-induced ameliorations of HE
In HE, BZRAs induce excitation of CNS neurons in vitro.
In HE, occupancy of BZ receptors by BZ agonists is demonstrated.
In HE, the BZ levels in CSF, blood, and brain tissue are increased.
Levels of BZs correlate with severity of HE.
Findings in humans
BZRA-induced ameliorations of HE
In HE, increased levels of BZs in CSF, blood, and postmortem brain tissue
Levels of BZs correlate with severity of HE.
Unresolved Issues
The source of these BZs is unknown.
The identity of many BZ receptor ligands in HE is unknown.
The properties of many BZ receptor ligands in HE are unknown.
Whether BZ levels in HE are sufficient to depress the CNS is unknown.
The precise role of BZs in the pathogenesis of HE is unclear.
Interactions between BZs and other putative toxins in HE is yet unexplored.

BZ, benzodiazepine; CSF, cerebrospinal fluid; HE, hepatic encephalopathy.

TABLE 116-3 Concept that Natural Benzodiazepines Contribute to Hepatic Encephalopathy

In normal conditions, glutamate is an excitatory neurotransmitter that counterbalances the inhibitory effect of the $GABA_A$ receptors. Regulation of brain extracellular glutamate levels involves presynaptic and postsynaptic control but is predominantly under the influence of reuptake and conversion into glutamine by perineuronal astrocytes. There is evidence suggesting that, in HE, hyperammonemia down-regulates glutamate binding sites on postsynaptic neurons and impairs glutamate reuptake, thus explaining the increase in extracellular cerebral glutamate [27] observed in HE. A different pool of glutamate, localized in astrocytes, contributes to the detoxification of ammonia through the synthesis of glutamine. This reaction is catalyzed by glutamine synthetase, solely localized to astrocytes in brain. [16] Accumulation of glutamine correlates with the degree of HE, as assessed in human cerebrospinal fluid. [28] Abnormalities in cerebral catecholamine transmitters may play a small role in HE. Noradrenaline levels are decreased in animal models of HE, and serotonin-synaptic defects may explain the high levels of cerebral serotonin metabolites (tryptophan and 5-hydroxindoleacetic acid). Serotonin is also increased in HE due to an increase in uptake of tryptophan across the BBB. Down-regulation and loss of D_2-dopamine receptors in the pallidum in HE may be the consequence of manganese accumulation and could explain the decreased magnetic resonance signal observed in this region of the brain and the extrapyramidal symptoms sometimes observed in HE. The origin of elevated manganese in cirrhotic patients may be due to both impaired biliary manganese excretion and portosystemic shunting. Finally, the “false neurotransmitter” hypothesis described by early authors is based on the observation that brain tyrosine hydroxylase is inhibited in HE. Certain amines (tyramine, octopamine, and ß-phenylethanolamine) can be synthesized from tyrosine through alternative pathways. It was hypothesized that these amines acted as weak neurotransmitters, competing with standard catecholamines. None of these hypotheses alone can fully explain the symptoms of HE. Synergism between each individual pathway most likely occurs. As shown in Table 116-2, hyperammonemia could directly produce HE but also induces a cascade of proencephalopathic mechanisms. Basile and Jones [8] recently put forth a concept uniting the ammonia and GABA-ergic concepts, which they consider as primordial in HE. They argue that ammonia can directly potentiate inhibitory GABA-ergic neurotransmission and synergistically augment the actions of natural BZ receptor agonists (Fig. 116-1). This could explain why some patients with HE have normal ammonia levels or do not respond to BZ receptor antagonists.

FIGURE 116-1. Postulated interrelationships between elevated brain concentrations of ammonia and increased GABA-ergic neurotransmission in the pathogenesis of hepatic encephalopathy. The mechanisms depicted, alone or in combination, can account for a substantial increase in GABA-ergic neurotransmission, which is a major factor contributing to the manifestations of hepatic encephalopathy. (From ref. [8].)

Modifications in Energy Metabolism Severe HE is accompanied by reductions in cerebral blood flow and in cerebral oxygen and glucose consumption. These abnormalities have been demonstrated in HE by positron emission tomography and magnetic resonance spectroscopy techniques and were shown to correlate with abnormalities of neuropsychiatric testing (see later). Rather than a cause of HE, these abnormalities appear to be secondary to severe HE.

Astrocyte Swelling Alzheimer type II astrocytes in HE are related to hyperammonemia and glutamine metabolism. [16] Additional abnormalities in astrocyte osmolarity [29], [30] have prompted a recently developed hypothesis whereby disturbances in astrocyte cell volume homeostasis are a critical event in the development of HE. [13] Magnetic resonance spectroscopy studies have shown that an astrocytic osmolyte, *myo*-inositol, is depleted in HE. This phenomenon is observed in cirrhosis, [29] experimental portacaval shunting, [31] and after transjugular intrahepatic portosystemic shunt (TIPS) [30] and is reversible, especially after liver transplantation. The extent of these changes may correlate to the severity of HE. This depletion in *myo*-inositol is a response to the increase in intracellular glutamine [32] triggered by hyperammonemia. Other organic osmolytes, such as taurine and a-glycerophosphorylcholine, exit the astrocyte to counteract astrocyte swelling. Furthermore, other phenomena known to precipitate HE and often encountered in cirrhotic patients (see later), namely hyponatremia (overdiuresis), elevated tumor necrosis factor-a (during sepsis), BZ, [32] and neurosteroids [33] can cause astrocyte swelling. This low-grade astrocyte swelling has multiple cascading consequences, including activation of extracellular regulated protein kinases, elevation of intracellular calcium concentration, up-regulation of PBR (and hence up-regulation of GABA-ergic tone), and alkalinization of endocytotic vesicles affecting receptor density and neurotransmitter processing. Finally, swelling may also induce changes in endothelial plasma membrane transporters responsible for the modifications in the BBB encountered in HE. As shown in Fig. 116-2, the authors of this novel pathogenic model suggest that this common astrocytic pathway could explain both the role of multiple factors triggering HE and the multiple abnormalities in neurotoxins and neurotransmitters described previously. The authors speculate that this model is applicable to acute HE as well, only with differences in kinetics and degree of swelling.

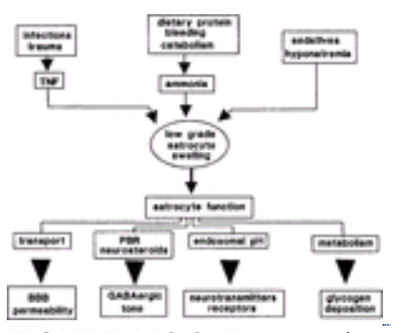

FIGURE 116-2. Proposed mechanism through which various precipitating factors can induce hepatic encephalopathy. This model views a disturbance of astrocyte hydration (low-grade cerebral edema) as a key event and one (not the only) major mechanism leading to astrocyte dysfunction and the clinical picture of hepatic encephalopathy. (From ref. [13].)

Mechanisms Involved in Fulminant Hepatic Failure The mechanisms described previously for chronic HE apply as well to the sudden onset of HE observed in the setting of FHF. Cerebral ammonia levels are generally very high, in excess of 4 mmol/L, [34] and correspond to high glutamine levels; abnormalities in the BBB may also play a pivotal role. The principal distinguishing factor of HE in FHF, however, is massive astrocyte swelling and cerebral edema. The causes of cerebral edema are twofold [35]: massive astrocyte glutamine uptake in response to hyperammonemia, [36] and cerebral vasodilation. The latter could be the result of systemically related cerebral vasodilation (through gut-derived endotoxins, proinflammatory cytokines, and stimulation of nitric oxide synthase) and locally induced cerebral hyperemia (through the release of lactate in response to hypoxia and the release of prostaglandins by the cerebral endothelium).

Clinical Aspects

Overt Hepatic Encephalopathy: Signs and Symptoms Overt hepatic encephalopathy (OHE) can present with a wide variety of signs and symptoms. [4], [37], [38], [39] and [40] The most typical are changes in consciousness, intellectual function, and behavior as well as neuromuscular abnormalities. Onset is most often rapid, and clinical features can worsen or improve rapidly within hours or days. Impaired consciousness can range from subtle changes in personality and inversion of the sleep-wake cycle to lethargy, stupor, and coma. Personality changes can be subtle, only apparent to the patient's friends and family. Abnormalities in intellectual function include unusual behavior; disorientation to time, place, or person; impaired antegrade or retrograde memory; and confusion. The most prominent neuromuscular abnormality is flapping tremor, a form of asterixis. Asterixis is defined as an inability to maintain posture actively due to deregulation of agonist and antagonist muscle tone. Flapping tremor is demonstrated by the development of rapid involuntary flexion and extension movements of the wrist when the patient is instructed to maintain wrists dorsiflexed, fingers spread, and arms outstretched anterior to a horizontal plane. This position is achieved when instructing the patient to push against an imaginary wall in front of them. Flapping tremor should be differentiated from fine tremulations of the hands seen in alcohol withdrawal. Instructing the patient to close his or her eyes can increase the sensitivity of the examination. In patients who are bedridden, the arms should not be outstretched too high above the plane of the body because this leads to a drop in the arms because of fatigue and can be falsely interpreted as flapping tremor. Other signs of asterixis are abrupt loss of tone during tongue protrusion, pedal dorsiflexion, and fist clenching. Asterixis is not demonstrable in the patient who is comatose. At this stage, abnormal ocular movements, a diffuse pyramidal syndrome, or even decerebrate posturing may be observed. Other neuromuscular abnormalities of OHE include ataxia, hypomimia, dysarthria, bradykinesia, and choreo- athetotic movements. Whether partial or generalized seizures are part of the clinical spectrum of OHE is debated. [41] Most cases are due to alcohol withdrawal or an underlying metabolic abnormality (hyponatremia) or are drug-induced. Typically, seizures due to OHE are observed in the acute setting of fulminant liver failure when cerebral edema is involved. One or more of these findings in a patient with chronic or acute liver failure or portosystemic shunting is diagnostic for OHE, after excluding differential diagnoses. In this clinical setting, there is seldom need to proceed with special blood tests, brain imaging, or neuropsychological testing to confirm the diagnosis. Foetor hepaticus can be detected in liver failure and portosystemic shunting and can be observed in patients with or without OHE. A sweet, musty breath reminiscent of rum, thought to be produced by volatile mercaptans and sulfides derived from methionine, characterizes foetor hepaticus. The pungent odor can be potent, easily detected when entering the patient's immediate environment; in other instances, it may be subtle and require that the patient exhale deeply in proximity to the examiner to be recognized. Foetor hepaticus can be associated with a peculiar body odor, known as fish-odor syndrome, due to impaired metabolism of trimethylamine. [42] Multiple schemes have been proposed to grade OHE. Grading of OHE is useful for clinicians to assess objectively patient status; it is an absolute necessity in clinical research to appreciate the effects of treatments and the diagnostic value of special tests, or in mechanistic studies. By far the most widely used and accepted system is the West Haven criteria of altered mental state in HE [43] (Table 116-4). This is a relatively simple semiquantitative 0 to IV point scale using readily identifiable clinical signs. This system does not give criteria for the diagnosis of stage 0 (MHE) or of stage IV (coma). Stage IV is best assessed by the Glasgow coma scale [44] (Table 116-5). The Portosystemic Encephalopathy Index [45] (PSEI) has been used in many clinical trials. This additive grading system is the ratio (0 to 1) of the sum of scores for mental state, asterixis, number connection test, [46] plasma ammonia levels, and electroencephalogram (EEG) grade over a total possible 28 points. The PSEI is not superior to the West Haven criteria in assessing OHE and suffers from the use of arbitrary unit multiplicators and the inclusion of plasma ammonia levels that do not correlate to symptoms of HE. Another system proposed by Gitlin [47], [48] combines the clinical features of the West Haven criteria with EEG features but is not widely used. Both the PSEI and Gitlin grading systems, therefore, incorporate testing for MHE. The simplest grading system is that which is included in the Child-Pugh score for severity of cirrhosis [49], [50]: absent (0), moderate or responsive to treatment (2), or severe or unresponsive to treatment (3). This three-point scale, however, is far too ambiguous and subjective. In 1998, a working party of experts in HE came to the following consensus regarding the grading of OHE [6]: only clinical grading should be used for quantification of HE; the West Haven criteria (I to IV) should be used for changes in consciousness, intellectual function, and behavior; the Glasgow coma scale can be used in addition for patients in stages III and IV.

Stage 0:	Lack of detectable changes in personality or behavior. Asterixis absent.
Stage 1:	Trivial lack of awareness. Shortened span. Impaired addition or subtraction. Hypersomnia, insomnia, or inversion of sleep pattern. Euphoria or depression. Asterixis can be detected.
Stage 2:	Lethargy or apathy. Disorientation. Inappropriate behavior. Slurred speech. Obvious asterixis.
Stage 3:	Gross disorientation. Bizarre behavior. Semistupor to stupor. Asterixis generally absent.
Stage 4:	Coma.

From ref. 43.

TABLE 116-4 West Haven Criteria for Altered Mental State in Hepatic Encephalopathy

EYES OPEN		BEST MOTOR RESPONSE		BEST VERBAL RESPONSE	
Spontaneously	4	Obeys verbal orders	6	Oriented, conversant	5
To command	3	Localizes painful stimuli	5	Disoriented, conversant	4
To pain	2	Painful stimulus, flexion	3	Inappropriate words	3
No response	1	Painful stimulus, extension	2	Inappropriate sounds	2
		No response	1	No response	1

*The best ocular, verbal and motor responses are summed. The best score is 15, the worst is 3. Severe hepatic encephalopathy is defined by a score of less than 12.

From ref. 44.

TABLE 116-5 Glasgow Coma Scale*

Minimal Hepatic Encephalopathy: Definition and Diagnosis The term *subclinical hepatic encephalopathy* (SHE) was coined in the 1970s when researchers determined that patients with cirrhosis who did not have OHE performed poorly in neuropsychiatric and electrophysiologic testing. [2], [4], [6], [40], [51], [52], [53], [54], [55] and [56] There has since been much debate and research on which tests best describe this condition, whether or not it is relevant in affecting patient prognosis or function, and whether SHE represents either HE at a stage at which it is not detectable by clinical observation or a pathologically distinct entity from HE. More recent research has provided conclusive evidence that SHE is clinically relevant and most likely an early expression of the clinical spectrum that constitutes HE. The experts in the field of HE now prefer the term *minimal hepatic encephalopathy*, or MHE, to subclinical encephalopathy. [6], [57] Dozens of neuropsychological tests have been used to characterize or have been proposed as methods to diagnose MHE. [2], [58] The choice of which constitutes the best test or tests is challenging. Analysis of performance is hampered by inconsistencies in use of controls or appropriate controls; lack of correction for the influence of age, gender, social status, education, and cultural background; data from small patient groups; and lack of validation. Certain tests are time consuming or require professional expertise in neurology or psychiatry that may not be attainable by an internist or gastroenterologist-hepatologist; and certain batteries of tests are more suitable for research purposes than for routine testing. The current consensus for clinical trials [2], [6] is to perform at least two of the following standardized tests: the number connection test (NCT) A and B, digit-symbol test (DST), or block-design test (BDT). There still is no consensus as to the most accurate tests to use in routine clinical practice. Conn [46] and Zeegen and colleagues [55] were the first to use a modified Reitan trail-making test, which became the NCT and the most widely used paper-and-pencil neuropsychological test for MHE (Fig. 116-3). The NCT tests cognitive dysfunction. In the NCT-A, the subject must connect in the correct order as quickly as possible a sequence of scattered circles numbered 1 through 25. The score is the time required for the subject to complete the trail, including time to correct errors. A low score indicates a good performance. The concept of the NCT-B is similar, except for an alternating sequence of scattered numbered and lettered circles, 1-A through 13-L. The subject must be given the opportunity to practice either test before doing a timed run, thereby decreasing training bias in follow-up testing. With a normal upper time limit of 30 seconds [46] for NCT-A and 100 seconds for NCT-B, the sensitivity and specificity in detecting SHE are estimated to be 56% and 100%, respectively, for the NCT-A and 68% and 99.2%, respectively, for the NCT-B. [2] The accuracy of the tests improves when taking into account age and educational level and when only considering results above 2 standard deviations (SD) from normal populations as being pathological: the sensitivity of NCT-A increases to 77% and that of NCT-B to 87%. [59] It has been clearly demonstrated that using an NCT uncorrected for age as a screen significantly overdiagnoses MHE. [60] The threshold for normal scores is further modified by the version of the test used. [45]

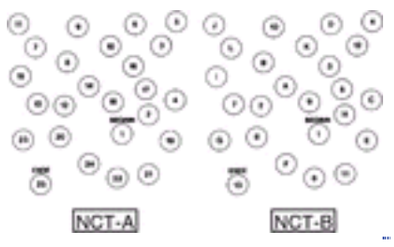

FIGURE 116-3. An example of number connection tests (*NCT*) A and B used to assess minimal hepatic encephalopathy. (From ref. [59].)

The DST is a subset of the Wechsler Adult Intelligence Scale [61] and measures motor speed and accuracy. The subject is given a list of nine line symbols (- =) associated with digits from 1 to 9. A "stimulus page" consisting in series of four rows of 20 blanks associated with random digits from 1 to 9 must be filled with the symbols that correspond to each digit. The test score is the total number of correct sequential matchings of digits to symbols in a 90-second interval. A high score indicates a good performance. Little data are available on the accuracy of this test. When considering scores 2 SD below those of normal populations, the sensitivity is reported to be 90%, with 95.8% specificity. [2] The BDT is not a paper-and-pencil test. The subject is given 1-inch-square red and white cubes with which patterns from either demonstration blocks or pictures must be produced with either four or nine blocks. It is recommended that the BDT be administered as part of a battery with the NCT and DST. [47], [62], [63] In fact, the best accuracy is obtained with a battery of paper-and-pencil–only tests coined the Psychometric Hepatic Encephalopathy Score (PHES) [2] or Portosystemic Encephalopathy Syndrome Test, [6] consisting of the NCT-A and -B, the DST, and two other less frequently used tests: the Line Drawing Test [62] and the Serial Dotting Test. [58] With this combination, diagnostic sensitivity for MHE is 96% and specificity is 100%. [2] Although the proponents of such a system state that it can be carried out effectively in 10 to 20 minutes, it is clear that psychometric tests in general must be administered methodically, in a quiet room with sufficient light, with the subject in a sitting position and that they require careful interpretation and adaptation to age, education, and learning effect. In an effort to overcome these limitations, Groeneweg and associates [64] studied correlations among clinical and laboratory parameters, quality-of-life assessment, the NCT and DST, and EEG assessment in patients with cirrhosis. Variables independently associated with MHE were male gender, a Child-Pugh score of more than 7, the presence of esophageal varices, and an affirmative response to 5 specific statements of 36 from the Sickness Impact Profile questionnaire. [65] For a given patient, the sum of each relative risk (total ranging from 0 to 14.7) establishes the SHE Probability Score, corresponding to a sigmoid curve of MHE probability (Fig. 116-4). A threshold score of 3.3 yields a sensitivity of 90% and a specificity of 77% in diagnosing MHE. The authors suggest that this score could be easily performed at the bedside or in an ambulatory setting to select only those patients with a score of 3.3 or higher for further psychometric or neurophysiologic testing to confirm the diagnosis of MHE. An obvious source for the low specificity is that impairment in quality of life in patients with cirrhosis may be due to factors other than HE. [66] The SHE Probability Score merits further validation in patients with liver disease, with and without cirrhosis.

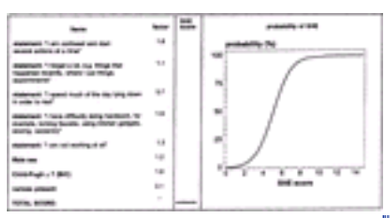

FIGURE 116-4. The subclinical hepatic encephalopathy score (SHE), proposed to screen for minimal hepatic encephalopathy (MHE). The score is the sum of points (regression coefficients) for each positive item. The probability of MHE can be derived by plotting the score on the sigmoid curve. (From ref. [64].)

The many drawbacks of neuropsychological testing have led researchers to evaluate different neurophysiologic methods to achieve an objective diagnosis of MHE. These tools include EEG, brainstem auditory-evoked potentials (BAEPs), visual-evoked potentials (VEPs), somatosensory-evoked potentials (SSEPs), P300 event-related potentials (P300), and critical flicker frequency. These methods are objective, are not biased by education or learning effects, and for the most part do not depend on age. They do, however, require sophisticated equipment and highly trained personnel to interpret results. In the opinion of the expert working party, [6] none of these tools is specific and can be used to diagnose MHE at this time. The key problem in the interpretation and comparison of these methods is the lack of consensus regarding the gold standard definition of MHE. The EEG is the neurophysiologic test most frequently used in routine clinical practice. EEG abnormalities in

patients with cirrhosis or liver failure can be due to multiple causes, including HE, electrolyte abnormalities, infection, alcohol withdrawal, seizure disorder, cerebral edema, cerebral ischemia, central pontine myelinolysis, and neurodegenerative processes. [41], [67] This explains in part why the reported frequency of abnormal EEG findings among cirrhotic patients without HE is 8% to 35% [68] and that in MHE there is no overlap between EEG and abnormal psychometric tests. [60], [69] On the other hand, the test may explore different aspects of HE. EEG patterns typical of HE are not epileptiform, but rather a continuous slowing of background rhythm and presence of atypical triphasic (theta) waves. [70] Conventional EEG analysis is inadequate to localize these patterns objectively in a reproducible fashion; quantitative spectral EEG analysis is the current standard test. [69], [71], [72] and [73] Evoked potentials are electrical signals generated by excitable regions of the brain subsequent to external stimulation. Different stimuli induce evoked potentials in different regions of the brain. Evoked potentials can describe abnormal sensory function qualitatively and quantitatively in the absence of overt clinical manifestations. They are routinely used to characterize multiple sclerosis and toxic-metabolic disorders, the extent and topography of brain disorders, and CNS dysfunction in comatose patients. BAEP, VEP, and SSEP testing use the exogenous components of evoked potentials and are influenced by the physical properties of the mode of stimulus. P300 evoked potentials are endogenous event-related cerebral potentials, generated in response to a change in visual or acoustical stimulus ("target stimulus"). It is thought that the P300 response correlates to cognitive processes and thus detects the impaired cerebral function of MHE demonstrated by psychometric testing. BAEP abnormalities correlate poorly with MHE in general [74], [75] and [76]; they are present in grade IV HE in nonalcoholic cirrhosis and may reflect the accumulation of toxic substances and portosystemic shunting. BAEP abnormalities are observed in earlier stages of HE in alcoholic liver disease and even in the absence of cirrhosis, possibly owing to ethanol-induced demyelination. Both flashlight-stimuli VEPs and pattern-reversal mode VEPs have been studied in HE; extremely heterogeneous results have been reported with poor sensitivity in detecting both OHE and MHE. SSEP [77], [78], [79] and [80] appears to be sensitive in detecting MHE but not specific; abnormalities can be detected in alcoholic cirrhotic patients without HE, possibly in relation to peripheral neuropathy. P300 peak event-related auditory and visual potentials have been studied in alcoholic and nonalcoholic cirrhotic patients with control populations and correlations to psychometric testing. [69], [81], [82], [83] and [84] P300 testing is limited to HE grades 0 to II because it requires cooperation of the patient and appears to be extremely sensitive in MHE; however, its sensitivity is decreased by recent alcohol abuse. In the opinion of the expert working party, [30] P300 testing holds the greatest promise of these EP tests in detecting and characterizing MHE. Kircheis and colleagues [85] recently presented the use of critical flicker frequency (CFF) in HE. CFF analysis is thought to reflect the efficiency of the visual apparatus and the functional competence of the cerebral cortex and has been used extensively to evaluate multiple sclerosis, Alzheimer's disease, and the effects of psychoactive drugs. Kircheis and colleagues [86], [87] hypothesized that CFF abnormalities in HE reflect astrocyte swelling incriminated in hepatic retinopathy. Their well-designed study included a large number of alcoholic and nonalcoholic cirrhotic subjects, an adequate control population, and correlations to an extensive battery of psychometric tests. The authors determined a threshold flicker frequency capable of diagnosing MHE with 100% specificity; however, sensitivity was low (55%). These data will most likely spark new investigations into the usefulness of this technique.

Imaging Modalities Routine imaging modalities of the brain, such as computed (CT) scanning and magnetic resonance imaging (MRI), are of little utility in making a positive diagnosis of HE, but rather are used to exclude differential diagnoses. [4], [6], [88], [89] Such diagnoses would include intracerebral infarction, hemorrhage, abscess or tumor, intraventricular hemorrhage, normal-pressure hydrocephalus, central pontine myelinolysis, and cortical atrophy. In most of these instances, the clinical presentation is not typical of HE and points to a localized CNS defect eventually in association with a risk factor such as head injury, coronary heart disease, sepsis, or rapid changes in serum sodium. Systematic CT screening for intracranial abnormalities in patients with suspected HE and typical risk factors but without any signs of CNS localization is not warranted. In typical HE, CT scan in nonalcoholic patients is typically normal, and CT frequently shows cortical atrophy in alcoholic patients. In fulminant hepatitis, CT is a quasi-obligatory procedure to rule out an unexpected intracranial process that may contraindicate liver transplantation; otherwise, it might reveal cerebral edema related to acute HE. CT cannot identify structural abnormalities that correlate to MHE. MRI findings in HE include symmetric T1 hyperintensities in the pallidum, nigral substance, and the dentate cerebellar nucleus, possibly due to accumulation of manganese. [90], [91] These findings may become more prominent as liver function worsens and tend to regress after transplantation [92]; nevertheless, they do not correlate to the degree of neurological dysfunction, [93] and such isolated findings in a cirrhotic patient cannot be used alone to diagnose MHE or to correlate overt abnormal consciousness to HE. In recent years, research has intensified in the use of magnetic resonance spectroscopy (MRS) to explore various features of HE. The same radiofrequency signals emitted by nuclear magnetic resonance–sensitive nuclei (^{1}H, ^{31}P, ^{13}C) can be either transformed into an image (MRI) or into a spectrum of frequencies (MRS) corresponding to chemical entities. To date, only ^{1}H-MRS (proton MRS) has shown promising results by demonstrating associations between HE and pathophysiologic mechanisms involving osmolytes in astrocyte swelling and cerebral ammonia detoxification. The most consistent findings are decreased levels of *myo*-inositol and increased levels of glutamine in the brain. [29], [30], [92], [94] Whereas the degree of variation in these neurometabolites does appear to correlate with the severity of OHE and response to treatment, they are not sensitive enough to detect MHE in asymptomatic cirrhotic patients. [95] ^{31}P-MRS has been used to characterize altered brain energy metabolism in HE with notable abnormalities in brain phosphocreatinine, inorganic phosphate, and adenosine triphosphate suggestive of decreased glucose use and modifications in the BBB [96], [97] and [98]; however, data on correlations with disease severity and the diagnosis of MHE are conflicting. The use of MRS in HE is still in its infancy and is reserved for clinical research; although this technology appears promising, it requires specialized equipment and highly trained personnel to operate the equipment. It also remains very time consuming and therefore is not suitable for routine clinical practice. Single photon and positron emission tomography have been used to study features of mechanisms of HE involving cerebral blood flow and metabolic rate, behavior of central BZs and GABA receptors and response to treatment, and cerebral ammonia metabolism. [15], [99], [100], [101], [102] and [103] This technology has not been studied in terms of its ability to diagnose or grade HE.

Biochemical Markers In the setting of OHE, routine blood biochemistry completes the clinical presentation of underlying liver disease in the form of suspected cirrhosis or hepatic failure, showing elements in favor of decreased hepatic synthesis (decreased serum albumin, prolonged prothrombin time) and portal hypertension (thrombocytopenia). In patients with HE due to portosystemic shunting alone, such as those with portal thrombosis without cirrhosis, routine blood work may be normal. Abnormalities associated with a precipitating factor can be observed, such as hypokalemic metabolic alkalosis secondary to diuretic treatment, elevated blood urea nitrogen relative to creatinine secondary to a gastrointestinal hemorrhage, and leukocytosis secondary to sepsis. Routine blood work may also aid in making a differential diagnosis of HE, such as uremia, hypoglycemia, or hypercapnia. In line with the hypothesis of cerebral ammonia in the pathophysiology of HE, venous and arterial levels of ammonia have been studied as a marker of HE. Venous ammonia levels are significantly lower than arterial ammonia to which the brain is exposed, [36], [104] owing principally to ammonia metabolism by muscle. [105] Both venous and arterial ammonia levels vary from fasting to feeding states and are affected by the hypercatabolic state, with negative nitrogen balance observed in cirrhotic patients with wasting. [106] Finally, correct arterial ammonia determination requires that specimens be placed on ice and analyzed within 20 minutes of blood draw. [107], [108] These limitations may explain the conflicting results reported for the diagnostic accuracy of peripheral ammonia and HE. Although arterial ammonia levels are increased in up to 90% of patients with HE and decrease with clinical recovery and increase with severity of liver failure, clinical manifestations may lag by 24 hours, and there is a poor correlation between the severity of HE and ammonia levels. [109] Earlobe capillary ammonia correlates closely with arterial ammonia and may be an alternative to facilitate routine testing but requires validation. [110] Partial pressure of arterial ammonia (pNH_3), which depends on arterial ammonia and pH, is thought to better represent the unionized ammonia that crosses the BBB and has been shown in one study to correlate better with the clinical stages of HE than do arterial ammonia levels. [111] Despite the limited accuracy of venous ammonia levels in diagnosing HE, they continue to be used in the setting of emergency medicine to screen for HE in patients with unexplained abnormal consciousness without evidence of underlying liver disease.

Hepatic Encephalopathy of Acute or Fulminant Hepatic Failure HE associated with AHF is characteristically rapid in onset and in progression toward coma. In a previously healthy patient with AHF, the onset of HE within 8 weeks of onset of symptoms of liver disease defines FHF and gravely compromises prognosis. This rapid progression without a precipitating factor (other than liver failure itself) and the absence of reversibility by medical treatments (see later) differentiate HE of FHF from that of cirrhosis or portosystemic shunting. The pathophysiologic mechanisms of FHF HE involve high levels of cerebral ammonia that cross the BBB, leading to the synthesis of glutamine and the accumulation of osmolytes, which result in astrocyte swelling, cerebral edema, and ultimately death by cerebral herniation. [36], [112] The key to management is the early detection of MHE by the methods discussed previously. In the presence of OHE, high arterial ammonia values above 200 µmol/L may be of value in predicting fatal intracranial hypertension. [112] Cerebral edema can be detected by CT scan and intracranial pressure monitored by epidural transducers. Medical treatment is based on the same principles as HE of cirrhosis (discussed later), in addition to therapies specifically aimed at decreasing cerebral edema and intracranial pressure, pending liver transplantation (if not contraindicated).

Hepatic Encephalopathy without Liver Disease HE without underlying liver failure is observed in the setting of either spontaneous or iatrogenic extrahepatic portosystemic shunt. In a patient with abnormal consciousness and no known underlying spontaneous portosystemic shunt, the diagnosis of HE can be quite difficult. Clues to HE are the absence of common causes of abnormal consciousness (see later) and signs of portal (sometimes segmental) hypertension, such as abdominal or lower-back superficial collaterals, splenomegaly, esophageal or gastric varices, and ascites. Etiologies of spontaneous extrahepatic portosystemic shunt include congenital vascular malformations, which are rare, and the development of shunts secondary to partial occlusion of the portal system at the extrahepatic or intrahepatic level. Thrombosis or occlusion of the portal vein or its branches can occur in the setting of previous abdominal trauma, a primary or secondary hypercoagulable state (carcinoma, myeloproliferative disease, circulating lupus anticoagulant or antiphospholipid antibody, factor V Leiden or prothrombin mutations, or a mass effect or invasion to the porta hepatis, such as metastasis, hepatocellular carcinoma cholangiocarcinoma, or lymphoma). MHE is not a consideration in this setting because it is OHE that will alert the physician. HE is a frequent complication of portosystemic shunt surgery in cirrhotic patients, estimated at a rate of 30% to 80%, depending on type and diameter of shunt. [113] Lower rates of HE are obtained with distal splenorenal shunts and small side-to-side portacaval shunts, which preserve some degree of prograde portal flow. [114], [115] In addition to high rates of HE, surgical shunts can result in high mortality rates in the setting of liver failure and have been largely (although not completely) replaced by the TIPS procedure. [116] Initially used to treat uncontrolled esophageal bleeding in cirrhotic patients as a bridge to liver transplantation, indications for TIPS now include refractory ascites, hepatohydrothorax, Budd-Chiari syndrome, and possibly hepatorenal syndrome, irrespective of ensuing liver transplantation. As in side-to-side surgical shunts, TIPS is plagued by an increased rate of postprocedure HE, estimated initially at a rate

of 3% to 80%. Improvements in techniques (smaller-diameter stents) and a better understanding of predictive factors of post-TIPS mortality have decreased the rate of post-TIPS HE to about 30%. The mechanisms of post-TIPS HE are twofold: circumvention of hepatic detoxification by the shunt and aggravation of hepatic insufficiency secondary to decreased portal flow. Predictive factors of new-onset or worsening post-TIPS HE include pre-TIPS HE, nonalcoholic cirrhosis, female gender, age, hypoalbuminemia, stent diameter larger than 10 mm, or a decrease in portacaval gradient of less than 10 mm Hg. [117], [118], [119], [120] and [121] More recently, it has been shown (as could be expected) that post-TIPS HE can persist in the form of MHE and that pre-TIPS MHE can progress to OHE after the procedure. [122], [123] Despite the relatively high rate of post-TIPS HE, most authors describe rapid onset within 1 month of the procedure and a gradual decay of symptoms after 3 months, presumably owing to gradual narrowing of the stent by endothialization. Furthermore, when carefully selecting recipients, debilitating persistent post-TIPS HE is infrequently observed, and symptoms usually respond to standard medical therapy. Recently, stent-narrowing techniques have been developed [120], [124] that may alleviate refractory cases.

Precipitating Factors In a patient with cirrhosis or portosystemic shunting, HE can develop spontaneously and persist without treatment. Spontaneous HE is typically observed in acute liver failure or in large-bore portosystemic shunts that may be either iatrogenic (surgical shunt and TIPS) or spontaneous. [39], [48] Lam and colleagues [125] observed that patients with large-bore spontaneous shunting (demonstrated by collateral circulation emptying into the inferior vena cava) have a significantly higher incidence of HE and spontaneous HE than do cirrhotic patients with small spontaneous shunts or with Cruveilhier-Baumgarten murmurs. In most instances, however, symptoms of HE are precipitated by a number of factors that exacerbate MHE. The treatment or correction of these factors may suffice in some instances to help resolve the episode of HE. The most frequent precipitating factors involve a sharp increase in arterial blood ammonia. Digestive sources leading to increased ammonia levels include excess dietary protein, severe constipation, and gastrointestinal hemorrhage. Any bacterial infection (in particular, spontaneous bacterial peritonitis) or massive blood transfusions (hemolysis) can exacerbate ammonia levels as well as azotemia and hypokalemia. Systemic alkalosis can increase the diffusion of ammonia across the BBB. Multiple phenomena can trigger HE by inducing transient hepatic anoxia resulting in reduced hepatic metabolism of toxins. These include dehydration, hemodynamic shock, severe anemia, and hypoxemia. Circumstances typically observed in cirrhotic patients are overuse of diuretics, fluid restriction and paracentesis, severe gastrointestinal bleed, and rarely, overuse of laxatives. All classes of psychoactive drugs, even at minimal doses, can precipitate HE by amplification of their CNS depressant effect owing to impaired hepatic drug metabolism. BZs are notorious for putting patients into encephalopathic coma by activating central GABA-BZ receptors. Finally, rapidly progressive or acute decrease in hepatic functional reserve can precipitate HE. The TIPS procedure not only produces an intended portosystemic shunt but also leads to decreased hepatic perfusion. Hepatocellular carcinoma can cause HE by replacement of functional hepatocytes, and this effect can be compounded by portal vein thrombosis due to encroachment or reduction of viable hepatocytes by transarterial hepatic embolization or surgical resection. Frequently, multiple mechanisms are involved in precipitating HE. Diuretics, the mainstay of ascites therapy, can cause hypokalemia, azotemia, and dehydration. Gastrointestinal bleeding from ruptured esophageal varices leads to decreased hepatic perfusion and increased gastrointestinal protein content. When assessing a patient with HE, these precipitating factors must be actively sought and corrected; the risk for iatrogenic precipitation of HE should be considered. Diuretics should be decreased in dose or withheld, especially if azotemia or hypokalemia is present. Family members should be questioned about a recent high-protein meal. Sepsis should be contained rapidly. Gastrointestinal hemorrhage should be controlled by standard therapies and bowel cleansing initiated even before the onset of HE. Coma after the use of psychoactive drugs can be due to either their sedative effects or to HE; these drugs should be avoided whenever possible, and in some instances, an antidote may be useful. When performing tolerable invasive procedures such as gastrointestinal endoscopy, minimal doses of sedative drugs (such as the commonly used midazolam) should be administered. [126] TIPS should not be performed in a patient who has a significant history of HE.

Prognosis In the setting of cirrhosis, HE completes the clinical and biochemical picture of liver failure and therefore in itself is a sign of poor prognosis. The Child-Pugh score recognizes this feature and includes stages of HE in the empiric scoring system to grade the severity of cirrhosis. [49], [50] The survival rate after a first episode of OHE in patients with cirrhosis, irrespective of Child-Pugh score or etiology, is about 40% at 1 year and 20% at 3 years. [127] In patients with HE, factors independently associated with poor outcome are male gender, elevated alkaline phosphatase, bilirubin, blood urea nitrogen and potassium, and hypoalbuminemia. Interestingly, neither the severity of the initial encephalopathic episode, the precipitating factor, nor the presence of an iatrogenic portosystemic shunt significantly modifies survival. Estimates of OHE in cirrhotic patients vary widely from 20% to 80% of cohorts and those of MHE from 30% to 84%, depending on the tests used. It was initially thought that MHE had little impact on daily life and represented an esoteric diagnostic entity. Sophisticated studies show conclusively that MHE significantly impairs daily functioning. As compared with healthy controls and cirrhotic patients without MHE, patients with SHE are significantly impaired when driving a car or performing at work [128] and have higher SIP [65] scores than control populations. [129] Furthermore, the onset of MHE may be predictive of a high risk for ensuing OHE. HE associated with FHF is of very poor prognosis, especially if HE develops rapidly after the onset of jaundice and is rapidly severe and prolonged. Unrelenting intracranial hypertension and loss of the oculovestibular reflex are associated with fatal outcome. [130]

Differential Diagnosis The differential diagnosis of HE is wide, depending on the clinical circumstances [4], [48] (Table 116-6). In a patient with known cirrhosis, with or without spontaneous or iatrogenic portacaval shunting, the onset of abnormal consciousness concomitant to a recognized precipitating factor of HE usually leaves little doubt as to the positive diagnosis of HE. In an alcoholic patient, a withdrawal syndrome should be considered if there is a history of recent alcohol cessation, the patient has hand tremors rather than asterixis, and auditory or visual hallucinations are present. Korsakoff psychosis is gradual and persistent and involves characteristic antegrade amnesia. Wernicke encephalopathy, occurring in the setting of thiamine deficiency and intravenous glucose infusion, can have a rapid onset but will not respond to usual therapy for HE. Non–alcohol-related differential diagnoses of HE in the setting of cirrhosis include: cerebral vascular accidents and intracranial hemorrhage secondary to head trauma, typically recognized by a compatible history and a localizing motor or sensory defect and diagnosed by brain CT scan; central pontine myelinolysis observed in the setting of an iatrogenic correction of hyponatremia with an increase in natremia of more than 10 mmol/L per 24 hours diagnosed by brain MRI; or rare instances of intracranial infection.

Metabolic encephalopathies
Hypoglycemia
Electrolyte imbalance
Hypoxia
Carbon dioxide narcosis
Azotemia
Ketoacidosis
Toxic encephalopathies
Alcohol
Acute intoxication
Withdrawal syndrome
Wernicke-Korsakoff syndrome
Psychoactive drugs
Salicylates
Heavy metals
Intracranial lesions
Subarachnoid, subdural, or intracerebral hemorrhage
Cerebral infarction
Cerebral tumor
Cerebral abscess
Meningitis
Encephalitis
Epilepsy or postseizure encephalopathy
Neuropsychiatric disorders

Adapted from ref. 48.

TABLE 116-6 Differential Diagnoses of Hepatic Encephalopathy

The onset of abnormal consciousness in a patient with acute liver failure should be considered as HE unless proved otherwise. CT scan of the brain can show cerebral edema and rarely shows spontaneous intracranial hemorrhage due to a hypocoagulative state. Gross metabolic abnormalities observed in the setting of FHF such as hypoglycemia and azotemia can also cause abnormal consciousness mimicking HE. Rare degenerative disorders of the CNS should be considered when neurological symptoms are atypical of HE and do not respond to standard treatment. Hepatocerebral degeneration and transverse myelitis can occur in protracted cirrhosis and portosystemic shunting. Histological changes include hyperplasia of the protoplasmic astrocytes and neuronal loss; however, the mechanisms involved and the role of hepatic failure or portosystemic shunting are not well understood. [131] Hepatocerebral degeneration can present with progressive signs of chronic cerebellar and basal ganglia involvement, signs of parkinsonism, focal cerebral symptoms, epilepsy, and dementia. Alper disease, described as a degeneration of the cerebral gray matter in infancy, is an inherited autosomal recessive disorder and has been observed in association with cryptogenic cirrhosis or subacute hepatitis with steatosis. [132], [133] and [134] Transverse myelitis can lead to paraplegia. Two cases have been described in the setting of primary biliary cirrhosis and Sjögren syndrome. [135], [136] Wilson disease is an inherited autosomal recessive disorder. It results in excessive accumulation of copper in various organ systems, particularly in the liver and brain, leading to hepatolenticular degeneration. The signs of hepatic dysfunction (FHF, chronic hepatitis, cirrhosis) tend to occur before those of neurological dysfunction; however, neurological Wilson disease can occur without signs of liver disease. Neurological signs are initially subtle and become chronic and progressive if the disease process is unrecognized or left untreated. The neuropsychiatric signs are numerous and varied and can be classified into three distinct subsets according to lesions of the CNS [137]: pseudoparkinsonian (dilation of the third ventricle leading to bradykinesia, rigidity, cognitive impairment, organic mood syndrome); pseudosclerosis (focal thalamic lesions leading to ataxia, tremor, reduced functional capacity); and dyskinesia (focal abnormalities of the putamen and globus pallidus leading to dys- kinesia, dysarthria, organic personality syndrome).

Diagnostic Approach The approach to the diagnosis of HE depends for the most part on the clinical setting. In patients with cirrhosis or portosystemic shunting, stereotypical abnormalities of OHE are sufficient to make the diagnosis, especially when symptoms follow a precipitating factor. Neuropsychometric or electrophysiologic testing in this setting is redundant, but differential diagnoses such as severe hypoxia, hypoglycemia, azotemia, and hyponatremia should be

excluded. Systematic CT scan of the brain is not justified and should only be performed if CNS defects are suspected on the clinical exam. Symptoms of OHE usually respond rapidly to the usual oral therapies, confirming the diagnosis. Organic brain syndromes usually have a clinical presentation that is not typical of OHE and do not respond to these therapies. When OHE is absent, patients should be screened for MHE as described earlier given the prognostic implications. The diagnosis of OHE in a patient with abnormal consciousness but unknown liver disease requires the demonstration of clinical or biochemical signs of acute or chronic liver failure and the systematic exclusion of differential diagnoses. The extent to which patients should be evaluated for differential diagnoses (see Table 116-6) depends of course on the clinical presentation. In this setting, increased arterial blood ammonia may be suggestive of HE but is not 100% sensitive or specific (may be elevated in azotemia).

Current Nomenclature

Surveys performed by the Organisation Mondiale de Gastroentérologie in 1998 showed that there is considerable discrepancy among specialists on terms used to define the different clinical settings of HE. [6] The term *portosystemic encephalopathy* is used for HE in cirrhotic patients and in patients with portosystemic shunting without liver disease. *Acute encephalopathy* is interpreted as either HE of AHF or a reversible episode in patients with cirrhosis. *Chronic encephalopathy* is used to describe either recurrent episodes or continuous HE. The working party of experts has elaborated a multiaxial nomenclature and proposes that it be adopted by clinicians to assess patients and by researchers for clinical endpoints. This novel nomenclature describes three HE types: A, B, and C. Type A HE refers to encephalopathy associated with **a**cute liver failure. Type B HE refers to encephalopathy associated with portosystemic **b**ypass and no intrinsic hepatocellular disease. Type C HE refers to encephalopathy associated with **c**irrhosis and portal hypertension or portosystemic shunts. Type C is characterized by three subcategories and other subdivisions: episodic HE that may be precipitated, spontaneous, or recurrent; persistent HE that may be mild, severe, or treatment dependent; and MHE (Table 116-1).

Treatment of Type B or C

As described previously, in most instances, a precipitating factor of HE can be found. A rigorous search to identify such a factor must be undertaken and removed if possible. [7], [39], [48], [138]

Meanwhile, measures to decrease the nitrogenous load should be implemented. These measures include nutritional management and reduction of gut-derived ammonia. Nutritional management should include careful limitation of animal proteins and supplementation of any vitamin or mineral deficiencies, especially in zinc. In theory, dietary protein restriction can significantly reduce ammonia load; however, protracted nitrogen restriction leads to malnutrition, especially in hypercatabolic cirrhosis, thus aggravating prognosis. In fact, a positive nitrogen balance can improve HE by increasing the muscle's capacity to detoxify ammonia. The recommendations are for 1 to 1.5 g protein/kg/day, mostly in the form of vegetables and dairy products, which provide a higher calorie-to-nitrogen ratio than meat proteins. Vegetable sources have the added benefit of providing fiber that improves intestinal transit and acidifies stools, thereby reducing the formation of toxic fatty acids and ammonia from colonic amino acids. Proteins should be withheld from the diet at onset of OHE for 24 hours and reintroduced rapidly by increments of 20 g/day.

Reduction of gut-derived ammonia or other putative compounds of HE is the mainstay and first-line treatment of HE. Most of the ammonia load involved in the pathogenesis of HE enters the circulation from the intestinal tract, derived from colonic bacteria and deamination of glutamine in the small intestine. The ammonia is absorbed by passive diffusion. Other putative substances are derived from the gut: BZ-like substances or precursors, toxic short-chain fatty acids, phenols, and mercaptans. The therapeutic goal is to shorten bowel transit in order to eliminate ammonia-producing bacteria and to lower the available absorbable colonic ammonia. This can be achieved with nonabsorbable disaccharides, either lactulose or lactitol. These agents promote the incorporation of lumenal ammonia into the bacterial protein wall and promote catharsis by acidification of the colon as the result of the bacterial production of acetic and lactic acid by bacterial fermentation. This decrease in pH is hostile to urease-producing bacteria and further reduces the production of ammonia in the colonic lumen. The inconveniences of these agents are flatulence, abdominal cramping, and diarrhea. Some patients cannot tolerate the excessively sweet taste of lactulose. In a noncomatose patient who is not fasting, lactulose is given orally and titrated from 15 to 45 mL every 8 to 12 hours to achieve two or three loose and acidic (pH < 6.0) stools daily. Diarrhea should be avoided because this will reduce patient compliance and may exacerbate HE by promoting dehydration or electrolyte imbalances. In patients who are comatose or maintained fasting because of variceal hemorrhage, lactulose can be given by enemas (300 mL in 1 Liter of tepid water) every 4 to 8 hours as needed to achieve resolution of HE. [139] Despite the lack of any large-scale study of nonabsorbable disaccharides in HE, [45], [140] most experienced physicians attest to the rapid efficacy of these agents (most often within 24 hours), especially if the precipitating factor can be removed. After an episode of HE, lactulose can be administered preventively at minimal effective doses. Lactitol, available in Europe, appears to be equally as effective as lactulose at the dose of 30 to 45 g/day and reportedly has the advantages of being associated with less flatulence and is more palatable. [141], [142] Lactose can be used in lactase-deficient patients at the dose of 100 g. [143] The efficacy of lactulose in MHE warrants further study. [144]

The use of oral antibiotics to eliminate the urease-producing bacteria should be a second-line treatment. Despite their comparable efficacy to nonabsorbable disaccharides, certain undesirable effects limit their use. Neomycin is the most widely used antibiotic for this indication, at a dose of 2 to 6 g/day. Despite its limited intestinal absorption (3%), long-term use can expose patients to nephrotoxicity and ototoxicity, especially in instances of renal failure. The most frequent complications are malabsorption and bacterial superinfection. For these reasons, neomycin should be tapered rapidly after 2 to 3 days of treatment for a total of 1 to 2 weeks of treatment. An alternative to neomycin is metronidazole, 500 mg/day for 1 week, but this has a risk for neurotoxicity, especially in cases of severe liver failure. Despite evidence suggesting that *Helicobacter pylori* infection could cause HE by generating ammonia, [145] there is insufficient evidence to date to warrant a systematic eradication in patients with HE who are *H. pylori* seropositive, unless they have upper gastrointestinal symptoms or lesions that otherwise warrant this strategy. The effectiveness of a combination of nonabsorbable disaccharides and antibiotics is still debated. There is limited evidence that they could be synergistic, [146] and logically this would occur if the nonabsorbable disaccharide acts on bacteria resistant to the antibiotic. However, in most cases, this is most likely not the case, and therefore the antibiotic will eradicate bacteria thereby bypassing the desired therapeutic effect of lactulose, which is to incorporate the ammonia into the bacterial proteins. [147] In fact, one study suggested that a combination of neomycin and lactulose resulted in an effect comparable to placebo. [140] Hence, the consensus is to start antibiotics only after failure of lactulose alone and to stop lactulose if stool pH increases above 6.0.

L-Ornithine-L-aspartate has been proposed in Europe for the treatment of HE with the hypothesis that this molecule decreases ammonia by recycling through the urea cycle and by increasing glutamine synthesis. Two placebo-controlled studies, one with an intravenous formulation [148] and the second with an oral formulation, [149] show promising results. Nitrogen excretion can also be increased by benzoate (by conjugating glycine to form hippuric acid) and by phenylacetate (by conjugating with glutamine to form phenylacetylglutamine). Benzoate has been successfully used to treat inborn errors in the urea cycle. [150] One controlled trial showed that benzoate was just as effective as oral lactulose [151] in treating HE. Benzoate can be given intravenously, which can be of benefit in severely confused or comatose patients.

Studies of treatments targeting false neurotransmitters such as branched-chain amino acids (BCAA), levodopa, and bromocriptine have not shown beneficial results of significance that warrant formal recommendations on their use. The theory that increased concentrations of aromatic amino acids produce false neurotransmitters forms the basis for trials of the BCAAs leucine, isoleucine, and valine. Increased levels of tyrosine, phenylalanine, and tryptophan enter the brain in exchange for glutamine generated from astrocytic ammonia detoxification. These aromatic amino acids in excess would then be metabolized into false neurotransmitters (octapamine and phenylethanolamine) and serotonin. Administration of BCAAs in theory could therefore reverse this excess in aromatic amino acids. Results have been conflicting: short-term crossover studies have shown no benefit of BCAAs in EEG or psychometric testing [152], [153]; one long-term trial found an improvement in mental state, blood ammonia levels, and psychometric testing. [154]

Flumazenil (1 mg intravenous bolus) may be beneficial in selected patients with severe HE, [21], [155] and no oral preparation is available for long-term treatment. This drug can also be considered when BZ use is suspected.

Finally, supportive care is also an essential part of the management of HE. Care must be taken in preventing bodily harm in confused patients and complications of decubitus in comatose patients; adequate intravenous or nasogastric hydration and feeding must be implemented when oral intake is contraindicated. Airway protection should be considered in deeply comatose patients if the prognosis warrants such a measure. In patients with persistent and progressively worsening HE, such as can be observed in severe acute alcoholic hepatitis with or without cirrhosis, the prognosis is irremediably poor, and therefore, minimally invasive life support is the most compassionate choice. In otherwise stable patients, next of kin should be informed of the reversible nature of HE and should be educated on how to recognize the beginning stages of HE once the patient has left the hospital. Compliance to diet and to preventive therapy with lactulose is greatly improved by repeated education of the patient and family through interviews by the attending physician, nursing staff, and dietitian.

HEPATOPULMONARY SYNDROME

Hepatopulmonary syndrome identifies a group of patients with cirrhosis exhibiting severe hypoxemia as a result of intrapulmonary vascular dilation. The first descriptions of patients with chronic liver disease accompanied by digital clubbing and cyanosis can be traced to the 1880s. [156] Although several clinical reports were published after 1950, the term *hepatopulmonary syndrome* was first used in the late 1970s to describe patients with cirrhosis that exhibited exercise-aggravated hypoxemia and orthodeoxia. [157] The increasing recognition of milder forms of the syndrome allows detection of compatible abnormalities in up to 17% of patients with cirrhosis awaiting liver transplantation. [158]

Definition

The classic triad of the hepatopulmonary syndrome encompasses liver disease, a gas-exchange abnormality, and intrapulmonary vascular dilations. The gas-exchange abnormality has been defined as one that results in a partial pressure of oxygen of less than 70 mm Hg. Mild hypoxemia is common in cirrhosis, seen in up to one third of patients. In a series of 100 subjects, PaO_2 values of less than 70 mm Hg were seen in 28% of patients, whereas PaO_2 values of less than 60 mm Hg were seen in 8% of individuals. [159] In the hepatopulmonary syndrome, hypoxemia can be severe. In a series of 22 patients, 13 of 22 subjects had a PaO_2 of less than 60 mm Hg. [160]

As patients with cirrhosis may have higher respiratory rates, an arterial-alveolar oxygen gradient of more than 20 mm Hg (accounting for alveolar carbon dioxide) may be a better reflection of functional impairment. [159] Age adjustments are also important when evaluating the alveolar-arterial oxygen difference. The syndrome was defined with two elements [159]: an alveolar-arterial oxygen difference greater than 15 mm Hg while breathing room air in an upright position, irrespective of the degree of arterial hypoxemia, and evidence of intrapulmonary vascular dilations using contrast-enhanced echocardiography.

In an earlier definition, the absence of underlying lung conditions was required for the diagnosis of the hepatopulmonary syndrome. [161] With the high prevalence of smoking and associated lung disease, as well as other liver-related lung problems (hepatic hydrothorax, pulmonary hypertension), this definition may be too narrow. Hepatopulmonary syndrome can coexist with other lung conditions. The increasing ability to detect the presence of intrapulmonary vascular dilations by noninvasive tools allows a definition based on anatomic abnormalities.

Clinical Features

Most patients with hepatopulmonary syndrome have underlying cirrhosis with variable degrees of hepatic decompensation. The severity of liver disease is not related to the degree of hypoxemia. [162] An association with other hepatic conditions has also been described. These conditions include entities with portal hypertension, such as inferior vena cava webs and nodular regenerative hyperplasia. The presence of portal hypertension or portosystemic shunting is important for the expression of the syndrome.

Patients describe the insidious and progressive onset of dyspnea. Although dyspnea is aggravated by exercise, it has unique features: An increase of symptoms while standing (platypnea) is the result of redistribution of blood to lower lung lobes (more perfusion, lower oxygenation). A corresponding sign is orthodeoxia, a worsening of oxygen saturation upon standing that is relieved by recumbency. Platypnea and orthodeoxia are associated with more severe forms of the syndrome.

Digital clubbing and cyanosis reflect the impact of chronic hypoxemia and are weakly sensitive but highly specific for the diagnosis of hepatopulmonary syndrome. [163] Spider nevi are commonly observed. Most series describe the presence of such angiomata in 80% to 90% of cases, raising the possibility of a similar pathogenic influence on the development of pulmonary vascular dilations. However, the specificity of spider nevi for the diagnosis of the hepatopulmonary syndrome does not appear to be high, 63% in a report on 112 patients. [163] Patients with spider nevi do exhibit more prominent features of the hyperdynamic circulatory state, [164] with a high cardiac output (CO) and low mean arterial pressure as a result of a decreased peripheral vascular resistance.

Hepatopulmonary syndrome with progressive hypoxemia is a debilitating condition. Mortality in these subjects is high, and appropriate candidates should be referred for liver transplantation.

Diagnosis

Abnormal Gas Exchange Lung function can be normal in patients with the hepatopulmonary syndrome. In cirrhosis, a restrictive lung pattern can reflect the presence of ascites or hepatic hydrothorax. Alveolar diffusion abnormalities are commonly seen in patients awaiting liver transplantation. In two large series, a decrease in the diffusion capacity for carbon monoxide was observed in more than half of the subjects. [165], [166] In a recent study, [158] a reduced carbon monoxide diffusing capacity (DL_{CO}) was more commonly seen in subjects with the hepatopulmonary syndrome. However, the mechanisms responsible for altered oxygen and carbon monoxide diffusion do not appear to be equal. After liver transplantation, a reduced DL_{CO} can still be observed in the presence of normalization of oxygen diffusion. [167] An alveolar-arterial gradient of 15 mm Hg [158] or 20 mm Hg [163] has been used to diagnose the hepatopulmonary syndrome. Determination of arterial oxygen levels is best obtained with the patient standing. In one series, the mean fall in PaO_2 was 12 mm Hg when going from the supine to the standing position. [168] Breathing 100% oxygen can also be used to demonstrate the presence of anatomic arteriovenous shunting, where there is perfusion without ventilation. Pulmonary vasodilation without anatomic shunts (excess perfusion with normal ventilation) can be corrected with 100% oxygen. This test appears specific, but not sensitive, in the diagnosis of the hepatopulmonary syndrome.

Pulmonary Vasodilation A mottled appearance of the chest radiograph has been described in patients with clubbing and dyspnea. [169] Bilateral interstitial markings, especially in the lower lobes, may reflect the presence of arterial vasodilation. The diagnosis of vasodilation requires more precise instruments.

Contrast echocardiography. With this approach, microbubbles derived from agitated saline are injected intravenously. Under normal circumstances, they are not visible in the left atrium because they cannot traverse the pulmonary circulation. Although the immediate appearance of bubbles (after one heart beat) suggests the presence of a patent foramen ovale or an atrial septal defect, the diagnosis of pulmonary vasodilation is supported by the appearance of bubbles within three to five beats. The transthoracic approach is preferred over transesophageal echocardiography because the marginal improvement in imaging does not justify the higher cost and effort. There is an improved sensitivity of the transesophageal approach in cases of early hepatopulmonary syndrome, [170] but such initial changes are unlikely to change management. There is disparity between findings at contrast echocardiography and blood gas exchange. In up to 40% of cirrhotic patients, an abnormal contrast echocardiogram is not accompanied by evidence of hypoxemia. [171] Compensatory mechanisms to vasodilation, including hyperventilation, maintain oxygenation in these circumstances. When other pulmonary abnormalities exist, such as hydrothorax or obstructive disease, contrast echocardiography is not an accurate tool. Hypoxemia can arise from the alternative condition, and a positive bubble echo may not be sufficiently specific. Contrast echocardiography is a sensitive tool, valuable for screening, but lacking specificity.

Radionuclide lung perfusion scanning. Injection of technetium-labeled macroaggregated albumin intravenously results in homogenous lung imaging as the macroaggregates lodge in pulmonary arterioles. When macroagreggates pass through the pulmonary vasculature, they are detected in extrapulmonary tissues. When the brain is scanned, less than 6% of total counts can be detected under normal circumstances. [172] In their series of 25 subjects with the hepatopulmonary syndrome, all patients with positive scans (more than 6% brain uptake) had hypoxemia with PaO_2 values below 60 mm Hg, with a positive correlation between the degree of shunting and arterial hypoxemia. The lung perfusion scan provides specificity to the diagnostic workup. It is well suited for patients with intrinsic lung problems, in whom we have reviewed the difficulties in using contrast echocardiography. As all specific tests, it is not appropriate when used as a screening tool. Contrast echocardiography should be used in such a role; in addition, this technique also provides information on cardiac function and pulmonary pressure, important for the differential diagnosis.

Pulmonary angiography. This invasive diagnostic procedure lacks sensitivity for the diagnosis of the hepatopulmonary syndrome. Two types of abnormalities have been described: a diffuse “spongiform” appearance of pulmonary vessels during the arterial phase and a distinct arteriovenous communication. [172] The latter can be suspected in patients with severe hypoxemia and a poor response to 100% oxygen. Such anatomic communications have been closed by embolization [173] and may even persist after liver transplantation. A less invasive approach to anatomic visualization is high-resolution chest CT. One report noted a good correlation between dilated pulmonary vessels and hypoxemia in patients with hepatopulmonary syndrome. [172] A diagnostic algorithm has been proposed (Fig. 116-5). It uses arterial blood gases, pulmonary function tests, and contrast echocardiography as the initial tools. Lung scanning is reserved for those individuals with hypoxemia, positive bubble echo, and abnormal pulmonary function tests.

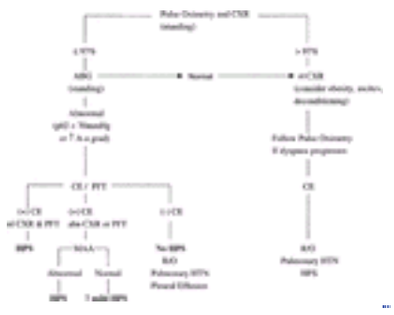

FIGURE 116-5. A diagnostic approach to the hepatopulmonary syndrome. (From ref. [163].)

Pathogenesis

The hyperdynamic circulation, a characteristic feature of the portal hypertensive state, arises from the effects of peripheral vasodilation. Pulmonary vasodilation could be viewed as part of this generalized hemodynamic picture. However, several observations indicate specific elements in its development. Although the degree of peripheral vasodilation worsens with the extent of liver failure, the development of the hepatopulmonary syndrome appears to be independent of the degree of hepatic dysfunction. Furthermore, only a subset of patients develop this unique pulmonary picture, in comparison to the more generalized prevalence of the hyperdynamic circulation.

Anatomic and Physiological Alterations Pathological studies point to a structural alteration of the pulmonary microcirculation. Among salient findings is vasodilation at the precapillary level, especially in gas-exchange areas. These were observed with postmortem injections of microopaque gelatin into the pulmonary vascular tree.[174] Spider nevi were seen on the pleura in almost half of the patients. One subject had a fully developed arteriovenous communication. No structural abnormalities were detected in the alveolar wall or connective tissue. Of interest, spider nevi have also been described in the pleura of patients dying from FHF.[175] Arteriovenous communications are likely to arise from the opening of preexisting anatomic pulmonary vascular communications as a result of increased blood flow. In children with tricuspid atresia, in whom a cavopulmonary communication is constructed to bypass the atretic segment, an angiographic picture similar to the hepatopulmonary syndrome develops in up to 25% of subjects, with dilated vessels and arteriovenous communications. Of interest, inclusion of hepatic vein flow directly into the pulmonary arterial bed appears to reduce the development of such complications.[176] The functional impairment can be defined as an alveolar-capillary oxygen disequilibrium.[177] In this concept, oxygen from the alveolar side has a longer path to traverse to reach the center of the capillary, where red cells constitute the center stream, resulting in hypoxemia. Although oxygenation would be improved by administering 100% oxygen, this measure would not correct hypoxemia if defined arteriovenous communications were present. A reduced transit time in the pulmonary capillary bed as a result of an increased CO further limits blood oxygenation, explaining the aggravation of symptoms with exercise. The input of multiple factors, including arteriovenous communications, cardiac performance, minute ventilation, and limitations of oxygen diffusion, explains the clinical spectrum of this condition. At one end of the spectrum are patients with severe hypoxemia have prominent pulmonary arterial vasodilation, on occasion with discrete arteriovenous communications. At the other end are patients with a more modest degree of shunting, in whom activation of compensatory mechanisms allows for maintenance of normal oxygenation.

Mechanisms of Vasodilation A critical role for nitric oxide has been established in the pathogenesis of the hyperdynamic circulation.[178] In the pulmonary circulation, a vasodilatory role for nitric oxide is also suggested by the demonstration of increased exhaled nitric oxide.[179] In 18 patients, a doubling of exhaled nitric oxide was detected, which normalized after transplantation. The normalization of the alveolar-arterial oxygen gradient was related to the reduction in exhaled nitric oxide. The effects of intravenous methylene blue, an inhibitor of guanylate cyclase (normally activated by nitric oxide to increase the level of cyclic guanosine monophosphate), further support a pathogenic role for nitric oxide.[180] In seven patients with severe hepatopulmonary syndrome (PaO_2 of 58 mm Hg), methylene blue improved PaO_2 to 74 mm Hg, associated with a rise of pulmonary and systemic vascular resistance (SVR). In a rat model of cirrhosis secondary to common bile duct ligation, intrapulmonary vasodilation and features of the hepatopulmonary syndrome (hypoxemia and increased alveolar-arterial oxygen gradient) can be observed. More recent studies demonstrate an increased exhaled nitric oxide in this model[181], [182] with demonstration of higher pulmonary total and calcium-dependent nitric oxide synthase activities. An increase in inducible nitric oxide synthase activity could be explained as a result of accumulation of intravascular macrophages. Treatment with an inhibitor of nitric oxide synthase for 6 weeks normalized features of the hepatopulmonary syndrome in this model. Other isoforms of nitric oxide synthase have been incriminated. Endothelial nitric oxide synthase was selectively increased in the lungs of rats with common bile duct ligation.[183] The possibility has been raised that production of endothelin-1 by the diseased liver, with subsequent increase in delivery to the lung vasculature, could be the stimulus for endothelial activation.[163] Endothelin-B receptors are present in the lumenal surface of the pulmonary vascular endothelium, and their activation results in vasodilation. Regardless of which isoenzyme is activated (pointing at different mechanisms of stimulation), it appears that pulmonary production of nitric oxide plays a critical role in the development of the hepatopulmonary syndrome. Further therapeutic interventions to inhibit its production are expected.

Treatment

Oxygen therapy is less likely to help those individuals who need it the most; severe hypoxemia is indicative of more conspicuous vasodilation. Nonetheless, a trial of oxygen therapy is often attempted in these patients.

A large number of medications have been tried, without definitive results. These include vasoconstrictors, such as phenylephrine[184] and somatostatin analogues.[160] Aspirin and indomethacin showed mild improvement in 4 subjects.[185], [186] More puzzling was the response to garlic powder: 6 of 15 subjects had improvements in PaO_2 of greater than 10 mm Hg.[187] The vasoactive component of garlic powder has not been identified. We have reviewed the experience with intravenous methylene blue; in one patient, L-NAME, an oral inhibitor of nitric oxide synthase, did not result in improvement.[188]

Hepatopulmonary syndrome occurs in the setting of portal hypertension. Relief of portal hypertension with TIPS results in complete portosystemic shunting with an increase in cardiac preload. The response of the hepatopulmonary syndrome to TIPS has been examined in a few patients. In one case,[189] an improvement of oxygenation of 20 mm Hg was detected 6 months after the procedure; the persistence of an abnormal lung scan suggested a mechanism of improvement whereby the CO was redirected to areas with better ventilation-perfusion characteristics. Worsening of oxygenation parameters has also been reported.[190] TIPS should not be used for the treatment of the hepatopulmonary syndrome unless more convincing evidence is provided.

In the 1980s, the presence of the hepatopulmonary syndrome was viewed as a contraindication to liver transplantation. Postoperative hypoxemia results in a more difficult recovery, and mortality is increased after the procedure. A PaO_2 of less than 50 mm Hg puts the patient at high risk for a morbid course.[191] Unique postoperative complications include the difficulty in discontinuing mechanical ventilation and the development of cerebral embolic hemorrhages. Newer approaches to postoperative management have been proposed, including the use of inhaled nitric oxide. However, when these patients are followed over a prolonged period, normalization of hypoxemia occurs. In 81 transplant recipients, improvement or normalization occurred in 82% of patients.[191] The recovery process may last more than 1 year.[192] At this time, liver transplantation is the only proven therapy for the hepatopulmonary syndrome.

The rise in pulmonary vascular resistance (PVR) that is seen after liver transplantation can unmask the presence of primary pulmonary hypertension.[193], [194] The coexistence of both entities can be difficult to diagnose before the procedure.

PORTOPULMONARY HYPERTENSION

Pulmonary artery hypertension complicating portal hypertension, known as *portopulmonary hypertension* (PPHTN), can be the cause of serious comorbidity and mortality in the patient with advanced hepatic disease. Like the hepatopulmonary syndrome, PPHTN is a pulmonary complication of portal hypertension. Hepatopulmonary syndrome results from pulmonary vasodilation and causes hypoxia. In contradistinction, PPHTN is a consequence of pulmonary vasoconstriction and is not a usual cause for hypoxia.

Mantz and Craige, in 1951, first described cor pulmonale in a patient with portal vein thrombosis, portal hypertension, and a spontaneous portosystemic shunt.[195] Later observations established that PPHTN can occur with cirrhosis and portal hypertension, extrahepatic portal hypertension and, rarely, after a surgically created portosystemic shunt. Portopulmonary hypertension may often be difficult to manage by medical therapy, can contraindicate an otherwise curative liver transplantation, and may persist after liver replacement. The reported mean survival of 15 months after diagnosis and a 50% 6-month mortality rate is poorer than the mortality

associated with primary pulmonary artery hypertension. [196] This emphasizes the dire significance of this diagnosis. Before the diagnosis of PPHTN can be made, other causes of elevated pulmonary artery pressure (PAP), including intracardiac shunts, valvular heart disease, chronic hypoxia, chronic pulmonary venous thrombosis, and connective tissue disorders must be excluded by relevant diagnostic testing.

Incidence

The reported prevalence of PPHTN in patients with portal hypertension is dependent on the patient population studied, the method of diagnostic detection, and the criteria selected for diagnosis. In an autopsy series of 17,901 patients, McDonnell and colleagues [197] recorded a 0.73% prevalence of pulmonary artery hypertension in patients with cirrhosis; in a comparative group of patients without cirrhosis, the prevalence was 0.13%. Hemodynamic study of cirrhotic patients with portal hypertension but without suspicion of pulmonary artery hypertension by Hadengue and associates [198] identified PPHTN in 2% of those patients. Ramsey and colleagues [199] reported a mean pulmonary arterial pressure (MPAP) greater than 25 mm Hg in 8.5% of patients and PVR greater than 120 dynes/sec/cm $^{-5}$ in 12.5% of patients evaluated for liver transplantation. A greater prevalence of PPHTN among patients evaluated for liver transplantation suggests that development of PPHTN is related to the duration and severity of portal hypertension.

Pathophysiology

The exact pathogenesis of PPHTN is not well understood. A current and best hypothesis is that the portosystemic shunting of splanchnic blood and impaired hepatic function allows arteriopathic and vasoactive mediators access to the pulmonary circulation. Endothelial cell injury may initiate a cascade of histological changes that are an early component of pathogenesis. [200] Eventually, a plexogenic arteriopathy of small precapillary pulmonary arterioles marked by laminar intimal fibrosis, medial hypertrophy, and concentric fibrosis characterizes the pathology of PPHTN. [201] A relative excess of humoral vasoconstrictors like endothelin and thromboxane A_2, and a relative decrease in mediators of vasodilation, like nitrous oxide and prostacyclin, favor vasoconstriction and the development of PPHTN. [200] Microvascular thrombosis because of excess thrombin, deficient fibrinolysis, and intrinsic platelet dysfunction caused by cirrhosis contribute to further increases in PVR. [202]

Most patients with cirrhosis and portal hypertension have a hyperdynamic circulation characterized by a high CO, elevated cardiac index, and a low SVR. Normally, flow-related increases in PAP caused by increases in CO induce pulmonary vascular dilation and recruitment of new pulmonary vasculature. PPHTN results when these adaptive mechanisms are attenuated by the progressive pulmonary arteriopathy. Further increases in hyperdynamic flow result in worsening severity of PPHTN.

Diagnosis

The diagnosis of PPHTN is based on clinical suspicion, the results of noninvasive diagnostic testing, and hemodynamic measurements allowed by a confirmatory right heart catheterization.

Clinical Considerations The patient with PPHTN may be asymptomatic. Usually, the diagnosis of PPHTN is made after the diagnosis of portal hypertension is established. Robalino and Moodie [196] described the clinical findings in cases of PPHTN. The most common presenting symptom was exertional dyspnea, which was present in most symptomatic patients. Other symptoms, including syncope, chest pain, fatigue, hemoptysis, and orthopnea, occurred infrequently. Systemic arterial hypertension, a pronounced pulmonic second sound (P_2), or a right ventricular heave predicted PPHTN in a group of patients with cirrhosis and portal hypertension being evaluated for liver transplantation. [203] Abnormal chest radiograph findings that are more common to cirrhotic patients with PPHTN include the prominence of the main and central pulmonary vessels, right ventricular enlargement, and peripheral vascular pruning that are also common to patients with primary pulmonary hypertension. [204] Electrocardiographic abnormalities of right ventricular hypertrophy, right atrial dilation, right bundle branch block, and premature atrial contractions in the patient with portal hypertension should alert the observer to the possibility of coexisting PPHTN.

Echocardiography Transthoracic Doppler echocardiography is the most important noninvasive test used to establish the diagnosis of PPHTN. Results of this examination can often exclude ventricular failure, intracardiac shunting, and valvular dysfunction as causes of elevated PAP. Echocardiographic indicators of PPHTN are right atrial dilation, right ventricular hypertrophy, interventricular septal wall thickening, and bulging of the interventricular septum into the left heart. Measurement of the tricuspid valve regurgitant jet velocity by echocardiography allows an indirect estimation of the MPAP. Importantly, most patients with PPHTN have tricuspid valve regurgitation. Torregrosa and associates [205] studied 107 patients with echocardiography who had cirrhosis and were referred for possible liver transplantation. Seventeen patients had suspected PPHTN when echocardiography diagnosed a systolic MPAP greater than 40 mm Hg or a pulmonary acceleration time of less than 10 ms. Hemodynamic monitoring confirmed PPHTN in only 5 of these patients.

Hemodynamic Assessment Right heart catheterization is the diagnostic gold standard used to establish the diagnosis of PPHTN. Catheterization allows direct measurements of PAP, CO, and pulmonary capillary wedge pressure (PCWP) and indirect calculations of PVR and SVR. Criteria from right heart catheterization that establish a diagnosis of pulmonary artery hypertension include an elevated MPAP of greater than 25 mm Hg at rest, an elevated PVR of greater than 120 dynes/second/cm $^{-5}$, and a PCWP of less than 15 mm Hg. [206] The high CO and low SVR characteristic of the hyperkinetic circulation of cirrhosis and portal hypertension is usually confirmed. Volume overload or diminished left ventricular function as a cause of the elevated PAP is excluded by a PCWP less than 15 mm Hg. The severity of PPHTN is classified as mild, moderate, or severe. Complete unanimity does not exist in terms of specific levels of MPAP defining each category. Generally, PPHTN is classified as mild when MPAP is 25 to 35 mm Hg, moderate when PAP is between 35 and 50 mm Hg, and severe when MPAP is greater than 50 mm Hg. Kuo and associates [204] compared selected hemodynamic and clinical data of 30 patients with PPHTN to similar data in equivalent patient groups with only cirrhosis and portal hypertension or primary pulmonary hypertension. Patients with PPHTN demonstrated hemodynamic findings also observed in patients with cirrhosis and portal hypertension or with only primary pulmonary hypertension. Patients with PPHTN had the hyperdynamic circulation common to cirrhosis. Portopulmonary hypertension patients demonstrated increases in PVR similar to those found in the patients with primary pulmonary artery hypertension. Echocardiography, chest radiography, and electrocardiographic findings suggesting pulmonary artery hypertension were similar in patients with PPHTN and primary pulmonary artery hypertension. Patients with PPHTN had a significantly more severe respiratory alkalosis than patients with primary pulmonary hypertension or cirrhosis alone. In patients with cirrhosis, a PCO_2 of less than 30 was an especially specific indicator for PPHTN.

Treatment

Medical therapy for the patient with PPHTN involves the administration of pharmacological agents that, by vasodilator effect, reduce PAP. When administration of a vasodilator agent during a pulmonary artery catheterization reduces PVR and MPAP (diagnostic response), a therapeutic trial of vasodilator therapy should be considered. [207], [208] Long-term treatment may result in progressive hemodynamic improvements as evidenced by repeat right heart catheterization. Liver transplantation may be considered in selected patients with mild PPHTN or patients with more severe PPHTN that have responded to vasodilator therapy.

Epoprostenol Therapy Although acute reduction of PAP has been reported to result from the administration of several different agents, including isosorbide-5-mononitrate and inhaled nitrous oxide, the contemporary medical treatment of PPHTN is mainly limited to epoprostenol (formally PGI_2 or prostacyclin) infusion therapy. [209] Epoprostenol is a potent vasodilator agent with anti–platelet-aggregating properties that is naturally produced by vascular endothelial cells. Instability of epoprostenol at a pH of less than 10.5 and a short half-life require constant intravenous infusion by way of long-term vascular access for chronic therapy. Drug treatment–related side effects can include systemic hypotension, headache, nausea, and venous catheter-related complications. [210] Effective epoprostenol treatment of patients with primary pulmonary artery hypertension has been reported. [210] Immediate vasodilation followed by promotion of vascular remodeling that causes further reduction of PAP is proposed as an explanation for this medication's therapeutic effect. Patients with at least moderate PPHTN (MPAP higher than 35 mm Hg) who have had a diagnostic response to epoprostenol are candidates for a trial of longer-term epoprostenol therapy. Kuo and associates [209] reported improved hemodynamic parameters in four patients with PPHTM while treated with epoprostenol for a period of 6 to 14 months. Krowka and associates [211] treated 10 patients with an MPAP higher than 35 mm Hg for 8 days to 30 months. Six patients showing improvements in PVR, MPAP, and CO after 1 hour had further reduction of PVR when treated with continuous therapy. Available data do not permit firm conclusion as to the long-term benefit of epoprostenol therapy, nor how often the beneficial effect of therapy might persist after the cessation of treatment. Epoprostenol therapy is most appropriate for the cirrhotic patient who would, except for moderate to severe PPHTN, be a candidate for liver transplantation. [212]

Newer Therapies Newer and still to be developed vasoactive agents will undoubtedly be of benefit as future treatments for PPHTN. Treatment with treprostinil, a prostacyclin analogue, is of reported benefit in patients with primary and secondary pulmonary artery hypertension. Administration by a subcutaneous infusion, rather than the continuous intravenous route required by the less stable epoprostenol, reduces the risk for adverse complications due to long-term venous access. [213], [214] The efficacy of treprostenol in the treatment of patients with PPHTN has not been described. Bosentan is an orally administered drug and endothelin receptor agonist with reported efficacy in the treatment of primary pulmonary artery hypertension. [215] Unfortunately, bosentan-associated hepatotoxicity contraindicates its use in patients with preexisting liver disease.

Liver Transplantation Krowka and associates [216] reviewed the results of orthotopic liver transplantation in 43 patients with PPHTN. The 30-day mortality rate was 22%. A preoperative MPAP greater than 50 mm Hg was associated with a 100% mortality rate. Four additional patients died from cardiopulmonary failure between 5 and 30 months after operation. Mortality in patients with an MPAP of 35 to 50 mm Hg before surgery was 50%. All patients with a preoperative MPAP of less than 35 mm Hg survived. Ramsey and associates [199] reported that only 2 of 7 patients with an MPAP of more than 60 mm Hg experienced a good quality of health and life after liver replacement. [199] During liver transplantation, morbidity and mortality in patients with PPHTN is caused by the hemodynamic stresses of reperfusion. Intraoperative events that contribute to depressed right ventricular function include hypothermia, hyperkalemia, hypercapnia, and acidosis. The potential liver transplant recipient must be evaluated for possible PPHTN by the described methods. In general, an MPAP of greater than 35 to 40 mm Hg is recognized as an absolute contraindication to liver transplantation. Dobutamine-assisted stress echocardiography documenting left ventricular dysfunction in patients with PPHTN further excludes orthotopic liver transplantation consideration. Patients with an MPAP of less than 35 mm Hg are candidates for further consideration of liver transplantation. Patients without other contraindications to liver transplantation who have moderate to severe PPHTN are candidates for epoprostenol therapy. [217] The goal of epoprostenol therapy is reduction of MPAP to a level that allows further consideration for transplantation. A reasonable reduction in MPAP is to no more than 35 to 40 mm Hg. Patients successfully transplanted after chronic preoperative epoprostenol treatment require continued epoprostenol infusion therapy after liver transplantation. [212] Eventual reversal of PPHTN after liver transplantation may allow discontinuation of treatment. [211], [218] The required duration of postoperative therapy varies and is dependent on the resolution of PPHTN that is documented by repeat right heart catheterization. [217] Persistence, or worsening, of elevated PAP after liver transplantation is an indication to continue epoprostenol therapy. [219] Recurrent PPHTN accompanying graft failure has been reported. [220] More radical surgical treatment that includes simultaneous heart, lung, and liver transplantation has been described but is experimental. [221]

Summary

Portopulmonary hypertension is a pulmonary complication of portal hypertension that has a poor prognosis. The diagnosis requires confirmatory right heart catheterization. Vasodilator therapy with epoprostenol in selected patients may result in hemodynamic improvement. Patients with mild PPHTN (MPAP of less than 25 mm Hg) or patients with moderate and severe PPHTN responsive to epoprostenol therapy may benefit from liver transplantation.

CHAPTER 117

Francis Y. K. Yao and Nathan M. Bass

LIVER TRANSPLANTATION

In the fourth decade since the inception of human orthotopic liver transplantation, [1] this procedure has become a highly successful treatment for patients with life-threatening, advanced liver disease. The 1-year patient survival according to the United Network for Organ Sharing (UNOS; Richmond, VA) registry for all adult liver transplants performed in the United States over a 2-year period from 1998 to 2000 was 87%, [2] compared to 79% from 1988 to 1994. [3] Many liver transplant centers have now achieved 1-year patient survival rates of about 90%, and 5-year survival rates of 70% to 80%. The success of liver transplantation is, however, limited by the serious crisis of donor shortage. [4] As of June 2001, a total of 17,983 patients in the United States were placed on the waiting list for liver transplantation, whereas only 4934 liver transplantation operations were performed in the year 2000 in over 120 liver transplant centers across the country [2] (Fig. 117-1). The rapid rise in the number of patients on the waiting list for liver transplantation has led to increased waiting time and a greater number of deaths each year among patients awaiting liver transplantation [2, 4, 5] (see Fig. 117-1). Organ donation has, however, remained relatively stagnant in recent years in spite of the concerted efforts to increase donation. [4]

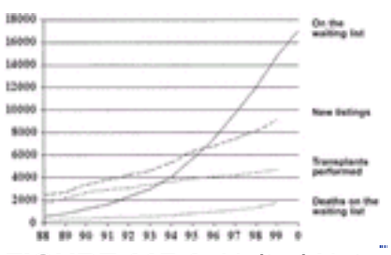

FIGURE 117-1. United Network for Organ Sharing (UNOS) data showing the trends in the liver waiting list, liver transplantation performed, and waiting list deaths over the past decade in the United States. Data for listed patients are for the end of each year up to and including 2000. (From UNOS data, March 2001; courtesy, John P. Roberts, M.D., Department of Surgery, University of California, San Francisco.)

This chapter reviews the surgical technique, organ preservation, indications and evaluation for liver transplantation, disease-specific issues and outcomes, and management of posttransplant complications.

SURGICAL TECHNIQUE AND PRESERVATION

Matching of an appropriate donor organ with a liver transplant recipient requires compatibility of the ABO blood type but not the human leukocyte antigen (HLA) tissue type. The conventional recipient operation involves orthotopic transplantation of the donor organ (i.e., in the normal anatomic location). The procedure is conventionally divided into three phases: the hepatectomy phase (removal of the recipient native liver), the anhepatic phase, and the reperfusion phase. The latter follows the complete vascular reconnection of the liver. The order of anastomoses of the donor liver usually commences with revascularization of the donor organ (suprahepatic vena cava, infrahepatic vena cava, portal vein, and hepatic artery) followed by biliary reconstruction. However, numerous variations exist in the technique of implanting the donor organ, based upon variations in anatomy, type of recipient liver disease, and surgical preference. [6] The hepatic arterial reconstruction is commonly achieved with an end-to-end anastomosis of the donor celiac axis with a Carrel patch of aorta to the recipient common hepatic artery or celiac axis. Vascular grafts directly from the recipient aorta may be used in some cases to ensure adequate arterial inflow. The usual approach to biliary reconstruction employs a direct duct-to-duct anastomosis (choledochocholedochostomy) except in instances where the recipient duct is diseased (primary sclerosing cholangitis, biliary atresia), a large discrepancy in size exists between the recipient and donor ducts, or there is inadequate length of bile duct for a tension-free anastomosis. In these cases, as well as in most very small children, a choledochojejunostomy with a Roux-en- limb of jejunum is performed. Finally, the donor gallbladder is removed. In order to avoid significant hemodynamic instability and congestion of the bowel and kidneys during the anhepatic phase, some centers employ a venovenous bypass circuit, which connects the portal vein and inferior vena cava to the left subclavian vein. [6]

In light of the critical shortage of donor livers in recent years, strategies that make use of segmental grafts have been developed and include splitting of cadaveric livers between two recipients, and the use of living donors. [7, 8] The latter has become almost routine in the case of the pediatric liver recipient in whom a left lateral segment, usually obtained from a blood-type–compatible parent, is sufficient, and is also a relatively safe procedure for the donor. [7] More recently, living adult-to-adult donor procedures have been developed and increasingly used. [8, 9] and [10] In order to provide a minimal functioning liver mass for the recipient, this procedure usually involves removing the right lobe from the donor and transplanting it orthotopically into the recipient (Fig. 117-2; Color Fig. 117-2). In both the donor and the recipient, there is rapid regeneration of the liver, with full size regained over 6 to 8 weeks. Despite the potential advantages of living-related liver transplantation, it carries inherent risks for the healthy donor, the full extent of which is yet to be fully elucidated. [9, 10] To date, there have been two known donor deaths among close to 1000 adult-to-adult living donor liver transplants performed in the United States. The American Society of Transplant Surgeons has published a position paper on adult-to-adult, living-related liver transplantation, [11] and practice guidelines have been established at a recent national consensus conference on living donor organ transplantation. [12]

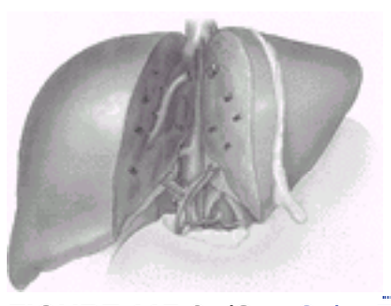

FIGURE 117-2. (See Color Fig. 117-2.) Illustration of technique of living donor right hepatic lobectomy. (Courtesy John P. Roberts, M.D., Department of Surgery, University of California, San Francisco.)

A major advance in the preservation of donor organ viability and extension of the geographic distance over which organs can now be procured and transported was the development of the University of Wisconsin (UW) cold storage solution with which the donor organ is flushed and cooled prior to removal and transportation. [13] The UW solution has extended the cold ischemia time for liver preservation for up to 24 hours, although it is uncommon for organs that have been preserved for longer than 16 hours to be used on a routine basis. Key principles of the UW solution are a high K^+ and Mg^{2+} and low Na^+ and Ca^{2+}. This solution will maintain intracellular ion concentrations, adenosine as a substrate for ATP synthesis, hydroxyethyl starch as an oncotic solute to reduce interstitial edema, and allopurinol and glutathione as antioxidants.

INDICATIONS FOR LIVER TRANSPLANTATION

Non–Disease-Specific Complications and Prognostic Models

Liver transplantation should be considered for patients with cirrhosis when one or more signs of hepatic decompensation develop. In a study from Barcelona, [14] the probability of decompensation was 58% at 10 years after the diagnosis of cirrhosis. Ascites was the most common manifestation of hepatic decompensation, followed by jaundice, hepatic encephalopathy, and variceal bleeding. The median survival with compensated cirrhosis was 8.9 years, compared to only 1.6 years for decompensated cirrhosis. [14]

Ascites and Related Complications Approximately 50% of patients with cirrhotic ascites succumb in 2 years. [15] Up to 10% of patients with cirrhotic ascites are refractory to standard diuretic therapy. [16] Treatment options for refractory ascites include serial therapeutic paracentesis, [17], [18] peritoneal venous shunt, [18], [19] and the transjugular intrahepatic portosystemic shunt (TIPS). [20] Survival for patients with refractory ascites is only about 50% at 1 year regardless of the type of treatment they have received. [17], [18], [19] and [20] Ascites may be associated with spontaneous bacterial peritonitis and hepatorenal syndrome, both of which further shorten survival. The 1-year probability of survival was reported in one study to be 66% for patients with cirrhosis and ascites without spontaneous bacterial peritonitis, compared to only 38% for patients with this complication. [21] In one third of patients with spontaneous bacterial peritonitis, renal impairment develops despite treatment of the infection. [22], [23] Hepatorenal syndrome is a particularly ominous complication of cirrhosis, associated with a median survival of only 1.7 weeks after its onset. [24] Renal failure prior to liver transplantation is a strong predictor of death [25], [26] and increased cost [27] after liver transplantation.

Portal Hypertensive Bleeding Bleeding from esophageal or gastric varices carries a high 30-day mortality ranging from 30% to 50%. [28] The risk of recurrent variceal bleeding is about 60% to 70% within 2 years of the index hemorrhage. [28] Better understanding of the basic pathophysiology culminating in portal hypertension and bleeding has led to important advances in pharmacological therapy including ß-blockade for primary and secondary prophylaxis of variceal bleeding, and vasopressin or somatostatin for the initial control of hemorrhage. [28] Endoscopic sclerotherapy has been the cornerstone of management of esophageal variceal hemorrhage, but endoscopic banding ligation appears to produce superior results with a lower incidence of rebleeding, and a trend toward lower mortality compared to sclerotherapy. [29] Another major advance in the treatment of variceal bleeding is TIPS which has a technical success rate of greater than 90% in experienced hands. [30], [31] Compared to endoscopic treatments, TIPS confers a lower rate of rebleeding but no survival advantage. [32], [33] The current accepted indications for TIPS include (a) emergency (rescue or salvage) therapy for uncontrolled, acute portal hypertensive bleeding and (b) prevention of recurrent portal hypertensive bleeding for which endoscopic or pharmacological therapy has either failed or cannot be applied. [28], [33] The Mayo Clinic group proposed a model based on serum bilirubin, serum creatinine, prothrombin time, and etiology of liver disease, which appears to be strongly predictive of 30-day mortality after TIPS. [34] Severe hyperbilirubinemia occurring after the creation of TIPS is a sign of rapid hepatic decompensation, associated with a particularly ominous short-term prognosis. [35] Encephalopathy develops in about 30% of patients after TIPS and is usually reversible with medical therapy. [28] A major problem with TIPS is the high incidence of shunt stenosis or occlusion, estimated to be 30% over the first year and 50% at 2 years. [36] TIPS has not been shown in a study from the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) Liver Transplant Database to have any significant impact on liver transplantation in terms of total operative time, blood product requirements, survival, or length of hospital stay. [37] Consequently, preoperative portal decompression solely for facilitating liver transplantation is not an acceptable indication for TIPS. Occasionally, TIPS also creates technical difficulties for liver transplantation secondary to stent migration or extension into the extrahepatic portal or hepatic vein. [28], [33] Portosystemic shunt surgery provides more definitive control of bleeding compared to sclerotherapy [28], [38], [39] or TIPS [40] in patients with adequate hepatic function to tolerate surgery, but does not improve survival and is also associated with an increased incidence of encephalopathy. Distal splenorenal shunt is the preferred surgical approach in consideration for future liver transplantation since the hepatic hilum is not invaded.

Hepatic Encephalopathy Hepatic encephalopathy is a complex neuropsychiatric syndrome which may be present in 50% to 70% of all patients with cirrhosis, including those with subtle abnormalities only demonstrable by psychometric testing. [41] Hepatic encephalopathy is aggravated by portosystemic shunting via collaterals secondary to portal hypertension, and is also associated with surgical portosystemic venous shunting and the creation of TIPS. [29] Nonabsorbable disaccharides such as lactulose, and antibiotics including neomycin with activities against urease-producing bacteria are effective in reversing hepatic encephalopathy. The efficacy of lactulose and neomycin in the treatment of hepatic encephalopathy appears to be equal. [42] Symptomatic hepatic encephalopathy is an indication for consideration of liver transplantation. Uncommonly, some patients with hepatic encephalopathy have progressive, debilitating neurological or neuropsychiatric syndromes such as dementia, spastic paraparesis, cerebellar degeneration, and extrapyramidal movement disorders, associated with structural abnormalities of the central nervous system. [41] If very advanced, neurological injury may not be reversible with liver transplantation, although one report has suggested that there may be gradual improvement after liver transplantation. [43]

Child-Turcotte-Pugh Score The Child-Turcotte-Pugh (CTP) score was originally used to stratify patients according to the risks for undergoing portal decompressive shunt surgery. [44] The CTP score has also become the predominant method for predicting prognosis of patients with cirrhosis irrespective of etiology. [45], [46] This scoring system is based on five variables: stage of encephalopathy, severity of ascites, serum bilirubin level, serum albumin level, and the international normalized ratio (INR) for prothrombin time (Table 117-1). In a natural history study from Innsbruck University, Austria involving 620 cirrhotic patients followed for 15 years, [45] the estimated 1- and 5-year survival rates were 95% and 75%, respectively, for Child class B, and 85% and 50%, respectively, for Child class C. Patients with Child class A cirrhosis had significantly better survival probabilities exceeding 90% for up to 10 years of follow-up. [45] According to the minimal listing criteria for liver transplantation implemented by UNOS in 1997, [47] the key criterion for eligibility of listing for liver transplantation is an estimated 90% or less chance of 1-year survival, which equates with a CTP score of 7 or higher (Child class B or C). In addition to using the CTP score for determining eligibility of listing for liver transplantation (minimal listing criteria), [47] the UNOS guidelines previously relied on this scoring system to determine the priority in organ allocation among patients with chronic liver disease. [48] Patients with fulminant liver failure, who are at greatest risk for short-term mortality, are classified in a separate category and listed with the highest priority (status 1) for liver transplantation. [48]

	1 POINT	2 POINTS	3 POINTS
Encephalopathy (stages)*	0	1–2	3–4
Ascites	None	Slight	Moderate
Bilirubin (mg/dL)	<2	2–3	>3
(PBC and PSC)	<4	4–10	>10
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
PT prolonged (sec)	1–4	5–6	>6
(INR)	<1.7	1.8–2.3	>2.3

*Encephalopathy stages: 0 to 4 (ref. 45).

INR, international normalized ratio; PBC, primary biliary cirrhosis; PSC, primary sclerosing cholangitis; PT, prothrombin time.

Notes: The individual measurements are allocated 1, 2, or 3 points, and the points from the 5 variables are added to give a total score ranging from 5 to 15 points.

Child's classes A, B, and C correspond to Child-Turcotte-Pugh score of 5–6 points, 7–9 and 10–15, respectively.

Adapted from ref. 44.

TABLE 117-1 The Child-Turcotte-Pugh Classification

Model for End-Stage Liver Disease The Model for End-Stage Liver Disease (MELD) prognostic score has been developed using a formula based on serum creatinine, serum bilirubin, and INR for prothrombin time to predict short-term mortality for patients with end-stage chronic liver disease [49] (Table 117-2). This model was based on multivariate analysis of readily and objectively measurable variables originally developed to assess the short-term prognosis of patients with cirrhosis undergoing the TIPS procedure. [34] The MELD scoring system was subsequently shown to also be useful in grading the risk of death at 1 week, 3 months, and 1 year for patients with end-stage chronic liver disease [49] (Table 117-2). The MELD score has been implemented by UNOS as a disease severity index to determine priority for organ allocation, [50] replacing the previous system based on the CTP score and other specific clinical criteria. [48] Using the MELD model, the patient with the highest score reflecting the greatest risk for short-term mortality will receive liver transplantation first, and the length of waiting time will be a minimal factor in determining organ allocation. [50]

TABLE 117-2 The Model for End-Stage Liver Disease (MELD) Scoring System Determining Disease Severity and Priority for Organ Allocation

Quality-of-Life Issues Encephalopathy, ascites, and debilitating fatigue are some of the common manifestations of end-stage liver disease that markedly impair a patient's quality of life. Even subclinical hepatic encephalopathy, determined only by psychometric analysis, can cause significant impairment of daily functioning. [51] Liver transplantation improves quality of life, and facilitates return to gainful employment in over half of the patients. [52], [53] and [54] Patients with severe impairment of quality of life but not meeting the listing criteria based on the CTP score may be listed for liver transplantation on exceptional grounds upon approval of a regional UNOS-appointed review board. [47]

Disease-Specific Issues and Outcome After Liver Transplantation

More than 60 distinct diseases have been treated with liver transplantation. [55] The relative frequencies of disease indications for liver transplantation in the United States based on recent UNOS data [5] are presented in Figure 117-3. Hepatitis C-related cirrhosis is currently the most common indication for liver transplantation in the United States, accounting for over 20% of all liver transplants. [5] The guidelines for liver transplantation, special considerations, the controversial aspects of certain disease indications, and posttransplant outcome for specific types of liver disease are selectively reviewed (Table 117-3). Many of the less common types of liver disease will not be discussed in detail in this chapter.

FIGURE 117-3. Liver transplantation in the United States according to the primary diagnosis. Data from ref. [5] for the year 1998. *ALD,* alcoholic liver disease; *PBC,* primary biliary cirrhosis; *PSC,* primary sclerosing cholangitis.

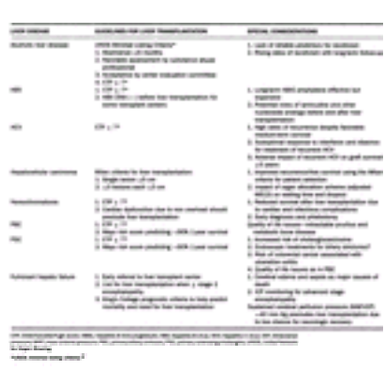

TABLE 117-3 Summary of Disease-Specific Guidelines for Liver Transplantation

Alcoholic Liver Disease Once considered a highly controversial indication for liver transplantation on both medical [56] and ethical grounds, [57] alcoholic liver disease is second only to hepatitis C as the most common indication for liver transplantation in the United States (see Fig. 117-3). Survival following liver transplantation for alcoholic cirrhosis has been reported to be at least as good as for most other indications. [58], [59], [60] and [61] The obvious concern, however, is the possibility of returning to alcohol consumption after liver transplantation. The patient transplanted for alcoholic liver disease who drinks again creates a highly emotional and demoralizing issue and is often perceived as a treatment failure, even though the absolute alcohol intake may be low and graft function normal. There is insufficient data to fully understand the impact of moderate alcohol consumption after liver transplantation, and the extent and pattern of graft injury. The reported incidence of recidivism following liver transplantation has typically ranged from 10% to 20% at 12 months after liver transplantation. [62] With longer follow-up, however, the recidivism rate for any alcohol use has exceeded 30%. [62], [63], [64] and [65] Better insight into patient selection, closer monitoring, and ngoing counseling for these patients after liver transplantation are therefore needed. There is a strong consensus based on a survey of liver transplant centers and a National Institute of Health workshop to require an established period of abstinence, typically 6 months, before approval for listing for liver transplantation. [66], [67] The required period of abstinence is useful since abstinence alone can often lead to sustained clinical improvement, [68] thereby obviating the need for liver transplantation. The 6-month rule for abstinence as a predictor of long-term sobriety remains controversial, [63], [69], [70] and should be used in conjunction with other psychosocial and psychiatric parameters in the patient selection process. The University of Michigan alcoholism prognosis scale [61] and several other models [62] have been proposed to predict the risk of recidivism, but the value of these models as a tool for patient selection has not been clearly established. The UNOS minimal listing criteria for alcoholic liver disease include:

- abstinence of at least 6 months
- favorable assessment by a substance abuse professional
- approval by the transplant center evaluation committee, in addition to fulfilling the medical criteria to be listed for liver transplantation. [47]

Hepatitis B Less than a decade ago, liver transplantation for patients with cirrhosis due to chronic hepatitis B infection was considered a relative contraindication due to high rates of hepatitis B recurrence and graft failure. [71], [72] and [73] The most aggressive form of hepatitis B recurrence, known as fibrosing cholestatic hepatitis, often leads to death within weeks of onset of graft reinfection. [74] Subsequently, the use of high-dose intravenous hepatitis B immunoglobulin (HBIG) after liver transplantation significantly reduced the incidence of hepatitis B recurrence and improved survival. [75], [76] and [77] The benefit of HBIG appears to be greatest among patients with negative hepatitis B DNA and hepatitis B e-antigen prior to liver transplantation. [75] Samuel and colleagues from France [78] reported their long-term survival and hepatitis B recurrence data on 89 patients with hepatitis B-cirrhosis who received liver transplantation and intravenous HBIG prophylaxis. Despite an excellent actuarial 10-year survival of 72.8%, the 5-year actuarial hepatitis B recurrence rate was still high at 65% with HBIG prophylaxis. [78] Graft reinfection despite HBIG prophylaxis may be caused by inadequate neutralization because of overwhelming amounts of hepatitis B viral replication or breakthrough infection by hepatitis B surface antigen protein escape mutants. [79], [80] Another concern of intravenous HBIG is its high cost, estimated to be $30,000 to $50,000 in the United States during the first year of therapy after liver transplantation. [81] Lamivudine, an oral nucleoside analog, has been used both in the prophylaxis and treatment of recurrent hepatitis B infection after liver transplantation. [81] Based on preliminary experience, lamivudine alone started preemptively before transplantation and continued thereafter appears to be less effective than HBIG for prophylaxis against hepatitis B recurrence after liver transplantation. [81], [82] A potentially more effective strategy for hepatitis B prophylaxis, based on limited data, is a combination of lamivudine with intramuscular or intravenous HBIG. [83], [84] and [85] Randomized, controlled studies are currently underway to evaluate these different strategies. Preliminary data have also suggested that HBIG can be safely discontinued after short-term (6–12 months) use

following liver transplantation, with continued long-term lamivudine. [86] Lamivudine is also effective in the treatment of recurrent hepatitis B infection after liver transplantation. In the largest published series by Perrillo and associates [87] using lamivudine for 52 weeks, 60% of the 52 patients cleared hepatitis B viral DNA, 31% cleared hepatitis B e antigen, 6% lost hepatitis B surface antigen, and 71% had normalization of alanine transaminase levels. In patients with decompensated hepatitis B-cirrhosis awaiting liver transplantation, data have emerged suggesting the effectiveness of lamivudine in stabilizing liver function and improving the CTP score, [88], [89] and [90] which may also confer a survival benefit. [90] An important concern of long-term use of lamivudine beyond 6 to 9 months, regardless of the clinical setting, is the high rate of emergence of lamivudine-resistant mutant virus (YMDD mutant), estimated to be about 20% to 30% per year in posttransplant patients. [81] This mutation may lead to deterioration of graft function in some patients. [81] Other nucleoside or nucleotide analogs, such as adefovir dipivoxil, may become available to serve as “rescue” therapy should lamivudine resistance occur with deterioration of liver function. [91], [92]

Hepatitis C Despite almost invariable persistence of serum hepatitis C RNA after liver transplantation and a rate of graft re-infection (histological evidence of hepatitis) of 40% to 75%, [93] survival up to 5 years is similar to that for other indications for liver transplantation. [94], [95], [96] and [97] While prospective long-term survival data following liver transplantation for hepatitis C infection are very limited, it is increasingly recognized that the course of posttransplant recurrent hepatitis C is more rapid when compared with that prior to liver transplantation. [93] About 10% to 20% of patients with recurrent hepatitis C infection progress to cirrhosis within the first 5 years after liver transplantation. [93], [94], [96] A severe form of recurrence, resembling the syndrome of fibrosing cholestatic hepatitis in hepatitis B-infected patients, has also been reported. [98] Factors predictive of more severe recurrent disease and worse outcome after liver transplantation have not been clearly elucidated, but include a high pretransplant hepatitis C RNA titer (at least 1 million mEq/mL) [95] and genotype 1b. [97], [99], [100] Other studies, however, have not supported these associations. [96], [101] Patients with severe and multiple rejection episodes may also have early and more severe recurrent hepatitis C, presumably related to more intense immunosuppression. [102], [103] and [104] The type of immunosuppression (cyclosporine versus tacrolimus) does not clearly appear to have any significant impact on the incidence or severity of hepatitis C recurrence, [105], [106] but additional studies to further evaluate the impact of these and other new immunosuppressive agents on the course of recurrent hepatitis C are needed. Treatment of recurrent hepatitis C after liver transplantation with either interferon or ribavirin alone has yielded disappointing results. [107], [108] and [109] Combination therapy with interferon and ribavirin for recurrent hepatitis C appeared promising initially in a pilot study, especially among patients treated early in the course of the disease. [110] However, subsequent studies using this therapeutic combination have shown suboptimal virologic response and poor patient tolerance. [111], [112] Factors contributing to the latter include renal insufficiency, anemia, and thrombocytopenia commonly observed in this population. The dose of ribavirin used in these patients is typically less than that in the nontransplant setting, [111] in large part due to reduced glomerular filtration rate associated with both cyclosporine and tacrolimus. Another approach has been to use interferon with or without ribavirin early after liver transplantation for prophylaxis against hepatitis C recurrence. [113] and [114] In a study by Sheiner and colleagues, [113] a 1-year course of interferon alone commenced within 2 weeks after liver transplantation significantly reduced the incidence of hepatitis C recurrence, particularly for patients with low hepatitis C RNA levels. [113] Multicenter, randomized controlled trials have been initiated in Europe and in the United States to assess the optimal timing and efficacy of interferon and ribavirin for posttransplant hepatitis C infection. Transplantation of a hepatitis C-positive donor liver into a recipient with hepatitis C-cirrhosis does not appear to result in a worse outcome in the initial years after liver transplantation, [115] and may prove to be an important strategy for expanding the donor pool for liver transplantation.

Hepatocellular Carcinoma Liver transplantation for hepatocellular carcinoma (HCC) in unselected patients, including those with extensive and bulky tumors, was associated with dismal outcome primarily due to aggressive tumor recurrence. More recent experience, however, has suggested excellent recurrence-free survival after liver transplantation in patients with small tumors, with 5-year survival rates consistently above 70%. [116], [117], [118], [119] and [120] In a study by Bismuth and associates from France, [116] patients with no more than 3 tumor nodules and none greater than 3 cm in largest diameter had a 3-year disease-free survival of 83% following liver transplantation compared to only 18% treated with hepatic resection. In a subsequent study by Mazzaferro and colleagues from Milan, Italy, [117] 35 patients who met the specific criteria of a solitary tumor not exceeding 5 cm or no more than 3 tumor nodules, none greater than 3 cm had excellent overall and recurrence-free survival rates of 85% and 92%, respectively, at 4 years after liver transplantation. [117] The recurrence-free survival in patients with small HCC was identical to that of patients without tumor. [118] The Milan criteria [117] have been incorporated into the UNOS guidelines for liver transplantation for HCC. Poorly differentiated tumor grade and microvascular invasion appear to correlate with advanced tumor-stage based on the size and number of lesions, and are also potential predictors for poor outcome after liver transplantation. [121], [122] Despite excellent survival after liver transplantation for selected patients with HCC, tumor growth in the face of increased waiting time for liver transplantation in this country presents a considerable challenge, as eventually, acceptable criteria for liver transplantation may be exceeded. Advances in living-related liver transplantation may be a potential solution for this major problem by overcoming the waiting time obstacle in those patients who have a suitable donor. [123] However, there are still logistic and ethical concerns about this option. [9], [10] In order to control tumor growth, many liver transplant centers use chemoembolization, percutaneous ethanol injection, or radiofrequency ablation as “bridging procedures” to liver transplantation. [120], [124] However, the benefit of these procedures in slowing the rate of tumor growth and ultimately preserving the chance for successful liver transplantation is unproven. [120], [124] Due to the high dropout rate related to tumor growth in patients on the waiting list, the current MELD system for organ allocation is adjusted to give higher priority to patients with HCC who are at increased risks for exclusion based on tumor characteristics. [125] This system is designed to reduce the waiting time and thus the rate of dropout from the waiting list. If the waiting time for liver transplantation can be significantly reduced for patients with HCC, it may also be possible to modestly expand the tumor size criteria, as proposed in a study from the authors’ institution, [120] without compromising survival after liver transplantation.

Hemochromatosis and Other Metabolic Liver Diseases Patients with hereditary hemochromatosis are at increased risks for the development of cirrhosis, liver cancer, cardiomyopathy, and diabetes. [126] Several studies have indicated a less favorable outcome following liver transplantation for patients with hemochromatosis. [127], [128], [129] and [130] In a retrospective analysis of 37 patients who underwent liver transplantation for hemochromatosis, [127] the 1- and 5-year survival rates were only 58% and 40%, respectively, compared to 62% 5-year survival for all patients reported to the UNOS registry over the same period. Infectious complications were the cause of 53% of all deaths within the first year after liver transplantation, whereas cardiac complications accounted for 50% of the late mortality. [127] A high incidence of hepatic malignancies (27%) was also observed at the time of liver transplantation. [128] The diagnosis of hemochromatosis was often not made until after liver transplantation, [129], [130] a factor that might have contributed to the poor outcome. Once the diagnosis of hemochromatosis is confirmed, early initiation of phlebotomy may diminish the likelihood of posttransplant cardiac complications. Thorough cardiac evaluations with right heart catheterization and possibly endomyocardial biopsy are recommended before liver transplantation. [130] Cardiac dysfunction due to excessive iron infiltration may preclude liver transplantation in view of the high perioperative and late postoperative cardiac mortality. [127], [130] The hallmark of Wilson disease, a relatively rare inherited disease of copper metabolism, is its highly variable clinical presentation. [131] The diagnosis of Wilson disease is suggested by a young age at presentation and the presence of low serum ceruloplasmin, neuropsychiatric symptoms, and Kayser-Fleischer rings on slit-lamp ophthalmologic examination, [131] although atypical clinical presentations and the absence of these classic signs are also common. Wilson disease may present as fulminant hepatic failure with a high mortality when managed with medical treatment alone. [132], [133] Such patients can be listed at UNOS status 1 for liver transplantation. [48] The presence of a Coombs-negative hemolytic anemia and a serum alkaline phosphatase to serum bilirubin ratio of less than 2 is suggestive, but not diagnostic, of fulminant Wilson disease. [129] Nazer and coworkers have also developed a useful prognostic score (based on serum bilirubin, serum transaminase levels, and prothrombin time) which stratifies patients with Wilson disease according to the risk of death without liver transplantation. [134] The neurological and psychiatric manifestations of Wilson disease improve in most but not all patients after liver transplantation. [129], [133] A long list of other diseases in the category of inborn errors of metabolism has been successfully treated with liver trans plantation. [55], [129] The indication for liver transplantation is end- stage cirrhosis caused by some of these diseases, including a-1-antitrypsin deficiency, [135] glycogen storage disease (types I and IV), [136] cystic fibrosis, [137] erythropoietic protoporphyria, [138] and tyrosinemia. [139] At the other end of the spectrum, liver transplantation has been performed solely for the correction of nonhepatic manifestations of certain metabolic diseases in which the genetic defect is expressed in the liver in the absence of significant hepatic dysfunction. Examples include Crigler-Najjar syndrome, [140] primary hyperoxaluria, [141] familial amyloid polyneuropathy, [142] and severe familial hypercholesterolemia. [143]

Autoimmune Hepatitis Progression of autoimmune hepatitis to cirrhosis and liver failure requiring liver transplantation is usually seen in patients refractory to conventional immunosuppressive therapy and those who present late in the course of disease without prior diagnostic confirmation or appropriate therapy. [144] Although the outcome of liver transplantation for autoimmune hepatitis is generally excellent, it is now increasingly recognized that there is a risk for disease recurrence. [145], [146] Bearing in mind a significant limitation with respect to the small number of patients in single-center reports, and the differences in the definition of recurrent disease based on histology, autoantibodies, liver biochemical profiles, or a combination of these factors, the recurrent rate is estimated to be between 20% to 30%. [146], [147], [148], [149], [150], [151] and [152] The diagnostic criteria for recurrent autoimmune hepatitis have not been well established. The use of monitoring autoantibodies after liver transplantation is unclear, and most studies have found that these markers persist to some extent in all patients transplanted for autoimmune hepatitis. Published data on titer or persistence of the autoantibodies are currently insufficient for predicting recurrence or disease activity after liver transplantation. [146] Histological features of recurrent autoimmune hepatitis may be difficult to differentiate from that in acute cellular rejection. Risk factors for recurrent disease include suboptimal immunosuppression and HLA haplotypes DR3 and DR4. [146] Recurrent autoimmune hepatitis rarely develops in the first year after liver transplantation, presumably because of the higher level of immunosuppression used during this period. [146], [147] The course of recurrent autoimmune hepatitis is typically indolent, and the histological features for recurrent disease rapidly resolve in most cases when adequate immunosuppression is restored. [146] One study, however, reported graft failure requiring re-transplantation in 6 of 24 patients with recurrent autoimmune hepatitis and more than 1 year of follow-up. [147]

Nonalcoholic Fatty Liver Disease Nonalcoholic fatty liver disease (NAFLD) includes a spectrum of histological lesions ranging from steatosis to nonalcoholic steatohepatitis (NASH), [153] the latter being increasingly recognized as a significant cause of cirrhosis. [153], [154] and [155] Many patients with cryptogenic cirrhosis may, in

fact, have NAFLD as the etiology. [154] Several reports have suggested that NAFLD may recur after liver transplantation. [155], [156], [157] and [158] This phenomenon has also been described in patients with cryptogenic cirrhosis following liver transplantation, with the presumption that NAFLD is the unrecognized underlying cause of their liver disease prior to liver transplantation. [159] Recurrent NAFLD after liver transplantation highlights the importance of host-dependent factors, as opposed to liver-dependent factors, in the pathogenesis of the disease.

Cholestatic Liver Disease Patients with cholestatic liver disease, chiefly primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC), have traditionally been considered the best candidates for liver transplantation based on superior survival statistics. [3], [160] In addition to the CTP score (Table 117-1), other prognostic models have also been used to predict survival and optimal timing for liver transplantation in these patients. [160] Quality-of-life indications for liver transplantation in patients with cholestatic liver disease include pruritus [161] and metabolic bone disease with osteopenia predisposing to fractures. [162] Intractable pruritus in the absence of overt liver failure has been considered an acceptable indication for liver transplantation. No therapy other than liver transplantation has been shown to increase bone mineralization in patients with cholestatic liver disease. [163] Although bone loss continues in the first 3 to 6 months after liver transplantation, bone density then returns back to pretransplant levels at 1 year, and may be restored toward normal within 2 to 3 years after liver transplantation. [163] Liver transplantation is also effective for xanthomatous neuropathy, an unusual complication of cholestatic liver disease. Biliary atresia is the most common indication for pediatric liver transplantation (see Fig. 117-3).

Primary biliary cirrhosis. Primary biliary cirrhosis (PBC) is characterized by progressive destructions of small intrahepatic bile ducts leading to eventual cirrhosis and liver failure. [164] The Mayo Clinic risk score has been validated and widely used as a prognostic model for predicting survival without therapeutic intervention. [165], [166] This model is based on five parameters: serum bilirubin, serum albumin, age, prothrombin time, and edema. Serum bilirubin is the most important prognostic variable for PBC. Bilirubin level above 10 mg/dL is associated with a particularly poor prognosis. [167] Liver transplantation has clearly been shown to improve survival for PBC as compared with the survival predicted by the Mayo Clinic model. [160], [168] Referral for liver transplantation should be initiated when the 1-year probability for survival falls below 90%, which correlates with a Mayo risk score of 6.0 or higher. [160] For practical purposes, a CTP score of 7 or higher is more widely used to determine eligibility for listing. The Mayo risk score now plays no role in identifying patients with PBC in need of liver transplantation and prioritizing them on the waiting list. This function is now served by the MELD scoring system [50] (see Table 117-2). Ursodeoxycholic acid (UDCA) improves the biochemical profiles, especially the bilirubin level in patients with PBC. Some concerns were raised that using the Mayo risk score and possibly also the MELD score in UDCA-treated patients might underestimate their mortality. [47], [169] Although existing data are still inconclusive, UDCA may slightly prolong the disease course before needing liver transplantation. [170] Whether PBC recurs after liver transplantation has been a controversial issue. Data emerging in the last few years appear to suggest that recurrence does happen in some patients. [145] The incidence of recurrence among the larger studies is reported in the 10% to 20% range, [145], [171], [172], [173], [174] and [175] with some centers reporting recurrence rates approaching 50% at 10 years. [176] Ambiguity in defining recurrence may explain the variations in the reported incidence of recurrence. The diagnosis of recurrent PBC can only be made based on histological criteria, which may be difficult to differentiate from other causes of bile duct damage in the allograft such as acute or chronic rejection and biliary complications. To date, disease recurrence has had little impact on the quality of life or graft survival, although a few patients have required re-transplantation. [145], [176] Preliminary data with a small number of patients have suggested that recurrence occurs earlier and more frequently in patients receiving tacrolimus as opposed to cyclosporine. [145], [176] This observation needs to be confirmed in larger studies. Whether UDCA alters the rate of progression of recurrent PBC has not been studied.

Primary sclerosing cholangitis. PSC typically involves both the intrahepatic and extrahepatic bile ducts; with segmental biliary strictures, beading, and dilations. [177] A number of prognostic models have been proposed for predicting survival in PSC, [160], [177] including the Mayo risk score which is based on four variables: age, serum bilirubin level, splenomegaly, and cirrhosis on liver biopsy. [178] The CTP score and MELD score now serve the function of determining eligibility for liver transplant listing for patients with PSC and prioritizing them on the waiting list, respectively. [50] No medical therapy, including UDCA, [179] has clearly been proven to be effective in improving the natural history of PSC. [177] High-dose UDCA may help some patients with earlier disease. [180] One of the indications for liver transplantation in PSC is recurrent bacterial cholangitis, which is often associated with bile-duct stones or obstructing strictures. [177] Endoscopic stenting or balloon dilation of strictures may benefit some patients, [177], [181], [182] although controlled data are limited. Because of extensive scarring of the diseased common bile duct, anastomosis to a Roux-limb of jejunum is the standard surgical approach at liver transplantation. Patients with PSC are also at risk for developing cholangiocarcinoma, with an estimated incidence of up to 20% to 30% at the time of liver transplantation. [183], [184] Establishing the diagnosis of cholangiocarcinoma in patients with PSC is often very difficult. Neither brush cytology [185] nor serum tumor markers including CA 19-9 [186] are reliable diagnostic tools. Preliminary data on positron emission tomography for detecting small cholangiocarcinoma have shown some promise. [187] Survival after liver transplantation is very poor when cholangiocarcinoma is present. [184], [188] About 70% of patients with PSC also have inflammatory bowel disease, [189] and are at risk for developing co- lorectal cancer. There have been several reports of colorectal cancer diagnosed after liver transplantation in patients with PSC and ulcerative colitis. [190], [191] and [192] Continued surveillance by yearly colonoscopy after liver transplantation to detect dysplasia is recommended. The reported incidence of recurrent PSC after liver transplantation has ranged from 10% to 40%. [193], [194], [195] and [196] Distinguishing cholangiographic features of recurrent disease from some other conditions, such as ischemic strictures related to prolonged cold ischemia time, ABO incompatibility, and hepatic artery thrombosis can be extremely difficult. [145] Compelling evidence for recurrent disease comes from the reports by Graziadei and associates, [195], [196] in which nonanastomotic strictures of intrahepatic and extrahepatic bile ducts developing more than 90 days after liver transplantation defined cholangiographic recurrence, whereas fibro-obliterative lesions and fibrous cholangitis were consistent with histological recurrence. The incidence of recurrence was 18% among 120 patients with PSC receiving liver transplantation, versus 1% of a control group of 415 patients transplanted for other indications. [195] Patients with hepatic artery thrombosis, chronic rejection, ABO incompatibility, and anastomotic strictures were excluded in the study. [195] Recurrent PSC does not appear to impact adversely on patient or graft survival over the intermediate term. [196]

Fulminant Hepatic Failure Fulminant hepatic failure is traditionally defined as the development of hepatic encephalopathy within 8 weeks after the de novo onset of jaundice. [197] Subacute or subfulminant hepatic failure is observed in a small subgroup of patients in which encephalopathy develops later, up to 26 weeks after the onset of illness. [198] The predominant cause of fulminant hepatic failure is acetaminophen-induced hepatic injury. [199], [200] Idiopathic liver failure possibly from an unidentified virus, other types of known viral hepatitis (hepatitis A, B, D, and E but not hepatitis C), and idiosyncratic drug-induced liver injury comprise the next most common group, [199], [200] although differences exist between Europe, the United States, and Asia. [199], [200] and [201] Patients with fulminant hepatic failure typically have no preexisting liver disease, but there are well-recognized examples of hitherto asymptomatic chronic liver disease, such as Wilson disease, presenting as fulminant hepatic failure. [132] Historically, only 20% to 30% of patients with fulminant hepatic failure have survived without liver transplantation. [197], [200] A variety of medical therapies, including charcoal hemoperfusion, hemodialysis, plasmapheresis, prostaglandin analogs, and corticosteroids have failed to improve outcome in controlled clinical trials. [202] The well-validated King's College prognostic criteria identify the subgroup of patients at highest risk of dying who should undergo liver transplantation as soon as possible [203] (Table 117-4). A coagulation factor V level of less than 20% also appears to have significant discriminatory prognostic value in nonacetaminophen-induced fulminant hepatic failure. [204], [205] Early referral of patients with fulminant liver failure to a liver transplant center is of paramount importance, and these patients should be listed for liver transplantation with the highest priority (UNOS status 1) as soon as they develop clinically evident hepatic encephalopathy. Rapid deterioration and death, most commonly from cerebral edema and sepsis, can occur within days after the development of stage 3 or 4 encephalopathy. [202] Intracranial pressure monitoring is commonly instituted in patients with grade 4 hepatic encephalopathy. [206], [207] and [208] At the authors' institution, patients deteriorating beyond stage 3 hepatic encephalopathy are electively intubated and ventilated with adequate sedation both to protect the airway and to prevent surges in intracranial pressure related to psychomotor agitation. Sustained elevation of intracranial pressure with cerebral perfusion pressure (mean arterial pressure-intracranial pressure) below 40 mm Hg for at least 2 hours despite treatment with mannitol and pentobarbital is associated with a very poor prognosis secondary to irreversible neurological damage and precludes liver transplantation. [206], [207] However, exceptions to this observation have been reported. [208] Monitor dysfunction must be carefully excluded since false readings may result in erroneous decisions with respect to the patient's candidacy for liver transplantation. [208] The usual protocol for patients in hepatic coma with intracranial monitoring is to maintain cerebral perfusion pressure =50 mm Hg and intracranial pressure below 20 mm Hg prior to and during liver transplantation to ensure full neurological recovery after surgery. [208]

ACETOMINOPHEN-INDUCED FULMINANT LIVER FAILURE	
Prognostic Factors	*Predicted Mortality Rate (%)*
pH < 7.3	95
Grade 3 or 4 encephalopathy	67
Prothrombin time >35 sec	
Serum creatinine >3.5 mg/dL	
Liver transplantation is indicated for pH <7.3 irrespective of the grade of encephalopathy; or prothrombin time >35 sec and creatinine >3.5 mg/dL with grade 3 or 4 encephalopathy.	
NONACETAMINOPHEN-INDUCED FULMINANT LIVER FAILURE	
Prognostic Factors	*Predicted Mortality Rate (%)*
Prothrombin time >35 sec	100
Age < 10 or > 40	96
Bilirubin >17.5 mg/dL	93
Jaundice for >7 d before encephalopathy	97
Unfavorable etiology	90
Idiosyncratic drug reactions	
Wilson disease	
Non-A, non-B hepatitis	
Halothane hepatitis	
Liver transplantation is indicated for prothrombin time >35 sec or any three of the remaining variables irrespective of the grade of encephalopathy.	

Data from ref. 203. The prothrombin time is converted to equivalent values in the United States.

TABLE 117-4 King's College Prognostic Criteria for Fulminant Hepatic Failure

The 1-year survival rates following liver transplantation for fulminant hepatic failure have traditionally ranged from 60% to 70%, [199], [207] while a much higher 1-year survival rate of 92% was reported from the authors' institution where aggressive monitoring and treatment of intracranial hypertension had been the rule. [209] More recent data from UNOS also revealed an improved overall patient survival rate approaching 90% at 1 year in the United States, [2] perhaps reflecting advances in the care of critically ill patients and improved patient selection. Liver transplantation for fulminant hepatic failure is, however, limited by the severe shortage of cadaveric organ donors and by the very brief time available to obtain suitable organs. There has been considerable interest in the use of extracorporeal liver support, including the bioartificial liver-assist device (BAL; Circe Biomedical, Inc., Lexington, MA) and the extracorporeal liver-assist Device (ELAD; Hepatix, Inc., Houston, TX), for providing temporary liver support and serving as a "bridge" to liver transplantation. [199] These devices differ in the nature of the hepatocyte component (porcine vs. human hepatoblastoma cell line) and bioreactor design. [199] Preliminary results of two controlled studies were, however, disappointing in that no survival benefit could be demonstrated among patients treated with these devices compared with those receiving supportive care only prior to liver transplantation, [210], [211] thus dampening the initial enthusiasm regarding this treatment. Extracorporeal liver perfusion using cadaveric livers judged unsuitable for transplantation, [212] or porcine livers [213] have been reported in a small number of patients. Auxiliary orthotopic liver transplantation [214] is a special procedure in which part of the native liver is left in situ and the reduced-size graft provides temporary support until subsequent regeneration of the native liver. Thereafter, the auxiliary graft is either surgically removed or allowed to atrophy following withdrawal of immunosuppression. In a series of 30 patients from Europe who underwent this procedure for fulminant hepatic failure, [214] 63% survived and 43% had restored normal native liver function after a mean follow-up of 18 months. Although auxiliary liver transplantation has the advantage of not subjecting patients to lifelong immunosuppression with its attendant risks, technical difficulties have prevented its widespread use for fulminant hepatic failure.

EVALUATION FOR LIVER TRANSPLANTATION

Although the approach to the evaluation of patients for liver transplantation may vary according to the individual liver transplantation center, the principles are generally similar (Fig. 117-4). The evaluation process typically involves a multidisciplinary team including hepatologists, transplant surgeons, transplant nurse coordinators, social workers, and individuals with expertise in substance abuse issues. The use of other consultants varies according to individual transplant centers and patient needs. The main roles of the transplant hepatologist are to

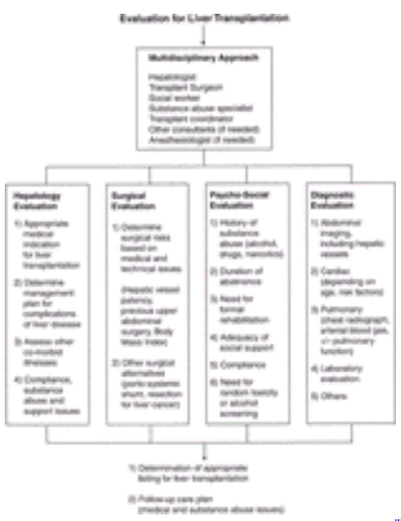

FIGURE 117-4. Principles in the evaluation of potential candidates for liver transplantation.

- confirm that the patient has appropriate medical indications for liver transplantation
- implement a plan for the management of the complications of liver disease
- evaluate disease-specific issues that may potentially impact on outcome after liver transplantation
- assess other co-morbid conditions and possible contraindications to liver transplantation.

Surgical risks and technical considerations for liver transplantation need to be carefully evaluated, primarily by the transplant surgeon. Extensive portal and mesenteric venous thrombosis, previous abdominal surgery near the hepatic hilum, and severe obesity can make the transplant operation difficult, if not impossible. In some patients with a TIPS, extension or migration of the stent into the extrahepatic portal vein, the hepatic vein, or vena cava may compromise the success of liver transplantation. [28] Patients should be fully informed of the risks for liver transplant surgery, the possibility and likelihood of recurrent disease after liver transplantation, and the potential alternatives to liver transplantation. For instance, some patients with well-compensated or mildly decompensated cirrhosis may benefit from portal decompressive surgery for refractory variceal bleeding. Surgical resection for HCC may be an alternative to liver transplantation in some patients with well-compensated cirrhosis, a single lesion less than 5 cm, and no portal hypertension. [120] Psychosocial assessment is an integral part of the liver transplant evaluation process to address substance abuse issues, the risk for recidivism, compliance, and adequacy of social support. In additional to a thorough history and physical examination, an abdominal imaging study (ultrasonography with Doppler study, computed tomography, or magnetic resonance imaging) to exclude intra- or extrahepatic tumors and to evaluate hepatic vessel patency, and laboratory tests are part of the routine evaluation process.

Cardiac evaluation prior to liver transplantation is intended to exclude coronary artery disease, valvular heart disease, and cardiac failure from various etiologies, the extent of which may also depend on the cardiac risk factors present in the individual patient. Special attention should be given to patients with alcoholic liver disease and hemochromatosis, since they are at increased risk for cardiomyopathy. A chest radiograph and arterial blood gas analysis are routinely done in most transplant centers. Patients with a1-antitrypsin deficiency, chronic tobacco use, or known or suspected intrinsic lung diseases should undergo full pulmonary function testing. It is also important to identify two pathophysiologically distinct pulmonary syndromes that are uncommon but clinically important among patients with cirrhosis. These are hepatopulmonary syndrome and portopulmonary hypertension. [215] Hepatopulmonary syndrome is characterized by arterial hypoxemia (PaO_2 <70 mm Hg or alveolar-arterial gradient >20 mm Hg) and pulmonary capillary bed dilation supported by contrast echocardiography and technetium macroaggregated albumin lung scanning. [215] Hepatopulmonary syndrome is reversible after liver transplantation, but patients with a baseline PaO_2 of =50 mm Hg undergoing liver transplantation have a perioperative mortality of about 30%. [215] Portopulmonary hypertension is defined as a mean pulmonary arterial pressure (PAP) of more than 25 mm Hg and pulmonary capillary wedge pressure of less than 15 mm Hg. [216] The perioperative mortality associated with liver transplantation was reported to be 50% among patients with moderate portopulmonary hypertension (mean PAP between 35 and 50 mm Hg) and 100% for those with severe portopulmonary hypertension (mean PAP of =50 mm Hg). [216] Right heart catheterization is indicated to confirm the diagnosis when the estimated mean PAP is =35 mm Hg by echocardiography.

Contraindications to Liver Transplantation

The commonly cited absolute and relative contraindications to liver transplantation, which also reflect the authors' opinion rather than a true consensus, are listed in Table 117-5. The absolute contraindications include severe co-morbid medical illness, such as cardiac and pulmonary diseases that are not reversible and adversely impact the patient's short-term life expectancy, and extrahepatic malignancies excluding certain skin cancers. Patients with advanced HCC and cholangiocarcinoma are generally excluded from liver transplantation, although some centers have performed liver transplantation on these patients under certain experimental treatment protocols. As already described, patients with severe portopulmonary hypertension should not undergo liver transplantation due to an unacceptably high perioperative mortality. [215], [216] At the authors' institution and some other transplant centers, selected patients with moderate or severe pulmonary hypertension are often placed on intravenous epoprostenol (prostacyclin) [217] under an experimental protocol in an attempt to decrease the PAP before liver transplantation. Systemic infections must be adequately treated before liver transplantation. Psychiatric and psychosocial contraindications include active substance abuse, high recidivism risk, noncompliance, and poorly controlled psychiatric illness. Poor social support is also a relative contraindication to liver transplantation. Technical contraindications include extensive thrombosis involving both the portal and mesenteric veins. Severe obesity, defined as a body mass index of = 35, was shown in a recent analysis of UNOS data to be associated with a significantly worse survival after liver transplantation. [218] Thus it is important for these patients to lose weight prior to liver transplantation.

Absolute contraindications
Severe, irreversible co-morbid medical illnesses that adversely impact short-term life expectancy
Severe pulmonary hypertension (mean PAP ≥50 mm Hg)*
Extrahepatic malignancy (excluding some skin cancers)
Extensive hepatocellular carcinoma or with macrovascular or lymph node invasion*
Cholangiocarcinoma*
Uncontrolled systemic sepsis
Extensive portal vein and mesenteric vein thrombosis
Active alcohol or drug abuse
Noncompliance
Unacceptable risks for recidivism from drugs or alcohol
Severe, uncontrolled psychiatric disease
AIDS (HIV)*
Relative contraindications
Moderate pulmonary hypertension (mean PAP between 35 and 50 mm Hg)*
Severe hepatopulmonary syndrome with Pa_{O_2} of ≤50 mm Hg
Severe obesity (body mass index ≥ 35)
Poor social support
Advanced age (≥70 y)

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; PAP, pulmonary arterial pressure.

*Liver transplantation has been performed in some centers under an experimental treatment protocol.

TABLE 117-5 Contraindications to Liver Transplantation

It is generally agreed that patients with established acquired immunodeficiency syndrome (AIDS) should not be considered for liver transplantation. However, individuals infected with the human immunodeficiency virus (HIV) without an AIDS-defining illness now survive longer with current advances in antiviral therapy. Whether they should be considered for liver transplantation is a highly controversial issue. Data on liver transplantation for HIV-infected patients are very limited. A number of early deaths from aggressive hepatitis C recurrence in co-infected patients who underwent liver transplantation have been reported. [219] At present, liver transplantation should not be performed in HIV-infected individuals outside of clinical trial protocols.

POSTTRANSPLANT MANAGEMENT

Factors Affecting Allograft Function and Survival

Immunosuppression and Rejection The calcineurin inhibitors, first cyclosporine and subsequently tacrolimus, have been the mainstay of immunosuppression for liver transplantation for two decades. [220], [221] Immunologic mechanisms of action for these and other immunosuppressive drugs used today are described in greater detail elsewhere. [220], [221] The first available formulation of cyclosporine (Sandimmune®) is dependent on bile for absorption leading to erratic absorption and suboptimal drug levels in the early posttransplant period when given orally. The introduction of a microemulsion formulation of cyclosporine (Neoral®) led to improved bioavailability and absorption. The usual induction immunosuppressive regimen in the early posttransplant period is high-dose intravenous corticosteroid therapy with tapering to oral doses of 20 mg per day by the end of the first week. Although the calcineurin inhibitors are usually started within the first 2 days after liver transplantation, they are nephrotoxic and there is a need to allow renal function to recover after liver transplantation before initiating these drugs in patients with impaired renal function. Daclizumab, an anti-interleukin-2 (IL-2) receptor antibody, and rapamycin (also known as sirolimus) are two new immunosuppressive agents that are nonnephrotoxic and can be used in place of the calcineurin inhibitors in this setting to reduce the risk for rejection. Defining the role of these new agents in liver transplantation either alone or in combination with a calcineurin inhibitor is currently the goal of active investigations. [220], [221] The typical maintenance immunosuppressive regimen consists of a calcineurin inhibitor and prednisone, with or without azathioprine or mycophenolate mofetil. Mycophenolate mofetil is a relatively new immunosuppressive agent, which works by reversible inhibition of inosine monophosphate dehydrogenase. This drug appears to be more potent than azathioprine with more specific enzyme inhibition. At the authors' institution, a primary regimen of tacrolimus, mycophenolate mofetil, and prednisone is used. The 5-year patient and graft survival rates are comparable for cyclosporin- and tacrolimus-based immunosuppressive regimen. [106] Although management of immunosuppression differs according to the individual transplant center's preference, most patients can be maintained on lower doses of immunosuppression with time and in the absence of acute rejection. The ultimate level of maintenance immunosuppression also depends on the pretransplant diagnosis of liver disease—lower level of maintenance immunosuppression in general for chronic hepatitis B or C and higher for patients with autoimmune hepatitis, primary biliary cirrhosis, and possibly fulminant hepatic failure. Prednisone can be withdrawn with close monitoring in some patients at 6 months to 1 year after liver transplantation. [222] Acute cellular rejection occurs in 30% to 60% of all liver transplant recipients within the first year after transplantation, [220], [221], [222], [223] and [224] and is thought to be secondary to mismatches in class I and II major histocompatibility complex (MHC) antigens. [225] In the study from the NIDDK Liver Transplant Database, [224] acute rejection was not shown to exert an overall detrimental impact on patient and graft survival. Only the subgroup of patients with a severe episode of rejection defined by histological criteria was at higher risk for death or re-transplantation. [224] These findings were in contrast to that in renal transplant recipients, in whom even a single acute rejection episode was associated with a significantly reduced graft survival. In the past decade, advances in immunosuppressive drugs have resulted in a progressive decline in the incidence of acute rejection episodes after liver transplantation. [226] A primary immunosuppressive regimen of a calcineurin inhibitor, mycophenolate mofetil, and prednisone is associated with a rejection rate of only about 30%. [226] Acute rejection is most commonly seen within the first 6 weeks, especially between day 4 and 14 after liver transplantation. [220], [221], [222], [223] and [224] The incidence of acute rejection generally decreases with time after liver transplantation. The diagnosis is suggested by nonspecific elevations in the liver enzymes. Fever, leukocytosis, and eosinophilia may be present, but are also nonspecific. The other diagnostic considerations for elevated liver enzymes in the early postoperative period include "preservation/reperfusion" injury, hepatic artery thrombosis, and biliary complications. Histologically, acute cellular rejection is characterized by the triad of portal mixed cellular inflammation with predominantly lymphocytes, bile ductular injury, and subendothelial inflammation of the portal or terminal hepatic venules (endotheliitis). [227] At least two of the three features are required for the diagnosis. [227] Eosinophils are commonly present in the mixed cellular infiltrate although this is a nonspecific feature. The initial treatment for acute cellular rejection is usually high-dose methylprednisolone at 1000 mg for 2 doses one day apart. This is followed by a 6-day taper of oral prednisone from 200 mg to 20 mg per day for a total "re-cycle" dose of 3 g. Some centers use a total of only 2 g of methylprednisolone. Steroid-resistant rejection occurs in 10% to 20% of patients treated with cyclosporine, but the incidence is reported to be less than 10% with a tacrolimus-based immunosuppressive regimen. [106], [223] Muromonab-CD3 (also known as OKT3), a murine monoclonal antibody to the CD3 receptor on T-lymphocytes, is most commonly used for the treatment of steroid-resistant acute cellular rejection. Muromonab-CD3 use is almost always accompanied by a cytokine-release syndrome, which includes fever, chills, and other symptoms within the first hour after administration. This resolves within 4 to 6 hours. Patients are given methylprednisolone, antipyretics, and antihistamines as a premedication regimen about 1 hour prior to receiving muromonab-CD3 to relieve some of these symptoms. Aseptic meningitis is associated with muromonab-CD3 in 3% to 5% of cases. The use of muromonab-CD3 is associated with an increased incidence of serious infections, particularly cytomegalovirus (CMV), and rarely, a capillary leak syndrome that can present as pulmonary edema. Antilymphocyte globulin may also be effective in steroid-resistant rejection. Hyperacute rejection is a rare and devastating event mediated by preformed antibodies that bind to allogenic epitopes on donor endothelial cells, leading to rapid graft failure within hours to days after liver transplantation. [225] It is most commonly due to ABO incompatibility. Chronic ductopenic rejection [228] is seen in about 10% of all liver transplant recipients, usually occurring beyond 60 days after transplantation. It is characterized by progressive loss of interlobular bile ducts and an obliterative arteriopathy. [228] Chronic rejection usually develops after multiple episodes of acute rejection, but may be seen after

an unresolved episode of acute rejection or indolently over months to years after liver transplantation without a definite rejection episode. Although chronic rejection is generally irreversible and requires re-transplantation, some cases of reversal after switching from cyclosporine to tacrolimus have been reported. [228], [229] Chronic rejection may also result in diffuse stricturing of bile ducts in the allograft.

Vascular Complications Hepatic artery thrombosis occurs in about 7% of all adult liver transplants and in 10% to 40% of pediatric transplants. [226], [230] Hepatic artery thrombosis usually occurs within the first 30 days after liver transplantation. Risk factors for hepatic artery thrombosis include small hepatic arterial size, complex anatomy, the need for extension grafts to perform arterial anastomosis, prolonged ischemic time, and a hypercoagulable state. [226] The cause of hepatic artery thrombosis is often unknown. [231] Since the bile ducts receive blood supply exclusively from the hepatic artery early after liver transplantation, hepatic artery thrombosis results in diffuse biliary strictures, often associated with cholangitis, and less frequently, hepatic abscesses. If hepatic artery thrombosis is identified early after liver transplantation, immediate arterial reanastomosis may reverse the long-term consequences to the allograft. [231] Nevertheless, re-transplantation is ultimately necessary in almost all cases. [226] Some patients, particularly in whom this complication occurs later following liver transplantation, may benefit from long-term, repeated biliary stenting and dilation. The second most common vascular complication is portal vein thrombosis, which may present with ascites, recurrent variceal bleeding, or hepatic encephalopathy. [226] In some cases, this condition is only associated with asymptomatic liver test abnormalities. Patients at risk for portal vein thrombosis include those requiring interposition of grafting during portal vein anastomosis or those with a history of hypercoaguable state or portosystemic surgical shunts. Balloon dilation and stenting may be effective in some cases of portal vein stenosis, thus abrogating the need for surgical revision or re-transplantation. [232] Thrombosis or stenosis of the hepatic vein or the inferior vena cava is uncommon. This complication has been reported in patients with recurrent Budd-Chiari syndrome following liver transplantation [233] and recipients of partial or split liver transplants either from a cadaveric or living donor. [234]

Biliary Complications Choledochocholedochostomy (end-to-end anastomosis) is the most frequently used biliary anastomosis in adult liver transplantation. A T-tube is often placed across the anastomosis to decrease the risk of anastomotic stricture. The T-tube is usually clamped between day 3 to 7 after liver transplantation and removed 6 weeks to 6 months later as the tract has matured. Bile leak at the T-tube exit site is nevertheless a frequent occurrence. [235], [236] At the authors' institution and some other transplant centers, the standard T-tube placement in end-to-end anastomosis has been abandoned and replaced by direct end-to-end anastomosis without an associated increase in adverse consequences. [237] The other type of anastomosis is the Roux-en- choledochojejunostomy, which is used mainly in patients with preexisting bile duct abnormalities such as PSC and biliary atresia or in whom technical difficulty is encountered in fashioning a conventional duct-to-duct anastomosis. The overall incidence of biliary complications after liver transplantation falls within the 10% to 15% range. [238] In a series of almost 1800 patients reported from the University of Pittsburgh, [239] 80% of biliary complications were identified within the first 6 months after liver transplantation, and one third were diagnosed in the first month. Bile leaks and biliary strictures account for 80% of biliary complications. [238], [239] and [240] Most of the biliary complications after liver transplantation can now be managed by nonsurgical techniques. [235], [236], [238] Bile leaks occur most commonly at the anastomotic site, T-tube exit site, or cut edge of reduced-size liver grafts. Bile leaks may result in a large biloma, bile peritonitis, and super-infection. Management with biliary stent placement and percutaneous drainage of biloma is successful in most cases. [235] Surgical revision is indicated when a large leak is present with severe disruption of the bile duct. Bile leaks from Roux-en- anastomosis more often require surgical revision. [235] Biliary strictures occur most often at the site of anastomosis, possibly related to poor local blood supply from hepatic artery branches, and edema. Endoscopic biliary stenting or balloon dilation is often adequate without surgical intervention. [238] A more difficult problem is the diffuse, "ischemic" type of strictures, which are most often due to hepatic artery thrombosis, ABO-incompatible allografts, or possibly prolonged, cold ischemia before graft revascularization. [241] However, no specific underlying cause can be identified in many cases. In summary, although the overall impact of biliary complications on mortality is small due to improvements in patient management, as well as diagnostic and therapeutic techniques for these complications, [238] they are still common and potentially serious, resulting in graft loss in 1% to 3% of liver transplant recipients. [238]

Recurrent Disease in the Allograft Disease-specific recurrence following liver transplantation has already been reviewed. In general, recurrent autoimmune hepatitis and cholestatic liver disease have a minor impact on graft survival, [145] whereas recurrent viral hepatitis has been a highly important cause of graft failure within the first 5 years following liver transplantation. [226] The use of HBIG, and potentially the addition of a nucleoside or nucleotide analog, have diminished the adverse impact of hepatitis B recurrence on graft survival. [81] The magnitude of the adverse impact of recurrent hepatitis C on graft survival, on the other hand, has become increasingly evident in the last few years. Interferon plus ribavirin therapy remains the only proven treatment for hepatitis C, but this treatment has been suboptimal thus far for the control of recurrent disease after liver transplantation. [110], [111] and [112] The problem related to liver transplantation for hepatitis C infection will likely worsen as many patients with hepatitis C infection are now at risk for cirrhosis, liver failure, and HCC as the disease advances to the 3rd and 4th decade following acute exposure of the chronically infected population. Liver re-transplantation is generally associated with a worse survival compared to primary liver transplantation, [242] and further depletes a limited donor pool. Despite improved outcome in recent years for liver transplantation among patients with HCC, [120] many patients still succumb to recurrent HCC, which tends to be highly aggressive in immunosuppressed, posttransplant patients and is rarely curable by surgical resection or re-transplantation. Better understanding of the mechanisms and predictors of tumor recurrence, refinements of the selection criteria for liver transplantation, and modification of organ allocation policies to reduce waiting time and the pretransplant risk of tumor dissemination may further improve the outcome for HCC. The course of recurrent NAFLD has not been well characterized due to the small number of patients studied. It appears that the course is relatively benign, although some cases progress to cirrhosis and graft failure. Finally, alcoholic liver disease may recur with heavy alcohol intake in the posttransplant period. [62] Surreptitious alcohol consumption should be considered in the diagnostic evaluation of unexplained graft dysfunction, especially among those with a history of heavy alcohol consumption prior to liver transplantation.

Medical Complications of Immunosuppression

The immunosuppressive drugs used today for liver transplantation have many inherent risks. Some of the well-known direct adverse effects of these immunosuppressive drugs are listed in Table 117-6. Nephrotoxicity, neurotoxicity, impaired glucose metabolism, and gastrointestinal disturbances are common with both cyclosporine and tacrolimus (calcineurin inhibitors). Both neuropathy and gastrointestinal adverse effects are more common with tacrolimus. Hyperkalemia is also more often seen with tacrolimus and is usually managed with fludrocortisone. [222] Hypertension and altered lipid profiles are more frequently associated with cyclosporine than tacrolimus. Hirsutism and gingival hyperplasia are specifically associated with cyclosporine and not tacrolimus. [223] It is important to recognize that a long list of drugs can interfere with the metabolism of the calcineurin inhibitors (Table 117-7). Most interactions occur as a result of either competitive inhibition or induction of metabolism at the level of cytochrome P450 3A4. Increased drug levels can lead to toxicities whereas decreased drug levels can precipitate rejection. A major adverse effect of both azathioprine and mycophenolate mofetil is bone marrow suppression. Gastrointestinal toxicity, including a hemorrhagic gastritis is also associated with mycophenolate mofetil. Frequent side effects of rapamycin include hyperlipidemia, thrombocytopenia, and leukopenia. Interstitial pneumonitis has been linked to the use of rapamycin.

CORTICOSTEROIDS	AZATHIOPRINE	MYCOPHENOLATE MOFETIL	RAPAMYCIN

TABLE 117-6 Side Effects of Immunosuppressive Drugs

Potential inhibitors of metabolism resulting in increased levels*
Macrolide antibiotics
Erythromycin
Azithromycin
Clarithromycin
Anti fungal agents
Ketoconazole
Fluconazole
Itraconazole
Calcium-channel blockers
Verapamil
Diltiazem
Nicardipine
Cimetidine
Doxycycline
Danazol
Potential inducers of metabolism resulting in decreased levels*
Antiseizure medications
Phenobarbital
Phenytoin
Carbamazepine
Anti tuberculosis medications
Isoniazid
Rifampin

*Most interactions occur as a result of either competitive inhibition or induction of metabolism at the level of cytochrome P450 3A4.

TABLE 117-7 Potential Drug Interactions with Cyclosporine and Tacrolimus (Partial List)

Among the most important short- and long-term complications of immunosuppression are opportunistic infections and malignancies, as well as cardiovascular, metabolic, and renal diseases. These are discussed in greater detail below.

Infectious Complications Over 50% of liver transplant recipients will experience one or more episodes of infection in the postoperative period. [243] Historically, infectious complications account for most cases of death in the first year after liver transplantation. [243] The timetable of infection in all forms of solid-organ transplantation is most easily organized into three periods according to Fishman and Rubin: [244] the first month, 1 to 6 months, and more than 6 months after transplantation. In the first month after liver transplantation, conventional bacterial and fungal nosocomial infections predominate. The typical bacterial infections in the early postoperative period are wound and intravenous line infections, as well as pneumonia. The most common bacterial pathogens are *Staphylococcus* and *Enterococcus* species. [243] Vancomycin-resistant *Enterococcus* has emerged in the past few years as an important nosocomial pathogen in liver transplant recipients. [245] After the first month, opportunistic infections, such as viruses (cytomegalovirus, herpes, Epstein-Barr virus, and others), fungal infections, *Nocardia, Listeria,* tuberculosis, and *Pneumocystis carinii* pneumonia (PCP) are important concerns. [244] Fungal infections usually present 1 to 6 months after liver transplantation. *Candida albicans* represent the most common fungal pathogen. [246] Invasive aspergillosis carries a high mortality, and its incidence among liver transplant recipients may be rising. [247] Other mycoses, such as cryptococcosis, coccidioidomycosis, and histoplasmosis are rare except in cases of exposure in specific geographic endemic areas. [243], [244] Oral nystatin or clotrimazole are the most frequently used agents for fungal prophylaxis. Fluconazole has also been shown to be effective as a fungal prophylactic agent, [248] but carries a risk of increasing the level of calcineurin inhibitors (see Table 117-7). PCP is now very rare in liver transplant recipients due to highly effective long-term prophylaxis with trimethoprim-sulfamethoxazole. [249] Beyond 6 months after transplantation, opportunistic infections are less common, as the degree of immunosuppression decreases in most patients. Community-acquired infections or various recurrent or persistent infections, such as viruses (Epstein-Barr virus, hepatitis B and C) may develop. Cytomegalovirus (CMV) is one of the most important infectious complications after organ transplantation, and has been suggested to be an important cause of reduced survival [250] and high resource use among liver transplant recipients. [251] Distinction should be made between CMV "infection," which refers to the detection of the virus in tissue or body fluids, versus CMV "disease," defined as CMV infection with symptomatic clinical manifestations. [251] About 50% of liver transplant recipients with CMV infection develop symptomatic CMV disease. The incidence of symptomatic CMV disease is estimated to be 15% to 40% after liver transplantation. [251] Patients at highest risk for CMV infections include those who are CMV-seronegative who received a CMV-positive donor liver, and those treated with muromonab-CD3 or antilymphocyte globulin. [252] CMV disease is most commonly seen within the first 3 months after liver transplantation, with a median time to onset of 6 weeks. CMV is uncommon beyond 6 months after transplantation except in profoundly immunosuppressed individuals. Many patients present with a "CMV syndrome" characterized by fever, malaise, arthralgia, myalgia, and hematologic abnormalities such as leukopenia and thrombocytopenia. In liver transplant recipients, clinical manifestations include fever, hepatitis, pneumonia, gastroenteritis, and chorioretinitis in descending order of frequency. [252] Conventional CMV cultures from tissue or blood are relatively insensitive, and the results may not be available for 1 to 2 weeks. The shell vial assay using a monoclonal antibody against the early CMV antigen has replaced the conventional culture methods in many laboratories because of improved sensitivity and the advantage of rapid detection of CMV as early as 24 hours. Histologically, the classic intranuclear inclusion bodies (Cowdry type A) are not always identified. A number of diagnostic assays for the early detection of CMV infection are now available, including:

- CMV antigenemia assay which uses monoclonal antibodies to detect the viral pp65 antigen expressed on blood leukocytes
- polymerase chain reaction (PCR)
- hybrid capture CMV DNA assay. [251], [253]

While these tests are highly sensitive and specific for detecting CMV infection, the specificity for predicting CMV disease is relatively low, in the 30% to 60% range. [251], [253] The CMV antigenemia assay is the predominant diagnostic test used at the authors' institution due to the rapid turnaround time compared to the PCR assay. Standard treatment of CMV disease is intravenous ganciclovir for 14 to 21 days. There is no evidence from controlled trials in solid organ transplantation that the addition of CMV immunoglobulin increases its efficacy. [251] Clinical response to intravenous ganciclovir is seen in two thirds of patients. Among the 20% of patients with recurrent CMV infections, about two thirds respond to a second course of ganciclovir treatment. [254] There have not been any reported cases of ganciclovir-resistant CMV infection in liver transplant recipients, although this possibility certainly exists. There is currently no consensus regarding the best regimen for CMV prophylaxis after liver transplantation, [251], [255] although a small number of randomized controlled trials are shedding some light on the optimal prevention regimen. At the authors' institution, intravenous ganciclovir is used for the first week posttransplantation in all recipients. Thereafter, oral acyclovir is used for CMV-positive recipients or CMV-negative recipients of CMV-negative livers, and oral ganciclovir is used in CMV-negative recipients who receive CMV-positive livers. Preemptive therapy using intravenous ganciclovir following detection of CMV viremia was shown in one study to be effective in preventing CMV disease. [256] Valganciclovir, the oral prodrug of ganciclovir, has much higher bioavailability compared to oral ganciclovir and is currently being tested in clinical trials for prophylaxis as well as treatment of CMV infections.

Posttransplant Malignancies De novo malignancy developing after transplantation has been a well-known complication of liver and other solid-organ transplantation. [257], [258] The most common is skin cancer, followed by lymphoma, cancer of the lip, Kaposi sarcoma, vulval and perineal cancers, hepatobiliary cancers, and sarcoma. [258] Posttransplantation lymphoproliferative disease (PTLD) develops in about 2% of liver transplant recipients in the first 5 years after transplantation under both cyclosporine and tacrolimus immunosuppressive regimens. [106], [222], [258] PTLD most often occurs within the first year after liver transplantation, and involves the liver allograft in one third of cases. The usual histology is B-cell derived, large cell non-Hodgkin's lymphoma. The association between PTLD and Epstein-Barr virus infection has been well documented. [259] Management of PTLD includes withdrawal of immunosuppression, intravenous ganciclovir, interferon, or chemotherapy.

Cardiovascular, Renal, and Metabolic Complications These complications are discussed together because they are closely related. Hypertension is common after liver transplantation and may be related to renal insufficiency or immunosuppressive drugs. The incidence of hypertension appears to be lower with tacrolimus than cyclosporine. [222] The first-line treatment for hypertension after liver transplantation has been the dihydropyridine calcium-channel blockers (nifedipine, amlodipine, isradipine, felodipine, and nicardipine). [260] With the exception of nicardipine, this group of calcium channel blockers has no significant interactions with the calcineurin inhibitors, in contrast to that observed with the other groups of calcium channel blockers such as verapamil or diltiazem (see Table 117-7). Second-line antihypertensive agents include ß- and a1-adrenergic agents, loop diuretics, and angiotensin-converting enzyme inhibitors. [260], [261] The use of the a-adrenergic agents such as clonidine and doxazosin is limited by their central nervous system toxicity, particularly drowsiness. It is best to avoid the angiotensin-converting enzyme inhibitors in the early posttransplantation period because they may aggravate renal dysfunction and hyperkalemia. [260] About one third of patients achieve effective control of their hypertension with a single agent, and another one third require the addition of a second agent. [261] Renal insufficiency following liver transplantation may be either acute or chronic, and multiple etiologies have been described. [260], [261] Direct toxicity of the calcineurin inhibitors is believed to be the cause in more than 70% of patients with renal insufficiency. [260] Other causes include unresolved renal dysfunction related to preoperative hepatorenal syndrome, acute tubular necrosis, and various forms of glomerulonephritis. [260] The incidence and mechanism of nephrotoxicity appear to be similar between cyclosporine and tacrolimus. [222], [262] The greatest decline in renal function occurs in the first 18 months after liver transplantation. Renal function then remains stable in most cases despite maintaining cyclosporine at therapeutic levels. [263] Even withdrawal of cyclosporine in the setting of established azotemia may not result in an improvement of renal function, but may increase the risk of chronic rejection. [264] One approach in the management of patients with chronic renal insufficiency after liver transplantation is to reduce the dose of the calcineurin inhibitors to a minimum and add either mycophenolate mofetil or rapamycin. The incidence of end-stage renal failure necessitating hemodialysis or kidney transplantation increases with time following liver transplantation, reaching about 5% at 5 years and 10% after 10 years. [260] Obesity, diabetes,

and hyperlipidemia are common after liver transplantation. [265], [266] In an analysis of about 800 adults from the NIDDK Liver Transplant Database, approximately 20% of nonobese liver transplant recipients became obese over the 2 years after liver transplantation. [267] The cause of posttransplant obesity, diabetes, and hyperlipidemia are multifactorial and interrelated. Diabetes is present in about 5% to 15% of patients with advanced cirrhosis awaiting liver transplantation. [265] These patients are at higher risks for posttransplant diabetes than those without diabetes prior to liver transplantation. The management of diabetes after liver transplantation is not substantially different than in the nontransplant setting, although the steroid tapering process may result in improved diabetic control with time after liver transplantation. Conflicting results have been reported with respect to the impact of diabetes on medium- to long-term survival. [265] One study revealed a fourfold higher mortality among diabetic patients, [268] whereas another study showed a higher survival rate in diabetics versus nondiabetics. [269] A more consistent finding, however, is a higher incidence of bacterial and fungal infections after liver transplantation among diabetic patients compared to nondiabetic patients. [265] The intriguing observation from a few studies that the prevalence of diabetes after liver transplantation is higher among patients with hepatitis C infection needs to be further investigated. [270], [271] Hyperlipidemia may be associated with obesity, diabetes mellitus, cyclosporine, rapamycin, and corticosteroids. Treatment of hyperlipidemia may be problematic after liver transplantation. Cholestyramine interferes with gastrointestinal absorption of calcineurin inhibitors and therefore should be administered at a separate time from the calcineurin inhibitors. Niacin has multiple side effects and can be hepatotoxic. Preliminary data regarding the safety and efficacy with HMG-coenzyme A reductase inhibitors in liver transplant recipients appear to be favorable. [272] Patients on tacrolimus may have a lower cardiovascular risk profile, based on hypertension and hyperlipidemia, than patients on cyclosporine. [273] Switching from cyclosporine to tacrolimus may benefit some patients with poorly controlled hyperlipidemia. Despite the increase in cardiac risk index for many of these patients after liver transplantation, long-term follow-up data regarding the risks and incidence for cardiovascular events and mortality following liver transplantation are only beginning to emerge. One study found that among patients who survived longer than 5 years after liver transplantation, the prevalence of cardiac disease was no higher than that in the nontransplant population in the United States. [274] Two other studies, on the other hand, reported cardiovascular events as the cause of 14% to 24% of deaths beyond one year after liver transplantation. [275], [276] Clearly, more studies with longer follow-up are needed. At present, it is important to try to correct potentially reversible cardiovascular risk factors following liver transplantation.

CHAPTER 118

Lewis R. Roberts and Gregory J. Gores

HEPATOCELLULAR CARCINOMA

EPIDEMIOLOGY

Hepatocellular carcinoma (HCC) is the fifth most common cancer and the third most frequent cause of cancer death worldwide, with an estimated 560,000 new cases per year. [1] Estimates from the International Agency for Research on Cancer for the year 2000 show worldwide age-specific incidence ratios of 14.97 cases per 100,000 per year in men and 5.51 cases per 100,000 per year in women. [1] Because of the low overall cure rate for HCC, the worldwide age-specific mortality ratios are nearly identical to the incidence ratios at 14.41 deaths per 100,000 per year in men and 5.46 deaths per 100,000 per year in women. There are strong etiologic associations with chronic hepatitis B virus (HBV), chronic hepatitis C virus (HCV), alcoholic cirrhosis, other causes of chronic liver disease, and dietary aflatoxin exposure. Because of the strong associations with diseases and risk factors that have distinct geographic distributions and different frequencies within different ethnic groups, there is also a preferential distribution of cases of HCC to certain geographic regions and specific at-risk populations.

International Variation

There is considerable international variation in rates of HCC. By region, the highest incidence is in Eastern Asia, with age-specific ratios of 35.46 per 100,000 in men and 12.66 per 100,000 in women. China, with the largest population in the region, had an estimated 306,000 cases of HCC in 2000, representing 54% of the total number of cases worldwide. Other regions of high incidence are sub-Saharan Africa, South Eastern Asia, and Southern Europe. The lowest incidence rates are found in Northern Europe; North, Central, and South America; South Central Asia; and Australia/New Zealand. The highest incidence regions in Asia and Africa have a high prevalence of chronic HBV infection as well as high-level exposure to dietary aflatoxins. These combined risk factors play a synergistic role in the development of HCC. Other combinations of risk factors that are important in the epidemiology of HCC include co-infection with HBV and HCV and alcohol use in individuals with chronic hepatitis from viral or other causes. Cigarette smoking and long-term use of oral contraceptives also appear to be independent risk factors for HCC. The risk for HCC increases with age. The age distribution of cases of HCC also varies in different populations. A significant proportion of HCCs occurs in young and middle-aged individuals at the peak of their productive lives. This results in a high public health and economic impact, particularly in the countries with the highest incidence rates. There is a 15- to 40-year lag time between development of chronic hepatitis or cirrhosis and diagnosis of HCC. This lag time is shorter in patients with active chronic hepatitis C; therefore, the increasing prevalence of chronic hepatitis C has led to a decrease in the age of onset of HCC in many populations. For HBV-induced HCC, the age at acquisition of HBV infection is important because individuals who become infected in the perinatal period or in early childhood are more likely to develop chronic hepatitis or become chronic carriers, with an attendant increased risk for cirrhosis and HCC. [2], [3]

Gender Variation

There is a significant effect of gender on the risk for HCC. The worldwide male-to-female incidence ratio is 2.7:1. In general, the male-to-female ratio is highest in the regions with the highest incidences of HCC. Higher levels of androgen signaling may be associated with the increased risk for HBV-related HCC in men. [4]

North America

In the United States, there has been a well-documented increase in the number of cases of HCC since the 1980s. Analysis of data from the Surveillance, Epidemiology, and End Results (SEER) database of the National Cancer Institute showed a 71% increase in incidence of histologically proven HCC from 1.4 per 100,000 population for the period from 1976 to 1980 to 2.4 per 100,000 for the period from 1991 to 1995. [5] In particular, the incidence of HCC increased significantly among younger people, 40 to 60 years old, during the period from 1991 to 1995 as compared with earlier periods. Between 1981–1985 and 1991–1995, there was a 41 percent increase in the overall mortality rate from HCC. There is also an effect of gender on the incidence of HCC in the United States, with an incidence in men that is three times the incidence among women. There is a striking effect of race on the incidence of HCC in the United States. For the period from 1991 to 1995, Hispanics, Asians, Pacific Islanders, and Native Americans had the highest age-adjusted incidence of HCC, 7.4 per 100,000. For black men, the incidence was 6.1 per 100,000 per year, whereas for white men, it was 2.8 per 100,000. The incidence of HCC is highest among recent Asian immigrants to the United States, with age-standardized rates of 23.9 per 100,000 in Korean men and 5.5 per 100,000 in Korean women. These immigrant populations have a high prevalence of chronic HBV infection. Subsequent United States–born generations typically have lower rates of chronic HBV infection and a lower risk for HCC. [5] In general, people of lower social class in urban U.S. communities have a higher risk for HCC. This is likely related to the inverse relationship of social class with prevalence of HBV infection and

cigarette smoking.

Analysis of hospitalization rates for HCC in a population of U.S. veterans showed that the recent increase in incidence of HCC was primarily due to chronic HCV infection. Between 1993–1995 and 1996–1998, age-adjusted hospitalization rates for HCC associated with HCV increased threefold, from 2.3 per 100,000 in 1993–1995 to 7.0 per 100,000 in 1996–1998. During the same time periods, the age-adjusted hospitalization rates for HCC associated with HBV or alcoholic cirrhosis and in patients without known risk factors remained relatively stable. [6,7]

Despite improvements in early diagnosis and management of HCC, survival of patients with HCC in the United States has not improved significantly since the 1980s. A recent analysis of data from the SEER database showed that the overall 1-year relative survival rate increased from 14% in the period from 1977 to 1981 to 23% in the period from 1992 to 1996. [8] However, 5-year relative survival rates did not change as much, increasing from 2% to 6%. Median survival after diagnosis increased only slightly, from 0.57 years in the period from 1977 to 1981 to 0.64 years in the period from 1992 to 1996. Because most of the improvement in survival occurred in the first year after diagnosis, the apparent improvement is likely to be due to lead-time bias resulting from earlier diagnosis of HCC rather than from improvements in long-term survival resulting from more effective treatment. There were no significant influences of gender or ethnicity on survival. Most patients with HCC had advanced disease at the time of diagnosis. In the period from 1987 to 1991, only 0.8% of patients with HCC underwent radical surgery with curative intent; these patients had a significantly better survival than patients with untreated advanced disease, with a 1-year relative survival rate of 60% and a 5-year relative survival rate of 40%. In the same period from 1987 to 1991, 7.4% of patients underwent palliative surgery; these patients had a 1-year survival of 50% and a 5-year survival of 20%. The proportion of patients undergoing radical surgery in the later period from 1991 to 1996 was unchanged from the earlier period at 0.8%. These data suggest that screening programs aimed at identifying patients with HCC early enough to allow radical surgery either were not widely practiced, were ineffective, or were not coupled with widespread availability of the specialized surgical skills needed for optimal radical surgery. The proportion of patients with HCC able to undergo radical surgery is probably also limited by the recognition in recent years that surgical outcomes in patients with cirrhosis and clinically significant portal hypertension are very poor. [9] There is an urgent need to develop methods of identifying the individuals who are at highest risk for HCC, to determine the optimal and most cost-effective screening methods to allow early diagnosis of HCC, and to provide access to specialized multidisciplinary management of HCC. Recent improvements in the management of HCC, particularly the increasing availability of liver transplantation for patients with early disease, may result in further improvements in survival.

The Alaskan Native population has a relatively high age-adjusted incidence of HCC of 7.9 per 100,000 in men and 1.4 per 100,000 in women. For Eskimos, the incidence rates are 13.1 per 100,000 in men and 2.2 per 100,000 in women. [10] Most cases of HCC in this population are related to chronic HBV infection. There is also significant familial clustering of HCC in the Alaskan Native population. In many cases, individuals develop HCC at a very young age, often as early as the second decade of life, suggesting a familial predisposition to HCC. In addition, there is no evidence of dietary contamination with fungal aflatoxins, and *p53* mutations have not been demonstrated in any HCCs tested so far in this population; this contrasts with the 29% rate of *p53* mutations in HCCs worldwide. [11] The available evidence, therefore, strongly suggests an inherited predisposition to HCC, potentiated by the high rates of chronic HBV infection. A hepatitis B immunization program that includes prevention of perinatal HBV infection, routine infant vaccination, and catch-up vaccination of older children and adults has been used to eliminate new chronic HBV infections in the Alaskan Native population. [12] Presumably, as has been documented in Taiwan, the decrease in HBV infections will result in a decrease in incidence of HCC in this population. [13]

ETIOLOGY AND RISK FACTORS

Chronic Hepatitis B

There are 350 million chronic HBV carriers worldwide. The prevalence of HBsAg positivity ranges from high (more than 8%) in Africa, Asia, and the Western Pacific, to intermediate (2% to 7%) in Southern and Eastern Europe, and low (less than 2%) in Western Europe, North America, and Australia. Fifty million new cases of HBV infection occur each year; of these, 5% to 10% of adults and up to 90% of infants become chronically infected. In the United States, at least 250,000 people contract hepatitis B each year. The predominant mode of viral transmission in a population varies with the prevalence of HBV infection. In low-prevalence countries, sexual contact among high-risk adolescents and adults is the predominant mode of transmission. In highly endemic countries, most HBV infections are contracted perinatally or in early childhood. One fourth to one third of individuals with chronic hepatitis B develop progressive liver disease. Cirrhosis develops in 0.1% to 2% of patients with chronic hepatitis B each year, depending on the duration of HBV replication, the severity of disease, and the presence of coexisting infections or alcohol use. In individuals who develop cirrhosis, the risk for progression to HCC varies from 2% to 10% per year. [14] Both host and viral factors influence the natural history of chronic hepatitis B. Certain HBV strains predominate in HCCs, suggesting that particular genotypes are more effective at initiating or promoting hepatocarcinogenesis. [15] Vaccination of infants and at-risk individuals decreases the prevalence of chronic HBV infection and the incidence of HCC. [13]

Chronic Hepatitis C

An estimated 170 million people are infected with HCV worldwide, and in some countries, HCV has overtaken HBV as the major cause of HCC. HCV is an RNA virus that causes acute and chronic hepatitis. It is contracted through parenteral exposure to infected material. Those at highest risk for acquiring hepatitis C are recipients of contaminated blood transfusions, injection drug users, people who snort cocaine with shared straws, and health care workers at risk for needle-stick and other exposures. Although the incidence of acute HCV infection has fallen dramatically in the United States since the 1990s, the prevalence of infection remains high (about 2.7 million Americans) because chronic hepatitis C develops in about 75% of those infected. Both acute and chronic hepatitis C are asymptomatic in most patients. Chronic hepatitis C is a slowly progressive disease that eventually results in severe morbidity in 20% to 30% of infected patients. Virologic features of HCV, such as genotype and viral load, are associated with progression and response to therapy. [3] There is a marked difference in the geographic distribution of HCV genotypes, with types 1, 2, and 3a being most frequently found in Western countries. Genotype 1b is associated with more severe liver disease and with lower response rates to antiviral therapy. The development of quasispecies and escape mutants enables viral persistence and the development of chronic liver disease. Persistent hepatitis, with high average annual alanine aminotransferase levels, is a significant predictor of the development of HCC. [16] Patients with active hepatitis, those with co-infections with HBV or human immunodeficiency virus (HIV), and those with other causes of chronic liver disease such as alcoholic liver disease are more likely to develop liver-related complications. Patients with combined hepatitis B surface antigen positivity and chronic HCV infection are at particular risk for HCC. [17] HCV-positive individuals who are hepatitis B core antibody positive also have a higher prevalence of cirrhosis, lower HCV RNA levels, and an impaired ability to respond to interferon treatment. [18]

Because of shared routes of transmission, patients infected with the HIV virus are at risk for co-infection with HCV. With the advent of highly active antiretroviral therapy, there has been decreased morbidity and better survival of patients with HIV infection. Co-infection with HIV may also be associated with more rapid progression of chronic HCV. As a result, hepatic cirrhosis, end-stage liver disease, and HCC due to chronic infection with HCV are important causes of both morbidity and mortality in co-infected patients. [19]

After surgical resection of HCC, the presence of active hepatitis and hepatitis C viremia are risk factors for tumor recurrence. Prior treatment of hepatitis C with interferon is protective against the initial development of HCC or recurrence after surgical resection. The protective effect of interferon is most marked in patients who respond to interferon treatment by clearing the virus, but it may occur to a lesser degree even in patients who do not clear the virus. [20]

Dietary Aflatoxin Exposure

Dietary exposure to fungal aflatoxin is an important risk factor for development of HCC. Aflatoxin (derived from *a* spergillus *fla* vus *toxin*) is a mycotoxin produced by two fungal species, *Aspergillus flavus* and *Aspergillus parasiticus*. *A. flavus* is widespread in nature, occurring in soil and decaying vegetation, hay, and grains, particularly in conditions of high moisture content and high temperature. There are at least 13 different types of aflatoxin, with aflatoxin B1 considered the most toxic. Epidemiologic studies have indicated a relationship between aflatoxin intake and incidence of liver cancer in several countries. [21]

Aflatoxins are metabolized in the liver by the cytochrome P450 and glutathione S-transferase enzyme systems. Aflatoxin B1 is a procarcinogen that is converted in the liver to the mutagenic metabolite aflatoxin B1-8,9-exo-epoxide by hepatic microsomal cytochrome P450. Glutathione S-transferases and other phase II enzymes subsequently detoxify this DNA-reactive metabolite. [22] Interindividual differences in the biotransformation of dietary aflatoxins result in differing susceptibility to aflatoxin-induced carcinogenesis. The glutathione S-transferase M1 (*GSTM1*) gene exhibits genetic polymorphism, with a proportion of normal individuals having a homozygous deletion of the gene. Individuals living in regions where dietary aflatoxin levels are high who have the *GSTM1* null genotype are at increased risk for HCC. [23] Aflatoxin exposure predisposes to mutations in the *p53* gene, particularly a G-to-T transversion at codon 249 of the *p53* gene, an event that contributes to the pathogenesis of HCC. [24] In many countries, particularly in tropical regions, grains, peanuts, beans, and other foods are harvested and stored under conditions that

allow fungal growth and accumulation of high levels of aflatoxin. Measures are being instituted in many countries to decrease contamination of foodstuffs with aflatoxin. There are also efforts to develop drugs that enhance aflatoxin detoxification and excretion. [25]

The carcinogenic potential of dietary aflatoxins is significantly increased by the presence of concomitant chronic HBV infection. In one study, patients testing negative for HBV had 0.01 cases of HCC per 100,000 population per year per nanogram of aflatoxin B1 ingested per kilogram of body weight per day. In contrast, patients testing positive for HBV had 0.3 cases per year per 100,000 population, a 30-fold higher risk than in the absence of hepatitis B surface antigen in the serum. Individuals with chronic HCV infection are also probably at increased risk from dietary aflatoxin. [26]

Cirrhosis from Alcohol and Other Chronic Liver Diseases

Cirrhosis from any cause, including chronic alcohol abuse, increases the risk for HCC. The HCC risk is higher for individuals with chronic hepatitis and ongoing hepatocellular injury. Therefore, individuals who stop drinking significantly reduce their risk for HCC. Similarly, patients with nonalcoholic steatohepatitis and cirrhosis who achieve reduced hepatic steatosis and those with hereditary hemachromatosis and cirrhosis who are iron depleted by phlebotomy have a reduced risk for HCC. Certain causes of cirrhosis, such as autoimmune hepatitis, carry a relatively low risk for HCC. [27]

Familial and Genetic Influences on Risk for Hepatocellular Carcinoma

Particularly in areas of the world with a high incidence of HCC, family history of HCC is a significant risk factor for HCC. [28] The biologic basis for this phenomenon is unknown. Epidemiologic studies have suggested either the presence of a recessive allele that contributes to risk for HCC or a familial predisposition to a prolonged HBV replication phase. [29], [30] Genetic polymorphisms of the carcinogen-metabolizing enzymes cytochrome P450 (CYP), glutathione S-transferase (GST) M1, and *N*-acetyltransferase (NAT2), as well as p53 polymorphisms, may contribute to familial risk for HCC. [31]

PATHOGENESIS

Oncogene activation and tumor suppressor inactivation play important roles in carcinogenesis. Oncogene activation occurs through transcriptional activation, gene amplification, or development of activating mutations of genes involved in cellular growth control. Tumor suppressor inactivation can occur through genomic deletions, translocations, or mutations or through epigenetic modifications such as promoter methylation. Normal human somatic cells have a finite lifespan in vivo and undergo senescence after a predictable number of cell divisions. Cellular senescence is triggered by the activation of two interdependent mechanisms. One mechanism leads to induction of cell cycle arrest due to activation of two tumor suppressor genes, *p53* and *pRb*. The second mechanism is activated by a critical shortening of chromosomal ends due to the progressive shortening of the telomeres with each cell division. When both cell growth regulatory mechanisms are inactivated, unchecked cell division and progression to cancer occurs. Cells that are turning over at higher than normal rates because of local growth factor up-regulation or chronic cell injury and regeneration have a higher likelihood of developing genomic alterations that lead to oncogene activation or tumor suppressor inactivation. Environmental exposure to carcinogens can also cause oncogene activation or tumor suppressor inactivation (Fig. 118-1). A number of approaches have been used to elucidate the molecular mechanisms of liver carcinogenesis. These include (1) the use of chemical tumor initiators and promoters in animal models; (2) studies of growth factors and their signaling pathways; (3) transgenic mouse models overexpressing cytokines, growth factors, or oncogenes; (4) studies of immune-mediated mechanisms of hepatocellular injury; (5) analysis of the molecular genetic changes that occur in HCCs, including studies of chromosomal allelic imbalance, comparative genomic hybridization, restriction landmark genomic scanning, and gene expression analysis using cDNA microarrays; and (6) studies of the molecular consequences of HBV integration and the interaction of the protein products of HBV and HCV with host cell processes. These studies have contributed to our growing appreciation of the multiplicity of mechanisms and pathways that may contribute to the carcinogenic process in toxin-affected, chronically inflamed, or otherwise injured liver tissue. In cirrhotic livers, macroregenerative nodules with foci of hepatocyte dysplasia have been identified as preneoplastic lesions of HCC. Histologically, dysplastic lesions are classified as small cell or large cell lesions or as foci of adenomatous hyperplasia; available evidence suggests that small cell dysplasia and adenomatous hyperplasia are the predominant preneoplastic lesions. [32] Unfortunately, we are still far from a unified, comprehensive understanding of liver carcinogenesis. This is in part because HCC is initiated in multiple genetic and environmental contexts and almost certainly emerges as a consequence of multiple possible pathways. The lack of a comprehensive view of the pathogenesis of HCC has also prevented the development of effective, targeted, preventive or therapeutic interventions that are elegant and also simple enough to be applicable to most patients with this disease.

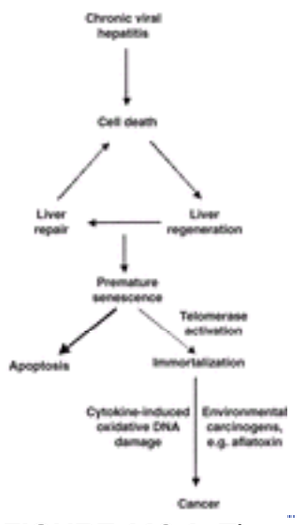

FIGURE 118-1. The role of chronic hepatitis with recurrent liver injury, regeneration, and repair in development of hepatocellular carcinoma. Premature senescence of liver cells occurs by apoptosis. Cells undergoing telomerase activation escape apoptosis. The resulting immortalized cells are susceptible to the influence of oxidative and environmental carcinogen-induced DNA damage, leading to the eventual development of transformed neoplastic hepatocytes.

Tumor Suppressor Genes

Tumor suppressor genes are normal cellular genes that, when homozygously inactivated, can contribute to tumor development. Tumor suppressor genes generally operate in a recessive manner, requiring loss of both copies for tumorigenesis, in contrast to oncogenes, which can exert their effects in a dominant fashion. Loss of heterozygosity (LOH) is loss of one allele in a tumor cell from a chromosomal region for which the individual's normal cells are heterozygous. LOH is detected using polymorphic DNA markers that can distinguish between the two alleles. If one allele of a tumor suppressor gene is inactivated by mutation, then deletion of the second allele, detected by LOH, is associated with loss of expression of the gene. Promoter hypermethylation also leads to decreased expression of tumor suppressor genes. DNA hypermethylation on CpG islands and DNA hypomethylation on pericentromeric satellite regions are early events during hepatocarcinogenesis. CpG island hypermethylation leads to decreased tumor suppressor gene expression, whereas pericentromeric hypomethylation results in chromosomal instability and deletions. [33]

Known or putative tumor suppressor genes shown to be mutated in HCC include *p53,* [34] retinoblastoma (*Rb*), [35] *p16,* [36] *axin1,* [37] *Smad2,* [38] *Smad4,* [38] *M6P/IGF2R,* [39] *BRCA2,* [40] and *DLC-1*. [41] In human HCCs, LOH has now been reported in multiple chromosomal regions, including 1p, 1q, 2q, 4q, 5q, 6q, 8p, 8q, 9q, 10q, 11p, 12p, 13q, 14q, 16q, and 17p. [42], [43] A number of these regions contain known tumor suppressor genes, such as at 17p13.1 (*p53*), 6q26-27 (*M6P/IGF2R*), 8p21.3-22 (*DLC-1*), and 13q12-q32 (*Rb* and *BRCA2*). For a few of these chromosomal loci, clinicopathological associations have been demonstrated, such as the association of LOH on chromosome 1p with early-stage HCC [44] and that of LOH on chromosome 16q with progression of HCC. [45] In addition, patients with LOH at multiple regions have more advanced stage of disease, less well-differentiated tumors, higher serum alpha-fetoprotein levels, and a worse prognosis. [46] Chronic HBV infection and integration of the HBV genome are also associated with high rates of genomic instability. [47] Comparative genomic hybridization (CGH) allows the identification of gains and losses of DNA sequences across the entire tumor genome. Analysis of HCC tumors and cell lines by CGH has revealed genomic DNA copy number gains on chromosomal arms 1p, 1q, 6p, 7p, 7q, 8q, 11q, 12q, 17q, 20p, and 20q. Recurrent losses were found on 3p, 3q, 4p, 4q, 5q, 6q, 8p, 9p, 11q, 13q, 14q, 15q, 16q, 17p, 18q, and 21q. [48], [49] and [50] Significantly, most of the overrepresented regions harbor known protooncogenes, and half of the underrepresented regions coincide

with sites of known or putative tumor suppressors. [49] Notably, a recent comparison of CGH analysis of HCCs due to HBV infection, as compared with HCCs from nonviral etiologies, showed a lower frequency of loss at 4q, 16q and 17p in nonviral HCC samples, suggesting that these abnormalities are associated with HBV infection. [51] CGH analyses also reveal a similar pattern of chromosomal alterations in HBV- and HCV-induced HCCs. Thus, a subset of alterations may preferentially contribute to virus-induced carcinogenesis. In general, LOH and CGH studies have shown variable rates of chromosomal instability. Patient populations with low rates of virus-induced HCC have lower levels of chromosomal instability than populations with high rates of virus-induced HCC. Despite this variability, there is remarkable consistency in the locations of chromosomal instability, suggesting that particular gene targets are affected by genomic instability in HCC.

Investigation of gene mutations in the tumor suppressor gene *p53* in HCC has been particularly revealing because HCCs from patients with high dietary exposure to fungal aflatoxin B1 have a high frequency of point mutations at the third position of codon 249 of the *p53* gene, resulting in a G:C-to-T:A transversion. [52] The frequency of this mutation in HCCs increases proportionally to the level of dietary exposure to aflatoxins. A G:C-to-T:A transversion at the second position of codon 249 is often found in patients with chronic HBV or HCV infection. The occurrence of this mutation correlates with oxyradical exposure. Both of these mutations lead to decreased binding of *p53* to its nuclear DNA targets. [53] Mutations in *p53* have been demonstrated in nonneoplastic liver cells in subjects from communities with high dietary aflatoxin B1 exposure, suggesting that the mutations are early events in neoplastic transformation (Fig. 118-2). However, *p53* mutations can also occur late in tumor progression. The HBV HBx gene product has also been shown to interact with *p53* and strongly inhibit *p53* sequence-specific binding, leading to inhibition of *p53*-mediated apoptosis. Abnormalities in the *Rb* gene have been noted in association with *p53* mutations in advanced HCCs, particularly in poorly differentiated tumors, and *p53* and *Rb* mutations may have an additive effect in liver carcinogenesis. [54] HCCs from different populations show different frequencies of *p53* mutations. In Alaskan Natives, *p53* mutations are rare or absent, suggesting that a difference in environmental or host factors leads to a different mechanism of hepatocarcinogenesis. [11] Molecular genetic studies show that HCCs appear to fall into two groups, with either low or high levels of chromosomal changes. [55] In general, the tumors with low-level chromosomal instability also are more likely to have disruption of the Wnt signaling pathway, with ß-catenin mutations, low-grade histology, and a better long-term prognosis (Fig. 118-3). In contrast, tumors with high-level chromosomal instability are more likely to have *p53* mutations.

FIGURE 118-2. Major molecular pathways of hepatocarcinogenesis. Hypermethylation of the *p16* gene promoter is one of the earliest changes in development of hepatocellular carcinoma. In regions with high dietary aflatoxin exposure, the development of *p53* mutations also occurs early. In areas with low aflatoxin exposure, *p53* and *pRb* pathway disruption occur late in hepatocarcinogenesis.

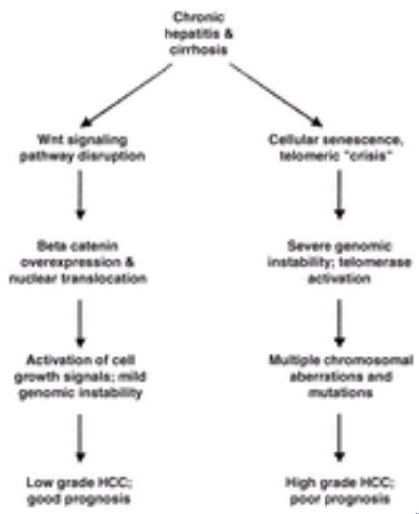

FIGURE 118-3. Two distinct pathways of liver carcinogenesis. Disruption of the Wnt signaling pathway occurs in about 25% of hepatocellular carcinomas. ß-Catenin mutations prevent degradation of ß-catenin and lead to accumulation of nuclear ß-catenin. ß-Catenin cooperates with the Tcf transcription factor to activate cellular growth control genes. Tumors with ß-catenin mutations tend to have lower rates of genomic instability and to be lower-grade tumors with a better prognosis.

Promoter hypermethylation is an important cause of loss of expression of tumor suppressor genes in hepatocarcinogenesis. Genes inactivated by this mechanism include *p16,* [56] *SOCS,* [57] *TSLC1,* [58] and E-cadherin. [59] In particular, *p16* inactivation by hypermethylation appears to be one of the earliest genetic events in hepatocarcinogenesis [60] (see Fig. 118-3).

Oncogenes

Protooncogenes are cellular genes involved in the control of cell growth. Mutation, overexpression, or amplification of these genes leads to oncogenic activity that contributes to neoplastic transformation. Oncogenes known to be overexpressed in HCC include *c-fos* and *c-myc,* [61] *c-erbB-2,* [62] *c-met,* [63] ß-catenin, [64] and gankyrin. [65] Overexpression of *c-myc* is frequently a consequence of amplification of the *c-myc* locus in HCC. [48] Activation of the *c-myc* and *c-fos* oncogenes also occurs as a consequence of the transactivating function of the HBV x protein (HBx) and the carboxyl-terminal truncated middle hepatitis B surface protein (MHBst). [66] Oncogene activation may also occur through promoter hypomethylation, [67] through reactive oxygen species–mediated pathways, or through protein kinase C or mitogen-activated protein kinase pathways. Reactive oxygen species– or lipid peroxidation–mediated processes are also important in the pathogenesis of chronic liver injury induced by alcohol, genetic hemachromatosis, and a $_1$-antitrypsin deficiency.

Growth Factors and Growth Factor–Signaling Pathways

A number of different growth factors are involved in hepatocarcinogenesis. Insulin and insulin-like growth factors (IGFs) I and II promote hepatocyte growth. IGF-II is frequently overexpressed in HCCs. In addition, insulin receptor substrate 1 (IRS-1), a cellular mediator of IGF signaling, is frequently overexpressed in HCCs. [68] Signaling events downstream of IRS-1 lead to activation of the mitogen-activated protein kinase cascade and cell proliferation through up-regulation of cellular growth genes and inhibition of apoptosis. [69] Transforming growth factor-a (TGF-a) and the structurally related epidermal growth factor are another potent class of hepatocellular growth factors. TGF-a is overexpressed in the liver of patients with chronic hepatitis. Because TGF-a levels are often increased in HCCs, it is likely that it contributes to cellular proliferation in cancer, and it may be a factor in tumor initiation or progression in patients with chronic hepatitis. In a transgenic mouse model, TGF-a dramatically enhances *c-myc*–induced hepatocarcinogenesis by promoting proliferation and survival of HCC cells. [70] The TGF-a/ *c-myc* transgenic mouse model also shows hyperphosphorylation of the retinoblastoma protein pRb, which results in inactivation of pRb and release of E2F transcriptional activity, resulting in cell cycle progression and enhanced mitosis. [71] Transforming growth factor-ß $_1$ (TGF-ß $_1$) inhibits cell proliferation and promotes cellular differentiation, fibrogenesis, and apoptosis. Increased TGF-ß $_1$ levels may create an environment in which selection of hepatocyte clones resistant to TGF-ß $_1$–induced apoptosis occurs. The *Smad* genes are involved in TGF-ß signaling, and mutations in the *Smad2* and *Smad4* genes have been described in HCC. [38] Hepatocyte growth factor, the ligand for the *c-met* oncogene, activates the Akt/PI-3 kinase pathway to suppress Fas-mediated cell death in human HCC. [72] High-molecular-mass forms of basic fibroblast growth factor have also been shown to have a mitogenic effect on hepatocytes. [73] Clearly, multiple growth-promoting molecules are involved in hepatocellular carcinogenesis.

Telomere Length and Telomerase Activity

Telomeres are specialized protein-DNA structures at the ends of chromosomes that contain long stretches of TTAGGG hexameric repeats. Telomeres prevent degradation of chromosome ends and end-to-end fusion with other chromosomes. Aging of somatic cells is associated with reduction in telomere length, owing to the inability of traditional DNA polymerases to replicate completely the end of the chromosomal DNA. In contrast, germ-line and neoplastic cells express telomerase, an enzyme that restores telomere length. There is progressive shortening of telomeres during progression from chronic hepatitis to cirrhosis and eventually to HCC. [74] This occurs as a consequence of the multiple cycles of cell injury, death, and regeneration that occur in injured liver, leading to premature hepatocellular senescence. Telomere shortening beyond a critical length leads to a proliferative block, referred to as *telomeric crisis,* which is characterized by chromosomal instability, end-to-end fusions, and cell death. Stabilization of the telomeric DNA through either telomerase activation or the activation of an alternative mechanism of telomere maintenance is essential if the cells are to survive and proliferate indefinitely [75] (see Fig. 118-2). There is cross talk between the oncogene and telomerase pathways because *c-myc* has been shown to activate the telomerase gene promoter. [76] Hepatocarcinogenesis is characterized by the evolution of clones of hepatocytes with increased telomerase expression and an immortalized phenotype. [77] Therefore, almost all HCCs show reactivation of telomerase activity. [78]

Microsatellite Instability

Microsatellite instability (MSI) is defined as a change of any length due to either insertion or deletion of repeating units in a DNA microsatellite within tumor genomic DNA when compared with normal tissue. This form of genomic instability is associated with defective DNA mismatch repair in tumors, which is important in the pathogenesis of the hereditary nonpolyposis colon cancer syndrome (HNPCC) and associated malignancies. [79] To date, six mismatch repair genes have been identified in humans: *hMLH1, hMSH2, hPMS1, hPMS2, hMSH3,* and *hMSH6*. Colorectal cancers are classified as having high-frequency MSI (MSI-H) if greater than 30% to 40% of more than five microsatellite loci analyzed show instability, as having low-frequency MSI (MSI-L) if less than 30% to 40% of more than five loci analyzed show instability, or as being microsatellite stable (MSS) if 0% of loci show instability. Of sporadic colorectal cancers, 70% are MSS, 15% are MSI-L, and 15% are MSI-H. MSS or MSI-L colorectal cancers do not have an associated defective mismatch repair phenotype or the clinicopathological features of HNPCC tumors; instead, they behave in the same manner as sporadic colon cancers. Clear criteria have not been defined for MSI in noncolonic tumors. To date, a number of studies have demonstrated either no instability or a relatively low frequency of low-level MSI in HCC. [80], [81] As is the case with other noncolonic tumors, it is unclear whether this finding is of significance in the etiology or pathogenesis of HCCs or is instead simply a consequence of the generalized genomic instability found in cancer. It has been suggested that cumulative low-level MSI at multiple loci leads to tumor progression. Further investigation is needed to resolve this potentially important question.

Chromosomal Fragile Sites

Chromosomal fragile sites are specific genetic loci that are susceptible to forming gaps, breaks, and rearrangements in metaphase chromosomes of cells cultured under conditions that inhibit DNA replication, such as treatment with the DNA a-polymerase inhibitor, aphidicolin. Fragile sites are grouped into “common” or “rare” classes based on their frequency of occurrence and the culture conditions required for their expression. Thus far, 89 common and 28 rare chromosomal fragile sites have been identified. Common fragile sites are present in all individuals. The most frequently observed common chromosomal fragile sites occur at 3p14.2 (FRA3B), 16q23 (FRA16D), 6q26 (FRA6E), 7q32 (FRA7H), and Xp22 (FRAXB). [82] Common fragile sites span a distance of 250 to 1500 kilobases and display characteristics of unstable, highly recombinogenic DNA in vitro. In particular, they are preferred sites for sister chromatid exchanges, chromosomal deletions and rearrangements, integration of viral sequences and transfected plasmid DNA, and initiation of bridge-breakage-fusion cycles, which lead to gene amplification. Because of these characteristics and the frequent coincidence of fragile sites with chromosomal breakpoints in malignant cells, it has been hypothesized that fragile sites are involved in carcinogenesis. [83] The most convincing evidence of the potential significance of the fragile sites in carcinogenesis is the location of FRA3B, the most highly inducible common fragile site, at chromosome 3p14.2. This chromosomal region is frequently deleted in lung cancer, renal cell carcinoma, and pancreatic cancer and is also the location of the fragile histidine triad (*FHIT*) gene. [84] The *FHIT* gene has been proposed to be a tumor suppressor and has recently been identified as a preferential target in HCC. [85] The cloning of additional fragile sites, particularly ones such as FRA16D (16q23) and FRA6E (6q26) that are located in regions at which there is known LOH in HCC, should provide additional information about the potential role of fragile sites in hepatocarcinogenesis.

Angiogenesis

New vessel formation is required for the continual growth of the tumor and provides a gateway for cells to escape the confines of the primary tumor. HCCs are usually hypervascular and show evidence of active angiogenesis. Arteriolar density in the tumors correlates with angiographic vascularity and also with the proliferating cell nuclear antigen labeling index. [86] It has been shown that IGF-II expression is stimulated by hypoxia, and that IGF-II in turn activates expression of vascular endothelial growth factor, an important regulator of tumor angiogenesis. [87] IGF-II has also been shown to stimulate angiogenesis directly. The hypoxia inducible factor (HIF-1) also plays a role in angiogenesis in HCC. [88] HIF-1 stimulates angiogenesis by activating transcription of the gene encoding vascular endothelial growth factor. In parallel with the increase in angiogenic stimuli, it has been shown that the expression of collagen XVIII, the precursor of the antiangiogenic molecule endostatin, is decreased in larger and more vascular HCCs. [89] Antiangiogenic agents have been shown to be effective against HCC in a mouse model, and it is likely that clinical trials of antiangiogenic agents in human HCC will be performed and reported soon. [90]

Hepatitis B Virus

Multiple mechanisms appear to contribute to HBV-induced hepatocarcinogenesis. Although persistent hepatitis with regenerative hepatocellular turnover and cirrhosis is presumed to play a significant role in HBV-induced carcinogenesis, a significant percentage of HBV-related HCCs occur in the absence of cirrhosis, suggesting a specific role for HBV in the development of these cancers. HBV integrates into the host genome in almost all patients with chronic hepatitis. Viral integration almost invariably precedes the development of HCC. HBV DNA appears to integrate into random sites in the human genome; however, with recent advances in molecular genetics, there is emerging evidence that, as with other viruses, viral integration preferentially targets specific genes or common chromosomal fragile sites. [91] Integrated HBV is thought to contribute to the pathogenesis of HCC through a number of potential mechanisms: (1) by local genomic effects due to production of genomic instability and focal deletions and translocations; (2) by interruption of genes, leading to overexpression, suppression, or production of novel fusion transcripts; and (3) by the transactivating effects of viral proteins, particularly the *X* and *preS* gene products. Viral integration has been shown to result in deletions, translocations, and gene amplification at the site of integration. [92] In a number of cases, HBV integration has been shown to occur adjacent to or within genes involved in cell growth or apoptosis. Genes found at HBV integration sites include the retinoic acid receptor-ß gene (*RARB*), [93] the cyclin A gene, [94] and the sarco/endoplasmic reticulum calcium ATPase (*SERCA*). [95] In the case of the *RARB* and cyclin A integrations, expression of a fusion transcript results in oncogenic effects. [96], [97] Integration of HBV into the *SERCA* gene leads to accumulation of chimeric HBx/SERCA 1 proteins that induce apoptosis. HBx protein inhibits the function of the tumor suppressor *p53* and activates cytoplasmic mitogenic signaling cascades, including the mitogen-activated protein kinase (MAPK) and the Janus family tyrosine kinase (JAK)/signal transducer and activators of transcription (STAT) pathways. HBx also interacts with transcription factors in the nucleus to transactivate multiple genes involved in cellular growth control, including the nuclear factor (NF)-?B, activator protein 1, and serum response element pathways. [98] The HBx protein has been shown to play a role in fibrogenesis. HBx interacts with *Smad4* and stabilizes the complex of *Smad4* with components of the basic transcriptional machinery, leading to enhanced transcriptional activity in response to TGF-ß. In addition, confocal microscopy studies suggest that HBx facilitates and potentiates the nuclear translocation of Smads, further enhancing TGF-ß signaling. This suggests that HBx-enhanced Smad-mediated signaling may contribute to HBV-associated liver fibrosis. [99] The hepatitis B surface and core genes and proteins may also play significant roles in hepatocarcinogenesis. It has been shown that a truncated carboxyl-terminal variant of the HBV S protein directly interacts with DNA and transactivates several cellular and viral promoters, including the *c-jun* and *c-fos* promoters. [100] HCC has also been associated with HBV strains that have deletions or insertions in the HBV core promoter region, suggesting a role for changes in core protein expression in persistence of HBV infection, HBV integration, and carcinogenesis. [101]

Hepatitis C Virus

In patients with chronic HCV viremia, persistent liver damage with abnormal alanine aminotransferase levels plays an important role in the development of HCC. This may be due to repeated cycles of liver cell injury and regeneration, resulting in premature cellular senescence and the development of genomic aberrations. However, in addition, it has been shown that individuals with persistent liver damage develop a population of HCV quasispecies that changes over time, whereas individuals with persistently normal transaminases have a stable infection with a single species of HCV. [102] Even within the same patient, tumor samples show greater variability in the core region of HCV isolates than is found in adjacent benign samples. [103] This phenomenon may be important in hepatocarcinogenesis, by allowing for selection

of more oncogenic variants of the HCV core protein. In a transgenic mouse model, HCV proteins suppress Fas-mediated hepatocellular apoptosis and may use this mechanism to maintain persistence of HCV infection. [104] Of the seven HCV proteins, core and nonstructural (NS) proteins NS2, NS3, NS4A, NS4B, NS5A, and NS5B, the core protein is the most potent cellular signaling activator, causing activation of the NF-?B, AP-1, and SRE pathways and the mitogen-activated protein kinase MAPK/ERK cascade. [105] Activation of these cascades leads to cell proliferation. The HCV core protein has been shown to interact with the 14-3-3 protein, leading to activation of Raf-1 kinase. [106] The NS4B protein also activates the NF-?B pathway, and the NS5A protein has been shown to repress the interferon-induced protein kinase, PKR. The envelope protein E2 is transcribed from the most variable region of the HCV genome and is thought to allow the virus to escape from neutralizing antibodies; in addition, E2 inhibits PKR and contributes to interferon resistance of HCV. [107]

SURVEILLANCE

Surveillance in a population assumes (1) the disease has an asymptomatic stage but if left alone will produce significant morbidity or mortality; (2) a high-risk population can be identified; (3) surveillance tests are inexpensive, noninvasive, and accurate; (4) clearly defined recall procedures exist, and (5) effective therapy is available (Table 118-1). For HCC, almost all of these criteria can be met in principle. Patients with cirrhosis from alcohol abuse, viral hepatitis, hemochromatosis, a $_1$-antitrypsin deficiency, and primary biliary cirrhosis all have an increased incidence of HCC. [108], [109], [110], [111] and [112] Asians and Africans who are chronic HBV carriers are also at significant risk for HCC. [113] In contrast, HCC is unusual in Wilson disease, autoimmune hepatitis, and primary sclerosing cholangitis. [114], [115] and [116] In high-risk cirrhotic patients, the incidence of HCC is 2% to 6%, greater than the calculated incidence of 1.5% thought to be the cut-off point in order for surveillance to be cost-effective. [117] Ultrasonography is relatively inexpensive, noninvasive, and accurate in the diagnosis of early-stage HCC, and, therefore, it is recommended that ultrasonography be used to screen for HCC at 6-month intervals in patients with cirrhosis. This radiographic technique has a sensitivity of 70% and a specificity of 90% for identifying HCC in an asymptomatic population. [118] The 6-month interval time schedule comes from data on the doubling time of these cancers. [119], [120] The utility of serum alpha-fetoprotein determinations in screening for HCC remains controversial [121]; however, an elevated serum alpha-fetoprotein does identify patients at increased risk for HCC. [122] Recall procedures (the definition of an abnormal result and the procedure for investigating abnormal results) are less well established. Most experienced clinicians would follow any lesion greater that 0.5 cm with a spiral enhanced computed tomography (CT) scan of the liver (see section, " Differential Diagnosis, Diagnosis, and Staging"). Based on this analysis, surveillance of individuals with cirrhosis for HCC is generally encouraged. However, evidence-based data for instituting screening for HCC are less compelling. Several retrospective, uncontrolled or nonrandomized trials show little benefit to surveillance. [118], [123], [124] and [125] These studies have been fraught with problems, such as being based entirely on hospital populations as opposed to non–referral-based populations, lack of established recall procedures, poor compliance, and failure to offer liver transplantation as a curative procedure for patients with small HCCs. Modeling data are more encouraging. We have developed a Markov model to assess the cost-effectiveness of screening for HCC (Fig. 118-4). The data demonstrate that screening for HCC is cost-effective and can be defended as a clinical strategy.

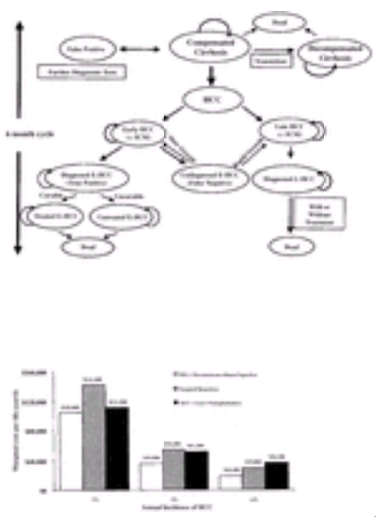

FIGURE 118-4. A Markov model for screening for hepatocellular carcinoma. The **upper panel** shows the different clinical states programmed in the model. The **lower panel** shows the cost per life-year saved for patients treated by percutaneous ethanol injection, surgical resection, or orthotopic liver transplantation.

CRITERIA	CRITERIA MET FOR HEPATOCELLULAR CARCINOMA
Asymptomatic stage	Yes
Late stages are incurable and cause mortality	Yes
High-risk population	Yes, cirrhosis
Surveillance testing is inexpensive and noninvasive.	Yes, ultrasonography
Established recall procedures	Not well developed
Effective therapy	Liver transplantation, surgical resection, ablative procedures*

*These therapies can only be applied on a selective basis, and the non-transplantation therapies are fraught with recurrent disease.

TABLE 118-1 Criteria for Instituting Population Surveilance

DIFFERENTIAL DIAGNOSIS, DIAGNOSIS, AND STAGING

The differential diagnosis of liver mass lesions is thoroughly reviewed in Chapter 47. Therefore, this section is limited to the differential diagnosis of liver mass lesions in the presence of cirrhosis. The major problem in cirrhosis is differentiating HCC from a macroregenerative nodule. Macroregenerative nodules (MRNs) are large nodules that form in the liver as part of the cirrhotic process. The presence of large MRNs is itself a risk factor for the development of HCC, and therefore, the distinction between MRNs and HCC is difficult. Indeed, current nomenclature suggests that instead of MRN the term *dysplastic nodule* be applied. [126] The imaging hallmark of HCC is increased vascularity of the lesion as compared with the surrounding tissue and is used to help make the diagnosis of HCC radiographically (Fig. 118-5). For lesions larger than 2 cm, a definite diagnosis needs to be established because the lesion is still amenable to therapy at this stage (see later). If the lesion is identified by two imaging studies and manifests contrast enhancement on spiral CT or dynamic magnetic resonance imaging (MRI) studies in the presence of cirrhosis, the diagnosis of HCC can be comfortably established. [127] Also, if the lesion is identified by two imaging studies and the alpha-fetoprotein level is higher than 400 ng/mL, the diagnosis of HCC also is likely. [127] If these strict criteria are adopted, imaging misdiagnosis is very unlikely. In a very robust study, the diagnosis of HCC was established preoperatively without biopsy with an accuracy of 99.6%, sensitivity of 100%, specificity of 98.9%, and positive and negative predictive values of 99.3% and 100%, respectively. [128] In the absence of these noninvasive criteria for the diagnosis of HCC (Table 118-2), histologic or cytologic verification of the malignancy should be obtained. However, the risk for tumor seeding has been estimated to be 3.4% to 5.1%, [129], [130] and a biopsy should only be performed if it will change therapy. In many instances, expert clinicians may elect to proceed with surgery or an ablative therapy based on the presence of a clear-cut mass lesion in a cirrhotic liver because it is difficult to interpret a negative biopsy. Lesions can be missed despite ultrasound guidance of the biopsy, and it is extremely difficult for the pathologist to distinguish between a dysplastic nodule and an early well-differentiated HCC. Finally, given the propensity of dysplastic nodules to evolve into cancer, ablative therapy for a dysplastic nodule is not necessarily inappropriate. The detection of small (less than 1 cm) hypoechoic or hyperechoic nodules during ultrasonography of the liver should raise the suspicion of HCC. Hypoechoic nodules are consistent with neoplastic growth of tissue, whereas hyperechoic nodules suggest the presence of steatosis. It is now well established that many small HCCs contain fat, which is subsequently lost as the cancer progresses. [131] Therefore, both hypoechoic and hyperechoic lesions must be considered malignant in a cirrhotic liver until further characterized. However, pathological studies have shown that only about half of such nodules smaller than 1 cm are neoplastic. These small lesions, unfortunately, are too small to assess their vascularity by imaging studies or to obtain tissue reliably for pathological examination. It is recommended that these lesions be followed with serial imaging studies at least 3 to 4 months apart. Growth of the lesion or the development of contrast enhancement on cross-sectional imaging studies would signify the development of HCC. Ultrasound and spiral CT scans are

the standard imaging modalities for the follow-up of these early and diagnostically challenging lesions.

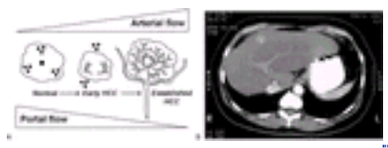

FIGURE 118-5. A: Schematic representation of arterialization during hepatocellular carcinoma development. **B:** Computed tomography scan showing contrast enhancement of an early hepatocellular carcinoma. This pathological feature of hepatocellular carcinoma allows more accurate detection of malignant nodules. The technique of transarterial chemoembolization also relies on the preferential arterial vascularization of hepatocellular carcinomas as compared with the normal hepatic parenchyma.

Radiographic criteria
Two concident imaging studies
Arterial hypervascularization
Combined criteria
One imaging study with hypervascularization
Alpha-fetoprotein >400 ng/mL

Natural History

An understanding of the natural history of HCC is necessary to interpret the results of the published treatment trials. The natural history of HCC is dependent on the severity of the underlying cirrhosis, tumor characteristics (i.e., size, multicentricity, presence or absence of vascular invasion, pathological grade, and metastases), symptoms as manifest by the performance status of the patient, comorbid diseases, and the efficacy of treatment interventions. Four prognostic classifications for HCC have been developed (Table 118-3). All of these are imperfect, in part, because they do not take into account specific information on the tumor (e.g., information on the genetic changes or specific mechanisms involved in pathogenesis of the tumor); are based on information at the time of the initial diagnosis and, therefore, do not incorporate changes in prognostic variables over time; and are based on retrospective analysis. The first was developed by Kunio Okuda and co-workers and is simply known as the Okuda classification. [132] This classification takes into account hepatic factors (bilirubin, albumin, and ascites) and a single tumor factor (extent of liver replacement more 50% or less than 50%). Given its relatively gross assessment of tumoral factors and absence of patient health parameters, this classification is seldom used in clinical assessment. The other three prognostic classifications take into account more refined assessments. The Barcelona Clinic Liver Cancer (BCLC) prognostic assessment takes into account the patient performance status, presence or absence of constitutional symptoms, vascular invasion, and extrahepatic spread. [133] The Cancer of the Liver Italian Program (CLIP) uses the Child-Turcotte-Pugh Score, tumor size and multicentricity, vascular invasion, and serum alpha-fetoprotein to establish a prognosis. [134], [135] The Group d'Etude et de Traitement du Carcinoma Hepatocellulaire (GETCHC) takes into account the Karnofsky index, serum bilirubin, alpha-fetoprotein, serum alkaline phosphatase, and vascular invasion. [136] It is clear from an assessment of these models that vascular invasion, poor performance status, and an elevated alpha-fetoprotein with tumor multicentricity are uniform poor prognostic parameters. More importantly, these studies also predict which patients will do well for extended periods of time. For example, using data from patients randomized to no treatment in well-designed randomized control trials, the BCLC group found that patients with unicentric disease, no symptoms, and no evidence of vascular invasion nor extrahepatic spread had a 50% 3-year survival rate [137] (Fig. 118-6). This subgroup of patients with HCC are frequently those selected for locoregional therapies (see later), and the survival in the treatment groups is frequently no better than that in this untreated group of patients (Fig. 118-7). This information on the natural history of HCC needs to be kept in mind when counseling patients and helping them select treatment options.

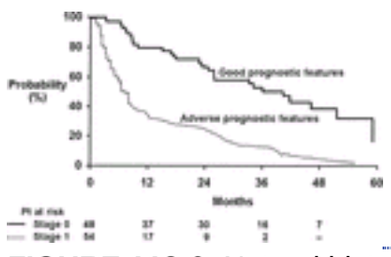

FIGURE 118-6. Natural history of hepatocellular carcinoma. Patients with good prognostic factors and early detection of hepatocellular carcinoma have a significantly better short- to mid-term outcome compared with patients with adverse prognostic features at the time of diagnosis. (Modified from ref. [137].)

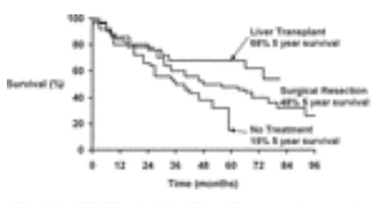

FIGURE 118-7. Results of surgical resection and orthotopic liver transplantation for hepatocellular carcinoma. Survival after surgical resection is limited by the development of recurrent hepatocellular carcinoma in the remaining cirrhotic liver. Liver transplantation results in improved long-term survival because of replacement of the liver with a noncirrhotic donor liver. (Adapted from ref. [9].)

CLASSIFICATION	PARAMETERS
BCLC	Performance status
	Constitutional symptoms
	Vascular invasion
	Extrahepatic spread
CLIP	Child-Turcotti-Pugh stage
	Tumor size or nodularity
	Vascular invasion
	Alpha-fetoprotein ≥400 mg/mL
GETCHC	Karnofsky index <80%
	Bilirubin ≥3 mg/dL
	Alpha-fetoprotein >35 mg/mL
	Alkaline phosphatase > 2 × upper limit of normal
	Vascular invasion
Okuda	Ascites
	Tumor size >50% of liver
	Albumin <3 g/L
	Bilirubin >3 mg/dL

TABLE 118-3 Prognostic Stage Classification Systems for Hepatocellular Carcinoma

Clinical Manifestations

With better institution of surveillance strategies, most HCCs will be identified at an asymptomatic stage. However, many patients continue to present with advanced HCC. The clinical manifestations of advanced HCC are protean and include decompensation of cirrhosis, tumoral symptoms, acute abdominal catastrophe, cholestasis, fever of unclear etiology, paraneoplastic phenomena, and the metastatic presentation (Table 118-4). HCC may result in decompensation of cirrhosis by vascular invasion of the major portal vein or its large branches. This event worsens portal hypertension and frequently results in the development of ascites and refractory variceal bleeding. Infiltrating cancers in the liver also increase portal hypertension at the level of the sinusoids, promoting ascites formation and variceal bleeding. Also, the diffuse infiltrating cancers further worsen hepatic function, resulting in hyperbilirubinemia, coagulopathy, and encephalopathy. Even small cancers may be associated with hepatic decompensation because either advanced cirrhosis is frequently associated with HCC or the small cancers have effects on the immune system or hepatic function in general. For example, about 20% of patients hospitalized with spontaneous bacterial peritonitis have HCC. [138] Because of this association, all hospitalized cirrhotic patients should have appropriate imaging studies to look for HCC.

PRESENTATION	CLINICAL SYNDROME
Tumor	Malaise, anorexia, weight loss, night sweats
Hepatic decompensation	Jaundice, ascites, variceal bleeding
Acute abdominal pain	Tumor bleeding, capsular extension
Pyrexia	Fever and leukocytosis
Metastases	Brain, lung, or bone metastases
Cholestasis	Large bile duct obstruction or diffuse infiltrating cancer
Paraneoplastic	Increased red blood cell mass, Ca^{++}; decreased glucose; diarrhea

TABLE 118-4 Clinical Manifestations of Symptomatic Hepatocellular Carcinoma

Tumoral and acute presentations of HCC are less common than the presentation of hepatic decompensation. The tumoral presentations include anorexia, weight loss, general malaise, and painful hepatomegaly. The acute presentation is associated with spontaneous rupture of the cancer into the peritoneum or extension through the capsule. Mortality is high with hemoperitoneum due to exsanguination. Selective acute arterial embolization of the bleeding artery is the preferred treatment for this complication. Patients with pain from tumor extension through the capsule likely have pain from this rupture event. The pain is usually acute, limited in time (less than 24 hours), and assumed to be biliary colic. The screening ultrasound of the liver often identifies unexpectedly a liver mass when the patient seeks medical attention.

Cholestasis may result from tumor-associated extrinsic compression of the large bile ducts, tumor invasion of the large bile ducts, or miliary metastasis throughout the liver. Tumor invasion of the bile ducts can be associated with hemobilia and gastrointestinal bleeding. [139] In our experience, the miliary pattern of metastases is usually associated with disproportionately high serum transaminases in addition to hyperbilirubinemia and jaundice.

Fever of unknown etiology is an unusual presentation of HCC. [140] Interestingly, the febrile episodes may be discrete episodes and associated with leukocytosis. Tumors need not be large to generate this symptom complex. Given the frequent difficulty in diagnosing HCC by a single imaging study, multiple imaging studies may be necessary to make the diagnosis of HCC in this context. In contrast to fever, night sweats are common in advanced HCC and portend a poor prognosis.

Paraneoplastic phenomena associated with HCC are rare but include hypercalcemia, erythrocytosis, hypoglycemia, thrombophlebitis migrans, arterial hypertension, and the syndrome of watery diarrhea, hypokalemia, and achlorhydria. The hypercalcemia is due to production of a parathyroid hormone–like molecule, the erythrocytosis is due to erythropoietin generation by the tumor, and hypoglycemia is mediated by insulin-like growth factors. [141] Arterial hypertension is uncommon in advanced cirrhosis, and its presence, therefore, should prompt imaging studies for HCC. In addition to the rare syndrome of watery diarrhea, hypokalemia, and achlorhydria, diarrhea without the electrolyte abnormalities is very common in some populations with HCC. [141] In children with hepatoblastomas, isosexual precocity may be a paraneoplastic syndrome. [141] In adults, feminization and gynecomastia are also associated with HCC, but these syndromes are often present in cirrhosis without HCC and are, therefore, difficult to attribute to HCC. Cutaneous manifestations of HCC are equally rare and include dermatomyositis, pemphigus foliaceus, and Leser-Trélat sign. The latter is the sudden onset of seborrheic dermatitis and freckles, with a rapid increase in the number of the lesions accompanied by pruritus. Pityriasis rotunda (round or oval hyperpigmented scaly lesions) may be associated with HCC in South African blacks. [141]

Metastatic complications of HCC are not dissimilar from the metastatic complications of other neoplastic diseases. However, HCC does have some unique metastatic presentations. One metastatic complication of HCC is dyspnea due to tumor pulmonary emboli, and another is headache associated with pituitary metastases. [142] Common sites for HCC metastases include the diaphragm with associated pleural effusions, bone metastases with pain, and regional lymph node metastases, which may be associated with abdominal discomfort. In general, abdominal pain in patients with HCC is a poor prognostic symptom and usually indicates advanced disease.

Staging of Hepatocellular Carcinoma for Selection of Therapy

The staging procedure depends in part on the intensity of the selected treatment. All patients should undergo a chest radiograph to exclude pulmonary metastases and at least two imaging studies to stage intrahepatic disease and exclude vascular invasion (ultrasound, contrast CT, contrast MRI); in addition, many centers will perform a CT scan of the chest and a bone scan if liver transplantation is being contemplated. It is important to note that abdominal lymphadenopathy is common in cirrhosis, especially perihilar lymph nodes and even more generalized lymphadenopathy in hepatitis C. Thus, one has to be very cautious in attributing lymphadenopathy to metastatic disease. In suspicious cases, we have found endoscopic ultrasound with fine-needle aspiration (FNA) of hypoechoic lymph nodes useful for detecting metastatic involvement of lymph nodes. Finally, the dilemma of what to do with a small HCC remote from a portal vein thrombosis remains problematic. If tumor thrombosis is present, radical or ablative therapies are not effective; if the thrombus is bland, then these therapies may be contemplated. Many experienced centers use color-flow Doppler and ultrasound-guided FNA of the thrombus to make a decision. [143], [144] and [145] The appearance of an arterial signal on the color-flow Doppler is most indicative of tumor thrombus because these lesions are frequently arterialized despite their residence in a vein. A negative color-flow Doppler along with a negative FNA would be strong evidence in favor of a bland thrombus.

LOCOREGIONAL THERAPIES

Locoregional approaches include surgical and percutaneous ablative techniques. The outcome of these therapies for HCC is dependent on several readily identifiable prognostic factors. Poor prognostic factors identified in numerous studies include unicentric tumors larger than 5 cm, multicentric disease with more than three 3 lesions, satellite lesions adjacent to the main tumor (a marker for tumor invasion and therefore metastatic potential), and vascular invasion. [133] In particular, invasion of the main portal vein or one of its segmental branches, a striking feature of HCC, is a relative contraindication to radical therapy.

Surgical Approaches

Surgical resection is commonly accepted as the initial treatment of choice for localized HCC worldwide. Despite the acceptance of surgery for the treatment of HCC, there are no randomized controlled trials demonstrating its efficacy. This approach is limited in its application because few patients are suitable for partial hepatectomy because of either tumor size, vascular invasion, multicentricity, the presence of portal hypertension, or overall hepatic functional reserve. Intrahepatic recurrence of HCC is common among patients who undergo apparent curative resection because the neoplastic potential of the nonresected liver remains unchanged. Indeed, the 5-year recurrence rate is 52% because of either de novo tumor recurrence or the progression of previously unrecognized intrahepatic metastases. [9] Hepatic decompensation is high in patients with any elevation of the serum bilirubin or evidence of portal hypertension [146] (Fig. 118-8). A wedged hepatic venous pressure gradient above 10 mm Hg is considered to be a contraindication to resection. However, few liver centers routinely perform this test; instead, many surgeons use a platelet count of less than 100,000 per µl or the presence of varices (indicative of a wedged hepatic venous pressure gradient of at least 12 mm Hg) as contraindications to surgery. Operation-related mortality is also high, especially in patients with limited hepatic functional reserve. Partial hepatec- tomy should therefore be considered only in patients without cirrhosis or in those with mild liver disease (Child A cirrhosis), normal portal pressure, and normal bilirubin. [133] The best outcomes are observed in patients with unicentric disease, no vascular invasion, tumors smaller than 5 cm, and relatively inactive liver disease. Given these selection criteria, it is estimated that only about 5% of patients with cirrhosis and HCC are candidates for surgical resection. [147] In this highly selected patient

population, the best reported outcomes are 50% at 3 years. [133] This outcome is not that much different from the natural history of untreated, asymptomatic, small, unicentric disease without vascular invasion or that obtained with ablative techniques (see earlier). Because of these observations, many hepatologists seldom advocate resection for HCC except in ideal candidates. However, if appropriate adjuvant therapies or secondary chemopreventive agents could be developed, surgery would be a more attractive option. Along these lines, polyprenoic acid has been shown in a single study to decrease recurrence rates after surgical resection of HCC. [148] If these studies can be confirmed, the use of this agent should enhance outcomes after surgery or ablative therapy.

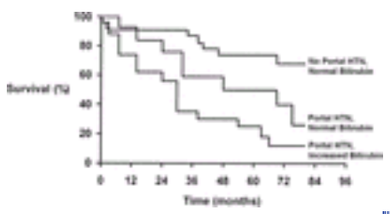

FIGURE 118-8. Hepatic decompensation leads to a worse outcome after surgical resection for hepatocellular carcinoma in patients with clinically significant portal hypertension (HTN) and an increased serum bilirubin. (Modified from ref. [9].)

Orthotopic liver transplantation (OLT) for patients with HCC offers several advantages over partial hepatectomy: (1) it can be employed in patients with all stages of liver disease; and (2) the cancer, the neoplastic potential of the underlying liver disease, and the liver disease itself are all therapeutically addressed at the same time. Indeed, numerous studies have now demonstrated that in patients with unicentric disease less than 5 cm or with multicentric disease of up to three lesions and each lesion 3 cm or smaller, the results with liver transplantation are superb (see Fig. 118-8). For example, a study of 120 cirrhotic patients with HCC showed that transplanted patients with a maximum of two small (less than 3 cm) nodules had improved survival without recurrence (83% at 3 years) compared with patients treated with partial hepatectomy (18% at 3 years) for tumors of the same size. [149] One large recent series found that HCC less than 5 cm in diameter or the presence of three or fewer tumors with a maximal diameter of 3 cm was associated with overall survival rate of 85% and disease-free survival rate of 92% at 4 years. [150] Thus, transplantation centers throughout Europe and the United States have adopted these criteria in HCC patients for OLT. However, limited studies have suggested that unicentric tumors with a capsule and without vascular invasion of up to 6.5 cm may do equally well with OLT. [151] In addition, data from Germany suggest that very-well-differentiated large tumors have acceptable outcomes after OLT. [152] Thus, the current guidelines of one lesion less than 5 cm or three lesions all less than 3 cm are restrictive criteria developed to ensure the best outcomes and need to be reevaluated as more information becomes available. The most important limitation of OLT is an increasing organ shortage, which is problematic for several reasons. OLT for HCC removes livers from the common donor pool and may thus aggravate the situation for patients with end-stage cirrhosis. In addition, a long waiting period for a donor organ often allows a small tumor to become large or even metastatic. Indeed, the dropout rate for patients initially meeting criteria for OLT may be as high as 25% during 6 months of waiting time in the absence of therapy. [9] However, these patients were selected on the criteria that all lesions had to be identified by two imaging modalities, resulting in an understaging bias. In contrast, most transplantation centers in the United States have an overstaging bias, which is to take the maximum number of lesions identified on any given study to be the actual number of tumors. Nonetheless, given the increasing waiting times for OLT, most centers prefer to treat the lesions before OLT to prevent tumor growth and dissemination. Ablative approaches and chemoembolization (CE) therapies are employed (see later). None of these therapies has been subjected to randomized controlled trials in combination with OLT; therefore, the optimal approach remains to be ascertained.

In summary, tumor criteria identifying patients with HCC who are most likely to benefit from surgical approaches (resection and transplantation) have now been established. Many experts feel that patients meeting criteria for surgical approaches should be offered this option as definitive therapy. In patients who are candidates for both resection and transplantation, the best outcomes are obtained with transplantation because of the high recurrence rate after liver resection. [9] However, if effective secondary chemoprevention therapies can be established, surgical resection may become preferred because it avoids the risks and need for long-term immunosuppression. For patients who are not candidates for surgical approaches, locoregional forms of treatment are reasonable. These options include percutaneous alcohol injection (PEI), radiofrequency ablation (RFA), and transcatheter arterial chemoembolization and are discussed in the following paragraphs.

Percutaneous Alcohol Injection

PEI has become a widely accepted form of therapy for small, localized HCC. The advantage of PEI over other local ablative minimally invasive therapies is its relatively simple technique and low cost. PEI can be safely performed in patients who are not candidates for resection or OLT, even in the presence of advanced cirrhosis. [153] It is generally agreed that HCC less than 3 cm in size and fewer than three nodules is suitable for PEI. The destruction of tumor cells by injection of absolute alcohol is probably due to a combination of cellular dehydration, coagulative necrosis, and vascular thrombosis followed by tissue ischemia.

For PEI, sterile ethanol (95%) is slowly instilled throughout the tumor nodule under ultrasound or CT guidance. Because it is important to achieve uniform distribution of the ethanol, the injecting needle is usually placed at the far end of the lesion and then withdrawn in a stepwise fashion during the injection. For small lesions, a single treatment is often sufficient, whereas larger lesions may require several treatments over a number of days. The extent of necrosis achieved is dependent on tumor size. Small nodules less than 3 cm in diameter are usually completely destroyed, larger tumors only partially. [154], [155] Patients should therefore be followed regularly with spiral CT scans. PEI can be repeated for local recurrences and new lesions within the liver. PEI is associated with a complication rate of 1.7% and a 0.1% mortality rate. Patients may experience abdominal pain, which is often due to leakage of ethanol into the peritoneal cavity and can be prevented by leaving the needle inside the lesion for 30 seconds or more after injection. A low-grade fever may be present for 1 to 3 days after the procedure as a result of tumor necrosis. Contraindications to PEI include massive ascites, coagulopathy, and obstructive jaundice, which increase the risk for postprocedural bleeding and bile peritonitis.

The long-term survival rate is as high as 70% in patients with cirrhosis undergoing PEI for a single HCC less than 3 cm in diameter. [154], [155] In the largest series published, Livraghi and colleagues [153] reported survival rates in 746 cirrhotic patients with HCC treated with PEI. In patients with a single tumor less than 5 cm in diameter (*n* = 462), the 3- and 5-year survival rates were 79% and 47%, respectively, for Child A patients, 63% and 29% for Child B patients, and only 12% and 0% for Child C patients. In patients with Child A cirrhosis, survival was much lower in those with multiple HCCs (35% at 5 years), single HCCs larger than 5 cm (30% at 5 years), and advanced HCCs (0% at 5 years). Unfortunately, there have been no prospective randomized controlled trials comparing PEI to surgical resection or transplantation for early stage HCC. In a large retrospective study from Japan in which patients were matched for severity of the liver disease and stage of tumor, there was no significant difference in survival between patients treated with PEI and those who underwent surgical resection. [156] Thus, long-term survival after PEI may be equivalent to survival after surgical resection in a selected subgroup of patients with small tumors and mild cirrhosis. Similar to the results after surgical resection, tumor recurred in 50% of patients after PEI. [157] In summary, PEI is a safe, simple, inexpensive treatment for patients with HCC. Although relatively few reports of long-term results are available, PEI seems to be an effective method for patients with single, small tumors. For this subgroup of patients, PEI might be equal to surgical resection, with fewer complications and less procedure-related morbidity and mortality. However, more controlled studies comparing PEI to other treatment modalities are needed to better define its role in the management of HCC. Treatment of larger lesions is also possible but is less likely to ablate the tumor completely and is therefore associated with higher rates of relapse and decreased survival rates.

Radiofrequency Ablation

Radiofrequency ablation (RFA) is emerging as a new therapeutic method in the management of HCC. The first papers reporting ultrasound-guided RFA of hepatic tissue were published in 1990 and suggested that RFA could prove useful to create focal coagulative necrosis of hepatic tumors while sparing normal liver tissue. [158] Significant advances in equipment design have led to increasing success in the use of this method in the management of HCC. RFA destroys tissue by thermal energy generated with an alternating electric current generator that operates in the radiofrequency range from 200 to 1200 kHz. Like PEI, RFA is usually performed by a percutaneous approach in the outpatient department. After local anesthesia, a needle electrode is introduced through the skin under ultrasonographic guidance and advanced into the center of the tumor. Treatment is guided by impedance measurements between components of the needle electrode. The goal of each procedure is to ablate the tumor and a small margin of normal tissue around the tumor. Depending on the equipment used, this can be achieved in one or two short sessions (less than 15 minutes) for lesions up to 5 cm. Because large blood vessels act as a heat sink, RFA is not effective for lesions adjacent to large veins in the liver. It is also more technically difficult to treat lesions in segment 8 (lesions high in the dome of the liver) with RFA than with PEI. Spiral contrast-enhanced CT scanning is usually used to assess tumor necrosis after RFA, since ultrasound is usually not sensitive enough for this purpose. RFA can be repeated for residual tumor found on

follow-up or for new tumor nodules that develop in the liver.

Although the experience with RFA is still limited, the first results are promising. In 1995, Rossi and colleagues [159], [160] reported initial results from 24 patients with one or more tumor nodules smaller than 3 cm that were treated with intent to cure. Complete tumor necrosis was achieved in all but two patients after one session; both patients successfully received additional thermal ablations. About half the patients had recurrence of the tumor during follow-up, which could be retreated in 70% of these patients. The survival rate was 95% the first year, 84% the second year, 67% the third year, and 45% the fourth and fifth years. Livraghi and associates [161] used a large cohort of patients (*n* = 112) with small HCCs (less than 3 cm in diameter) to compare the effectiveness of RFA with that of PEI. Complete tumor necrosis was achieved in 90% of tumors with RFA in an average of only 1.2 sessions per tumor and in 80% of tumors with PEI in 4.8 sessions. However, in contrast to other series, one major and four minor complications were reported in patients treated with RFA; in contrast, no complications occurred in patients treated with PEI. Finally, a recent study suggests RFA may be associated with a high rate of needle track seeding (12.5%) because of the large needle used in this approach. [162] It is not clear whether this result is generalizable.

In conclusion, RFA appears to be a fast, safe, and effective technique for ablation of small liver tumors. Larger controlled studies are needed to determine whether RFA, rather than PEI, should be the method of choice for small HCCs. Nonetheless, because it usually requires fewer sessions, is better tolerated, and has more easily assessed treatment margins, RFA is the preferred choice in many centers. Until more information becomes available, the availability of experience and equipment in individual centers, location of the lesion within the liver, and closeness of the tumor to large vessels should determine the method used for treatment.

Transcatheter Arterial Chemoembolization

CE is a technique that uses angiography to embolize selectively the arterial supply to an HCC. A cytotoxic agent such as doxorubicin or cisplatin is mixed with lipiodol, Gelfoam, or Ivalon particles to form a suspension that is then injected into the feeding artery of the tumor by angiographic technique through the common femoral artery. This results in both selective ischemic and chemotherapeutic effects on the HCC. Because of the dual blood supply of the liver, CE causes minimal damage to normal liver parenchyma; 80% to 100% of the blood flow to liver tumors but only 20% to 30% of the flow to normal liver is supplied by the hepatic artery. After the procedure, the suspension remains in the tumor, where the cytotoxic agent is slowly released to exert its effect. Although lipiodol serves a dual role in CE by carrying the chemotoxic agent to the tumor and also embolizing the vasculature, it can remain in the lesion for prolonged periods of time and preclude adequate radiographic assessment of tumor necrosis by contrast-enhanced CT scanning. The relative contribution of the chemotherapeutic agents to treatment of HCCs, compared with the simple ischemic effect of occluding the tumor vasculature, has never been established.

Risks associated with CE include contrast allergy, contrast-induced nephropathy, and bleeding or pseudoaneurysm formation at the catheter site. Most patients develop a postembolization syndrome with fever and right upper quadrant pain and are therefore hospitalized. Liver function tests can be elevated for up to 2 weeks. Major complications include hepatic abscess, which is most common in patients with a preexisting biliary-enteric anastomosis; hepatic artery dissection or thrombosis; and ischemic cholecystitis. The morbidity rate of CE was 5.1% and the treatment-related mortality rate 4.1% in one retrospective study. [163] Advanced Child C cirrhosis is a relative contraindication to CE because of the high risk for potentially fatal complications such as liver failure. Other contraindications include hepatic encephalopathy, biliary obstruction, portal vein occlusion, a surgical portosystemic shunt, a transjugular intrahepatic portosystemic shunt device, bilirubin higher than 5 mg/dL, International Normalized Ratio higher than 1.7, or creatinine higher than 1.8.

The efficacy of CE is determined by the size of the lesion. One study reported a survival rate of 100% at 3 years for tumors less than 2 cm in diameter, whereas 3-year survival was 0% for tumors greater than 5 cm. [164] Because CE also avoids the risk for needle track seeding, transplantation centers often use CE as a bridge to transplantation for HCC patients. CE prevents progression of the lesions and potential micrometastases while the patient waits for a donor organ. In a pilot study at our institution, none of the transplant recipients pretreated with CE has developed recurrent HCC during a mean follow-up of more than 2 years. [165] However, the role of CE as a palliative procedure remains controversial. Indeed, one large controlled study that compared CE to conservative treatment for unresectable HCC of any size was stopped because an interim analysis failed to show the expected benefit of CE. [166] These results have been confirmed by several other randomized controlled trials, which did not show improved survival in patients with nonsurgical HCCs. [167], [168] and [169] Based on the current evidence available in the published literature, CE cannot be recommended for the treatment of large, unresectable HCC.

SYSTEMIC THERAPY

Four forms of systemic therapy have been applied to the treatment of advanced HCC, including cytotoxic therapy, immunotherapy, hormonal therapy, and gene therapy.

Cytotoxic Chemotherapy

HCC is extremely refractory to current available cytotoxic therapies. Moreover, the presence of cirrhosis with impaired clearance of drugs metabolized by the liver increases drug toxicity. Portal hypertension with leukocytopenia and thrombocytopenia also exacerbate drug-induced bone marrow toxicity. The overall response rate is less than 20% for systemic chemotherapy given intravenously using either single or combined agents. [170] Intra-arterial therapy also has not been shown to affect disease progression or survival. [171] Thus, there is no current proven chemotherapeutic regimen for HCC.

Hormonal Therapy

The presence of androgen receptors in HCC, the sexual dimorphism of the liver, and the male predominance of HCC led to the use of antiandrogen therapy for this cancer. Unfortunately, studies were negative, and this approach was abandoned. [172] The presence of estrogen receptors in the liver also led to the use of tamoxifen (an antiestrogen) for the treatment of this disease. Initial studies suggested a survival benefit. [173] However, several randomized controlled trials and a metaanalysis of these trials have shown no survival benefit. Finally, HCCs express somatostatin-2 receptors, and administration of somatostatin appeared to improve survival of patients with advanced HCC in a pilot study. [174] Larger randomized trials are needed to evaluate further the use of somatostatin in HCC.

Immunotherapy

Two forms of immunotherapy have been applied in HCC, using systemic therapy with interferon or employing lymphokine-activated natural killer cells. Although interferon was superior to no treatment or doxorubicin (Adriamycin) in one study, this result was not reproduced in a second study. [175] Further, the administration of interferon in doses required for antitumoral effects was associated with a high rate of adverse side effects, necessitating discontinuation of therapy. Lymphokine-activated killer cell therapy is associated with significant toxicity, is expensive, and is difficult to implement. [176] Results with this approach have also been modest, and, therefore, it has not been adopted as a therapeutic option.

Gene Therapy

Gene therapy is rational for HCC because a transient transfection (e.g., liposome-mediated transfer of plasmid DNA constructs) or transduction (e.g., administration of a virus expressing the desired construct) may be sufficient to destroy the tumor cells. It also may be possible to effect selective tumor targeting using the alpha-fetoprotein promoter or angiography. In addition, bystander effects have been observed with all gene therapy strategies, indicating that not all cells have to be transduced. However, these goals have yet to be realized in the clinical context. Several trials, including those attempting to transfect HCC cells with wild-type *p53,* have evolved to human studies, but the results have been disappointing so far. Nonetheless, it is premature to abandon this approach, and further developments are likely.

SUMMARY

The selection of an appropriate treatment strategy for patients with HCC depends on careful tumor staging and assessment of the underlying liver disease (Fig. 118-9). All patients with localized HCC (involvement of one single lobe, no vascular invasion or extrahepatic disease) should be evaluated for the potentially curative therapy options of partial hepatectomy or OLT. Candidates for partial hepatectomy must have no liver disease or Child A cirrhosis, normal portal pressure, and normal serum bilirubin. For patients not meeting these criteria, OLT should be considered if there is a solitary lesion smaller than 5 cm or three or fewer lesions smaller than

3 cm. Local ablative therapies, such as PEI, RFA, and CE, offer palliation for patients with contraindications for surgical approaches. PEI and RFA are minimally invasive and can be used on an outpatient basis, usually for tumor nodules smaller than 3 cm. When used for small tumors, the survival rates can be similar to those achieved by partial hepatectomy. CE may be used as an interim treatment for patients waiting for OLT. Given the paucity of efficacy data, there are no proven systemic chemotherapy regimens, immunotherapy approaches, or hormonal therapies that can be recommended at this time.

CHAPTER 119

David S. Raiford

LIVER ABSCESS

AMEBIC VERSUS PYOGENIC ABSCESS

This chapter describes the clinical presentation, imaging characteristics, laboratory findings, natural history, and response to treatment of hepatic abscess. Although there is considerable overlap in these features between amebic and pyogenic abscesses, the differences in epidemiology, associated conditions, treatment, and prognosis underscore the need for the physician to distinguish these entities. Effective management depends critically upon prompt and correct definition of the abscess type.

EPIDEMIOLOGY

There are important differences in the epidemiology of amebic abscess, as it presents in the United States, and pyogenic abscess. Because intestinal amebiasis is a necessary prelude to hepatic amebic abscess, patients with amebic abscess typically have emigrated from or traveled to areas where intestinal amebiasis is prevalent. [1] Ethnicity of the local patient population is important. For example, in a large series from Los Angeles, 92% of 457 patients with amebic liver abscess had Hispanic surnames, compared with 37% of the local patient population. [2] In contrast, ethnicity of patients with pyogenic abscess did not differ from the general hospital population. Another difference identified between amebic and pyogenic liver abscess in this series was a striking male predominance (84%) in those with amebic abscess, whereas the gender distribution in those with pyogenic abscess was about equal. The median age of patients with amebic abscess (28 years) was significantly lower than that of those with pyogenic abscess (44 years). [2]

Since the classic review of Ochsner and associates [3] in 1938, and after the introduction of antibiotics in the 1940s, the frequency of pyogenic liver abscess associated with intraabdominal infection has diminished. Although pyelophlebitis (mostly due to appendicitis) accounted for 43% of cases of pyogenic liver abscess in the first decades of the 20th century, [3] a series of patients from 1973 to 1993 indicated that in only 7% of cases was pyogenic liver abscess believed due to portal bacteremia. [4] During the past few decades, biliary obstruction, both benign and malignant, has emerged as the most common etiology of pyogenic liver abscess, now accounting for 50% to 60% in several recent series. [4], [5] and [6] This trend undoubtedly reflects improvements in early diagnosis and management of extrabiliary abdominal infections attributable to modern imaging modalities and use of antibiotics. Importantly, over time, the incidence of cryptogenic hepatic abscess has remained stable at 15% to 20% of cases. [3], [4], [7] Several series suggest that diabetes mellitus may predispose to pyogenic liver abscess because 15% to 25% of cases occur in patients with diabetes. [2], [4], [5], [8] Finally, since the 1980s, it has become apparent that recipients of liver transplant allografts have an elevated risk for pyogenic liver abscess. [9]

CLINICAL MANIFESTATIONS

Fever and right upper quadrant pain are the principal symptoms of hepatic abscess, both amebic and pyogenic. Fever is evident in virtually all patients. Although spiking fever and chills favor pyogenic abscess, these may be seen with amebic abscess. Pain is reported by 75% to 90% of patients, is usually constant, is of variable intensity, and may exhibit pleuritic features with radiation to the right shoulder if diaphragmatic involvement is present. [2], [10], [11] and [12] Most patients have symptoms for less than 2 weeks before seeking medical care. Nonspecific symptoms, such as weakness, anorexia, nausea, and weight loss, are common. About one third of patients with either type of liver abscess report diarrhea, and one fourth have a nonproductive cough.

On physical examination, sequential measurements of body temperature should be made to detect fever. Hepatic enlargement and tenderness are typical, but not invariably present. Jaundice is rare in amebic abscess and, when present, should suggest biliary tract obstruction with pyogenic infection or underlying chronic liver disease. Percussion dullness, diminished breath sounds, or other chest findings at the right lung base are evident in 20% to 30% of patients and suggest involvement of the superior portion of the right hepatic lobe. Occasionally signs of weight loss, dehydration, and anemia are evident. [2], [4], [11], [13]

DIAGNOSIS AND DIFFERENTIAL

Imaging Modalities

The clinical constellation of fever, right upper quadrant discomfort, and hepatic enlargement with tenderness should prompt an imaging study early in the diagnostic assessment. Depending on the age of the patient and level of clinical suspicion for cholelithiasis or biliary obstruction, either ultrasonography (US) or computed tomography (CT) will be performed. These techniques facilitate discrimination of liver abscess from cholecystitis, bile duct obstruction, or pancreatitis. Radionuclide liver-spleen scanning after administration of ^{99m}Tc sulfur-colloid has been supplanted by US and CT because the latter two are more sensitive for small lesions (less than 3 cm) and offer better precision in localizing lesions that may require percutaneous aspiration or drainage. Of note, lesions near the dome of the right hepatic lobe may be difficult to visualize by US. Typically, on US, an abscess appears as a rounded, hypoechoic mass, sometimes with internal echoes [14], [15] (Fig. 119-1). CT scanning with intravenous contrast identifies an abscess as a low-density lesion (Fig. 119-2), often with peripheral enhancement, and may provide better definition of extrahepatic pathology associated with pyogenic abscess (e.g., appendiceal or diverticular abscess). [16] Although both modalities are sensitive for detecting abscesses and biliary obstruction, neither can distinguish reliably between amebic and pyogenic abscesses. [17], [18] and [19] Although less widely used, magnetic resonance imaging (MRI) also has high sensitivity for detection of hepatic abscess. Characteristically, liver abscesses are hypointense on T1-weighted and hyperintense on T2-weighted images, and wall enhancement soon after gadolinium infusion is typical. [20] Thus, MRI may provide complementary data if US and CT findings are ambiguous or when coronal images will help guide management of a lesion in the superior portion of a hepatic lobe (Fig. 119-3). Most abscesses, both amebic and pyogenic, occur in the right hepatic lobe. The presence of multiple abscesses strongly suggests pyogenic infection, as does identification of concomitant biliary tract obstruction. Chest radiographs in patients with an abscess adjacent to the diaphragm may show elevation of the right diaphragm, subpulmonic effusion, and right lower lobe atelectasis or infiltrate. It is well to remember that hepatic tumors may present with necrosis and secondary infection, [21] mimicking a primary abscess.

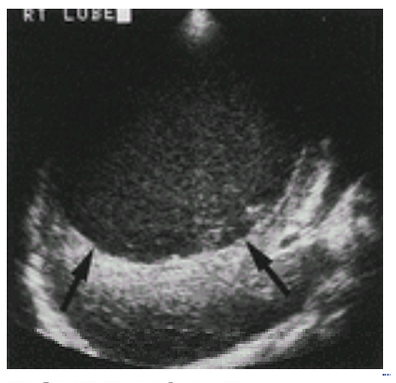

FIGURE 119-1. Transverse sonogram of the right hepatic lobe showing a large hypoechoic amebic abscess (*arrows*). This lesion is homogeneous, as is typical, although any ultrasonographic pattern may occur. The image is from a 26-year-old man who had strongly positive amebic serology and recovered rapidly with metronidazole treatment. (From Reynolds TB. Liver abscess. In: Kaplowitz N, ed. Liver and biliary diseases. 2nd ed. Baltimore: Williams & Wilkins, 1996:463–468.)

FIGURE 119-2. Computed tomography scan showing a low-density lesion in the anterosuperior segment of the right hepatic lobe of a 34-year-old man. *Klebsiella pneumoniae* was cultured from the blood and from the abscess cavity. The patient recovered with antibiotic treatment and a single abscess aspiration. (From Reynolds TB. Liver abscess. In: Kaplowitz N, ed. Liver and biliary diseases. 2nd ed. Baltimore: Williams & Wilkins, 1996:463–468.)

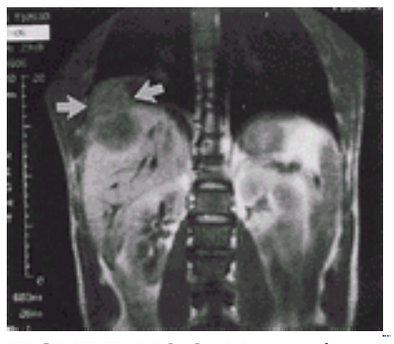

FIGURE 119-3. Magnetic resonance image showing a 6-cm lesion in the dome of the right hepatic lobe with apparent penetration into the thoracic cavity (*arrows*). The patient was a 35-year-old Hispanic man with 3 weeks of pleuritic, right-sided chest pain and fever. Red-brown material was aspirated from the right chest. Amebic serology was strongly positive. He recovered with metronidazole therapy. (From Reynolds TB. Liver abscess. In: Kaplowitz N, ed. Liver and biliary diseases. 2nd ed. Baltimore: Williams & Wilkins, 1996:463–468.)

Laboratory Testing

Although commonly employed blood tests are of limited utility in reaching a specific diagnosis of hepatic abscess, certain abnormalities are typically present. Leukocytosis (more than 10,000/mm ^{3}) is present in more than 90% of patients. Mild anemia is common, with hemoglobin levels of less than 12 g/dL seen in two thirds of patients. Mild to moderate elevation of serum alkaline phosphatase activity is typical but of little discriminating value in the absence of information from imaging studies. [2], [4], [22]

Detection of antiamebic antibodies is of primary importance in diagnosis of amebic liver abscess. Although serologic tests may rarely be negative very early in infection, more than 90% of patients with hepatic abscess develop antibodies to *Entamoeba histolytica* in high titer. A positive serologic response to *E histolytica* indicates tissue invasion by the parasite and not simply intestinal colonization. Both indirect hemagglutination and enzyme-linked immunosorbent assays are available. [23] Importantly, seropositivity does not distinguish current from prior disease. Thus, persistence of antiamebic antibodies after resolution of amebic abscess (usually in diminishing titer) may lead to confusion in the differential diagnosis of a subsequent liver lesion, especially in areas in which infection is endemic. [1], [24], [25] and [26]

A key element in diagnosis and treatment of pyogenic liver abscess is identification of the organisms in the abscess. Blood cultures are positive for bacteria in about 50% of patients. Thus, at least two separate specimens of blood should be taken for culture before administration of antibiotic agents. Most pyogenic abscesses are caused by enteric gram-negative aerobic rods, streptococci, and anaerobes. Although blood cultures typically identify a single organism, cultures from abscess aspiration are frequently polymicrobial. [2], [28], [29] Needle aspiration of an abscess is the best and most direct method to distinguish amebic from pyogenic abscess. Material from an amebic abscess is brown-red in color and typically is not particularly malodorous. A pyogenic abscess yields material that is creamy, tan-green in color, and often putrid, reflecting anaerobic infection. Gram stains of amebic abscess contents show neutrophils but no bacteria, unless secondary infection is present. Smears of pyogenic abscess contents usually identify at least one bacterial form. Meticulous handling of aspirated material to avoid exposure to air enhances recovery and identification of anaerobic species. Reliable and complete identification of infectious agents ensures proper selection of an antibiotic treatment regimen. [29]

COURSE AND COMPLICATIONS

Amebic Abscess

Without treatment, amebic liver abscess tends to enlarge and ultimately extend through the diaphragm or rupture into the peritoneal cavity. Pleuropulmonary involvement is the most common complication. [10], [30], [31] and [32] Upon extension through the diaphragm, amebic empyema or lung involvement with development of hepatobronchial fistula may occur. Rupture into the right pleural cavity is less frequent than into the lung, probably because of fusion of the diaphragmatic and visceral pleura induced by inflammation. Erosion into a bronchus may be followed by expectoration of amebic pus and by amelioration of symptoms. This mechanism of abscess drainage affords an opportunity for spontaneous resolution. Less frequently seen is rupture into the pericardium, typically a complication of amebic abscess within the left hepatic lobe. This may be accompanied by retrosternal pain, a pericardial friction rub, and findings of cardiac tamponade, such as jugular vein distention with pulsus paradoxicus. Historically, rupture into the pericardium has carried a high mortality. [10], [30]

When an amebic abscess ruptures abruptly into the peritoneum, diffuse abdominal pain and signs of peritonitis occur. Less frequently encountered is a contained abscess adjacent to the site of hepatic rupture. In neither instance is surgery required because cure typically results from antimicrobial therapy alone. [10], [31] Other rare intraabdominal complications include rupture into bowel and hemobilia due to formation of an arteriobiliary fistula.

Pyogenic Abscess

The mortality rate associated with untreated pyogenic liver abscess approaches 100%. [3], [5], [7] As with amebic abscess, complications of pyogenic liver abscess include rupture and extension into surrounding tissues, with pleuropulmonary involvement most common. In contrast to amebic peritonitis, should rupture into the peritoneum occur from pyogenic liver abscess, mortality is very high without surgical management. Abscess-associated thrombosis of the portal vein or a hepatic vein can lead to residual portal hypertension or the Budd-Chiari syndrome after otherwise successful treatment of the abscess. Patients with large or multiple pyogenic abscesses are at increased risk for developing infections at remote body sites due to bacteremia. Patients with polymicrobial abscesses have a higher mortality rate than do those with monomicrobial infections. In one series, all 14 patients who had two or more organisms isolated from blood cultures died. [5] Mortality appears to be higher in patients with pyogenic abscesses of biliary origin, probably because these patients tend to have multiple abscesses. Even with prompt diagnosis and treatment, the mortality rate from pyogenic liver abscess remains high, ranging from 10% to 30%. [2], [5]

TREATMENT

Liver abscess should be considered in any patient with fever, leukocytosis, pain in the right upper quadrant, and tenderness over the liver or right lower chest wall. Depending on the age of the patient and the nature of the discomfort and associated symptoms elicited by history, either US or CT should be obtained. Either modality will detect reliably one or more hepatic lesions, with imaging characteristics suggesting abscess. Should jaundice or evidence for biliary obstruction be discovered, consideration of cholangiography and biliary decompression is appropriate. Regardless of whether amebic or pyogenic abscess is believed more likely, at least two sets of blood cultures should be obtained before administration of antibiotic agents.

Amebic Abscess

If the patient is a young man who has emigrated from or traveled to an area where amebiasis is endemic, who has a single lesion on an imaging study, and who does not appear toxemic, then amebic abscess is the more likely diagnosis. Stool specimens should be examined for amebic cysts and trophozoites and serum tested for *E histolytica* antibodies. Treatment in adult patients should then be initiated with metronidazole, 750 mg given orally three times daily for 10 days. [1], [29] An alternative regimen is chloroquine phosphate, 1000 mg (600 mg chloroquine base) given orally daily for 2 days, and then 500 mg (300 mg chloroquine base) given orally daily for 2 to 3 weeks. [1], [33] Clinical improvement is expected within three days. After treatment with either of these tissue amebicides, therapy with a lumenal amebicide is appropriate to eradicate amebas within the bowel because these may cause relapsing or persisting infection. Iodoquinol, 650 mg given orally three times daily for 20 days, is the drug of choice for this purpose. [33] Aspiration of the abscess is indicated if there is no clinical improvement within several days, if the diagnosis is in doubt, or if the abscess is large or located such that rupture is believed likely. Amebic pleural effusions are treated by aspiration and one of the amebicidal regimens. Amebic pericarditis is treated by pericardiocentesis and by aspiration of the (usually left lobe) hepatic abscess in addition to amebicidal antibiotics. Surgery is not indicated for uncomplicated amebic liver abscess but may be appropriate in some instances for rupture or, rarely, for failure of medical therapy alone. [34] US-guided percutaneous drainage is effective and should obviate the need for surgical management in most cases. [35] In uncomplicated amebic liver abscess, the prognosis is good, with a mortality rate of about 1%. [10] Extension into the chest or pericardium increases mortality significantly, to 6% and 25% to 30%, respectively. [10], [31]

Pyogenic Abscess

If the patient is older, lacks a history suggesting risk for amebiasis, or has multiple lesions or bile duct obstruction on an imaging study, pyogenic abscess is more likely. After blood cultures have been obtained, treatment with a broad-spectrum antibiotic regimen is appropriate. Because of the mixed nature of many pyogenic infections, the initial empiric regimen should provide effective coverage against aerobic enteric bacilli, microaerophilic streptococci, and enteric anaerobes. Suitable regimens include ampicillin-sulbactam, piperacillin, cefoxitin, imipenem, or a third-generation cephalosporin plus metronidazole. [29] Previous instrumentation or obstruction of a patient's biliary tree and local patterns of bacterial antibiotic resistance should prompt broader coverage or antibiotic selection to strengthen coverage against specific pathogens such as *Enterococcus* and *Pseudomonas* species. [4] In most instances, diagnostic aspiration for bacterial culture is appropriate. Ideally, this should occur before antibiotics are administered, but treatment should not be delayed injudiciously if prompt aspiration is not feasible. Many choose to leave a drain in place after aspiration. Several series have indicated that aspiration (with or without catheter drainage) and antibiotics are curative in most instances. [2], [4], [6], [13], [36], [37], [38], [39], [40], [41] and [42] Antibiotic therapy alone should be employed only for those with multiple small abscesses not amenable to aspiration and for those with a contraindication to aspiration and drainage (e.g., coagulopathy). [43] Surgical drainage, either open or laparoscopic, [44] is appropriate for patients who fail to improve with percutaneous drainage and antibiotic therapy and for those who have an extrahepatic or biliary source of hepatic abscess in need of surgical treatment. Surgical intervention may ultimately be necessary in up to one third of patients with pyogenic abscess. [45], [46] Although percutaneous drainage and current antibiotic regimens have reduced mortality from pyogenic liver abscess significantly, it remains high (20% to 40%) in patients with significant comorbidity, multiple abscesses, malignant biliary obstruction, and inadequate drainage. [4], [5]

Acknowledgments

I am grateful for the use of Figure 119-1, Figure 119-2, and Figure 119-3. *These appeared previously in Reynolds TB. Liver abscess. In: Kaplowitz N, ed. Liver and biliary diseases. 2nd ed. Baltimore: Williams & Wilkins, 1996:463–468.*

CHAPTER 120

Laurie D. DeLeve

VASCULAR DISEASES OF THE LIVER

SYSTEMIC CIRCULATORY DISEASE

Ischemic Hepatitis

Ischemic hepatitis may occur as a result of reduction in systemic blood pressure with or without hypoxemia. Ischemic hepatitis often occurs in patients with underlying heart disease, [1], [2] and [3] and it has been suggested that right-sided heart failure with hepatic venous congestion predisposes to ischemic hepatitis due to systemic hypotension. [3] Decreased cardiac output may be due to cardiac causes such as myocardial infarction, severe congestive heart failure, cardiac arrhythmias, severe cardiomyopathy, cardiogenic shock, constrictive pericarditis, and pericardial tamponade. Systemic causes of hypotension include septic shock or hypovolemia due to massive hemorrhage, extensive burns, or extravasation of fluid into the peritoneum, such as in acute pancreatitis. Primary pulmonary causes of hypoxemia may include massive pulmonary embolus, end-stage chronic obstructive lung disease, or restrictive lung disease.

The diagnosis is made on clinical grounds when there is systemic hypotension and severe and rapidly reversible elevation of serum aminotransferase in the absence of other causes of acute hepatitis. In addition to these features, a marked, rapid elevation of lactate dehydrogenase (LDH) [4] with a low ratio of serum aminotransferase to LDH is helpful in distinguishing ischemic hepatitis from acute viral hepatitis. [5] Serum aminotransferases are most commonly 20 or more times the upper limit of normal, and an elevation less than 20 suggests the need for further confirmation of the diagnosis. [6] Concomitant renal hypoperfusion with elevation in creatinine and blood urea nitrogen are also usually present. The classic histological feature is centrilobular necrosis.

Congestive Hepatopathy

Causes of congestive hepatopathy include chronic right-sided heart failure due to cardiomyopathy or valvular heart disease, constrictive pericarditis, and pulmonary hypertension. Clinical findings include a dull ache in the right upper quadrant, hepatomegaly, increased jugular venous pressure, and hepatojugular reflux. Liver tests are usually normal. Congestion causes sinusoidal dilation in the centrilobular sinusoids with preservation of normal architecture in the periportal areas. Histologically, this pattern is referred to as a “nutmeg” appearance. Centrilobular fibrosis may occur with long-standing disease, but frank cardiac cirrhosis is rare.

Treatment of both ischemic hepatitis and congestive hepatopathy is directed toward the underlying cardiopulmonary disease.

BUDD-CHIARI SYNDROME

Classic Budd-Chiari syndrome is defined as obstruction or occlusion of the hepatic veins due to thrombus, fibrous obliteration, or tumor invasion. In the West, classic Budd-Chiari is more common, whereas in South Africa, India, Japan, Nepal, and China, membranous obstruction of the hepatic portion of the inferior vena cava (IVC) is more frequent. The symptoms of these two forms of hepatic vein obstruction are the same, but etiology and management differ. [7], [8] For the sake of clarity, the former will be referred to as *Budd-Chiari syndrome,* and the latter will be referred to as *membranous obstruction of the IVC*.

Clinical Features

Budd-Chiari syndrome may present with hepatomegaly, abdominal pain and tenderness, ascites, mild jaundice, and eventually, liver failure. The presentation may be acute, subacute, or chronic, although the latter two are more common. Severity of symptoms depends on the extent of the involvement of the hepatic veins, the time course over which the obstruction develops, and the duration of untreated disease. Slower development of the obstruction or occlusion allows the formation of collaterals, which alleviates sinusoidal congestion. There is a wide spectrum in presentation of the disease. Patients with an acute presentation are more likely to present with fulminant hepatic failure with coagulopathy, encephalopathy, and hepatorenal syndrome. Patients with a chronic presentation may present with chronic liver disease with (near-) normal aminotransferases, low albumin, and a prolonged prothrombin time. If there is extensive formation of collaterals or involvement of a single hepatic vein, the patient may have preservation of normal liver function and no ascites. Budd-Chiari syndrome may be asymptomatic in up to 25% of cases. The most common presentation is a history of vague complaints for less than 6 months and onset of ascites. The serum ascites–albumin gradient is greater than 1.1 g/dL.

The caudate lobe drains through the right inferior hepatic vein into the IVC, which thromboses less frequently, so that flow through the caudate lobe may become an important route of blood flow when there is occlusion of two or all three main hepatic veins. This increased flow leads to caudate lobe hypertrophy in about half of the patients with Budd-Chiari syndrome. Significant caudate lobe hypertrophy may compress the IVC behind it, complicating decompression by portacaval shunts (which are below the level of compression of the IVC).

Risk Factors

Most cases of Budd-Chiari syndrome can be categorized into two groups: hepatic vein thrombosis and mechanical outflow obstruction. Risk factors can therefore be divided into these two categories. The major risk factors for hepatic vein thrombosis (Table 120-1) are chronic myeloproliferative diseases and prothrombotic coagulation disorders. About 25% to 30% of patients have multiple concurrent risk factors. [9], [10] Myeloproliferative disorders are the leading causal factor in 50% of

patients. [9], [11], [12] and [13] The chronic myeloproliferative disorder most closely associated with hepatic vein thrombosis is polycythemia vera, whereas essential thrombocythemia is a less common cause. In a large series, 10% of patients with polycythemia vera and 13% of patients with essential thrombocythemia developed hepatic vein thrombosis. [14] None of the 232 patients with chronic myelogenous leukemia in this series developed thrombosis of the major abdominal vessels. The increased risk for hepatic vein thrombosis is linked to both overt and latent myeloproliferative disease.

RISK FACTORS FOR HEPATIC VEIN THROMBOSIS	MECHANICAL OUTFLOW OBSTRUCTION
Myeloproliferative diseases	Hepatocellular carcinoma*
Polycythemia vera	Renal cell carcinoma*
Essential thrombocythemia	Adrenal carcinoma*
Prothrombotic coagulation disorders	Leiomyosarcoma*
	Right atrial myxoma*
Factor V Leiden mutation	Hydatid cysts*
Protein C deficiency	Amebic or pyogenic abscess*
Antiphospholipid antibodies (prothrombin G20210A mutation)	Sarcoidosis
	Trauma*
	Aspergillosis
Oral contraceptives, pregnancy, puerperium	Abdominal surgery
Hepatocellular carcinoma	
Behçet disease*	
Paroxysmal nocturnal hemoglobinuria	

*More commonly associated with membranous obstruction of the hepatic portion of the inferior vena cava.

TABLE 120-1 Risk Factors for Budd-Chiari Syndrome

In a recent series, one or more prothrombotic risk factors were identified in 87% of patients with hepatic vein thrombosis. [9] Two recent case series have identified factor V Leiden as an important risk factor, [9], [10] but these studies differed as to whether protein C deficiency was a risk factor. The prevalence of antithrombin III deficiency, protein S deficiency, the G20210A prothrombin gene mutation, and the methylene-tetrahydrofolate reductase (*MTHFR*) gene mutation in patients with hepatic vein thrombosis is similar to that expected for a healthy control population. Once Budd-Chiari syndrome causes chronic liver disease, diagnosis of protein C deficiency, protein S deficiency, or antithrombin III deficiency may be misleading because synthesis of these coagulation factors decreases as liver function declines. Antiphospholipid antibodies are a risk factor for hepatic vein thrombosis and may be primary or related to one of the various connective tissue diseases. Oral contraceptives, pregnancy, and the puerperium are associated with an increased risk for hepatic vein thrombosis, but there most commonly is a concurrent risk factor. Hepatocellular carcinomas that invade the hepatic veins may cause hepatic vein thrombosis or may cause a mechanical obstruction, usually at the level of the IVC. Uncommon risk factors for hepatic vein thrombosis include paroxysmal nocturnal hemoglobinuria, [15] postoperative complications, and Behçet's disease. Although Behçet disease may cause hepatic vein thrombosis, it is more likely to cause obstruction of the IVC. [16], [17]

Procoagulants and anticoagulants circulate systemically throughout the vasculature. If the hemostatic balance of coagulation factors were the only determinant of thrombosis, then any change in the balance would have an impact on all vascular beds. As noted in the preceding paragraph, some of the prothrombotic disorders do and others do not cause hepatic vein thrombosis. Predisposition to thrombosis in a particular vascular bed is a characteristic feature of prothrombotic disorders. This selectivity of thrombosis for discrete segments of the vasculature may be due to endothelial cell–dependent procoagulant and anticoagulant activities. [18]

The classic definition of Budd-Chiari syndrome includes both hepatic vein thrombosis and obstruction or occlusion of the hepatic veins that is nonthrombotic. The major causes of mechanical outflow obstruction are cancers and infections (see Table 120-1). Some of the causes listed in Table 120-1 may cause mechanical obstruction at the level of the hepatic veins, but they are more commonly associated with obstruction of the hepatic portion of the IVC. Uncommon causes of mechanical obstruction of hepatic veins are trauma with formation of an intrahepatic hematoma, granulomata due to sarcoidosis, and aspergillosis invading hepatic veins. [19]

Diagnosis

Imaging in conjunction with liver biopsy establishes the diagnosis of Budd-Chiari syndrome but also allows the hepatologist to plan management based on the anatomy and the severity of liver disease. Initial evaluation includes noninvasive imaging with ultrasound, dual-phase computed tomography (CT), or magnetic resonance angiography. These studies determine whether there is obstruction or absence of flow at the level of the major hepatic veins or IVC; intrahepatic, capsular, or systemic collateral formation; hepatic parenchyma with variegated appearance and nodularity; caudate lobe enlargement; ascites; or splenomegaly. If normal hepatic veins with phasic flow are detected, the diagnosis of Budd-Chiari syndrome is excluded. The definitive diagnosis requires angiography with visualization of the hepatic veins and IVC and pressure measurements. Alternatively, percutaneous transhepatic venography can be used to measure hepatic vein pressure. In addition to the diagnosis of Budd-Chiari, the diagnostic workup needs to uncover the risk factors. Because there are frequently two or more causes, one of which may be an occult myeloproliferative disorder, [9], [10] bone marrow biopsy is mandatory.

A liver biopsy is needed to establish whether there is necrosis or fibrosis, features that are deciding factors in management. On histopathology, the thrombi in the hepatic veins have multiple layers, consistent with ongoing or recurrent thrombosis. Portal vein thrombosis occurs secondarily in some of the small branches of the portal vein and in the main portal vein in about 25% of cases. In acute Budd-Chiari syndrome, there is centrilobular and sometimes midlobular sinusoidal congestion, acute hemorrhage, and liver cell ischemia. Chronic outflow obstruction leads to bridging fibrosis between central veins with sparing of the portal tracts. Commonly, there is marked heterogeneity of the lobular changes. Areas of the liver subject to the most severe outflow obstruction demonstrate sinusoidal fibrosis. Benign regenerative nodules are common.

Management

A decision tree for management is shown in Fig. 120-1. Medical therapy may not alter progression of liver disease or improve survival, but diuretics and paracentesis can be used to alleviate symptoms. In selected cases of recent thrombosis, thrombolytic agents such as tissue plasminogen activator and streptokinase have been used successfully, but the literature on this is limited to case reports. Increased sinusoidal pressure and decreased liver perfusion in Budd-Chiari syndrome lead to parenchymal necrosis, fibrosis, cirrhosis, and portal hypertension. Patients must be monitored by serial liver biopsies to detect persistent necrosis and early fibrosis. Biopsy from a single liver lobe may be misleading because not all three major hepatic veins may be equally affected, so that a bilobar liver biopsy is more reliable. Sinusoidal decompression performed before significant fibrosis and loss of liver function may stabilize disease progression. Other indications for decompression include refractory ascites and uncontrollable gastrointestinal hemorrhage. Options for decompression of obstruction in the hepatic vein include transjugular intrahepatic portosystemic shunt (TIPS) and surgical shunt. TIPS may also benefit individuals with fulminant hepatic failure. [20], [21] and [22] Given the high rate of reocclusion, TIPS is perhaps best suited as a bridge therapy for liver transplantation in Budd-Chiari syndrome. The goal of a surgical shunt is to create hepatofugal flow through the portal vein. The choice of surgical shunt often depends on the preference of the surgeon. If there is significant compression of the IVC by caudate lobe hypertrophy or substantial obstruction of the IVC by thrombosis or a web, pressure in the retrohepatic IVC may be higher than in the portal vein. Under these conditions, shunts proximal to the obstructed IVC (portacaval or mesocaval shunt) may fail, and a mesoatrial shunt should be considered. Side-to-side portacaval shunts, with direct anastomosis of the side of the portal vein to the side of the vena cava, have the highest patency rate but may make future liver transplantation more difficult: a portacaval shunt will require extensive dissection around the porta hepatis, and reversal of the shunt is a major undertaking. Mesocaval shunts are technically less demanding and may facilitate surgery at the time of liver transplantation, but when performed with a synthetic graft, they have a higher thrombosis rate than a side-to-side portacaval shunt.

FIGURE 120-1. Management of Budd-Chiari syndrome.

Liver transplantation is the treatment of choice for acute Budd-Chiari syndrome with fulminant hepatic failure and for end-stage liver disease after a chronic course. In more recent series of patients who underwent liver transplantation for Budd-Chiari syndrome, survival rates have been much improved over earlier series. Three-year survivals of 78% to 88% and 5-year survival rates of 75% have been reported. [23], [24] The improved survival is likely due to earlier treatment after onset of symptoms and the recognition of the need for lifelong anticoagulation in most patients. Liver transplantation may cure one of the underlying predispositions, such as factor V Leiden, protein C deficiency, or antithrombin III deficiency, but a thorough diagnostic workup may reveal the presence of two or more remaining prothrombotic risk factors that still require anticoagulation.

In addition to management of the liver disease, the predisposing factor needs to be addressed. In some cases, risk factors may be avoided, such as oral contraceptives or pregnancy. Phlebotomy alone increases the risk for thrombosis in patients with polycythemia vera, whereas one nonrandomized trial has suggested a reduced risk for thrombosis in patients receiving phlebotomy plus hydroxyurea. [25], [26] Hydroxyurea reduces the risk for thrombosis in patients with essential thrombocythemia. [27]

OBSTRUCTION OF THE INFERIOR VENA CAVA

In non-Western countries, IVC obstruction is more common than hepatic vein obstruction. Membranous obstruction of the hepatic portion of the IVC is one of the entities frequently seen in countries such as South Africa, India, Japan, Nepal, and China, whereas in the West, it is uncommon. The original theory was that the membrane was congenital, but current thinking is that it is a consequence of thrombus organization. [28], [29] One of the initiating factors for the initiating thrombophlebitis or thrombosis may be an infectious process. Behçet disease is more likely to cause obstruction in the hepatic portion of the IVC than in the hepatic veins. [16], [17] Patients with prothrombotic disorders also have a predisposition to obstruction of the IVC across the hepatic portion, but it is unknown why that particular section of the IVC is more vulnerable to thrombosis.

A characteristic difference between hepatic vein obstruction and IVC obstruction is the development of collateral venous circulation across the abdomen, chest, and back in the latter disease. IVC obstruction predisposes to hepatocellular carcinoma, even in the absence of cirrhosis. The reported incidence of hepatocellular carcinoma in these patients varies widely in the literature. [8] In contrast, hepatocellular carcinoma does not seem to be a consequence of hepatic vein thrombosis, but tumor involvement of the hepatic veins may lead to Budd-Chiari syndrome.

Management of IVC obstruction differs somewhat from that for Budd-Chiari syndrome. If there is a thin occluding membrane, this may be perforated by angioplasty or surgically. Portacaval shunt is not indicated, but decompression may be achieved by TIPS or by cavoatrial or mesoatrial shunt.

PORTAL VEIN THROMBOSIS

Clinical Presentation

Most patients have splenomegaly and some have a tender enlarged liver. Unless the patient has underlying cirrhosis, ascites resolves over time and is therefore an uncommon finding.

Most commonly, the course of portal vein thrombosis is chronic. Initially, patients develop extensive collaterals throughout the upper gastrointestinal tract, portal hypertensive gastropathy, splenomegaly, and ascites. Blood flow to the liver from the hepatic artery and from perihepatic varices is usually adequate to maintain normal liver function. Recanalization of the portal vein clot leads to formation of small tortuous veins, so-called cavernomatous transformation. The most common presentation in patients with chronic portal vein thrombosis is gastrointestinal hemorrhage due to varices, although the presenting complaint in cirrhotic patients may be worsening ascites. [30] An alternate presentation to the more chronic course described earlier is an acute course with abdominal pain. This may signify propagation of the clot into the mesenteric circulation with bowel ischemia or infarction.

Risk Factors

Hepatoma, pancreatic cancer, and cirrhosis are common risk factors for portal vein thrombosis. When patients with cancer or cirrhosis are excluded, one or several factors associated with increased risk for thrombosis may be identified in 70% to 80% of patients. [9], [10] Primary myeloproliferative diseases, notably polycythemia vera and essential thrombocythemia, are a common risk factor. As noted earlier for hepatic vein thrombosis, many of the patients have latent myeloproliferative disease that is not detected in peripheral blood smears. Two inherited disorders that have been identified relatively recently, the prothrombin gene mutation (factor II G20210) and factor V Leiden, appear to be risk factors for portal vein thrombosis, although there is some discrepancy in the literature on this. [9], [10] Inherited protein C, protein S, and antithrombin III deficiency need to be distinguished from acquired deficiency due to impaired hepatic synthesis in liver disease, but it is again unclear from the literature whether the inherited forms occur more commonly in this population than in controls. [9], [10] Local precipitating factors play a common role in portal vein thrombosis. [10] Intra-abdominal infection with pylephlebitis, malignancy, abdominal trauma, or surgery, either alone or in concert with other risk factors, may precipitate portal vein thrombosis. Oral contraceptive use, Behçet disease, [31] and antiphospholipid antibodies are other risk factors for portal vein thrombosis. Portal vein thrombosis is a rare complication of liver transplantation. Septic portal vein thrombosis can occur in appendicitis, diverticulitis, or *Bacteroides* bacteremia.

Analogous to hepatic vein thrombosis, most patients have two or more risk factors for portal vein thrombosis. Portal vein thrombosis in patients with malignancy may be due to local tumor invasion or to a hypercoagulable state. Pancreatitis may cause portal vein thrombosis either through extrinsic compression of the portal vein by a pseudocyst or through pylephlebitis secondary to acute pancreatitis. Cirrhosis may predispose to portal vein thrombosis because of sluggish blood flow through the liver in intrahepatic portal hypertension.

Diagnosis

Doppler ultrasound can detect size and patency of the portal vein and cavernous transformation of the portal vein. The latter diagnosis is made when a cluster of small irregular collateral vessels are present instead of a normal portal vein. Contrast-enhanced CT can determine patency of the portal vein. If orthotopic liver transplantation is planned for patients with portal vein thrombosis, it is crucial to determine the extent of thrombosis. This can be determined more accurately with double-helical CT than with standard CT.

After the diagnosis is established, it is crucial to determine the underlying risk factors for thrombosis, which often requires a hematology consult. Among the risk factors listed earlier, the ones most easily missed are the primary myeloproliferative disorders, polycythemia vera and essential thrombocythemia. These disorders are frequently occult (i.e., not manifested in peripheral blood) at the time the patient presents with portal vein thrombosis. Diagnosis of occult myeloproliferative disorders therefore requires a bone marrow biopsy.

Management

The most common presenting symptom of portal vein thrombosis is variceal hemorrhage. Acute variceal bleeding may be managed endoscopically. Prevention of recurrent variceal bleeding can be addressed with endoscopic band ligation and beta-blockers. The two options for intractable variceal hemorrhage are shunt surgery and TIPS. Shunt surgery in this population carries an increased risk for thrombosis of the shunt and should be performed with larger veins. [32] TIPS is technically difficult in this setting and should be considered for intractable bleeding. [22] Portal vein thrombosis is an infrequent complication after liver transplantation. Two case

reports have described the use of a combination of local thrombolytic therapy, angioplasty, and stenting in this setting. [33], [34]

Liver transplantation in patients with portal vein thrombosis requires a special approach to the vascular reconstruction. Options include combined liver and small bowel transplantation, interposition of a venous graft between the donor portal vein and the recipient portal vein proximal to the thrombus, cavoportal hemitransposition (portal perfusion with inflow from the IVC), or arterialization of the portal vein. [35], [36] and [37]

Given the risk for variceal hemorrhage on one hand and extension of thrombosis on the other, the question arises as to the risk-benefit ratio of anticoagulation. In a recent retrospective study in a cohort of patients without underlying malignancy or cirrhosis, the benefit of anticoagulation was found to outweigh the risk. [38]

SINUSOIDAL OBSTRUCTION SYNDROME (HEPATIC VENOOCCLUSIVE DISEASE)

In 1920 and again in 1945, papers were published describing a novel liver disease. [39], [40] The most striking histological feature was occlusion of the central veins, and it was subsequently named *hepatic venoocclusive disease*. [41] Clinical studies have demonstrated that involvement of the central veins is not essential to the disease, [42], [43] and experimental studies, discussed later in this chapter, have shown that the disease process originates in the sinusoids. [44], [45] Based on these findings, investigators in this field have proposed renaming this *sinusoidal obstruction syndrome* (SOS). [46]

Pathogenesis

In contrast to most liver diseases, SOS presents with features of portal hypertension, and evidence of parenchymal dysfunction follows later. This is indicative of the primary circulatory nature of the disease. Experimental studies indicate that the drugs that cause SOS target the sinusoidal endothelial cell. [44], [47], [48] and [49] Sinusoidal endothelial cells round up, and gaps form within and between these cells. [44] This permits blood to enter into the space of Disse and dissect off the sinusoidal lining, which then embolizes downstream and blocks sinusoidal flow. [45]

Clinical Presentation

The originally described cases of SOS were due to ingestion of herbal teas (“bush tea disease”) or foodstuffs contaminated with pyrrolizidine alkaloids, particularly in protein-malnourished individuals. In many parts of the world, ingestion of pyrrolizidine alkaloids is still the major cause of SOS. In North America and Western Europe, the most frequent cause of SOS is treatment with a conditioning regimen for hematopoietic stem cell transplantation (bone marrow transplantation), either high-dose combination chemotherapy or chemotherapy plus irradiation. [43], [50], [51] and [52] SOS may occur after long-term immunosuppression with azathioprine therapy, such as in kidney or liver transplantation patients. [53], [54], [55], [56] and [57] SOS is also seen after treatment with chemotherapeutic agents unrelated to stem cell transplantation and has been associated with drugs such as actinomycin D, dacarbazine, cytosine arabinoside, 6-thioguanine, and urethane. [58] More recently, SOS has been reported in patients treated with a novel drug for acute myeloid leukemia called gemtuzamab ozogamicin (Mylotarg). [59], [60], [61] and [62].

The classic features of SOS are hyperbilirubinemia, right upper quadrant pain of liver origin or hepatomegaly, and weight gain. The course of disease is protracted in SOS owing to chronic exposure to pyrrolizidine alkaloids, whereas SOS in the setting of stem cell transplantation evolves more rapidly. In patients treated with cyclophosphamide-containing conditioning regimens, onset is within 10 to 20 days of initiation of treatment. [51] In other conditioning regimens, onset of SOS may occur later than for cyclophosphamide-containing regimens. [63]

Diagnosis

In the setting of stem cell transplantation, a tentative diagnosis can be made based on the presenting features, but other conditions need to be ruled out. Clinical criteria for SOS after stem cell transplantation have been published by two groups of investigators (Table 120-2). The differential diagnosis in this population includes acute or hyperacute graft-versus-host disease, sepsis, medication-induced cholestasis, congestive heart failure, and tumor infiltration. Imaging studies can confirm hepatomegaly and ascites and can exclude biliary obstruction and tumor invasion into the hepatic parenchyma or vasculature, but there are no definitive diagnostic features by imaging. The main differential diagnosis that might warrant a liver biopsy is acute or hyperacute graft-versus-host disease.

SEATTLE CRITERIA[65]	BALTIMORE CRITERIA[52]
Diagnosis requires two of three criteria within 20 days of transplantation: Bilirubin >2 mg/dL Hepatomegaly or pain of liver origin >2% weight gain due to fluid retention	Hyperbilirubinemia (>2 mg/dL) plus at least two of the following three findings: (Tender) hepatomegaly >5% weight gain Ascites

TABLE 120-2 Criteria for Diagnosis of Sinusoidal Obstruction Syndrome

Prevention and Treatment

Prevention is largely limited to identification of those at high risk for SOS, who may then be limited to less hepatotoxic alternatives. The major risk factors are hepatitis C, hepatic fibrosis or cirrhosis, previous exposure to a myeloablative regimen, and previous history of SOS. Strategies to reduce the risk for SOS might be use of a nonhepatotoxic, nonmyeloablative regimen, [64] lower dose of total-body irradiation, [65] reversing the order of drugs in the busulfan-cyclophosphamide regimen (i.e., cyclophosphamide first), [66] or avoiding cyclophosphamide-containing regimens altogether.

Adjustment of busulfan dosing based on plasma concentrations has been shown in some studies to be beneficial, but this could not be confirmed in a number of studies (see review [67]). The value of therapeutic monitoring of busulfan may depend on other factors, such as the age of the patient, the underlying disease, and the other drugs in the conditioning regimen. [67]

Prophylactic treatment has been tried with heparin, low-molecular-weight heparin, prostaglandin E, pentoxifylline, and ursodeoxycholic acid, but none of these compounds has been shown to reduce the incidence of fatal SOS (see review [46]).

Most patients with SOS recover spontaneously. For those who require therapy, the approach is largely supportive. Ascites is treated with sodium restriction, diuretics, and therapeutic paracentesis when indicated for discomfort or respiratory impairment. In patients with severe SOS with multiorgan failure, hemodialysis and mechanical ventilation may be used but are unlikely to affect the outcome. [51], [68], [69] and [70]

For patients with a poor prognosis (see section “ Prognosis”), tissue plasminogen activator (t-PA) plus heparin should be considered. Just less than 30% of patients with severe SOS treated with t-PA plus heparin may show improvement. [71], [72] and [73] t-PA plus heparin should not be used in patients with increased risk for intracerebral or pulmonary hemorrhage, and patients who already have renal or pulmonary failure may not benefit. [72]

Defibrotide is an experimental compound that has been tried for a variety of vascular diseases. It is a single-stranded polydeoxyribonucleotide with antithrombotic, antiischemic, and thrombolytic effects and reduces leukocyte accumulation. Uncontrolled clinical trials in moderate to severe SOS have been promising.

TIPS decompresses portal pressure and relieves ascites but does not improve outcome of SOS. [35], [74], [75] Liver transplantation may be considered in patients who develop SOS after stem cell transplantation for a benign disease or in those whose underlying malignancy is expected to have a good outcome (e.g., chronic myelogenous leukemia in chronic phase). However, liver transplantation is not indicated when the risk for recurrent malignancy is high.

Prognosis

Definitions of SOS and of fatal SOS vary among transplantation centers. These differences may account for the wide range in published case-fatality rates, which range from 0% to 67%. [51], [52], [76], [77] and [78] Two large studies with cyclophosphamide-containing regimens reported a 70% recovery rate from SOS, [51], [76] and a study with SOS due to other alkylating agents reported an 84% recovery rate. [63] For patients who develop SOS due to cyclophosphamide-containing regimens, outcome can be predicted based on bilirubin level and weight gain using published graphs. [79]

NODULAR REGENERATIVE HYPERPLASIA

Nodular regenerative hyperplasia (NRH) is an uncommon disorder in which there are nodules of hyperplastic hepatocytes surrounded by areas of hepatocyte atrophy. In contrast to cirrhosis, there are no fibrous septa surrounding the nodules. Most commonly, the nodules are scattered diffusely throughout the liver. Two large autopsy studies have reported prevalence rates of 2.1% and 2.6%. [80], [81]

Etiology

The etiology is not known, but the widely accepted hypothesis is that NRH is initiated by impaired perfusion of areas of the liver. [82] Hepatocytes in areas of hypoperfusion become atrophic or apoptotic, [83] and parenchyma in areas where perfusion is maintained develops reactive hyperplasia.

Underlying predispositions to NRH include collagen vascular diseases, several hematologic malignancies, some immunologic disorders, and a variety of drugs and toxins (Table 120-3). Although the diseases and predisposing factors for NRH vary greatly, a shared element is the ability to impair the circulation at the level of the portal vein or sinusoids. Inflammation of the hepatic artery in collagen vascular diseases or immune complex diseases may lead to inflammatory destruction of adjacent portal veins. [84], [85] Prothrombotic disorders, such as agnogenic myeloid metaplasia, polycythemia vera, or antiphospholipid syndrome, may cause thrombosis in portal veins. [86] Damage to sinusoidal endothelial cells by long-term azathioprine therapy, [48], [53] such as in renal or liver transplant recipients, or after conditioning therapy for stem cell transplantation [42], [87] may lead to NRH.

Collagen vascular diseases
Rheumatoid arthritis
Scleroderma
Systemic lupus erythematosus
Polyarteritis nodosa
Glomerulonephritis
Hematologic diseases
Polycythemia vera
Essential thrombocythemia
Agnogenic myeloid metaplasia
Chronic myeloid leukemia
Hodgkin disease
Non-Hodgkin lymphoma
Multiple myeloma
Immunologic disorders
Cryoglobulinemia
Antiphospholipid syndrome
Myasthenia gravis
Drugs and toxins
Anabolic steroids
Azathioprine
Oral contraceptives
Conditioning regimen for stem cell transplantation
Thorotrast
Toxic oil syndrome
6-Thioguanine

TABLE 120-3 Conditions Associated with Nodular Regenerative Hyperplasia

Clinical Aspects

NRH is most commonly asymptomatic, and the lesion is most likely to be detected incidentally at autopsy. When symptomatic, the disease presents with evidence of portal hypertension with variceal hemorrhage, ascites, splenomegaly, or hypersplenism. Although rare, NRH may present as end-stage liver disease. [88]

Imaging studies may detect the manifestations of portal hypertension, but not the 2- to 5-mm nodules themselves. The diagnosis can be established by liver biopsy. The pathologic appearance is of scattered nodules of hyperplastic hepatocytes surrounded by atrophic parenchyma and the absence of fibrotic septa around the nodules.

In most patients, no treatment is needed for the liver disorder itself, although the underlying predisposing condition or precipitating factor may require therapy. Manifestations of portal hypertension are treated along conventional lines.

PELIOSIS HEPATIS

Peliosis hepatis is a rare abnormality characterized by blood-filled cystic lesions in the hepatic parenchyma distributed irregularly throughout the liver. The peliotic cavities range in size from less than 1 mm to several centimeters. Although most common in the liver, peliotic lesions may also be present elsewhere in the reticuloendothelial system, notably the spleen, abdominal lymph nodes, and bone marrow.

Etiology

Historically, peliosis was found at autopsy in patients with chronic wasting illnesses, in particular, tuberculosis and cancer (Table 120-4). Peliosis was also observed in patients on androgenic anabolic steroids or after long-term treatment with azathioprine. In patients with acquired immunodeficiency syndrome (AIDS), infection with *Bartonella henselae* or *Bartonella quintana* may cause peliosis as well as bacillary angiomatosis.

Acquired immunodeficiency syndrome and *Bartonella* species infection
Tuberculosis
Myeloproliferative diseases
Leukemia
Lymphoma
Multiple myeloma
Macroglobulinemia
Anabolic steroids
Oral contraceptives
Azathioprine
Arsenic
Thorotrast
Vinyl chloride
6-Thioguanine

TABLE 120-4 Conditions Associated with Peliosis Hepatis

The initial change in peliosis hepatitis appears to be sinusoidal dilation, followed by formation of cavities without sinusoidal endothelial cells. [89], [90] Eventually, endothelial lining may be restored in parts of the peliotic cavities. Although it had been suggested that the initial target in peliosis was the sinusoidal endothelial cells, this concept has been most clearly supported by studies of peliosis due to *Bartonella* species. *Bartonella* bacilli can be detected by electron microscopy in sinusoidal endothelial cells of AIDS patients, [91] and there is disruption of the sinusoidal endothelial cell lining. [89] Interestingly, *Bartonella* causes bacillary angiomatosis in the skin, an organ with a continuous endothelial lining, but causes peliosis in the reticuloendothelial system, which has a discontinuous endothelium. [90]

Peliosis due to drugs and toxins has also been attributed to damage to sinusoidal endothelial cells. A few xenobiotics have been linked to SOS, NRH, peliosis hepatis, or sinusoidal dilation, and in some cases, up to all four have been described within the same liver. Azathioprine (all four lesions), urethane (peliosis, SOS), 6-thioguanine (peliosis, NRH, SOS), Thorotrast (peliosis, NRH), oral contraceptives (sinusoidal dilation, peliosis hepatis, NRH) and anabolic steroids (peliosis, NRH)

cause an overlap of these injuries. [53], [80], [92], [93] Damage to sinusoidal endothelial cells and sometimes to hepatic venular endothelial cells seems to be the common link in these four types of liver injury. [53], [94]

CHAPTER 121

Sareh Parangi and Richard Hodin

ABDOMINAL CAVITY: ANATOMY, STRUCTURAL ANOMALIES, AND HERNIAS

EMBRYOLOGY OF THE ABDOMINAL CAVITY

Abdominal Cavity

Understanding of the embryology of the abdominal contents is imperative to understanding the pathophysiology of the various congenital and structural anomalies of the abdominal cavity. The abdominal or peritoneal cavity is formed from a large intraembryonic coelomic cavity during the fourth week of embryonic development. The cells of the somatic mesoderm lining the intraembryonic coelomic cavity become mesothelial and form the parietal layer of the serous membranes lining the outside of the peritoneal, pleural, and pericardial cavities. In a similar manner, the cells of the splanchnic mesoderm layer form the visceral layer of the serous membranes covering the abdominal organs, lungs, and heart. [1] During the fifth to seventh weeks of development, the pleuroperitoneal folds fuse with the septum transversum, and the mesentery of the esophagus thus separates the thoracic cavity from the abdominal cavity. In the cephalic and caudal parts of the embryo, the primitive gut (an endodermal lined cavity) forms a blind-ending tube, the foregut and the hindgut, respectively. The middle part, the midgut, remains temporarily connected to the yolk sac by means of the vitelline duct or yolk stalk. The upper gastrointestinal tract develops from the foregut and includes the esophagus, the stomach, the duodenum, the liver, the gallbladder and the pancreas. The midgut develops into the small bowel, the right and transverse colons. The hindgut development forms the left colon, sigmoid, rectum, and the upper part of the anal canal.

Development of the Foregut, Midgut, and Hindgut

During embryonic development, the foregut rotates 90 degrees clockwise around its longitudinal axis, causing the left side of the stomach to face anteriorly and its right side, posteriorly (Fig. 121-1). The foregut blood supply is the celiac artery.

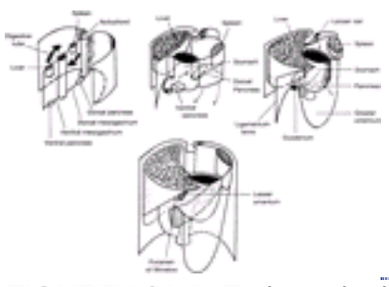

FIGURE 121-1. Embryonic development of the foregut. The organs of the upper gastrointestinal tract rotate 90 degrees clockwise (when reviewed from above) in a transverse plane. Originally, ventral structures like the liver and ventral pancreas are situated to the right, and posterior organs such as the spleen and dorsal pancreas and the dorsal aspect of the future stomach are positioned to the left side of the abdominal cavity. The dorsal mesogastrium elongates and folds to the left to form the greater omentum.

The development of the midgut is characterized by rapid elongation of the gut and its mesentery, resulting in the formation of the primary intestinal loop. Over its entire length, the midgut is supplied by the superior mesenteric artery. As a result of this rapid elongation and the simultaneous expansion of the liver, the abdominal cavity of the fetus becomes too small to contain all the intestinal loops. These loops enter the extraembryonic coelomic cavity in the umbilical cord, forming a physiologic umbilical herniation during the sixth week of development (Fig. 121-2). Coincident with this rapid growth, the midgut rotates 270 degrees counterclockwise around the axis of the superior mesenteric artery. At about the third month, the herniated intestinal loops return to the abdominal cavity. The proximal portion of the jejunum is the first part to reenter, and it comes to lie on the left side, whereas the primitive cecum is the last to enter back and descends into the right iliac fossa.

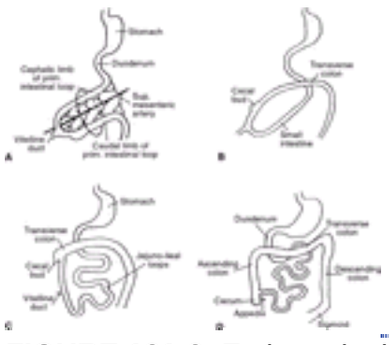

FIGURE 121-2. Embryonic development of the midgut. **A:** Schematic drawing of the primary intestinal loop before rotation (lateral view). The superior mesenteric artery forms the axis of the loop, and the *arrow* indicates the counterclockwise rotation around this axis. **B:** Similar views as in **A,** showing the primary intestinal loop after 180-degree counterclockwise rotation. The transverse colon is shown as passing in front of the duodenum. **C:** Anterior view of the intestinal loop after the 270-degree counterclockwise rotation. Note the cecal bud in the right upper quadrant **D:** Similar views as in **A** with the intestinal loops in the final position. Cecum and appendix are now in the right lower quadrant. (Adapted from ref. [1].)

The hindgut gives rise to colon and rectum past the distal third of the transverse colon as well as the upper part of the anal canal. The junction of the endodermal and ectodermal parts of the anal canal is formed by the pectinate line, which is found just below the anal columns. The endoderm of the hindgut also gives rise to the

internal lining of the bladder and urethra. The hindgut blood supply is the inferior mesenteric artery.

Mesenteries of the Abdominal Cavity

During the development of the peritoneal cavity, the splanchnic mesoderm covers the developing gut. Eventually, most of this ventral mesentery is resorbed, except for a small portion between the liver and the stomach that persists as the gastrohepatic ligament (or lesser omentum) (see Fig. 121-1), and the ligaments of the liver, that is, the coronary, falciform, and teres. The dorsal mesogastrium remains and changes in position and size; the spleen is positioned to the left, the pancreas is situated posteriorly, and the space within the mesogastrial fold becomes the lesser sac. The dorsal mesogastrium enlarges, forming the greater omentum, which drapes anteriorly. As the midgut elongates during development, the dorsal mesodermic attachment elongates as well and forms the mesentery. The right colon adheres to the posterolateral abdominal wall and becomes retroperitoneal; the rest of the midgut is intraperitoneal.

ANATOMY OF THE ABDOMINAL CAVITY

The abdominal cavity in the adult is defined by the diaphragm superiorly, the abdominal walls laterally, and the pelvis inferiorly. The peritoneal covering is the endodermal investment of the surface of the organs of the abdominal cavity. The pancreas, parts of the duodenum, right and left colon, and the rectum, being retroperitoneal, are only covered anteriorly by peritoneum. The organs are supported by thickened bands of peritoneum: the gastrohepatic, gastrosplenic, splenorenal, and splenocolic ligaments. The liver is suspended to the diaphragm also by the falciform and coronary ligaments as well as to the abdominal wall by the ligamentum teres that contains the remnant of the umbilical vein.

The abdominal cavity has three compartments: lesser sac, supramesocolic, and inframesocolic. The lesser sac is limited by the stomach and gastrocolic ligaments anteriorly; by the spleen, splenorenal, and gastrosplenic ligaments on the left side; and by the pancreas and duodenum posteriorly (see Fig. 121-1). The lesser sac communicates with the rest of the abdominal cavity through the foramen of Winslow. The boundaries of the foramen are the liver superiorly, hepatic pedicle anteriorly, duodenum and pancreas inferiorly, and the retroperitoneum posteriorly.

The supramesocolic compartment lays cephalad to the transverse mesocolon and contains the duodenum, pancreas, liver, spleen, and lesser sac. The inframesocolic compartment contains the small intestine, the colon, and the suspensory ligaments of the spleen and liver. The area between the colon and the inferior margin of the liver is called the *Morison pouch* and acts as a potential space for fluid accumulation. In addition, fluid can accumulate along the pouches created by the right and left parietocolic peritoneal coverings.

The inferior limit of the peritoneum covers the pelvic urogenital organs and the inguinal region. Most inferiorly is the pouch of Douglas, a peritoneally covered pouch between the rectum and uterus in females and the rectum and bladder in males.

The anatomy of the inguinal region (the groin) is complex and is discussed in the section “Groin Hernias.”

CONGENITAL ANOMALIES

In the embryo, the abdominal cavity is too small to accommodate the intestines, and a physiologic herniation occurs into the umbilical cord with return of the intestines to the abdominal cavity by the 10th week. An *omphalocele* (Fig. 121-3A) is failure in the growth of the coelomic walls with a large herniation of the abdominal viscera into the base of the umbilical cord. The herniated viscera are covered by a sac composed of amnion. The incidence of omphalocele is estimated to be 1 in 6000 to 10,000 live births. *Gastroschisis* (see Fig. 121-3B) is a similar anomaly, but the defect in the abdominal wall is located lateral to the umbilicus and is caused by failure of closure of the abdominal wall. No sac is present to cover the herniated intestines, and the size of the defect is often smaller. In gastroschisis, the intestines can be inflamed and thickened, and the mesentery may be foreshortened. The incidence of gastroschisis is 1 in 3200 to 10,000 births, with some male predominance; associated congenital anomalies include incomplete rotation and fixation of the midgut in 40% of cases. At least 50% of infants with omphalocele have associated anomalies of the skeleton, gastrointestinal tract, or nervous or genitourinary system. [3] Ultrasound can detect these defects prenatally, and vaginal delivery is safe for all newborns but those with the biggest omphalocele, which may contain liver. [4] Both conditions are surgical emergencies of the newborn. The airway should be managed first, and a nasogastric sump tube should be placed to prevent intestinal distention. If present, the sac is painted with antiseptic solutions, and the herniated contents are kept moist and covered with a warm moistened saline soaked gauze and plastic to prevent dehydration and desiccation. Alternatively, the entire lower torso can be covered by a plastic intestinal bag. Once stable, an operation is needed to reduce the herniated viscera and perform a fascial closure. If necessary, the viscera are wrapped in a sheet of silicone (Silastic chimney) that is sutured to the abdominal wall, allowing time for growth of the abdominal wall and eventual reduction of the herniation.

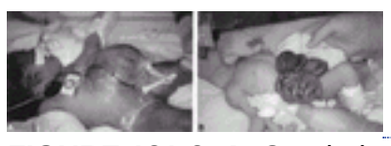

FIGURE 121-3. A: Omphalocele with large herniation of the abdominal viscera. Note the amnionic sac covering the viscera. **B:** Gastroschisis with defect lateral to the umbilicus. Note that the herniated intestines are engorged and discolored and that no sac is present.

Remnants of the omphalomesenteric (vitelline) duct may present as abnormalities related to the abdominal wall or remain asymptomatic for long periods. An *umbilical sinus* results from the continued presence of the umbilical end of the duct and can result in persistent drainage and infection at the umbilicus. Persistence of the entire duct is heralded by passage of enteric contents from the umbilicus, and excisional treatment avoids complications of intussusception or volvulus. Cystic remnants should be excised if seen at operation or if presenting as an infection at the umbilicus. *Meckel diverticulum* results when the intestinal end of the vitelline duct persists. This is a true diverticulum, composed of all layers of the intestinal wall.

CONGENITAL DIAPHRAGMATIC HERNIAS

The diaphragm appears in the third week of development as a septum transversum that separates the thorax from the abdomen. The diaphragm is derived from the following structures: the septum transversum, which forms the tendinous part of the diaphragm; the pleuroperitoneal membranes; the muscular components from the lateral and dorsal body walls; and the mesentery of the esophagus, which forms the crura of the diaphragm (Fig. 121-4A). A diaphragmatic hernia is one of the more common malformations of the newborn (1 in 2200) and is most frequently caused by failure of the pleuroperitoneal membranes to separate completely the peritoneal and pleural cavities posteriorly. [5]

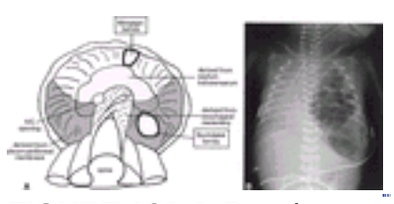

FIGURE 121-4. Development of the diaphragm and congenital diaphragmatic hernia. **A:** Abdominal surface of the diaphragm and the derivation of the components during development. The pleuroperitoneal membranes, the septum transversum, and the esophageal mesentery form the diaphragm. A Bochdalek hernia forms when there is a posterolateral defect. Morgagni hernias are less common and are present anteriorly. **B:** Chest radiograph of a child with a congenital posterolateral (Bochdalek) diaphragmatic hernia on the left. The mediastinum is displaced to the right by the intestinal loops present in the left chest.

Posterolateral hernia defects (hernia of Bochdalek) are usually large and on the left side; the intestinal loops, stomach, spleen, and part of the liver may enter the thoracic cavity (see Fig. 121-4). The presence of abdominal viscera in the chest results in compression of the heart and hypoplasia of the lung. Animal models have shown that long-term compression of the lung leads to abnormal development of the lung and the pulmonary vascular bed. [6] The neonate presents with acute respiratory distress; the heart, mediastinum, and lungs are displaced to the right, and the abdomen may be scaphoid. Respiratory sounds are absent on the affected side, and heart sounds may be audible in the right chest. The diagnosis is easily made with a chest radiograph showing one or more air-fluid levels in the left thorax, displacement of the mediastinum, and loss of the sharp diaphragmatic line separating the thorax and abdomen (see Fig. 121-4B). Radiologic studies with water-soluble contrast show the intra-abdominal contents in the left chest. Lung hypoplasia results in acute respiratory distress and is the main cause of death in these patients. Bowel obstruction, strangulation, and other gastrointestinal malformations can result in other complications. Mortality depends on the age of the patient, associated malformations, and most importantly the degree of lung hypoplasia. Mortality rates are as high as 50% in those infants requiring emergency operations during the first week of life but decrease to 10% in infants with a higher degree of lung maturity. Extracorporal membrane oxygenation is used in some instances to support the maturing lungs before and after repair of the hernia. [7]

Occasionally, a small part of the muscular fibers of the dia- phragm fails to develop, and a hernia may remain undiscovered until later in life. Such a defect is seen in the anterior portion of the diaphragm and is known as a *parasternal hernia* (hernia of Morgagni; see Fig. 121-4A). These hernias are usually small and can contain stomach, omentum, colon, or small intestine with a peritoneal covering.

UMBILICAL HERNIAS of CHILDHOOD

Herniation of intra-abdominal viscera through the umbilicus is an *umbilical hernia*. A congenital defect in the umbilical ring during development of the abdominal wall results in this hernia. Congenital umbilical hernias are more common in black and male infants, most not reaching maximal size until the infant is 1 month of age. The younger the neonate, the more common this congenital deformity, reaching 20% in premature infants. Predisposing conditions include Down syndrome, gargoylism, amaurotic familial idiocy, cretinism, Beckwith-Wiedemann syndrome, and diseases that increase intra-abdominal pressure. This type of hernia has a high propensity to reduce and heal spontaneously, so that repair is generally not indicated in children younger than 3 years of age. [8] Large or symptomatic hernias, especially with incarceration or strangulation, require immediate attention.

HERNIAS OF THE ABDOMINAL CAVITY IN ADULTS

“Hernia is a protrusion of any viscus from its proper cavity” (Sir Astley Cooper, 1804). Hernias are composed of a herniated viscus, the hernia sac, and the opening of the hernia (the hernial ring) (Fig. 121-5). The hernial sac is the internal wall of the hernia lined by peritoneum. An external hernia is comprised of a viscus abnormally located outside the abdomen; an internal hernia is when the viscus is abnormally located within the intra-abdominal space. Any viscus can become part of a hernia, but most commonly, a segment of intestine is partially or completely herniated.

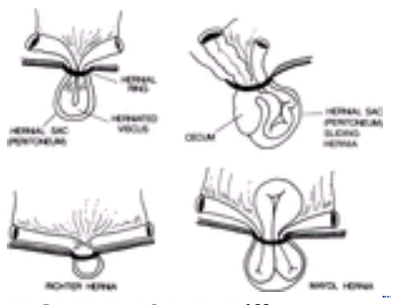

FIGURE 121-5. Different types of intestinal hernias.

A *Richter hernia* occurs when only a portion of the wall of the herniated bowel is included in the hernia (see Fig. 121-5). Such a hernia is unique in that it can strangulate without causing a complete small bowel obstruction. A herniation of two adjacent loops through the same hernial opening is called a *Maydl hernia* (see Fig. 121-5). This kind of hernia is dangerous because the closed loop may perforate, leading to peritonitis. A *sliding hernia* is when a partially retroperitoneal structure (such as colon) is part of the wall of the hernial sac (see Fig. 121-5). The symptoms of hernias depend on a number of factors, such as the exact viscus that is herniating, the location of the herniated bowel (i.e., jejunum or ileum), and whether there is a full or partial strangulation. When omentum alone is strangulated within a hernia, obstruction of the gut does not occur.

A *reducible hernia* occurs when the hernial sac contents return to the abdominal cavity spontaneously or with external manipulation. The major complications of hernias are incarceration, bowel obstruction, and bowel strangulation. A complication is more likely to occur if the hernial opening is small and in hernias in which the bowel has access to the sac. Bowel incarceration greatly increases the chance that strangulation will occur. An *incarcerated hernia* occurs when the hernial contents cannot be dislodged from the sac. Incarceration occurs when there are adhesions from the hernial contents or around the opening of the hernia, making reduction impossible, or when there is edema or contortion of the hernial contents such that hernial contents once entered into the sac cannot exit. A hernia, reducible or incarcerated, becomes a *strangulated hernia* when the blood supply to the herniated viscus is compromised.

Epidemiology

Hernias are common occurrences. Five percent of people have a spontaneous abdominal hernia during their lifetime. Many people also develop secondary hernias, most frequently at the site of a previous incision or injury to the abdominal wall. Hernia is the most common cause of intestinal obstruction worldwide, and in the United States, it is the third most common cause. In surgical practice, 10% to 15% of all procedures are related to hernias. Of all hernias, 90% are incisional, umbilical, or inguinal hernias. Groin hernias account for 85% of all hernias (Table 121-1). Indirect inguinal hernias are the most common, followed by direct inguinal hernias. Incisional hernias develop in 3% to 5% of all abdominal operations and represent 7% of abdominal wall hernias. Internal hernias are uncommon and have been seen in 0.5% of autopsies.

TYPE	OCCURRENCE
Inguinal	80%
Indirect	60%
Direct	30%
Both	10%
Femoral	5%
Inguinal and femoral	2%
With a sliding component	12%
Sigmoid	8%
Cecum	4%
Maydl hernia	2%

*Groin hernias account for 85% of all hernias.

Adapted from Fonkalsrud EW, Ament ME. Hernias of the abdominal wall. In: Fonkalsrud EW, Ament ME, eds. Hernias of the Abdominal Wall. Philadelphia: WB Saunders, 1980, and Nyhus LM, Condon RE, eds. Hernia. Philadelphia: JB Lippincott, 1978.

TABLE 121-1 Epidemiology of Groin Hernias*

There is a male-to-female prevalence in inguinal hernias of about 7:1, whereas there is female dominance in femoral, umbilical, and incisional hernias of about 2:1. Although femoral hernias are seen more commonly in females, the most common hernia in women still remains an indirect inguinal hernia.

Pathophysiology /H4>

Our understanding of the pathophysiology of inguinal hernias has changed over the years. In the past, indirect hernias were attributed at least in part to a patent processus vaginalis, which is present in many infants and up to 25% of young children. However, more recent studies have shown the inguinal ring and any patent processus vaginalis to close with a valvelike effect because of tension on the abdominal wall musculature when there is increased intra-abdominal pressure. [9] In cases of indirect inguinal hernia, this valvelike effect may becomes ineffective, allowing a viscus to enter the patent processus vaginalis. [10] Chronic injury in the form of traumatic overstretching of muscles and aponeurotic structures undoubtedly contributes to hernia formation, although rigorous scientific studies have not been performed. Clinicians often see the onset of herniation related to such activities as extreme athletics, conditions associated with increased intra-abdominal pressure such as pregnancy, chronic cough, chronic obstructive pulmonary disease, obstructive uropathy, massive ascites, or obstipation from colorectal cancer.

In cases of incisional hernias, infection or tension during the wound healing or scar remodeling phase can lead to weakened musculoaponeurotic tissue, which in turn leads to herniation at a later date. Some studies have shown altered collagen formation and breakdown in tissue samples from the inguinal floor of patients with hernias. [11]

Diagnostic Considerations

Most hernias are detected using a history and physical examination. The patient needs to be questioned regarding the presence of a bulge, conditions that make the bulge appear and disappear, and any associated pain or gastrointestinal symptoms. History of any previous hernias, abdominal wall incisions, or a family history of any connective tissue disorder such as Marfan syndrome should be sought. A review of systems to include any of the above-mentioned causes of intra-abdominal pressure should be obtained because failure to recognize these factors will increase the chance for recurrence if repair is undertaken. A complete physical examination of the abdomen and rectum should be done, including a prostate exam and testing of the stool for occult blood. All scars should be noted. The exam is best initiated with the patient in the standing position because gravity tends to pull the intra-abdominal contents into hernias. If no bulge is obvious, a Valsalva maneuver is used to increase intra-abdominal pressure. If a bulge is seen, a gentle attempt to reduce the hernia can be made with the patient standing or in the recumbent position. Examination of the area in the recumbent position often allows better palpation of the hernial defect and opening.

Radiographic studies are rarely needed but may be useful in cases in which the abdominal wall fat layer prevents accurate diagnosis. Ultrasound is rarely helpful, but in some cases, it can delineate the abdominal wall musculature and note the presence of air or peristalsing bowel. Computed tomography (CT) is good at detecting abdominal and pelvic defects; use of Valsalva may sometimes be helpful during imaging. [9], [12]

Specific Types of Hernias

Epigastric Hernias Epigastric hernias occur in the midline of the abdominal wall between the umbilicus and the xiphoid in 5% of the population (males more than females). Most epigastric hernias are asymptomatic. An area of congenital weakness in the linea alba allows protrusion of bowel, omentum, or just preperitoneal fat. Symptoms range from a small painless nodule below the xiphoid to epigastric pain with exertion or rarely small bowel obstruction. Diagnosis is easy if the hernia is large but can be difficult if there is a small hernia in an obese patient. Tenderness while palpating the linea alba with elevation of the head can sometimes be produced in small hernial protrusions. These hernias should be surgically repaired. About 20% of patients have multiple hernial defects in other locations along the linea alba, [13] and this should be taken into consideration at the time of repair.

Umbilical Hernias Umbilical hernias in adults often occur in obese people, multiparous women, and patients with ascites. The diagnosis is usually self-evident with a protuberant mass at the umbilicus. Incarceration of omentum or small bowel is common, and up to 30% of cases present with strangulation of bowel. Forty percent of patients with ascites and end-stage liver disease have umbilical hernias. In this setting, ulceration and perforation of the hernia can lead to peritonitis with a high mortality rate. [14] Discoloration or ulceration of overlying skin heralds imminent rupture. Umbilical hernias in adults generally need surgical repair. Small defects can be repaired primarily if there is no tension; defects larger than 3 cm should be repaired with prosthetic mesh or by using some other method to ensure tension-free repair (e.g., release of the lateral fascial attachments). Patients with ascites should have their ascites controlled before repair; otherwise, the repair will likely fail. In some cases of refractory ascites, portacaval shunt or transjugular intrahepatic portacaval shunt allows for a successful surgical herniorrhaphy after the ascites has disappeared. Alternatively, concomitant peritoneovenous shunt and herniorrhaphy should be considered to prevent breakdown of the repair. [15] Liver transplantation is another alternative in the appropriate candidate.

Groin Hernias Hernias of the groin are the most common of all hernias. The inguinal anatomy is defined superiorly by the arch of the aponeurosis of the transversus abdominis muscle and inferolaterally by the upper ramus of the pubis and the psoas muscle. The inguinal canal is about 4 cm in length and is located just above the inguinal ligament between the internal and external rings (Fig. 121-6). The inguinal canal contains the spermatic cord in males (vas deferens, spermatic artery and vein, and cremasteric muscle) and the round ligament in females, in addition to the ilioinguinal nerve. The superior entrance to the inguinal canal is the internal ring (the deep inguinal ring) and is an outpouching of the transversalis fascia lateral to the inferior epigastric vessels. The external ring is a slitlike opening between the diagonal fibers of the aponeurosis of the external oblique muscle (see Fig. 121-6A). The anterior wall of the inguinal canal is composed mainly by the aponeurosis of the external oblique. The superior wall is formed by the arching fibers of the internal oblique and transverse abdominal muscles, otherwise called the *conjoined tendon*. The inferior wall is formed by the inguinal ligament (the folded aponeurosis of the external oblique) that forms a shallow ledge, and more medially by the lacunar ligament along the pectineal line of the pubis. The inguinal ligament is the landmark between the abdomen and thigh. It is fixed medially to the pubis and laterally to the anterosuperior spine of the ilium and fascia of the thigh. The pectineal ligament (Cooper ligament) lies between the pubic tubercle and the femoral vein. The posterior wall (floor) is formed mainly by transversalis fascia; medially, this wall is reinforced by formation of the conjoint tendon (inguinal falx), the merging of the internal oblique and transverse abdominal aponeuroses. The floor or the posterior wall has no intrinsic strength, and as the fibers of the transversalis fascia deteriorate, a direct hernia results. [2] Hesselbach triangle is bounded by the inguinal ligament inferiorly, the inferior epigastric vessels laterally, and the lateral border of the rectus medially (see Fig. 121-6A). A weakness in the floor of this triangle (the transversalis fascia) results in a direct inguinal hernia. Hernias protruding lateral to Hesselbach triangle are termed *indirect hernias* (see Fig. 121-6B). Inguinal hernias include direct and indirect hernias found above the inguinal ligament, and femoral hernias are found below the inguinal ligament in the femoral canal. The inferior epigastric artery serves as an important defining anatomic landmark. Indirect hernias originate lateral to this artery and protrude into the inguinal canal along the spermatic cord. Direct hernias are located medial to the inferior epigastric artery and come through a weakened inguinal floor composed of the transversalis aponeurosis and fascia (see Fig. 121-6). A *pantaloon hernia* is composed of both direct and indirect components. *Sliding hernias* have one wall composed of colon or bladder. A special type of indirect inguinal hernia containing a Meckel diverticulum is *Littré hernia*.

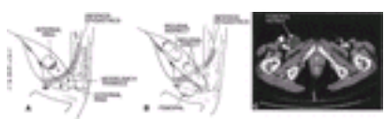

FIGURE 121-6. The right inguinal region. **A:** Schematic anatomy showing internal and external rings and Hesselbach triangle. Spaces where hernias occur include Hesselbach triangle (2), the inguinal canal (1, 2) and the femoral space (3). **B:** The most common groin hernias are direct and indirect hernias above the inguinal ligament and femoral hernias below the inguinal ligament. **C:** Computed tomography of an incarcerated femoral hernia on the right. Note a loop of small intestine is present medial to the femoral vessels; the vessels are marked by a *white arrowhead*.

The main symptom of groin hernia is a bulge in the inguinal area that appears intermittently or with increased intra-abdominal pressure. Pain is usually mild; local pain or colicky abdominal pain is suggestive of incarceration or strangulation. Palpation should be performed in the standing and recumbent position and using Valsalva maneuver to sustain increased intra-abdominal pressure. Both sides of the groin and scrotum should be examined. To perform a digital exam, the index finger is introduced into the inguinal canal through the external inguinal ring by invaginating the skin in the area (Fig. 121-7). Using the index finger, the external inguinal ring is first palpated, and with a small further push, the internal ring can be palpated. Using this simple technique, an indirect hernia can be felt exiting the internal ring at the fingertip, and a direct hernia can be felt more medial to the finger. In femoral hernias, the inguinal canal has no hernia, but a mass is felt below the inguinal ligament in the medial thigh near the saphenofemoral junction, medial to the femoral vein. Obesity makes the examination difficult, especially in detection of femoral hernias, and radiologic studies may be helpful [16] (see Fig. 121-6C).

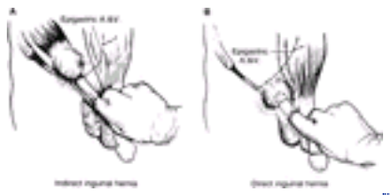

FIGURE 121-7. Digital examination of inguinal hernias. **A:** Indirect inguinal hernias are palpated in the inguinal canal at the fingertip. **B:** Direct inguinal hernias are palpated on the sides of the examiner's finger.

The differential diagnosis of an inguinal bulge includes lipoma, tumors, lymphadenopathy, abscess, cysts, endometrial deposits, testicular torsion in an undescended testicle, hydrocele, varicocele, pseudoaneurysm, and saphenous varix. Strangulated hernia can present with signs and symptoms of small bowel obstruction with the addition of a painful, tender, or tense swelling in the groin. Without an operation, it is difficult to determine whether bowel loops are strangulated; therefore, all painful, tense hernias should be considered strangulated and repaired emergently. Because both strangulated inguinal and femoral hernias require urgent operations, differentiating them is of intellectual but not practical interest. [17] Surgical treatment is generally recommended for most inguinal and femoral hernias, because of the chance of strangulation—5% in indirect hernias and up to 30% in femoral hernias. Elective repair can be undertaken as outpatient surgery using general anesthesia, spinal anesthesia, intravenous sedation, or local anesthesia alone. Repair of the hernia requires delineation of anatomy, identification of the hernia sac, and reduction of sac contents. Indirect hernia sacs are ligated at the level of the internal inguinal ring; direct hernia sacs are pushed below the repair site. Suitable native tissue can be used for repair. The modified Bassini repair apposes the shelving edge of the inguinal ligament to the conjoint tendon (inguinal falx), the merging of the internal oblique and transverse abdominal aponeuroses. The Shouldice repair is similar but uses an overlapping technique with two rows of sutures. The McVay repair involves opening the inguinal floor and approximates the conjoint tendon and transversalis fascia to the pectineal ligament (Cooper ligament); this repair is suitable for femoral hernias. Relaxing incisions of the anterior rectus sheath are used to reduce tension on repairs using native tissue. Polypropylene mesh repair is now widely used as standard repair for all direct and larger indirect hernias. The Lichtenstein repair involves overlay of the mesh along the inguinal floor underneath the spermatic cord; the mesh is sutured to the shelving edge of the inguinal ligament, the pubis medially, and the internal oblique fascia superiorly. A slit in the mesh allows passage of the spermatic cord. [18] Recurrence rates are thought to be somewhat lowered by the use of mesh, but a higher risk for infection must be taken into consideration. [19] The laparoscopic approach to repair of hernias has recently been popularized. A transabdominal or preperitoneal approach can be taken, and knowledge of anatomic considerations is key [20] (Fig. 121-8A). The transabdominal preperitoneal and the totally extraperitoneal repairs are the most commonly used laparoscopic approaches. [21] After reducing the hernia contents, the repair is performed by securing a sheet of polypropylene mesh over the internal aspect of the inguinal floor and internal ring area using surgical clips or staples (see Fig. 121-8B, Fig. 121-8C). Proponents of laparoscopic inguinal hernia repair cite advantages such as improved cosmesis, less postoperative discomfort, earlier return to work, and easier repair of bilateral hernias. The laparoscopic approach also has disadvantages. Complications related to laparoscopy, such as intestinal or vascular injury during trocar insertion, potential for adhesions, the need for general anesthesia, and increased cost, are potential downsides of laparoscopic repair. Prospective randomized trials have been performed showing advantages of laparoscopic repair for one or more of the above-cited parameters. [22], [23] and [24] However, many surgeons still feel the potential risks associated with laparoscopy and the increased cost outweigh the advantages and do not routinely recommend laparoscopic hernia repair. The laparoscopic approach has been recommended by some surgeons as ideal for repair of recurrences, for bilateral hernias, and for patients who need to return to a very active lifestyle rapidly. [19], [25]

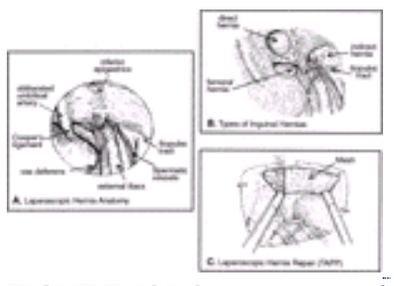

FIGURE 121-8. Laparoscopic repair of inguinal hernias. **A:** Anatomy of the inguinal region as seen through the laparoscope using the transaabdominal preperitoneal (TAPP) approach. **B:** Spaces through which hernias commonly occur as seen through the laparoscope. **C:** After reduction of the hernia, the polypropylene mesh is secured over the inguinal floor using surgical clips or staples.

Pelvic Hernias The intestine can herniate through the pelvic floor (weakness, perhaps, from multiparity or previous trauma) in areas such as the obturator foramen, the greater or lesser sciatic foramina, or the perineal muscle. The most common of these hernias is the *obturator hernia*. The obturator foramen is covered by a membrane except for one small area, and herniation occurs when the intestine (usually ileum) enters the foramen through this small defect and into the obturator region of the thigh (Fig. 121-9). This hernia is seen more commonly in females (male-to-female ratio of 1:6), on the right side, and in the sixth decade of life. Bilateral hernias can be seen, albeit rarely. [26] Most obturator herniations present with acute intestinal obstruction with no previous signs or symptoms. Occasionally, dysesthesias occur in the medial thigh because of compression of the obturator nerve. The Howship-Romberg sign (pain in the medial thigh radiating to the knee or hip exacerbated with extension, adduction, or medial rotation of the thigh) is present in 50% of the patients. A tender mass may be palpated near the obturator canal on rectal or vaginal exam. Radiologic studies may show a gas shadow in the region of the obturator foramen; a small loop of intestine in this region can be also seen on CT. [26] Surgical treatment using a transabdominal approach is indicated in all cases. [27], [28]

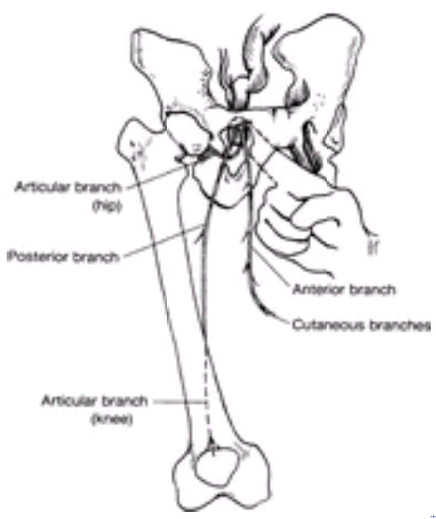

FIGURE 121-9. Rectal or vaginal palpation of the obturator foramen may confirm the existence of an obturator hernia. (Adapted from Nyhus LM, Condon RE, eds. Hernia. Philadelphia: JB Lippincott, 1978.)

Sciatic hernias are extremely rare and can present with a slowly enlarging mass in the gluteal fold area. A CT scan is often needed for diagnosis, and treatment is surgical using a transabdominal or combined transabdominal and gluteal approach. *Perineal hernias* occur through the pelvic floor musculature, and symptoms can vary but are usually related to a protruding mass in the perineal area, worst with standing. These hernias can be seen after removal of the rectum in abdominoperineal resection for rectal carcinoma. Repair is undertaken using a transabdominal approach; polypropylene mesh may be needed.

Lumbar Hernias The posterior abdominal wall has two naturally weak areas. The superior triangle of Grynfelt-Lesshaft, also called the *lumbocostoabdominal triangle,* is the most common site for lumbar herniation. This area is bordered by the 12th rib, the posterior border of the internal oblique, and the anterior border of the sacrospinalis. The inferior triangle of Petit or lumboiliac abdominal triangle is limited by the iliac crest, the anterior border of the latissimus dorsi, and the posterior border of the external oblique muscle. Lumbar hernias are seen most commonly in men and are either congenital (20%), acquired (50%), or due to trauma (25%), for example, rib fractures or removals, iliac crest fractures, or removal of a segment of iliac crest for bone grafting. [13] These hernias are usually left sided. Symptoms usually include a tender mass or pain in the lumbar area or radiating to the pelvis. Lumbar hernias should be surgically fixed when first noted because they tend to enlarge, and larger hernias are more difficult to repair.

Spigelian Hernias A Spigelian hernia is rare, occurring through the linea semilunaris, lateral to the rectus abdominis, with protrusion through the external oblique fascia. Spigelian hernias occur in elderly people, are often small and difficult to diagnose, and always present below the arcuate line of Douglas. Symptoms include local pain or discomfort worsened by increased intra-abdominal pressure. Diagnosis can be made with ultrasound or CT scan if physical examination is difficult

because of obesity or if differentiation is needed from abdominal wall tumor. [29] Surgical repair is needed because of the risk for incarceration; the results are excellent.
Diaphragmatic Hernias Acquired diaphragmatic hernias are the result of blunt or penetrating trauma. Most hernias occur on the left, and herniated viscera can include stomach, spleen, colon, or the left lobe of the liver. Herniation and traction on the mesentery can lead to nausea, vomiting, diaphoresis, and general abdominal discomfort. Respiratory symptoms occur if there is lung or mediastinal compression. Some patients present years after a traumatic injury. [30] The diagnosis is made based on physical examination with dullness to percussion along the left chest; and chest radiograph shows abdominal viscera or a nasogastric tube curled in the thorax (Fig. 121-10). CT scans can be useful in visualizing defects with protruding viscera. [31] If the index of suspicion is high for a diaphragmatic injury, normal radiologic studies should not deter one from laparoscopy or surgical exploration of the diaphragm. [32] All diaphragmatic hernias should be fixed upon diagnosis to avoid strangulation or acute respiratory distress. Chronic herniations may be best approached transthoracically to allow release of intrathoracic adhesions, but most can be repaired transabdominally.

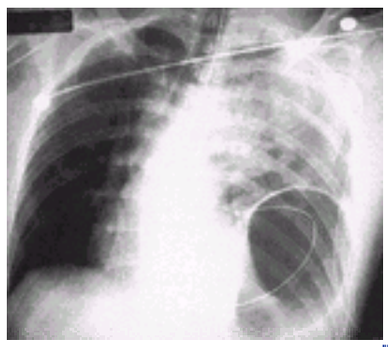

FIGURE 121-10. Traumatic hernia of the diaphragm on the left. The diaphragmatic line has disappeared and the gastric fundus is in the left thoracic space. The contour of the nasogastric tube should be noted in the left chest.

Internal Hernias An internal hernia is a protrusion of any intraperitoneal viscus into a compartment within the abdominal cavity. There is no hernia sac, and most often, the herniated viscus is entering a known anatomic space or foramen; some hernias occur in surgically created or congenital defects. In one review, 0.2% to 0.9% of cadavers had incidentally noted internal hernias, most commonly paraduodenal (53%), followed by pericecal (13%) and the foramen of Winslow (8%), and supravesical and intersigmoid hernias (6% to 7% each). [33] Most symptoms are intermittent, and patients often present with small bowel obstruction or signs and symptoms of strangulation. Radiologic studies are not always helpful, and the differential diagnosis must include foreign bodies, intestinal volvulus, adhesions, and tumors. [34] , [35] Surgical treatment is needed and includes reduction of the herniated viscus and repair of the defect.
Paraduodenal Hernias The left paraduodenal fossa of Landzert is a peritoneal pocket located lateral to the fourth portion of the duodenum and posterior to the inferior mesenteric vein. A left paraduodenal hernia (75%) results from a dorsal malrotation of the midgut resulting in a hernial opening with the inferior mesenteric artery covering the anterior margin. A right paraduodenal hernia (25%) is formed by incomplete rotation of the midgut such that the small intestine is in a sac covered anteriorly by the mesocolon and the superior mesenteric artery. The cecum remains in the right upper quadrant and is attached to the right abdominal wall by thickened parietocolic peritoneal bands of tissue called *Ladd bands*. Signs and symptoms are elusive and can include any signs associated with chronically incarcerated hernias. Contrast radiographs show stasis and delay in transit with large portions of small bowel trapped in one anatomic position. Surgical correction is necessary, and damage to the small bowel vasculature should be carefully avoided.
Hernias of the Foramen of Winslow Herniation of a mobile cecum and distal ileum can occur into a larger than usual foramen of Winslow. Signs and symptoms are vague but can include crampy epigastric pain relieved with flexion of the torso. Radiographic studies show a gas-filled loop of bowel behind the stomach and pushing the stomach anteriorly and to the left. Surgery with reduction and cecopexy may be needed.
Pericecal Hernias, Intersigmoid Hernias The distal ileum can pass through a defect in the cecal mesentery occupying the right paracolic gutter. Most present with right lower quadrant pain with or without a small bowel obstruction. Intersigmoid hernias are composed of herniated small bowel present in the peritoneal pocket between the two loops of sigmoid. These hernias are usually picked up incidentally at operation or during a radiologic study such as barium enema or CT. [35]
Transmesenteric and Transomental Hernias About 5% to 15% of internal hernias occur through defects in the mesentery or the omentum. Transmesenteric hernias occur most commonly in children, along the mesentery of the jejunum. Prenatal ischemic events may be the causative agent because the area of defect is often associated with atretic segments of intestine. Symptoms of small bowel obstruction may develop, and surgery is required at diagnosis.
Iatrogenic Hernias Iatrogenic hernias result from alteration of intra-abdominal anatomy, most often at surgery. Seventy-five percent of iatrogenic hernias manifest in the first postoperative year.
Retroanastomotic hernias. A retroanastomotic hernia occurs through any defect in the mesenteric space left open after completion of an intestinal anastomosis. Hernias can occur after a Billroth II anastomosis in the space between the gastrojejunostomy and the posterior abdominal wall. Most patients present with intestinal obstruction and require immediate surgical correction.
Incisional hernias. Incisions of the abdominal wall result in future herniation 2% to 5% of the time. Multiple factors are responsible for a postoperative incisional hernia, including defective suture material, undue tension on the sutured fascia, obesity, previous incisions, infections, seromas or hematomas, malnutrition, and smoking. [36] Different incisions have different rates of future herniation. Midline incisions have the highest rates; paramedian and transverse incisions have lower rates of herniation. Incisional hernias can range in size from 1 cm to large hernias containing nearly all the intestines. With increasing popularity of laparoscopic surgery, attention needs to be paid to all trocar site defects larger than 0.5 cm to avoid future herniation. The diagnosis of incisional hernia is usually evident by history as well as physical exam. The hernial ring is often palpable with the edges of the muscle retracted laterally. Incisional hernias often incarcerate but tend not to strangulate. Operative repair should be undertaken in most patients. For many years, the repair of incisional hernia was associated with a high recurrence rate. Most recurrences are thought to be due to infection, insufficient dissection and exposure of other defects, or closure under excess tension. Tension should be avoided at the time of repair, and prosthetic mesh is often needed. In more recent years, the introduction of synthetic prosthetic materials has provided the opportunity to perform a tension-free repair, thereby reducing the rate of recurrence. [36] In addition, more recently, musculoaponeurotic flaps are used along with relaxing incisions in cases in which prosthetic material is best avoided. In addition, natural tissue substitutes, such as fascia lata or pig small intestinal submucosa, are being used to repair incisional hernias. [37]

INTRA-ABDOMINAL ABSCESSES AND FISTULAE

INTRA-ABDOMINAL ABSCESSES

An *intra-abdominal abscess* is a well-defined collection of pus that is isolated from the rest of the peritoneal cavity by inflammatory adhesions, omentum, abdominal viscera, and loops of intestine. Abscesses may or may not contain viable bacteria and represent successful but incomplete attempts of normal host defense mechanisms to eradicate peritoneal infection. Complete resolution of an abscess is impaired by the inaccessibility of its contents to host cellular defenses.

Intra-abdominal abscesses may occur within the peritoneal cavity or the retroperitoneum; they may be either within or adjacent to abdominal viscera. Visceral abscesses usually result from lymphatic or hematogenous spread of bacteria to the organ. Intraperitoneal, nonvisceral abscesses most commonly follow perforation of an abdominal viscus or anastomotic dehiscence. Less frequently, nonvisceral abscesses may occur after incomplete resolution of diffuse peritonitis with a loculated, residual site of infection. Retroperitoneal abscesses may occur as a result of perforation of the gastrointestinal tract or through lymphatic or hematogenous spread of bacteria to retroperitoneal organs. Pancreatic abscess is an example of the latter mechanism.

Intra-abdominal abscesses frequently arise in a postoperative context, with one half to three fourths occurring after an abdominal, particularly colonic, operation. [1] Most postoperative abscesses result from a documented anastomotic leak. In decreasing order of frequency, diverticular disease, appendicitis, inflammatory bowel disease, and perforated visceral carcinomas account for primary, noniatrogenic intra-abdominal abscesses.

Anatomic Considerations

The peritoneal attachments of the intra-abdominal organs and the small bowel mesentery divide the intraperitoneal space and have an important influence on abscess formation. The transverse colon, its mesentery, and the attached omentum separate the abdominal cavity into upper and lower spaces. The upper abdominal space, in turn, is divided into left and right compartments by the falciform ligament. The diagonal attachment of the small bowel mesentery divides the lower abdominal compartment into left and right spaces.

In good health, the peritoneal cavity contains a small amount of fluid that circulates within the abdominal cavity in a pattern determined by visceral attachments. Fluid adjacent to the small bowel mesentery moves dependently into the pelvis and then moves caudally along the right and left pericolic gutters. Peritoneal fluid on the right reaches the corresponding subhepatic and subphrenic spaces, whereas left-sided fluid is impeded from reaching the left subphrenic space by the phrenocolic ligament. The peritoneal fluid circulation favors unilateral spread of bacteria within the abdominal cavity. For example, duodenal perforation frequently is associated with right subphrenic collections, whereas a perforated appendicitis may result in right subhepatic abscess. Intraperitoneal fluid is absorbed along the inferior surface of the diaphragm by specialized lymphatic vessels.

The foramen of Winslow is formed by the free border of the gastrohepatic omentum and the posterior parietal peritoneum (Fig. 122-1). The lesser sac communicates with the general peritoneal cavity through the foramen, but the amount of cross-circulation is small, and perforations within the general cavity rarely produce infection within the lesser sac. Conversely, primary lesser sac abscesses remain confined and usually do not produce diffuse peritoneal contamination (Fig. 122-2).

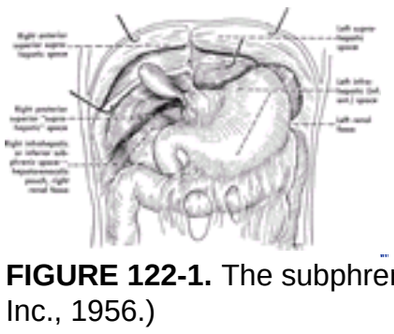

FIGURE 122-1. The subphrenic spaces, the diaphragm and liver being elevated. (From Hollinshead WH. Anatomy for surgeons. Vol 2. New York: Paul B. Hoeble, Inc., 1956.)

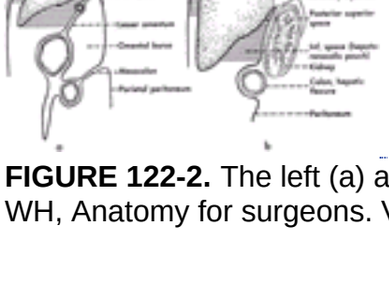

FIGURE 122-2. The left (a) and right (b) subphrenic spaces, as seen in diagrammatic parasaggital sections. The spaces are horizontally lined. (From Hollinshead WH, Anatomy for surgeons. Vol 2. New York: Paul B. Hoeble, Inc., 1956.)

The retroperitoneum is a potential space bordered superiorly by the diaphragm, inferiorly by the pelvic brim, laterally by the quadratus lumborum muscles, and posteriorly by transversalis fascia. The renal fascia separates the retroperitoneum into anterior and posterior compartments. The anterior retroperitoneal space contains the esophagus, pancreas, bile duct, portal and splenic veins, sometimes the appendix and border portions of the duodenum, and the posterior surfaces of the ascending, descending, and sigmoid colonic segments. Posterior perforation in any of these intestinal segments can result in retroperitoneal abscess. The posterior retroperitoneal space contains the kidneys, ureters, gonadal vessels, inferior vena cava, aorta, and lymphatic channels. Extra-abdominal manifestations may occur because of these anatomic relationships. Retroperitoneal perforation of a cecal carcinoma may cause an abscess, which initially develops along the psoas muscle and then passes through the femoral canal to produce an abscess in the right thigh (Fig. 122-3).

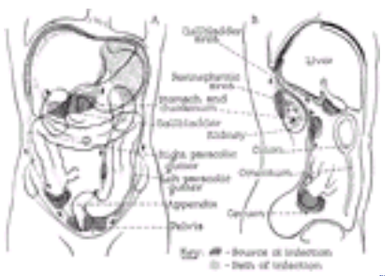

FIGURE 122-3. Etiology and paths of infection causing subdiaphragmatic abscess. (From Anson BJ, Maddock WG. Callander's surgical anatomy. 4th ed. Philadelphia: WB Saunders, 1958.)

Etiology

Primary peritonitis (spontaneous bacterial peritonitis) is defined as inflammation of the peritoneal cavity without a source of contamination from the gastrointestinal tract (see Chapter 46). *Secondary peritonitis* occurs because of necrosis or perforation of the gastrointestinal tract with spillage of enteric contents and bacterial contamination. Intra-abdominal abscesses occur as a consequence of secondary peritonitis. After peritoneal contamination, bacteria are initially cleared by subphrenic lymphatics, undergo phagocytosis by resident peritoneal macrophages, and are sequestered by fibrin deposition. Continued bacterial contamination promotes the influx of polymorphonuclear leukocytes, increases capillary permeability, and results in fluid exudation. These peritoneal defense mechanisms are crucial for effective bacterial clearance and killing, but they also can have adverse effects for the host. Lymphatic clearance of microorganisms can lead to sepsis and development of distal sites of infection. Increased capillary permeability with fluid exudation dilutes bactericidal opsonic activity and inhibits phagocytosis. Fibrin entraps bacteria, inhibiting phagocytic migration and function. Whereas these events help initially to localize peritoneal contamination, they also promote formation of intra-abdominal abscesses.

The normal bacterial flora of the esophagus, stomach, and duodenum is sparse and is composed of swallowed viridans streptococci, microaerophilic streptococci, *Lactobacillus* species, *Fusobacterium* species, and *Candida* species. Bacterial counts increase and enteric organisms proliferate in the presence of achlorhydria or gastric or duodenal obstruction.

The small bowel flora from the proximal jejunum to the distal ileum is characterized by progressively increasing numbers of Enterobacteriaceae, *Enterococcus* species, and anaerobic species. The distal ileum has an endogenous flora that resembles the colon. The colonic lumen contains up to 1012 organisms per gram of stool, with anaerobes outnumbering aerobes by a ratio of 1000:1. Anaerobic organisms include *Bacteroides fragilis, Eubacterium* species, and *Bifidobacterium* species. Aerobic organisms include *Escherichia coli, Klebsiella* species, *Enterococcus* species, and *Proteus* species.

With secondary peritonitis, polymicrobial anaerobic and aerobic infection is expected. Polymicrobial infections are documented in 60% to 80% of cases, with an average of four distinct isolates per patient at the time of initial operation. [2] *B fragilis* is the anaerobic bacteria isolated most often; *E coli* is the most common aerobe. Most chronic intra-abdominal abscesses are polymicrobial, but only aerobes are cultured in more than half of cases. [3] Abscess formation is promoted in the presence of barium, feces, necrotic tissue, or hemoglobin. These adjuvants promote the growth of bacteria by blocking lymphatic clearance, inhibiting bacterial clearance and killing, and providing bacterial nutrients such as iron. [4] Preexisting immune compromise and prior antibiotic exposure may significantly influence the bacteriologic spectrum of intra-abdominal abscesses in seriously ill patients. In two studies of patients in intensive care units, a reduced frequency of *E coli* and *B fragilis* isolates was noted, with an increased frequency of fungi, *Staphylococcus epidermidis, Pseudomonas* species, *Enterococcus* species, and *Enterobacter* species. [5], [6]

Clinical Manifestations

Generalized peritonitis produces intense abdominal pain and obvious physical findings; the diagnosis is seldom in doubt. Patients with intra-abdominal abscesses are usually subacutely to chronically ill, and symptoms and physical findings may be subtle or sometimes equivocal. Fever and chills are extremely common. Malaise and anorexia are universal but also nonspecific. Leukocytosis with a shift to immature forms is usually present. Most other common laboratory tests are noninformative.

An abscess that abuts the parietal peritoneum may produce localized pain, tenderness, and a palpable mass. In contrast, intramesenteric and interloop abscesses usually do not contact the somatically innervated parietal peritoneum and produce diffuse, poorly localized visceral pain; a mass usually cannot be appreciated. Subphrenic abscesses often are associated with diaphragmatic splinting, tachypnea, cough, and hiccup. An associated pleural effusion is frequently present and can be detected by physical examination or chest radiograph. Pelvic abscesses may produce tenesmus, diarrhea, or urinary retention as a result of irritation to the adjacent rectosigmoid colon or bladder. These symptoms should prompt rectal and pelvic examinations to detect mass, fluctuance, or tenderness. Retroperitoneal abscesses produce fewer constitutional symptoms than intraperitoneal processes. Lumbar or iliopsoas muscle spasm may be present, and involvement of psoas muscle may cause pain on flexion of the hip (psoas sign).

Detection of intra-abdominal abscesses in postoperative patients is especially difficult. Incisional pain, the effects of postoperative analgesics and antibiotics, and the impediment of incisions, drains, and bandages to physical examination compound the problem. The mean time postoperatively to clinical signs of abscess is 8 days. [7]

Diagnostic Studies

Plain abdominal radiographs, intralumenal contrast studies, and radioisotope scanning have unacceptably low diagnostic accuracy rates, ranging from 15% to 50%, when used for the detection of intra-abdominal infection. [8] These older modalities have been supplanted by computed tomography (CT) and ultrasonography.

Ultrasonography Ultrasonography has been used frequently as the initial screening and diagnostic tool for investigation of suspected intra-abdominal abscess. Ultrasonography has the advantages of portability, speed, low cost, and lack of radiation exposure. The anatomic areas best suited for ultrasound investigation are the right upper quadrant, the pelvis, and the left upper quadrant if the spleen is present. Ultrasound also has significant limitations for the detection of intra-abdominal abscesses: it is operator dependent in its performance, and the images are not intuitively understandable or accessible to many nonradiologists. Obesity, open wounds, surgical dressings, ostomy appliances, and overlying bone severely limit ultrasound access. Because gas reflects transmitted sound waves, intestinal ileus and overlying lung preclude ultrasound examination of many areas of the abdomen. These limitations are most pronounced in postoperative patients, the group at highest risk for abscess and the group in which clinical signs and physical examination are least reliable. Reported sensitivities of ultrasound for detection of intra-abdominal abscess range from 75% to 80%. [9]

Computed Tomography Computed tomography is the superior mode for investigating patients with suspected intra-abdominal abscesses (Fig. 122-4). CT scanning is much less operator dependent than ultrasonography, the visual information is less abstract, and CT provides better anatomic resolution that is not affected by surgical incisions, bandages, body habitus, or the presence of bowel gas. Intralumenal fluid collections, interloop areas, and retroperitoneal structures all can be visualized.

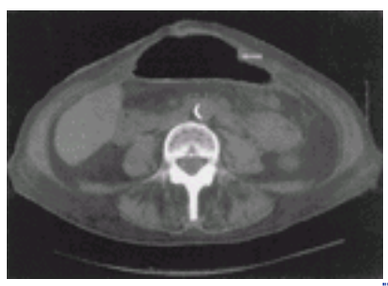

FIGURE 122-4. Computed tomography scanning provides a highly accurate means for evaluating the presence of an abscess and its relationship to contiguous visceral and vascular structures. Localized accumulations of fluid of low attenuation plus the presence of loculations, gas, or debris are highly suggestive of an abscess. The *arrow* points to a large, gas-filled loculation in the mid-upper abdomen that eventually proved to be a localized abscess.

The presence of an abscess is suggested by a localized accumulation of fluid of low attenuation (Fig. 122-5). CT provides information about the size and shape of cavity walls as well as the presence of loculations, gas, or debris. CT has a reported sensitivity of 80% to 100% for the detection of intra-abdominal abscesses. [10] Interloop abscesses are detected less reliably, with about 60% sensitivity.

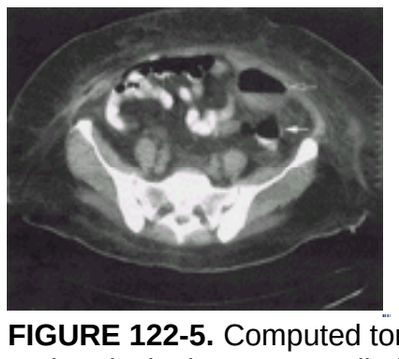

FIGURE 122-5. Computed tomography findings suggestive of diverticular abscess include thickening of the colonic wall (*closed arrow*) along with mesocolic edema and pericolonic or mesocolic fluid accumulations. The *open arrow* points to a localized collection of fluid and gas that represents a pericolonic diverticular abscess.

CT-guided diagnostic aspiration is not complicated and may be performed with the patient under local anesthesia using an 18- to 22-gauge needle. The needle is directed into the fluid collection, often using additional CT imaging for guidance. Selection of a safe route for diagnostic aspiration is crucial. The sampling needle must not transgress intestine before entering the fluid collection. False-positive results may occur if intestinal or colonic contents are inadvertently aspirated. In addition, sterile fluid collections, such as a pseudocyst or hematoma, could be contaminated and converted into an abscess. Samples should be analyzed by Gram stain and for aerobic and anaerobic culture. Usually, a decision regarding therapeutic drain placement can be made at the time of diagnostic sampling on the basis of Gram stain.

Endoscopic Ultrasound Endoscopic ultrasound (EUS) has recently been recommended as an adjunct for localizing pancreatic pseudocysts or abscesses. EUS has been found to be helpful in precisely identifying pseudocysts, thereby facilitating accurate and complete endoscopic or open cyst decompression. [11], [12] The presence or absence of associated varices resulting from portal hypertension can be determined, thereby redirecting the site of decompression and improving the safety of the procedure. EUS can also be helpful to differentiate between a cystic neoplasm and an inflammatory pseudocyst. [13], [14] When combined with cyst fluid aspiration and fine-needle aspiration cytology, EUS can provide useful information to guide subsequent therapy, particularly for lesions that are not amenable to CT or ultrasound-guided drainage because of their location or anatomy. This can be especially useful in patients with evidence of occult, undrained infection and loculated fluid collections.

Therapy

Successful management of patients with intra-abdominal abscesses is based on the following principles: control of the source of intraperitoneal or retroperitoneal contamination; drainage of established abscess cavitiesAelimination of residual bacterial infection through use of appropriate antibiotics; and physiologic support of the patient. Patients with acute secondary peritonitis require immediate operation to resect necrotic or perforated tissue, to remove blood or intestinal contents, and to eliminate continuing contamination. In contrast, patients with established intra-abdominal abscesses, especially those with postoperative sepsis, present more difficult decisions. Although delayed therapy is associated with poor outcome, so too is an inappropriate or poorly executed operation. Patient selection is greatly aided by cross-sectional imaging techniques combined with the judicious use of percutaneous fluid aspiration and continuous external catheter drainage. CT-guided therapy has permitted many patients to avoid laparotomy and has helped to convert others from emergent operation to staged, urgent, or elective procedures.

Established intra-abdominal abscesses can be drained percutaneously using CT or ultrasound guidance, by transperitoneal laparotomy, or by an extraperitoneal surgical approach. Most studies comparing percutaneous drainage with surgical drainage are flawed in that they are not prospective or randomized and include patients with widely varying etiologies of abscess. Nonetheless, the overall conclusion is that percutaneous drainage of intra-abdominal abscesses can be performed as safely as surgical drainage and with similar long-term clinical outcome. [15] The most important issue is proper patient selection and not the technique used; severity of illness and the nature of underlying intra-abdominal pathology determine outcome.

Percutaneous catheter drainage requires a safe drainage route that avoids solid organs and bowel. A safe passage can be identified in 85% to 90% of cases. [16] Complex or loculated cavities, suggested by persistent fever and leukocytosis, may require the placement of additional catheters. Necrotic tissue, thick pus, and infected hematomas respond less well to catheter drainage. Fungal abscesses, which have thick pus and invade surrounding tissues, usually contraindicate percutaneous drainage. Extensive collections; interloop, intramesenteric, splenic, and pancreatic abscesses; and abscesses that communicate with bowel have lower success rates and require individualized judgment. The success rates for percutaneous CT-guided drainage of established, well-defined, unilocular intra-abdominal abscesses is 80% to 90%. [17] The rates for complex abscesses, as defined herein, are significantly lower, about 50%.

Complications relating to the performance of percutaneous drainage occur in 5% of patients with simple abscesses and 20% of those with complicated fluid collections. [18] Bacteremia is the most common complication. Catheter manipulation and irrigation increase the risk for bacteremia; prophylactic intravenous antibiotics should be administered before catheter changes. Bleeding can occur because a catheter traverses a vessel during insertion or erodes a vessel over time. Inappropriate placement trajectories that pass through the pleural space may result in pneumothorax, empyema, or pleural effusion. The complication rates for percutaneous drainage are generally lower than for surgery when equivalent patient groups are compared. Surprisingly, mortality rates are similar, suggesting that preexisting illness and the underlying cause of abscess are more important determinants of mortality than the technique of drainage. [19]

Surgery

Operative therapy should be individualized for each patient and depends on the underlying pathology as well as the resulting intra-abdominal abscess. Surgical treatment of established intra-abdominal abscesses requires either a transperitoneal or an extraperitoneal surgical approach. Drainage of a subphrenic abscess posteriorly through the bed of the 12th rib is an example of extraperitoneal drainage. Extraperitoneal drainage has the advantages of not violating the peritoneum and spreading bacterial contamination and is generally less physiologically stressful. Extraperitoneal procedures do not permit detailed evaluation for coexisting intraperitoneal pathology, which is present in up to one fourth of these patients. [20]

Patients with coexisting intraperitoneal pathology, such as intestinal infarction, anastomotic dehiscence, or extensive infected hematoma, require transperitoneal laparotomy to address the primary problem. In these patients, a number of additional techniques have been proposed to treat the septic component more aggressively, including radical peritoneal debridement, intraoperative lavage, continuous postoperative lavage, and open abdominal drainage. In controlled, prospective trials, none of these techniques has conferred significant benefit. [21], [22], [23], [24] and [25]

Appendiceal Abscess

An abdominal mass is be present on physical examination in about 2% to 3% of patients with appendicitis at their initial evaluation. [26] A periappendiceal mass, which

is formed by inflamed omentum and adherent loops of intestine, usually indicates appendiceal perforation and signifies the development of a phlegmon or an abscess. The risk for perforation is increased if the patient has been symptomatic for more than 24 hours, temperature exceeds 38°C, or the white blood cell count is greater than 15,000/mL. The wound infection rate is 1.8% after an uninflamed appendix is discovered at laparotomy, 8.5% if the appendix is inflamed but not perforated, and 17% with appendiceal perforation. [27] Pelvic abscesses occur postoperatively in 15% of patients with appendiceal perforation.

An appendiceal mass or abscess may be treated by both operative and nonoperative means, although immediate operation is not favored because the intense inflammatory reaction increases the risk for injury to adjacent bowel or ureter. CT is not justified as a routine procedure in the diagnosis of acute appendicitis, but it is essential in the nonoperative management of a periappendiceal mass. Initial management should include percutaneous drainage of periappendiceal fluid collections and intravenous antibiotics. Elective interval appendectomy, which can be performed after the resolution of periappendiceal inflammation, is associated with a 0.2% mortality rate and a major complication rate of only 1.2%. [28]

Diverticular Abscess

CT, the preferred initial test when a diverticular abscess is suspected, [29] has several advantages: it causes less discomfort than barium enema, the risk for inducing a perforation is negligible, and pericolonic complications of diverticulitis can be evaluated. CT findings that indicate diverticulitis include thickening of the colon wall, mesenteric edema, pericolonic and mesenteric abscesses, and pneumoperitoneum (see Fig. 122-5). If diverticulitis is suspected, intravenous contrast should not be administered initially; visualization of contrast material (administered orally or rectally) within the bladder is presumptive evidence for colovesical fistula. The sensitivity of CT is reported to be 65% for uncomplicated diverticulitis and 90% to 100% for detecting the complications of perforation, abscess, or fistula. [30]

The ability of CT to define accurately the complications of acute diverticulitis has had a major impact on clinical management. Cross-sectional imaging of pericolonic abscess permits CT-guided percutaneous drainage (Fig. 122-6), which minimizes the need for colostomy formation, provides optimal conditions for resection with primary anastomosis, and improves patient safety. Small pericolic or intramesenteric abscesses that can be resected en bloc with the sigmoid colon usually do not require preoperative percutaneous drainage. Diverticular abscesses associated with fecal peritonitis, pneumoperitoneum, or colonic obstruction should be treated by emergent operation. The diseased colonic segment should be resected and the abscess debrided. The formation of a proximal colostomy and closure of the rectum (Hartmann procedure) are the safest surgical options. The colostomy is closed in 2 to 3 months after resolution of the septic process.

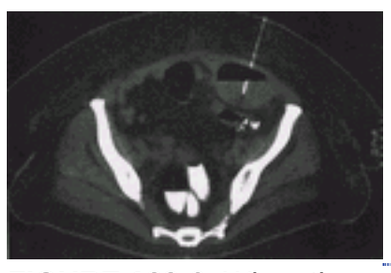

FIGURE 122-6. When they are localized, pericolonic diverticular abscesses may be amenable to percutaneous aspiration and continuous catheter drainage. The suspected abscess depicted in this figure is being safely aspirated using computed tomography guidance.

Patients treated by percutaneous drainage of diverticular abscesses should experience definite clinical improvement within 24 to 48 hours, with decreased pain, defervescence, and diminished leukocytosis. Interval catheter injection is used to demonstrate progressive collapse of the abscess cavity. In a selected series of patients, percutaneous drainage was associated with resolution of sepsis in 89%. [31] Fistulous communication with the colon was demonstrable radiologically in 47% but clinically significant in only 16%. In three fourths of treated patients, single-stage sigmoid resection with primary anastomosis was performed subsequently without complication.

Pancreatic Abscess

CT of the pancreas is used to estimate the severity of acute pancreatitis and to distinguish acute pancreatitis from pancreatic abscess. [32] Glandular enlargement, loss of internal structure, and blurring of pancreatic margins characterize mild disease. Increasing severity is demonstrated by the development of peripancreatic fluid collections. Severe cases are associated with fluid collections in the lesser sac, perirenal and posterior pararenal space phlegmons, and pancreatic ascites.

Contrast-enhanced CT is the preferred method of identifying necrotizing pancreatitis, which may serve as a precursor for pancreatic abscess. In enhanced CT pancreatography, thin tomographic cuts of the pancreas are obtained during infusion of intravenous contrast medium. Contrast-deficient areas correlate with regions of pancreatic nonperfusion and necrosis. The sensitivity of dynamic CT for detecting pancreatic necrosis has been reported to be 85% to 95%. [33], [34]

Pancreatic abscess represents one form of intra-abdominal abscess in which operative drainage remains the primary therapeutic modality. CT imaging is essential for diagnosis and as a guide for the timing of therapy, but it has a lesser therapeutic role than for other forms of intra-abdominal abscesses. In pancreatic abscess, interventional radiology has a supportive rather than primary role. Pancreatic abscesses tend to be poorly localized and to contain solid, devitalized material that cannot be evacuated by catheter (Fig. 122-7). Operative therapy for a pancreatic abscess is more properly termed a debridement rather than an abscess drainage. In one study, percutaneous drainage was successful in only 10% of pancreatic collections. [35]

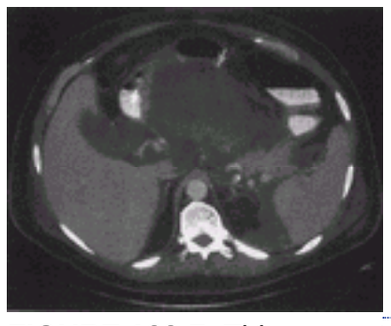

FIGURE 122-7. This computed tomography scan of a patient with a suspected pancreatic abscess (*arrow*) shows fairly typical findings: relatively poor localization, surrounding inflammation, and poor contrast enhancement suggesting devitalized pancreas or peripancreatic fat and debris. These lesions generally are not amenable to percutaneous catheter drainage because they contain solid debris and are best managed with surgical debridement and drainage.

GASTROINTESTINAL FISTULAE

A *fistula* is defined as an abnormal communication between the lumen of a hollow viscus and another hollow organ or the integument. Abdominal fistulae generally are classified by their sites of origin and termination, by the volume and composition of drainage, and by their etiology. They pose difficult management problems because of the resulting fluid, electrolyte, and protein losses. These losses, coupled with the increased metabolic stress of recent surgery, infection, or malignancy, may lead to significant malnutrition. Before 1970, mortality and complication rates associated with abdominal fistulae exceeded 50%. Advances in parenteral and enteral forms of nutrition and the refinement of surgical techniques have improved the rate of fistula closure and reduced associated comorbidity and mortality.

Etiologies

Gastrointestinal fistulae develop from multiple factors, including complications of abdominal surgery (anastomotic dehiscence, erosion by an adjacent drain, unrecognized iatrogenic injury), blunt or penetrating trauma, inflammatory bowel disease including Crohn's disease and diverticulitis coli, malignancy, and radiation. Prosthetic mesh materials used to reconstruct the large abdominal wall or pelvic floor defects have been associated with enterocutaneous fistulae, presumably by erosion of the mesh through the adjacent bowel wall. Most enteric fistulae develop as complications after surgery.

Clinical Manifestations

The major clinical problems of gastrointestinal fistulae include fluid and electrolyte losses, skin excoriation, hypermetabolism, abscess formation, sepsis, and malnutrition. Loss of gastric juice, containing high concentrations of hydrogen and chloride ions, can result in hypochloremic, hypokalemic metabolic alkalosis. Loss of alkaline pancreatic secretions can produce significant metabolic acidosis. Large-volume fluid losses result in dehydration and oliguria, and, if uncorrected, may progress to altered renal function. The presence of activated digestive enzymes in the fistula effluent may cause skin excoriation, especially when the external opening of the fistula is located at the base of a skin crease or in a surgical wound that impairs secure adherence of a protective dressing.

Sepsis frequently accompanies fistula development. A localized fistula may rupture freely into the peritoneal cavity or cause an abscess in distant areas such as the pelvic, subhepatic, or subdiaphragmatic spaces. A fistula also may masquerade as a wound infection and become apparent only when enteric contents breach the fascial closure and appear on the dressings. Operative or radiologic drainage of a postoperative abscess also may demonstrate an unsuspected fistula. Rarely, fistulae may develop when an abscess erodes into adjacent bowel.

The importance of aggressive nutritional support in patients with gastrointestinal fistulae cannot be overemphasized. Malnutrition adversely affects reparative and immune processes. Several factors contribute, including protein and nutrient losses from the fistula, the anorexia and decreased food intake associated with malignancy and chronic illness, and the increased metabolic demands imposed by recent operation. Before 1970, the reported mortality and morbidity rates associated with enterocutaneous fistulae ranged from 40% to 65%. [36] These figures have been reduced to 15% or less with regimens that use aggressive parenteral or enteral nutrition. [37]

Therapy

Fistula management is multifaceted. Adequate external drainage, control of infection, and intensive nutritional support are the keys to improved patient survival. Total parenteral nutrition (TPN) should be used initially, but enteral support with elemental or polymeric diets can be used during the later phases of treatment. Enteral support requires about 1250 cm of intact small intestine irrespective of the fistula location. The caloric and nutrient requirements for enteral nutrition are the same as those for TPN. Immediate surgical correction of the fistula is not generally a priority and may represent an unacceptable risk to an already septic, immunocompromised patient. Undrained abscesses should be searched for aggressively with CT and drained percutaneously whenever feasible with CT or ultrasound guidance. Once the patient has been stabilized, the source organ and extent of the fistula should be evaluated radiographically, preferably with water-soluble contrast media if there is question of continued communication between the fistula tract and the peritoneal cavity.

Intensive nutritional support should be continued for 4 to 8 weeks in anticipation of spontaneous closure of the fistula. Several factors decrease the likelihood of spontaneous closure (Table 122-1) and alter the surgical strategy and require delaying definitive reoperation. The general principles of surgical management include resection, serosal patching or internal drainage of the fistula, correction of any associated pathology, and provision of adequate wound coverage. These fundamentals are essential for decreasing the potential lethality of this condition.

Partial or complete obstruction
Persistent inflammation or infection
Foreign body in fistula tract
Cancer
Inflammatory bowel disease
Radiation enteritis
Fistula tract < 2 cm long
Fistula volume > 500 mL/24 h

TABLE 122-1 Factors that Impair Fistula Closure

Effective management of gastrointestinal fistulae requires establishment of treatment priorities. Dehydration should be corrected rapidly along with any derangements in electrolyte or acid-base balance. Sterile central venous access should be established to initiate and maintain parenteral nutrition. A separate peripheral intravenous catheter should be used to replace measured fistula losses, nasogastric suction volumes, and third-space losses resulting from peritoneal inflammation or hypoalbuminemia.

Control of Sepsis Uncontrolled sepsis is the major determinant of mortality in patients with gastrointestinal fistulae. [38] Control of infection requires systemic antibiotics coupled with surgical or radiologic drainage of abscesses. Signs of occult sepsis, including rigors or chills, unexplained leukocytosis, acid-base disturbances, or evidence of single or multiple organ dysfunction, suggest undiagnosed abscesses that should be investigated aggressively using ultrasonography or CT and percutaneously drained whenever feasible. Patients commonly present with multiple or loculated abscesses that may recur after successful percutaneous or surgical drainage. Antibiotics should be used selectively, based on appropriate culture and sensitivity testing.

Control of Drainage Drainage along the fistula tract also should be established to prevent pooling of secretions, to permit accurate quantification and analysis of fluid losses, and to minimize excoriation of surrounding skin. A fistulogram should be obtained to identify the source organ and to establish optimal drainage. Soft catheters with multiple side holes can be positioned radiologically into the proximal and distal arms of the fistula for collection and reinfusion of gut secretions. Such catheters provide access for enteral nutrition, although their presence will retard and ultimately prevent spontaneous closure of the fistula. Suction catheters should be positioned carefully adjacent to but not through the bowel opening so as not to impair spontaneous closure of the fistula. Failure to configure a reliable device for collection of fistula drainage compromises wound care and complicates fluid and electrolyte management, especially in patients with high-output fistulae. Fastidious care of the skin and tissues surrounding the fistula site is essential. Uncontrolled leakage of gastrointestinal secretions containing activated digestive enzymes causes severe skin excoriation and is both painful and unsanitary for the patient. The help of a qualified and experienced enterostomal therapist can be invaluable in difficult cases.

Management of Nutrition Prompt initiation and maintenance of adequate nutrition are imperative for the successful treatment of patients with gastrointestinal fistulae. Formulations vary, but the essential components include 2000 to 5000 Kcal, 70 to 200 g of amino acids, and 500 to 1000 mL of 10% fat emulsion per 24 hours, plus vitamins, trace minerals, and electrolytes as needed to meet daily requirements. Before the development of TPN, many patients died of malnutrition and starvation. Complete bowel rest and TPN are recommended for patients with proximal or high-volume fistulae. When the fistula is distal and of low volume, enteral nutritional support may be feasible. A variety of nutritional formulations can be used. Enteral nutrition is more economic and physiologic than TPN, avoids the risk for catheter-related and metabolic complications, and yields comparable results. [39] Enteral feeding also prevents gut atrophy and bacterial translocation, potentially reducing the risk for portal pyemia and septic complications. Enteral feeding is associated with well-recognized complications, the most serious of which is aspiration pneumonia; this occurs at a fairly low fixed rate, irrespective of the type of access (nasal or percutaneous) or the terminal position of the catheter (stomach or small intestine). Diarrhea usually can be managed by altering the type, rate, or concentration of the enteral formulation.

Management of Fistula Drainage Decreasing fistula output is an important component of therapy. This can be accomplished by giving the patient nothing by mouth, inserting a nasogastric tube to evacuate gastrointestinal secretions and ensure bowel rest, and administering drugs or hormones to decrease gastric and pancreaticobiliary secretions. Complete and long-term bowel rest may control fistula output and encourage natural closure but may result in hepatic cholestasis. In one clinical study of patients with enterocutaneous fistulae, collection of effluent from the proximal limb and reinfusion through a soft catheter into the distal limb of the fistula prevented or reversed biochemical evidence of intrahepatic cholestasis. [40] Reinfusion of fistula effluent is generally innocuous and should be considered whenever feasible. Supportive management of gastrointestinal fistulae with TPN, skin care, and control of infection results in spontaneous closure rates of 60% to 75%, although the chances of cure vary according to the anatomy of the fistula and underlying condition or conditions. [41] The characteristics that predict a low likelihood of spontaneous fistula closure are outlined in Table 122-1. In most studies, the mean time to fistula closure with TPN alone is 4 to 5 weeks. [39] The major detractors from conservative treatment are its long duration, high cost, and patient inconvenience. Hormonal suppression of gastrointestinal fistulae with somatostatin,

a tetradecapeptide with potent inhibitory actions on gastrointestinal and pancreaticobiliary secretions, [42] was facilitated by the development of long-acting synthetic analogs (octreotide; SMS 201-995) that are resistant to degradation. Several retrospective studies showed that subcutaneous administration of somatostatin effectively reduces the volume of fistula output and reduces the mean time to spontaneous closure, [42], [43] particularly in patients with high-output fistulae in whom spontaneous closure with conservative treatment rarely exceeds 50%. In one study, subcutaneous administration of SMS 201-995 [42] and octreotide (both at 100 µg/8 hours) rapidly reduced fistula output regardless of the fistula site or pretreatment output and achieved spontaneous closure in 77% of patients, within 14 days [43] (mean treatment duration, 5.8 days). [42] The final closure rate was the same for patients with high- or low-volume output fistulae. Fistula output was not a reliable predictor of fistula closure. Serum albumin levels below 3 g/dL and a history of chemotherapy or radiation had a negative influence on fistula closure.

Nonoperative Management

Endoscopic obliteration with fibrin sealant has been used with varied success in patients with upper gastrointestinal tract fistulae that are small-caliber, straight fistulae of relatively short duration with little or no associated infection. [44] Permanent occlusion is not always achieved, but repeat endoscopic occlusion can be attempted with little risk to the patient. Fibrin sealants stimulate fibroplasia, unlike other compounds, such as the tissue adhesives prolamine or *N*-butyl-2-cyanoacrylate (Histoacryl), which induce a foreign-body reaction. Based on recent reports, large fistulae and fistulae associated with radiation injury or neoplasia respond poorly to this technique.

Operative Management

Despite the development of parenteral nutrition, innovative pharmacological or hormonal therapies, and interventional radiographic techniques, about 20% to 30% of patients with gastrointestinal fistulae require operative closure, usually combined with treatment of associated conditions (e.g., bowel obstruction, foreign body, cancer, damaged bowel). Any experienced surgeon knows these corrective operations can be quite formidable, with high morbidity for the patient. One of the keys to successful fistula treatment is individualization of care. The clinical course of patients with gastrointestinal fistulae tends to be protracted, but continued improvement and eventual resolution can be anticipated if serious management errors are avoided. [45]

The surgical management of gastrointestinal fistulae has changed dramatically since the pre-TPN era, when heroic operations were often necessary to close fistulae and establish gastrointestinal continuity. Adherence to the principles of nonoperative care has been associated with a decreased need for surgical correction. Now, 50% to 80% of simple (single) external fistulae close spontaneously within 4 to 6 weeks. [38], [46] Complex or multiple fistulae occurring within an eviscerated wound are associated with increased mortality and morbidity and invariably require surgical correction. The optimal timing of surgical intervention in these patients must be individualized, but delayed reconstruction is often advisable, and a staged, multidisciplinary approach may be necessary. Despite the complexity of these problems, eventual closure can be achieved in most patients. [47] Many patients require extensive mobilization of skin flaps and the use of skin grafts to close large abdominal wall defects. The optimal timing of reoperation in complex fistula patients is undefined, but delays of 4 to 6 months may be advisable to allow for resolution of intra-abdominal inflammation and adhesions. As inflammatory processes resolve, the abdominal wall generally becomes softer and more compliant.

Gastric Fistulae

Gastric fistulae are uncommon, constituting fewer than 15% of all gastrointestinal fistulae. [48] They may develop after stomach surgery for benign peptic ulcer disease or malignancy resulting from dehiscence of a surgical anastomosis, or they may be caused by inadvertent injury to an otherwise normal segment of stomach wall after splenectomy, surgery for morbid obesity, or highly selective vagotomy. The first indication of a gastric fistula is usually the development of a subphrenic or lesser-space abscess. Diagnosis can be made by oral water-soluble contrast study or CT examination. Urgent laparotomy is warranted in patients with free dye extravasation and signs of generalized peritonitis, but percutaneous CT-directed catheter drainage may be feasible in patients with localized, perigastric fluid collections. The bacteriology of gastric fistulae includes anaerobic bacteria from the oropharynx and fungi, which commonly are identified in conditions associated with hypochlorhydria or malignancy.

The reported success rate for nonoperative treatment of gastric fistulae ranges from 43% to 100%, but there are few reliable criteria that predict success. [45] Radiologic positioning of a nasoenteric feeding tube beyond the fistula site into the distal duodenum affords access for enteral nutrition and avoids the need for TPN in most patients. Definitive reoperation should be delayed for at least 6 to 8 weeks after diagnosis and initial drainage. Surgical options include debridement and two-layer closure of the stomach wall defect or the use of a Roux-en-Y serosal patch or anastomosis. [49] Most gastric fistulae can be closed successfully (about 90%), but the success rate varies with the underlying condition and whether the fistula is simple or complex (e.g., involves other organs, such as the colon or pancreas). [50]

Pancreatic Fistulae

Pancreatic fistulae develop as complications of severe pancreatitis, penetrating or blunt abdominal trauma, or surgery directly on or around the pancreas. The major consequences of pancreatic fistula are metabolic, including bicarbonate loss with resulting acidosis and malabsorption caused by a loss of digestive enzymes. Diversion of alkaline pancreatic secretions from the duodenum also may predispose to mucosal ulceration and warrants treatment with H_2-receptor antagonists or proton pump inhibitors. Additional medical treatment includes pancreatic enzyme supplementation and octreotide acetate to decrease fistula losses. Pancreatic fistulae that require operation are uncommon, especially if there is no evidence of proximal pancreatic duct obstruction or malignancy, but closure may be protracted if the fistula tract is tortuous and associated with a residual abscess cavity. [51]

Endoscopic retrograde cholangiopancreatography is used to identify variations in duct anatomy or duct obstruction that would affect closure. In selected cases, placement of a pancreatic duct endoprosthesis may improve ductal drainage and expedite fistula closure. [52], [53] Pancreatic endoprostheses have been used successfully to treat a variety of chronic inflammatory conditions, with an estimated complication rate of about 20% and rare procedure-related deaths. The major complications are related to obstruction or migration of the stent or erosion of the duodenal wall by a malpositioned endoprosthesis. Additional diagnostic studies, including a CT scan and a fistulogram, should be obtained to detect pathology that might alter management. Nonoperative therapy for pancreatic fistulae is generally successful, and only 10% to 30% of patients ultimately require reoperation. Interestingly, fistula output has not proved to be a reliable predictor of spontaneous fistula closure.

The surgical options for managing a pancreatic fistula include internal drainage of the fistula into a defunctionalized Roux-en-Y limb of jejunum or pancreatic resection. Resection is appropriate for a fistula arising from the pancreatic tail and carries little risk for endocrine and exocrine dysfunction. In contrast, resection of a pancreatic head fistula (Whipple operation) is rarely indicated. The perioperative use of octreotide acetate may decrease the risk for fistula recurrence. Despite the complexity of these problems, reoperative success rates of 85% or greater have been reported from various institutions. [54], [55]

Duodenal Fistulae

Duodenal fistulae usually arise after gastric surgery for peptic ulcer disease or malignancy. The mortality rate of duodenal fistulae remains high (10% to 35%), with uncontrolled sepsis accounting for most deaths. [41] Unlike other gastrointestinal fistulae, early reoperation to establish adequate drainage and abort septic complications should be considered a high priority in duodenal fistula patients.

There are two types of duodenal fistulae. End fistulae result from dehiscence of the duodenal stump after distal gastrectomy and Billroth II reconstruction. The incidence of this complication in postgastrectomy patients ranges from 1.5% to 5%. [56] Lateral fistulae develop after blunt or penetrating trauma or result from inadvertent duodenal wall injury after operations in the right upper quadrant involving the colon, kidney, or biliary tract. Although uncommon, duodenal perforation also can occur after endoscopic interventions for biliary disease, including papillotomy and retrograde stone extraction.

The combined use of TPN, nasogastric suction, proton pump inhibitors, and octreotide acetate markedly diminishes fistula output and facilitates management. Early attempts at definitive reoperation should be resisted because the surrounding inflammatory response will jeopardize a successful result. The reported rates of spontaneous duodenal fistula closure range from 40% to 73%. [45]

Definitive reoperation should be considered after 6 to 8 weeks of conservative therapy. A contrast study of the fistula tract and the distal bowel should be obtained to detect unsuspected obstruction. For simple fistulae, a Roux-en-Y serosal patch technique achieves excellent results. [57] For large defects or dehisced duodenal

stumps, the end of the Roux limb can be anastomosed to the freshened end of the defect. [58] Primary repair of the defect is generally unsuccessful, and resection with primary anastomosis is unnecessary and hazardous, especially for defects located close to the ampulla of Vater.

CHAPTER 123

B. Mark Evers

DISEASES OF THE PERITONEUM, RETROPERITONEUM, MESENTERY, AND OMENTUM

PERITONEUM

Embryology, Anatomy, and Physiology

The peritoneum is the mesothelial lining of the peritoneal cavity and its contained viscera. Embryologically, it develops from the primitive coelom, which is formed by a splitting of the lateral mesoderm into somatic and splanchnic layers. [1] The parietal peritoneum, derived from the somatic layer, lines the abdominal cavity, diaphragm, and pelvis. The visceral peritoneum, from the splanchnic layer, covers the intraperitoneal organs and forms the mesenteries by which they are suspended.

The peritoneum and mesentery are supplied mainly by the splanchnic blood vessels and, to a lesser extent, by branches of the lower intercostal, lumbar, and iliac arteries. Differences arise in the innervation of the visceral and parietal peritoneum, which lead to different perceptions of painful stimuli. The visceral peritoneum receives afferent innervation from the autonomic nervous system and responds primarily to traction and pressure; painful stimuli are perceived as a poorly localized, dull pain. In contrast, the parietal peritoneum is innervated by both somatic and visceral afferent nerves; noxious stimuli are perceived as a localized, sharp pain with rebound tenderness.

The peritoneum, with a total surface area of about 2 m^2, serves as a bidirectional dialysis membrane through which the passage of both high- and low-molecular-weight solutes is accomplished predominantly by simple passive diffusion. [2], [3] Factors that can alter absorption include intra-abdominal pressure, temperature, pH, increased portal pressure, lymphatic blockade, and scarring of the peritoneum. [4], [5] The peritoneum contains a complex multileveled defense system that provides an innate immune system to protect against inflammatory processes. [6], [7] This system consists mainly of mechanical clearance of the peritoneal cavity; sequestration mechanisms, such as fibrin trapping of bacteria activation of complement, particularly C3a and C5a, which stimulate neutrophil chemotaxis; and the bacteria-killing actions of polymorphonuclear neutrophils and macrophages. The disease processes of the peritoneum discussed in this section include inflammation of the peritoneum (i.e., peritonitis), primary mesothelioma, and pseudomyxoma peritonei.

Peritonitis

Peritonitis involves a local or generalized inflammation of the parietal and visceral peritoneum. With the development of broader-spectrum antibiotics, newer anesthetic techniques, and modern preoperative and postoperative monitoring in the intensive care unit, the mortality from peritonitis has been greatly reduced; however, despite these advances, peritonitis remains a formidable challenge confronting physicians.

Peritonitis can be classified as either *primary* or *secondary*. Primary peritonitis is less common and involves a spontaneous infection of preexisting ascites in the absence of any obvious intra-abdominal source. [8], [9] The spectrum of bacteria causing this syndrome and the patient population primarily affected have changed. Spontaneous bacterial peritonitis is now more common in adults than in children and shows no differential gender incidence. The group most commonly affected, formerly children with nephrosis, is now adults with cirrhosis. Whereas gram-positive organisms formerly caused most of these infections, gram-negative enteric bacteria now account for 60% to 80% of organisms in ascitic fluid cultures, with *Escherichia coli* and *Klebsiella pneumoniae* the most common species. Primary peritonitis is discussed in Chapter 46.

Secondary peritonitis is caused by diseases of or injury to the intra-abdominal organs. Acute suppurative peritonitis, granulomatous peritonitis, and chemical (aseptic) peritonitis belong to this category and are discussed in this section.

Acute Suppurative Peritonitis

Etiology. Spillage of intestinal contents into the peritoneal cavity as a result of primary intra-abdominal disease (e.g., perforated peptic ulcer, appendicitis, diverticulitis, perforated carcinoma), penetrating trauma, or iatrogenic perforation after instrumentation or radiologic procedures is the usual cause of acute suppurative peritonitis. [10], [11]

Clinical manifestations. Abdominal pain, which may be sudden in onset if associated with a perforated viscus, is the predominant symptom. [12] Characteristically, patients with peritonitis lie supine with knees flexed and with frequent and limited intercostal respirations. Examination of the abdomen of a patient with generalized peritonitis reveals distention and bowel sounds that are either hypoactive or absent. Of the various physical findings of peritonitis, tenderness and muscle guarding are the most important. Tenderness is often maximal over the organ in which the process originated; however, as the inflammation spreads, tenderness may be present over the entire extent of the peritoneum. Rebound tenderness, defined as the sudden and severe pain produced with the release of the hand after deep abdominal palpation, is often described as a useful adjunct in the diagnosis of the acute abdomen. This test, however, elicits no more information than that obtained from a careful and gentle examination of the abdomen and, furthermore, may cause unexpected and undue pain to the patient. Symptoms associated with acute suppurative peritonitis include anorexia, nausea that is often accompanied by vomiting, fever (38 to 40°C), and signs of hypovolemia (e.g., tachycardia, dry mucous membranes, hypotension). Typical diagnostic findings in patients with acute peritonitis include leukocytosis, often with an increased number of bands in the differential count. Roentgenographic findings are usually nonspecific, with evidence of a paralytic ileus of both the small bowel and colon in some patients. Free air under the diaphragm may be seen in an upright chest radiograph if a ruptured viscus is the cause (Fig. 123-1). Generally, the diagnosis of acute suppurative peritonitis is based on clinical manifestations and a thorough physical examination; laboratory and radiologic procedures serve mainly a confirmatory role.

FIGURE 123-1. Upright chest film demonstrating free air under both diaphragms after perforation of a duodenal ulcer. (Courtesy of Charles J. Fagan, M.D., Galveston, TX.)

Clinical course and complications. Usually, suppurative peritonitis has an abrupt onset and a relatively short course with a rapid progression. Mortality results from fluid shifts and systemic endotoxin, which may cause hypovolemia and septic shock. Early diagnosis with prompt surgical intervention and aggressive preoperative and postoperative management is essential to reduce the morbidity and mortality from multiple organ system failure resulting from untreated peritonitis. [13], [14], [15] and [16]

Treatment. The hallmarks of treatment include resuscitation with intravenous fluids to restore normal physiology, broad-spectrum antibiotics, and operative management to control the source of peritoneal contamination and irrigate the peritoneal cavity (Table 123-1).

Restore normal physiology
Fluid resuscitation
Correct electrolyte imbalances
Supplemental O_2
Monitoring (e.g., vital signs, urine output, central venous pressure, pulmonary capillary wedge pressure)
Broad-spectrum antibiotics
Operative intervention
Control source of infection
Irrigate peritoneal cavity
Planned reoperations if source of infection not controlled
Investigational adjuvant therapies
Immunostimulation (e.g., administration of biologic response modifiers, vaccination)
Immunorepletion (e.g., administration of antiendotoxin antibody)
Immunoabrogation (e.g., cytokine antagonism, inhibition of prostaglandin synthesis)

TABLE 123-1 Treatment of Acute Suppurative Peritonitis

Resuscitation involves aggressive administration of isotonic crystalloid fluids (e.g., Ringer lactate) to correct hypovolemia and electrolyte imbalances. Careful monitoring of the response to rapid fluid resuscitation is necessary, particularly if large fluid volumes are required or the patient has impaired cardiac reserve. Monitoring usually entails frequent assessment of vital signs, hourly measurement of urine output, and frequent determination of central venous pressure or, preferably, placement of a Swan-Ganz catheter for pulmonary capillary wedge pressure and pulmonary artery pressure determinations. Oxygen may be administered to overcome the mild hypoxemia that is commonly present, and nasogastric intubation is required to decompress the stomach. Antibiotics play an important, albeit adjuvant, role in the management of patients with peritonitis. To be effective in the treatment of peritonitis, antibiotic therapy must be initiated before and continued during and after surgical therapy. In addition, broad-spectrum antimicrobial therapy should be directed toward both aerobic and anaerobic pathogens. An aminoglycoside (e.g., gentamicin, tobramycin, amikacin), in combination with either clindamycin or metronidazole, provides coverage for most aerobic and anaerobic organisms encountered in the gastrointestinal tract. [17], [18], [19] and [20] Because of concerns about toxic effects, most notably nephrotoxicity, third-generation cephalosporins, newer broad-spectrum penicillins, and a new class of ß-lactam antibiotics, called *carbapenems,* are being evaluated as single agents for the treatment of bacterial peritonitis. Prospective randomized clinical trials indicate that these single agents may be as effective as the combination of an aminoglycoside and clindamycin. [21], [22] Expeditious surgical intervention remains the mainstay of treatment. [23] After an adequate period to ensure resuscitation, laparotomy should be performed to irrigate the peritoneal cavity copiously and to repair the rupture. Aerobic and anaerobic cultures should be obtained to ensure appropriate antibiotic coverage. If the source of infection is not eliminated, the debridement is incomplete, or definitive abdominal closure cannot be accomplished, staged laparotomies may be required for re-debridement, removal of abdominal packs, and repeat irrigation until the source of infection is controlled and abdominal closure obtained. [18] In this situation, the placement of a large abdominal zipper can greatly facilitate abdominal opening and closing. Other procedures that have been described, but found not beneficial, include continuous postoperative irrigation with Tenckhoff catheters and radical peritoneal debridement. Recently, laparoscopy has been used as both a diagnostic and therapeutic modality in selected patients with peritonitis. [24] The future role and possible advantages of laparoscopy compared with a formal laparotomy remain to be defined. Novel agents directed at immunomodulation are under investigation and may become clinically useful in the treatment of sepsis. One investigational therapy attempted to neutralize the deleterious effects of lipopolysaccharides (LPS) released from the bacterial wall using either monoclonal or polyclonal antibodies directed to different regions of the LPS molecule. LPS, one of the most potent bacterial toxins, is an important trigger of the cytokine cascade. The acute exaggerated release of cytokines (e.g., tumor necrosis factor, interleukins, interferons) may produce many of the hemodynamic manifestations of septic shock; chronic production leads to tissue wasting and cachexia. Two anti-LPS monoclonal antibodies are being studied: HA-1A, a human monoclonal antibody directed against the lipid A domain of LPS; and E5, a murine monoclonal immunoglobulin M antibody. [25], [26] Initial prospective randomized trials suggest some efficacy with this treatment. Other areas of active research include strategies to neutralize the effects of cytokines using either neutralizing antibodies or specific cytokine receptor antagonists. [27], [28] A receptor antagonist to interleukin-1 (IL-1ra) has been developed and has proved useful in experimental models of shock and cachexia. [29], [30] Finally, responses elicited by cytokines appear to be mediated by secondary agents (e.g., eicosanoids, nitric oxide) acting at the effector sites. A competitive inhibitor of nitric oxide, N^G-methyl-L-arginine, protected against the hypotensive effects of tumor necrosis factor in a canine model, which suggests that the effect of this cytokine on hemodynamic stability may be mediated through nitric oxide and further suggests a potential clinical use of nitric oxide inhibitors in the treatment of sepsis. [31]

Granulomatous Peritonitis

Etiology. Granulomatous peritonitis is a disease process characterized by peritoneal inflammation that is associated with formation of granulomata and an increased incidence of adhesions. The disease most commonly associated with granulomatous peritonitis is tuberculosis. [32], [33] Other, less common causes include fungal (e.g., *Candida* species, histoplasma), amebic, and parasitic infections. [34], [35] and [36] Iatrogenic causes of granulomatous peritonitis also occur, usually related to the presence of glove lubricants (e.g., talc, cornstarch) or cellulose fibers from gauze, surgical drapes, or gowns within the peritoneum. [37]

Tuberculous Peritonitis

Epidemiology. After years of a decreasing incidence of tuberculosis in the United States, there has been a general reemergence of this disease secondary to an increase in the cases of acquired immunodeficiency syndrome (AIDS) and an increase in the number of immigrants. [38], [39], [40], [41], [42] and [43] Since 1985, cases of tuberculosis have increased 18% nationwide, with the highest increases occurring in certain highly populated areas of the country. Particularly disturbing is the recent appearance of multidrug-resistant strains of tuberculosis. [43], [44] and [45] In addition to patients with AIDS, other groups at high risk include poorly nourished, debilitated patients and those with cirrhosis.

Etiology. Tuberculous peritonitis is a form of abdominal tuberculosis that can involve the omentum, intestinal tract, liver, spleen, or female genital tract in addition to the parietal and visceral peritoneum. The overall incidence of abdominal tuberculosis in the United States is about 0.5% to 1% of all cases of tuberculosis. [32], [33] Tuberculous peritonitis usually is associated with a primary focus of tuberculosis elsewhere. This primary focus is usually the lung; however, only about one third of cases have clinical or radiographic evidence of pulmonary tuberculosis. The pathologic organism, *Mycobacterium tuberculosis,* can gain entry to the peritoneal cavity by one of three mechanisms: transmurally from diseased bowel, from tuberculous salpingitis, or, more commonly, by hematogenous spread from a pulmonary focus. [32], [33]

Clinical manifestations. Generally, the onset is insidious, with more than 70% of patients having had symptoms for more than 4 months before definitive diagnosis. The most common symptoms are constitutional and include fever, anorexia, weakness, malaise, and weight loss. Abdominal distention caused either by ascites or by partial obstruction may be present. On examination, the abdomen is diffusely tender in most patients; however, the classic doughy abdomen is rarely found. Tuberculous peritonitis should be suspected in high-risk or immunocompromised patients with ascites, fever, unexplained generalized symptoms, and diffuse abdominal pain or tenderness. [32], [33]

Differential diagnosis and diagnostic studies. Routine laboratory and radiographic studies are rarely diagnostic. A normal leukocyte count is present in most

patients, and anemia is found only occasionally. Tuberculin skin tests are usually positive in patients with tuberculous peritonitis; however, a negative result is of no help in excluding the disease. Chest radiographs are abnormal in 80% of patients and include findings of pleural effusions or pulmonary infiltrates. Radiographs of the abdomen are seldom of benefit; however, a computed tomography (CT) scan may be useful in identifying thickened bowel and ascites (Fig. 123-2).

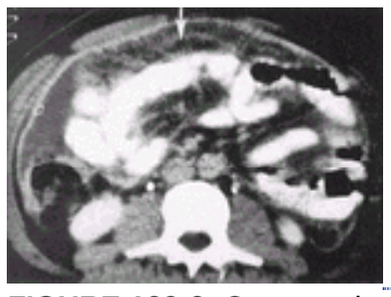

FIGURE 123-2. Computed tomography scan demonstrating ascites (*open arrow*) and small bowel thickening (*closed arrow*) in a patient with tuberculous peritonitis. (Courtesy of Charles J. Fagan, M.D., Galveston, TX.)

Examination of the peritoneal fluid may prove useful (see Chapter 46). In patients with tuberculous peritonitis, the protein content characteristically exceeds 3 g/dL, and glucose concentration is below 30 mg/dL in more than 80%. Most patients have a leukocyte count higher than 250 cells/mm ^{3} and a relative lymphocytic pleocytosis. Acid-fast stains are rarely positive unless at least 1 L of ascitic fluid is obtained, concentrated by centrifugation, and then examined. To compound the diagnostic problem, bacterial cultures of *M tuberculosis* often require 4 to 6 weeks of incubation. For these reasons, much attention has been given to the development of a rapid diagnostic test for tuberculosis. The most promising approach involves amplification and detection using the polymerase chain reaction procedure. Although not in widespread use, this procedure requires about 24 to 48 hours and can detect as few as 10 to 100 bacilli in a sample. [46], [47] The diagnosis of tuberculous peritonitis often is suggested by findings at laparoscopy or laparotomy. Tuberculous peritonitis is characterized by stalactite-like fibrinous masses from the parietal peritoneum; in addition, the peritoneum may be studded with small granulomata. The differential diagnosis of tuberculous peritonitis is variable, depending on the acuteness of the symptoms. In patients with a prolonged history, tuberculous peritonitis most commonly is confused with Crohn's disease or carcinoma. In patients presenting acutely, the differential diagnosis must include such entities as acute appendicitis, cholecystitis, perforated ulcer, and salpingitis. In summary, the diagnosis of tuberculous peritonitis is often difficult to make and requires an initial suspicion based on the clinical presentation (i.e., fever, anorexia, and abdominal pain) in combination with findings of a nonexudative ascites. It is crucial that a suspected diagnosis be confirmed by open or laparoscopy-assisted biopsy before committing the patient to a long-term treatment regimen with multiagent therapy.

Clinical course and therapy. Before the advent of chemotherapy, the mortality rate from tuberculous peritonitis was as high as 60%; now the disease is, for the most part, readily curable with the available agents. Therapy with isoniazid in combination with one or two additional drugs for 18 to 24 months is the treatment of choice. Although not proven experimentally, corticosteroids for 2 to 3 months may be beneficial in preventing the formation of dense fibrous adhesions, which could lead to bowel obstruction. The most worrisome feature of the resurgence of tuberculosis has been the recent outbreaks of multidrug-resistant isolates that often fail to respond to both isoniazid and rifampicin, the two cornerstone antituberculosis drugs. [38], [39], [40], [41], [42], [43], [44] and [45]

Chemical (Aseptic) Peritonitis

Etiology. Peritoneal inflammation can result from spillage of irritant materials that are initially sterile; with time, secondary bacterial contamination occurs with signs and symptoms similar to those of acute suppurative peritonitis. Most of the substances that cause chemical peritonitis are capable of acting as adjuvants to promote the growth of bacterial contaminants. These agents include bile, usually resulting from open or laparoscopic biliary tract operations without adequate external drainage, from inadvertent injury to the biliary tract, or from external trauma [48], [49] and [50]; urine, from intraperitoneal bladder rupture [51]; and chyle, which occurs secondary to injuries of large lymphatic vessels during operations on retroperitoneal organs. [52] In addition, spillage of barium sulfate, secondary to perforation of the gastrointestinal tract from diagnostic procedures, results in a severe peritoneal irritation, and, in combination with accompanying enteric bacteria, poses a lethal threat to the patient. [53], [54]

Treatment. The same principles that apply to the management of acute suppurative peritonitis also apply to the treatment of chemical peritonitis. Adequate intravenous fluids to replace the peritoneal fluid sequestration and antibiotics are followed by laparotomy to irrigate the abdomen and control the source of the peritoneal contamination.

Peritonitis as a Complication of Chronic Peritoneal Dialysis

Etiology. Continuous ambulatory peritoneal dialysis (CAPD) has gained increasing acceptance as an efficacious and cost-effective alternative to chronic hemodialysis in patients with end-stage renal disease. It is estimated that, in the United States alone, about one fourth of the more than 100,000 dialysis patients use CAPD. Despite its obvious advantages, the most common complication of CAPD is infectious peritonitis resulting from bacterial contamination of the peritoneal cavity. [55], [56] and [57] Even with better patient education regarding sterile techniques and proper cleaning around the catheter site, peritonitis in this group of patients is the major source of morbidity and the largest single cause of patient failure on CAPD. Although the incidence of peritonitis varies with the institution, peritonitis as a complication of CAPD averages 1.4 episodes per patient-year of treatment. [55], [56] and [57]

Epidemiology. The most frequent portals of entry for bacteria in CAPD patients include the exit site of the dialysis catheter and the tunnel through which the catheter traverses the abdominal wall. This usually occurs as a result in a break in aseptic technique with secondary contamination. Other possibilities for contamination include hematogenous or lymphatic dissemination from a septic focus originating from the patient. In contrast to other types of peritonitis, CAPD-related peritonitis usually is caused by a single organism, in most cases by gram-positive cocci (*Staphylococcus epidermidis, Staphylococcus aureus, Streptococcus* and *Enterococcus* organisms). [55], [56], [57], [58] and [59] Gram-negative bacteria account for about 25% of all cases of CAPD peritonitis, with the most common being *E coli* and *Pseudomonas aeruginosa*. The presence of anaerobic organisms or a mixed flora should raise suspicion of an intestinal perforation or other intra-abdominal disease as the cause of peritonitis. Fungal peritonitis is relatively uncommon but remains the most serious type of infective peritonitis in CAPD patients because of treatment difficulties. [60] At least 20 different fungal species have been cultured; however, *Candida albicans* and *Candida tropicalis* remain the most common.

Clinical manifestations. The severity of symptoms is dependent on the infecting organism; however, the signs and symptoms in most patients with CAPD peritonitis are clinically less severe than those in patients with suppurative peritonitis. Some cases may even be asymptomatic and detected only by the presence of a cloudy effluent. The predominant symptom found in patients is a diffuse abdominal pain, usually associated with a low-grade fever and leukocytosis. Other symptoms may include hyperhydration, diarrhea, hypotension, and pressure pain above the catheter tunnel. Characteristically, a turbid dialysis effluent is found in nearly all cases of CAPD peritonitis.

Diagnosis. The diagnosis of CAPD peritonitis is based on both clinical and laboratory findings. [55], [56] and [57], [61] The clinical diagnosis should be based on the presence of two of three criteria: abdominal pain or tenderness, a turbid dialysate containing more than 100 neutrophils/mm ^{3}, and a positive culture from the peritoneal fluid. Even if the patient's history and examination are consistent with the diagnosis of peritonitis, it is essential that the dialysate be evaluated to confirm the diagnosis and to identify the causative organisms. In some centers, the use of bacteria-concentrating techniques yielded positive cultures in more than 90% of cases.

Therapy and clinical course. Of patients with CAPD peritonitis, 70% to 80% can be treated successfully on an outpatient basis without hospitalization or interruption of dialysis. [55], [56], [57], [58], [59] and [60], [62], [63] CAPD peritonitis is treated most effectively by intraperitoneal administration of antibiotics. The initial choice of antibiotics should be broad enough to cover the most common pathogens causing CAPD peritonitis and then changed according to susceptibility testing. Vancomycin, cephalosporins, and aminoglycosides are the agents most commonly used to treat CAPD-associated peritonitis. In addition to antibiotics, heparin also is added to the dialysis bag to reduce fibrin formation and, thereby, the incidence of postinfective adhesions. Indications for catheter removal include persistence of peritonitis after 4 to 5 days of treatment and the presence of fungal or tuberculous peritonitis, fecal peritonitis, or severe skin infection at the catheter site.

Peritonitis in the Immunocompromised Host

Etiology and diagnosis. The AIDS epidemic and increasing use of immunosuppressive therapy for cancer, autoimmune disease, and multiple organ transplantation procedures have combined to increase greatly the incidence of opportunistic infections of the gastrointestinal tract. [64], [65] The differential diagnosis of abdominal pain in AIDS is quite broad and involves both AIDS-related and non–AIDS-related disorders [64], [65] and [66] (see Chapter 124). Perforation of the small bowel or colon secondary to cytomegalovirus enteritis is a frequent cause of peritonitis in AIDS patients. [67] Other organisms reported to cause peritonitis in these patients include *Mycobacterium avium–intracellulare, M tuberculosis, Cryptococcus neoformans*, *Strongyloides* organisms, and *Leishmania* organisms. [64], [65], [66], [67], [68], [69] and [70]

Clinical manifestations and treatment. Immunocompromised patients with peritonitis usually present with severe abdominal pain as the predominant symptom, like patients with suppurative peritonitis. Principles of management include emergent laparotomy and resection of the involved portion of bowel, intravenous fluid resuscitation, and broad-spectrum antibiotics.

Primary Mesothelioma

Incidence and Etiology Primary mesotheliomas, arising from mesenchymal and epithelial components, are uncommon. The reported incidence in the United States

is only 2.2 cases per million population; however, studies suggest that the incidence is increasing throughout the world and especially in industrialized countries. [71], [72], [73] and [74] Only 20% to 40% of mesotheliomas occur in the peritoneum, with most of these tumors originating from the pleura. Malignant mesothelioma is linked to exposure to asbestos, and there is a strong association with occupations that require workers to handle or work in proximity to asbestos, such as those in the textile, insulation, building, demolition, and shipyard industries. [73], [74], [75], [76] and [77] There is a latency period of 20 to 40 years from significant asbestos exposure to development of mesothelioma; two thirds of the patients are diagnosed at 45 to 64 years of age, and there appears to be a male predominance. Crocidolite is considered the most oncogenic type of asbestos, whereas the oncogenic potential of chrysotile is still debated. Although asbestos is the predominant cause of this disease, other etiologic agents may be associated with primary mesothelioma, including use of the angiographic contrast material Thorotrast (thorium dioxide), radiation exposure, and recurrent peritonitis.

Clinical Manifestations The clinical presentation is nonspecific, with the predominant complaint being abdominal pain present in the epigastrium or right upper quadrant. Other symptoms include nausea and vomiting, malaise, fever, weight loss, diarrhea, and anemia. Ascites is the most common physical finding and occurs in 90% of patients. Peritoneal mesotheliomas can produce and secrete a variety of ectopic hormones, including antidiuretic hormone, growth hormone, and insulin-like factors, which can produce associated paraneoplastic syndromes with symptoms of hypoglycemia, hyponatremia, thrombocytosis, and increased production of fibrin-degradation products. [71], [72], [73] and [74] Interestingly, peritoneal mesothelioma has been described in association with other synchronous neoplasms such as colorectal cancer.

Differential Diagnosis and Diagnostic Studies Malignant mesothelioma is a difficult malignancy to diagnose early. [71], [72], [73] and [74], [78] Mesotheliomas are generally firm, white tumors that present as individual nodules studding the peritoneal surface and tend to spread over the surface of the intra-abdominal organs, eventually encasing the viscera. Ultrasound and CT studies can suggest the diagnosis, demonstrate the extent of tumor, and also aid in directed biopsy of suspicious lesions (Fig. 123-3); however, in most cases, the diagnosis is confirmed after diagnostic laparoscopy or laparotomy.

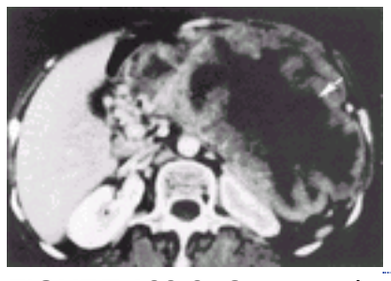

FIGURE 123-3. Computed tomography scan demonstrating diffuse mesenteric and peritoneal involvement of a soft tissue mass (*arrow*) causing displacement of intra-abdominal organs in a patient with peritoneal mesothelioma. (Courtesy of Charles J. Fagan, M.D., Galveston, TX.)

Microscopic and immunohistochemical studies are available to aid in the diagnosis. [79], [80] Immunohistochemistry is useful for two reasons: (1) to determine whether the mesothelial cells present are benign or malignant, and (2) to distinguish mesothelioma from an adenocarcinoma. The typical analysis of a suspected mesothelioma should include electron microscopy, periodic acid-Schiff (PAS) stain, Alcian blue stain to detect hyaluronic acid, and an anticarcinoembryonic antigen (anti-CEA) antibody stain. Ultrastructural features on electron microscopy include long, slender microvilli and diffuse cytoplasmic or perinuclear distribution of tonofilaments. Mesotheliomas lack intracellular mucin on PAS stains, should produce negative results on anti-CEA antibody stain, and often stain positively for hyaluronic acid. In contrast, adenocarcinomas often stain positively for mucin and CEA and do not contain hyaluronic acid. Well-characterized monoclonal and polyclonal antibodies hold great promise for improving the diagnostic accuracy. [81] Recent studies indicate that calretinin, a member of the family of calcium-binding proteins, and cytokeratin 5/6 stains appear to be the most sensitive and specific positive members for distinguishing between malignant epithelial mesotheliomas (positive staining) and metastatic adenocarcinomas (negative staining). [80] Among the antibodies considered negative members for mesothelioma, MOC-31, CEA, and BG-8 appear to be the best diagnostic discriminators. Other useful negative markers include B72.3, Leu-M1, Ber-EP4, and thrombomodulin. Immunostaining for N-cadherin and E-cadherin appears to be promising in the diagnosis of mesothelioma. Another useful marker is epithelial membrane antigen, which has been shown to be of value in distinguishing between benign and malignant mesotheliomas. Additional molecular studies that may serve as useful adjuncts to the diagnosis include the identification of high levels of the platelet-derived growth factor (PDGF) in malignant mesotheliomas. [81] Less common primary peritoneal neoplasms that should be included in the differential diagnosis include benign papillary mesotheliomas, benign fibrous mesotheliomas, adenomatoid tumors, and multicystic peritoneal mesotheliomas. [73], [74]

Genetic Factors With the advances in molecular techniques and the ability to identify genetic abnormalities in various tumors, studies have focused specifically on potential genetic abnormalities in mesotheliomas. [71], [72], [75], [76] and [77], [82], [83] The accumulation of numerous chromosomal deletions in a number of mesotheliomas suggests a multistep process of tumorigenesis, characterized by the loss or inactivation of various tumor suppressor genes. Genetic abnormalities that have been identified include frequent deletions of specific sites within chromosome arms 1p, 3p, 6q, 9p, 13q, 15q, and 22q. [82], [83] Loss or mutation of the *p16 Ink4a* tumor suppressor gene at 9p21 has been noted with high frequency (about 85%) and may contribute to the pathogenesis of these tumors. In addition, another recurrent theme of genetic abnormalities in mesotheliomas is mutation or allelic loss of neurofibromatosis type 2 (*NF2*), a tumor suppressor gene, at 22q12. Recent studies have identified the presence and expression of simian virus 40 (SV40) in a number of mesotheliomas. [84] SV40 large T antigen has been shown to inactivate the tumor suppressor gene products *Rb* and *p53,* suggesting the possibility that asbestos and SV40 could act as co-carcinogens in mesothelioma. Furthermore, circulating antibodies to SV40 antigens have been described, raising the possibility that the immune system may be modulated to treat patients with mesothelioma. Finally, expression of growth factors, including PDGF-A and -B, insulin-like growth factors I and II, and transforming growth factor-a and -ß, have been identified in these tumors. A possible paracrine and autocrine role for PDGF has been postulated because the PDGF receptor is expressed in a number of mesotheliomas. Continued studies are required to determine whether these genetic abnormalities play a role in the pathogenesis and progression of the mesothelioma tumors and may serve as potential targets for novel treatment strategies.

Treatment and Prognosis Therapy for mesothelioma has proved disappointing, mainly as a result of the advanced stage of the disease at diagnosis and the local aggressiveness of the tumor. [85], [86] Rarely can surgery be performed for a curative resection; rather, laparotomy serves to establish a tissue diagnosis and to perform palliative procedures such as bypassing obstructive lesions or tumor debulking. Chemotherapy offers little improvement in overall patient survival. Doxorubicin, alone or in combination with other antineoplastic agents, achieves the best, albeit minimal, response. Studies suggest that surgical cytoreduction and multimodality therapy, especially with paclitaxel and cisplatin chemotherapy, may confer a survival advantage. In addition, there may be an advantage in using hyperthermic intraperitoneal infusion of the chemotherapeutic agent in patients with primary peritoneal mesotheliomas. [85], [87] Radiation therapy has been used in combination with intracavitary instillation of various chemotherapeutic agents or with systemic chemotherapy, but with only minimal success. Future directions for the management of mesothelioma include the use of interleukin-2, interferon-?, tumor necrosis factor-a, monoclonal antibodies, and cancer vaccines, which may prove beneficial when used in combination with other therapies. The results of recent trials suggest potential benefits of chemo-immunotherapy for the treatment of mesothelioma. Novel treatment strategies currently under investigation include the introduction of the herpes simplex virus thymidine kinase gene into the mesothelioma, so that growth is inhibited after administering ganciclovir, and the transfection of antisense oligonucleotides to the growth factor PDGF-A or -B. [71], [72], [88] Multiple obstacles, including transfection efficiency and proper vector construction, must be overcome before these types of gene therapy protocols will be clinically beneficial. The prognosis for mesothelioma of the peritoneum is poor. Death usually occurs within 12 to 14 months of the diagnosis from progressive gastrointestinal tract obstruction and debility.

Pseudomyxoma Peritonei

Incidence and Etiology Pseudomyxoma peritonei is a rare condition manifested by diffuse, gelatinous implants of the peritoneal cavity and omentum arising from mucinous neoplasms of either the appendix or ovary. The reported incidence of pseudomyxoma peritonei is about 2 in 10,000 laparotomies. Most female patients with pseudomyxoma peritonei have disease in both the appendix and ovary; therefore, there is no general agreement regarding the tissue of origin. Recent applications of immunocytochemistry and genetic analysis by polymerase chain reaction strongly suggest that most cases are due to metastases from appendiceal neoplasms. [89], [90]

Clinical Features and Diagnosis Women between 45 and 55 years of age make up about 75% of patients with pseudomyxoma peritonei. This is usually an unexpected diagnosis made at laparotomy for a preoperative diagnosis of appendicitis or ovarian tumor. Patients can present with an increasing abdominal girth secondary to mucinous ascites or intestinal obstruction, abdominal pain, or a mass in the abdomen. [89], [91], [92] Histologically, pseudomyxoma peritonei is characterized by a benign appearance with simple columnar epithelium containing mucin-filled vacuoles. [93], [94] Certain features noted on ultrasonography or CT scan are characteristic for this disease. Ultrasonographic findings include multiple intraperitoneal multilocular cysts and ascitic septation. A characteristic CT finding of pseudomyxoma peritonei is “scalloping” of the hepatic and bowel margins secondary to extrinsic compression by ascitic spaces containing gelatinous material (Fig. 123-4). The role of magnetic resonance imaging (MRI) in diagnosing pseudomyxoma remains to be defined. T2-weighted images accentuate differences between mucinous and fluid ascites; however, a major disadvantage of MRI is the added expense compared with CT scan.

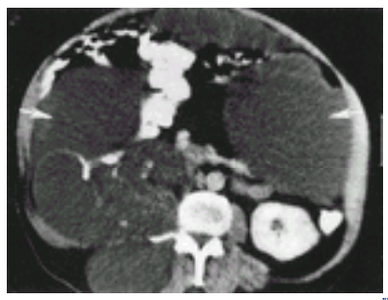

FIGURE 123-4. Computed tomography scan demonstrating large gelatinous masses (*arrows*) in a patient with pseudomyxoma peritonei. (Courtesy of Charles J. Fagan, M.D., Galveston, TX.)

Treatment and Prognosis Pseudomyxoma peritonei is a low-grade malignancy that rarely metastasizes or invades contiguous viscera. The treatment of pseudomyxoma peritonei is primarily surgical, with aggressive debulking of all intra-abdominal tumor and omentectomy. [95], [96] In addition, because of the usual involvement of both the appendix and the ovaries, it is recommended that appendectomy and bilateral oophorectomy be performed in all patients. Recurrence occurs in about 75% of patients; repeat laparotomies are indicated for recurrent disease. Recently, new strategies in the treatment of this disease have included a chemotherapy regimen with surgical treatment. [95], [97], [98] These reports suggest a survival advantage using early postoperative chemotherapy (intraperitoneal or systemic) combined with cytoreductive surgical treatment, compared with repeated surgical procedures in the absence of chemotherapy. Radiation treatment, mucolytic agents, and phototherapy have been described but appear to be of little benefit. [89] Long-term survival is about 54% at 5 years, with death occurring usually as a result of extensive peritoneal disease and intestinal obstruction.

RETROPERITONEUM

The retroperitoneum is the space behind the abdominal cavity extending from the posterior peritoneum and the mesenteries to the spinal column and the psoas, quadratus lumborum, and transversus abdominis muscles. It extends superiorly from the diaphragm and inferiorly to the levator muscles of the pelvis. The retroperitoneum is divided into the anterior compartment, which contains the pancreas, duodenal loop, and ascending and descending colon, and the posterior compartment, which contains the perinephric space with the kidneys, ureters, and adrenal glands and an extensive network of vessels, lymphatics, and neural structures. The space also contains fatty and areolar tissue and connective tissue.

Modern diagnostic techniques, such as ultrasonography, CT scan, MRI, and arteriography, have greatly enhanced our ability to diagnose and treat pathologic processes in the retroperitoneum; however, this region remains elusive. Early clinical manifestations are nonspecific, thus allowing pathologic processes to become relatively advanced before producing symptoms. Retroperitoneal disease processes often present as a mass. (The differential diagnosis of retroperitoneal masses and other disease processes is shown in Table 123-2.) This section specifically discusses retroperitoneal hemorrhage and infections, idiopathic retroperitoneal fibrosis, and primary neoplasms of the retroperitoneal space. In addition to these clinical entities, fluid collections consisting of lymph, gastrointestinal secretions (e.g., duodenal, pancreatic), bile, or urine also may collect in this space, usually secondary to iatrogenic or traumatic injuries. [99], [100], [101] and [102] A CT scan or ultrasound may be a useful diagnostic imaging study; percutaneous drainage with fluid analysis may aid in further establishing the diagnosis and, in certain instances, may be useful in the treatment.

Fluid collections
Lymph
Duodenal succus
Pancreatic juice
Bile
Urine
Hematoma
Spontaneous hemorrhage
Traumatic hemorrhage
Fat necrosis
Acute necrotizing pancreatitis
Abscess
Primary
Secondary: extension from abdomen, kidney, vertebra
Neoplasm
Benign
Cyst
Benign soft tissue tumor
Malignant
Sarcoma
Germ cell–derived neoplasm
Lymphoma
Lymph node metastases
Aortic aneurysm
Retroperitoneal fibrosis

TABLE 123-2 Differential Diagnosis of Retroperitoneal Masses and Disease Processes

Retroperitoneal Hemorrhage

The most common etiology for retroperitoneal bleeding and hematoma is secondary to traumatic injuries associated with pelvic or vertebral fractures, avulsion of the vascular pedicle of the kidney, or penetrating injuries. [102], [103], [104], [105] and [106] Other causes for hemorrhage may be secondary to anticoagulation therapy, acute pancreatitis, spontaneous hemorrhage into an adrenal gland or retroperitoneal tumor, ruptured aortic aneurysm, and ruptured ureteral or ovarian veins during pregnancy. In addition, massive retroperitoneal hemorrhage has been associated with femoral vein catheterization and liposuction. [107], [108]

If hemorrhage occurs quickly and in significant amounts, signs of hypovolemic shock may be present. Signs of retroperitoneal hemorrhage that may occur late include pain felt most in the abdomen and back and ecchymosis of the flank (Grey Turner sign). Laboratory examination may demonstrate a low hematocrit. Evaluation of the retroperitoneal hemorrhage may include plain films of the abdomen, which can show obliteration of the psoas shadow. A CT scan may be useful in the stable patient to evaluate the possible etiology and extent of the hemorrhage (Fig. 123-5).

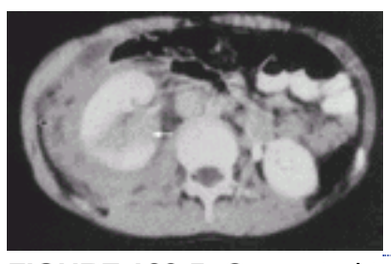

FIGURE 123-5. Computed tomography scan demonstrating a large retroperitoneal hematoma (*open arrow*) due to blunt injury to the kidney (*closed arrow*). (Courtesy of Melvyn H. Schreiber, M.D., Galveston, TX.)

Treatment of retroperitoneal hemorrhage is secondary to the specific etiology. For example, retroperitoneal hemorrhage secondary to a pelvic fracture may be treated by fracture stabilization or arteriography and embolization of the bleeding vessel. Vascular injuries or a ruptured abdominal aortic aneurysm require emergent surgical intervention and control of the ongoing hemorrhage.

Retroperitoneal Infections

Abscesses in the retroperitoneal space are normally secondary to diseases of surrounding abdominal organs, the urinary tract, or the vertebral column. [109], [110], [111] and [112] Most commonly, the abscesses result from perforated diverticular disease or colonic cancer, appendicitis, acute pancreatitis, penetrating duodenal ulcer, or biliary tract disease. A psoas abscess may occur secondary to intra-abdominal or vertebral infections; extension from Crohn's disease, appendicitis, colon diverticulitis, and cancer are the most frequent causes. Primary bacterial infections in the retroperitoneal space can occur but are rare. Except for the Gerota fascia, there are no anatomic boundaries to the retroperitoneal space; therefore, abscesses can be large, extend bilaterally, and present late in their course. As a result, retroperitoneal abscesses may be associated with higher mortality rates.

Clinical manifestations include fever, chills, anorexia, and weakness; pain in the lower back and abdomen, thigh, or flank is present in about 60% of the patients. A palpable mass may be present on physical examination. Leukocytosis is often noted as the most common laboratory abnormality. The CT scan is the most useful test to establish the diagnosis (Fig. 123-6); CT-guided percutaneous needle aspiration of the abscess may allow for bacteriologic examination, so that an appropriate antibiotic treatment regimen can be chosen based on the specific organisms and sensitivities. Depending on the etiology, percutaneous drainage may be effective treatment for some of these collections; surgical drainage is required secondary to inadequate fluid evacuation. Coliform organisms and *S aureus* are the most common organisms encountered. Other organisms can occur rarely and include tuberculosis, which most commonly develops in the urinary tract or spine; opportunistic fungi (e.g., *Candida, Aspergillus, Cryptococcus* organisms) may spread to the retroperitoneum, particularly in patients who are immunocompromised. Actinomycosis or retroperitoneal infections with *Nocardia* organisms can be the result of secondary extension from a primary focus. For example, actinomycosis may be secondary to perforation of the appendix or colon and nocardiosis associated with a pulmonary infection.

Retroperitoneal Fibrosis

Etiology and Epidemiology Retroperitoneal fibrosis is an uncommon disease process characterized by progressive nonspecific inflammation and fibrosis of connective and adipose tissue in the retroperitoneal space. [113], [114], [115] and [116] This process originates just below the level of the aortic bifurcation near the sacral promontory and then spreads throughout the retroperitoneum with extension bilaterally along the aorta and inferior vena cava. Symptoms are the result of gradual compression of the tubular structures in the retroperitoneal space, particularly the ureter. Retroperitoneal fibrosis was first described by the French urologist Albarran in 1905. [113] The initial description of retroperitoneal fibrosis in the English literature is credited to Ormond in 1948. [114] In fact, idiopathic retroperitoneal fibrosis is often referred to as *Ormond disease*. Retroperitoneal fibrosis is relatively uncommon, with an instance of 1 in 200,000. There appears to be an overall male predominance of 2:1 or 3:1, with presentation usually in the fifth and sixth decades of life. The etiology of this disease is, for the most part, not known. A number of factors have been postulated to contribute to this disease process, including extravasation of urine, surgery, and nonspecific gastrointestinal inflammatory diseases, including Crohn's disease; however, most cases of retroperitoneal fibrosis are considered idiopathic (Table 123-3). Various medications have been associated with retroperitoneal fibrosis as a side effect. Methysergide, an antiserotonin drug, is the best described agent in which the occurrence of retroperitoneal fibrosis has been clearly linked. [117] Other drugs implicated in this fibrotic process include ergotamine, pergolide, hydralazine, methyldopa, and, most recently, ß-adrenergic blocking agents such as metoprolol. [118] An immune etiology for retroperitoneal fibrosis has been suggested, particularly because an association with other immune-mediated connective tissue disorders, such as systemic lupus erythematosus, Raynaud disease, systemic vasculitis, and ankylosing spondylitis, has been demonstrated in certain cases. [119] In addition, amelioration of symptoms can occur with corticosteroid treatment. In some patients, retroperitoneal fibrosis can occur secondary to severe retroperitoneal infection (e.g., pancreatitis) or inflammatory aortic aneurysms and in response to neoplasms, most commonly Hodgkin lymphoma, sarcomas, carcinoid tumors, and certain adenocarcinomas. [120], [121]

Primary
Idiopathic
In conjunction with other fibrotic processes (e.g., mediastinal fibrosis, mesenteric fibrosis, sclerosing cholangitis)
Drug-associated (e.g., methysergide, ergotamine, hydralazine, and β-adrenergic drugs)
Paraneoplastic (e.g., sarcoma, Hodgkin disease, carcinoid tumor)
Secondary
Radiotherapy
Retroperitoneal infection
Retroperitoneal fluid collection or hematoma
Inflammatory abdominal aortic aneurysm

TABLE 123-3 Etiologies of Retroperitoneal Fibrosis

Pathology Retroperitoneal fibrosis appears grossly as a woody, white, fibrous plaque that, as it progresses, surrounds the ureters and vascular structures in the retroperitoneum. [115], [116] Early microscopic features include active chronic inflammation occurring with abundant lymphocytes, plasma cells, and macrophages interspersed with fibroblasts and collagen bundles. [115], [116], [122] As the disease progresses, the tissues become relatively acellular with scattered calcifications, an abundant collagen deposition, and fibrous scarring.

Clinical Manifestations The symptoms of retroperitoneal fibrosis are generally nonspecific, the most common symptom being a dull, constant pain localized to the back or flank. [113], [114], [115] and [116] This pain may radiate to the lower abdomen, groin, or anteromedial aspect of the thigh. Other symptoms include anorexia, nausea, diarrhea, fever, and weight loss; patients may present with hypertension. Laboratory abnormalities may include leukocytosis, an elevated erythrocytic sedimentation rate, and elevated alkaline phosphatase levels. As the disease progresses, late complications of retroperitoneal fibrosis occur as the result of encasement and compression of the tubular retroperitoneal structures, most commonly involving the ureters, and eventually leading to azotemia, renal insufficiency, and possible renal failure. Lower extremity edema may occur from compression of lymphatics and venous obstruction. [123] The aorta can be involved, albeit uncommonly, with symptoms consistent with arterial insufficiency (e.g., claudication, rest pain). Rarely, this fibrotic process may involve the duodenum, common bile duct, or colon, resulting in obstruction. [115], [116], [124], [125]

Differential Diagnosis and Diagnostic Studies The differential diagnosis of retroperitoneal fibrosis includes retroperitoneal hemorrhage, primary neoplasms, and metastasis to the retroperitoneum. Imaging studies useful in establishing the diagnosis of retroperitoneal fibrosis include an intravenous pyelogram, in which a triad of classic findings have been described: delayed excretion of contrast material with hydronephrosis, narrowing of the ureters at about the L-4 to L-5 level, and a medial displacement of the ureters [115], [116] (Fig. 123-7). In fact, this medial deviation of the ureters was considered a pathognomonic sign of retroperitoneal fibrosis, in contrast to retroperitoneal neoplasms, in which deviation of the ureters normally occurs laterally. Recent studies, however, indicate that medial deviation is not a constant finding in patients with retroperitoneal fibrosis. The CT scan has emerged as the procedure of choice for the diagnosis and follow-up of patients with retroperitoneal fibrosis. [116], [126] Findings include a periaortic soft tissue mass of variable thickness that envelops the retroperitoneal structures, with obliteration of the fat plane between the mass and adjacent psoas musculature. The MRI also has been used to assess retroperitoneal fibrosis, particularly using T2-weighted images to delineate the stage of the disease more clearly [127], [128] and [129] (Fig. 123-8). The advantages of MRI compared with CT are a more exact anatomic definition because of multiplanar capability and the avoidance of nephrotoxic contrast agents.

Treatment Goals of treatment include establishing the diagnosis, relieving the obstruction (usually involving the urinary tract), and preventing progression of the disease. Medications associated with retroperitoneal fibrosis should be discontinued. Surgical management is directed at ureterolysis for ureteral obstruction with intraperitoneal transposition of the ureters. Other maneuvers described to prevent recurrence of the ureteral obstruction include wrapping the ureters in omental fat or interposing retroperitoneal fat between the ureters and the fibrosis. [130], [131] The use of laparoscopic ureterolysis in selected cases has been described with good results at short-term follow-up. [132] Symptoms caused by venous obstruction are best treated nonoperatively, with elevation and elastic support of the leg eventually resulting in the development of collateral circulation. The medical management of retroperitoneal fibrosis includes corticosteroids, which are effective in the early, active inflammatory stage. Other immunosuppressive drugs, such as azathioprine and cyclophosphamide, also have been used with varying success. [133] A recent case report demonstrated remission of an advanced case of retroperitoneal fibrosis using a combination of prednisone and the new immunosuppressive agent mycophenolate mofetil, a selective inhibitor of T and B lymphocytes. [134] Recent studies suggest that tamoxifen, a nonsteroidal antiestrogen agent, may be effective in regression of the fibrotic process and amelioration of symptoms secondary to increased synthesis and secretion of transforming growth factor-ß, an inhibitory growth factor. [135] In patients with idiopathic retroperitoneal fibrosis without renal compromise and effective ureterolysis, the prognosis is excellent, with long-term success rates exceeding 90%. [115]

Retroperitoneal Neoplasms

Etiology and Pathology Tumors in the retroperitoneal space arise from mesodermal, neuroectodermal, or embryonic remnants, including fat, connective tissue, fascia, muscle, nervous tissue, lymph vessels, and lymph nodes. Malignant tumors are about four times more prevalent than benign neoplasms, with the most common neoplasms being malignant lymphomas or lymphosarcomas. [136], [137] Other malignant neoplasms in this area include other types of sarcomas, such as liposarcoma and leiomyosarcoma. [138], [139] and [140] Of the benign tumors, the most frequent are lipomas. Most patients presenting with primary retroperitoneal tumors are in the fifth or sixth decades of life, although about 15% of these tumors are found in children aged younger than 10 years. In addition to primary tumors of retroperitoneal structures, the retroperitoneum is also a common site for metastasis, primarily lymphatic metastasis from neoplasms of abdominal organs.

Clinical Manifestations Retroperitoneal tumors can grow to a large size before becoming symptomatic. [136], [137] Early symptoms are normally vague or lacking and may include fatigue, weakness, weight loss, abdominal discomfort, and a sense of fullness or abdominal heaviness. Nausea and vomiting and a change in bowel habits may occur with intestinal compression. Swelling of the lower extremities may occur secondary to obstruction of lymphatics or venous return. Larger tumors can cause pain radiating to both thighs as a result of involvement of the lumbar and sacral nerve roots. Rarely, patients may present with hypoglycemia. The most common physical finding is the presence of a nontender abdominal mass.

Differential Diagnosis and Diagnostic Studies Primary retroperitoneal tumors should be differentiated from other masses in this region, including renal lesions, pancreatic cysts and tumors, malignancies of the gastrointestinal tract, ovarian tumors, and cysts of the omentum and mesentery. The CT scan is a useful imaging modality to identify the mass, determine its size and origin, and assess its relationship, proximity, and invasion of surrounding structures [141] (Fig. 123-9). In addition, CT-guided needle biopsy often can provide a histological diagnosis preoperatively. MRI has become increasingly important as a diagnostic tool for retroperitoneal neoplasms. [129], [142] This study provides a better degree of definition between the mass, surrounding muscle groups, and vascular structures compared with CT (Fig. 123-10). Before surgery, angiography provides important information about the vasculature supplying the neoplasm. The main value of barium studies is to delineate primary intestinal malignancies from retroperitoneal tumors.

FIGURE 123-10. Coronal T1-weighted magnetic resonance scan after administration of the contrast medium gadolinium shows a large retroperitoneal sarcoma (*closed arrow*) with displacement of the left psoas muscle laterally (*open arrow*). (Courtesy of Greg Chalchub, M.D., Galveston, TX.)

Treatment Surgical excision offers the greatest prospect for cure and remains the best option for treatment of these retroperitoneal malignancies. [143], [144] Some retroperitoneal tumors are benign and are cured by complete excision. Treatment of malignant tumors involves surgical resection or radiation or a combination of the two modalities. With the exception of lymphomas, chemotherapy appears to offer little to the multimodality management of these tumors. It is important to remember that even though the overall prognosis for malignant retroperitoneal tumors is relatively low, en bloc resection of a primary malignancy can achieve 5-year survival rates of greater than 60%. Furthermore, debulking procedures can provide symptomatic relief and may offer a better response rate to radiation therapy in the postoperative period in patients with tumors that cannot be excised because of size or invasion of surrounding structures. Malignant tumors have a recurrence rate in the range of 30% to 50% over a 3-year period.

MESENTERY AND OMENTUM

During fetal development, the splanchnic mesoderm forms the mesentery covering the developing gut. [1] The greater omentum, which extends from the greater curvature of the stomach caudally to fuse with the transverse colon and mesocolon, develops from the dorsal mesogastrium. The omentum and mesentery are rich in lymphatics and blood vessels and provide a major source of macrophages and lymphocytes to aid in removal of foreign material or infection in the abdominal cavity. The small bowel mesentery contains the lymphatic and vascular network responsible for transporting all of the nutrients absorbed from the small bowel. Primary diseases of the mesentery and omentum are relatively uncommon. This section describes some of the diseases that primarily or prominently involve the omentum, mesentery, or both mesenchymal structures (Table 123-4).

Mesenteric Diseases
Primary mesenteric inflammatory diseases
Mesenteric panniculitis
Retractile mesenteritis
Mesenteric cysts
Embryonic and developmental cysts
Traumatic or acquired cysts
Neoplastic cysts
Infective and degenerative cysts
Mesenteric tumors
Benign tumors
Lipoma
Hemangioma
Leiomyoma
Ganglioneuroma
Malignant tumors
Leiomyosarcoma
Liposarcoma
Rhabdomyosarcoma
Metastatic disease
Mesenteric fibromatosis
Omental Diseases
Mass lesions
Primary tumors and cysts
Metastatic disease
Vascular lesions damaging blood supply
Torsion
Primary
Secondary: hernia, adhesion, tumor
Infarction
Primary
Secondary: torsion, incarceration in hernia

TABLE 123-4 Classification of Mesenteric and Omental Diseases

Mesenteric Panniculitis and Retractile Mesenteritis

Incidence and Etiology Mesenteric panniculitis (also called primary liposclerosis, lipogranuloma, isolated lipodystrophy, and mesenteric Weber-Christian disease) is a nonspecific, rare inflammatory process involving the adipose tissue of the mesentery. [145], [146] This process includes a spectrum of diseases, from inflammatory to fibrotic lesions, which have been called *mesenteric panniculitis* and *retractile mesenteritis,* respectively. Possible etiologies include trauma, autoimmunity, infection, ischemia, previous abdominal surgery, or abdominal malignancy, but in most cases, the precise etiology is not known.
Pathology Gross pathologic findings include a diffusely thickened and rubbery mesentery, usually as a solid mass in the root of the mesentery or as several adherent masses. Microscopic findings include excessive growth of normal fat, with subsequent degeneration, fat necrosis, and xanthogranulomatous inflammation with lipid-laden macrophages, infiltration with histiocytes, lymphocytes, and occasional foreign-body giant cells, leading to fibrotic scarring and calcification. [145]
Clinical Manifestations Patients with mesenteric panniculitis generally present in middle or late adulthood (average age, 53 years). There is a slight male predominance. When symptomatic, patients may present with cramping abdominal pain, which may be local or generalized; weight loss; nausea and vomiting; and low-grade fever. Patients may occasionally present with findings consistent with an acute abdomen. About 60% of patients present with a palpable abdominal mass noted by physical examination; the remainder of patients present with an incidental mass noted at examination or laparotomy. [145], [146] The differential diagnosis includes a wide range of mesenteric pathologies, such as mesenteric lymphoma, fat necrosis, primary or secondary mesenteric tumors, and mesenteric fibromatosis. In certain instances, an abdominal aortic aneurysm may be considered, owing to transmission of aortic pulsations to the anterior abdominal wall. [147] This diagnosis can be suspected by various radiographic studies. Plain radiographic findings include displacement of intestinal segments and extrinsic compression of the bowel. Findings by CT scan include fat density masses arising from the mesentery, surrounding mesenteric vessels, displacing bowel loops without evidence of invasion, a left-sided orientation, a hypodense fatty halo surrounding nodules and vessels, and a hyperattenuated stripe [148] (Fig. 123-11). Ultrasonography has also been successfully used as a diagnostic tool in these patients. [149]

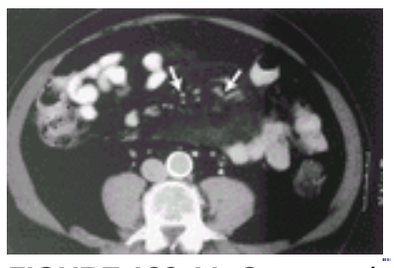

FIGURE 123-11. Computed tomography scan of mesenteric panniculitis demonstrating a fat density mass surrounding mesenteric vessels with a characteristic “fatty halo” surrounding the vessels (*arrows*). (Courtesy of Luis B. Morettin, M.D., Galveston, TX).

Over time, some cases of mesenteric panniculitis progress to retractile mesenteritis characterized by a thickened mesentery that is fibrotic and retracted. There may also be mesenteric pseudocysts from fat necrosis. Rarely, there is involvement of the colonic mesentery, and fewer than 5% of patients have retroperitoneal involvement. Symptoms include continuous abdominal pain, fever, and weight loss. Some patients develop small bowel obstruction, mesenteric thrombosis, and lymphatic obstruction with ascites, steatorrhea, or protein-losing enteropathy.
Treatment and Prognosis Patients with mesenteric panniculitis should undergo biopsy of the lesion to rule out malignancy. This may be accomplished laparoscopically or by an open procedure. Resection of the entire mass is usually not possible and should not be attempted. In patients with symptomatic progressive sclerosing or retractile mesenteritis, dramatic responses have been reported after treatment with prednisone and azathioprine or with cyclophosphamide. [150], [151] Experience with these immunosuppressive agents is too limited to determine their efficacy in this usually self-limiting disease. Surgical diversion or bypass is

indicated for symptomatic relief in cases in which extrinsic bowel obstruction due to mesenteric inflammation and scarring has occurred. The prognosis for mesenteric panniculitis is usually good but depends on underlying disease processes.

Mesenteric Fibromatosis

Incidence and Etiology Fibromatous proliferation of the mesentery, called *mesenteric fibromatosis* or *mesenteric desmoid,* is a rare and noninflammatory condition.[152] These mesenteric lesions can infiltrate the surrounding structures, and similar to desmoid tumors in other locations, they tend to recur locally, but they never metastasize. Most of the reported cases have been associated with familial adenomatous polyposis syndromes (in particular, Gardner syndrome). Mesenteric fibromatosis affects about 3% of patients with familial adenomatous polyposis and 14% to 29% of patients with Gardner syndrome.[153],[154] This process has also been reported after abdominal surgery, trauma, prolonged estrogen intake, and pregnancy.[152] In addition, it may occur as a primary condition (primary mesenteric fibromatosis) in the absence of predisposing factors.
Clinical Manifestations Patients with mesenteric fibromatosis may present with an asymptomatic abdominal mass on physical examination or a mesenteric mass at laparotomy. Symptoms of intestinal obstruction are the most common complaint. Aggressive mesenteric desmoids can become infiltrative and can involve mesenteric vessels, leading to intestinal infarction and perforation. The radiographic features of mesenteric fibrosis are generally nonspecific. The desmoid tumor appears as a solid mass by ultrasound. CT scan shows a nonenhancing mass with soft tissue density. At laparotomy, desmoids are found to involve the mesentery of the small bowel or transverse mesocolon, and the most common site is the base of the small bowel mesentery.[155],[156] These lesions can be difficult to differentiate from low-grade sarcoma and can lead to misdiagnosis at operation and extensive small bowel resection.
Treatment and Prognosis In the past, the treatment of choice for patients with mesenteric desmoids has been wide local excision, but, unlike extra-abdominal desmoids, no clear evidence exists showing a benefit from negative margins on the rate of recurrence of mesenteric fibromatosis. Furthermore, the severity and frequency of complications, recurrence rates as high as 85%, and relatively good long-term survival in unresectable patients lead some to reserve resection for patients suffering from complications secondary to desmoid tumors (e.g., obstruction, perforation, or fistula formation).[157],[158] There are anecdotal reports of successful treatment with prostaglandin inhibitors (i.e., sulindac or indomethacin) and antiestrogens (e.g., tamoxifen) alone and in combination.[159],[160] and[161] Cytotoxic chemotherapy with dactinomycin, vincristine, and cyclophosphamide and radiotherapy have been used, individually or in combination, with variable success.[162],[163] and[164]

Cysts and Tumors of the Mesentery and Omentum

Mesenteric and Omental Cysts

Incidence and etiology. Cysts of the mesentery and omentum are uncommon lesions, with an incidence of about 1 case for every 140,000 general hospital admissions and about 1 per 20,000 pediatric hospital admissions.[165],[166] These cysts represent benign proliferation of ectopic lymphatics lacking communication with the normal lymphatic system.[167] Although they are most commonly found in the small bowel mesentery, they can occur anywhere along the gastrointestinal tract. Some authors differentiate between mesenteric or omental cysts and cystic lymphangiomas.
Clinical manifestations. Cystic lymphangiomas characteristically are found in children (mean age, 6 to 10 years) and are frequently large and almost always symptomatic, usually presenting with abdominal distention, pain, or vomiting and occasionally with an acute abdomen mimicking appendicitis.[168] Lymphangiomas are most often located in the small bowel mesentery but occasionally may be found in the mesocolon, the omentum, or, more rarely, the retroperitoneum. They may be single or multiple. In contrast to cystic lymphangiomas, the mean age of presentation of patients with nonlymphangiomatous mesenteric cysts is 44 years.[169] These cysts include nonpancreatic pseudocysts, enteric cysts, and mesothelial cysts. As many as one third of the nonlymphangiomatous cysts may be located in the omentum, and only 25% are symptomatic.
Diagnosis and treatment. The identification of an intra-abdominal cystic mass can be obtained by radiographic studies. Plain radiographs often demonstrate a mass displacing bowel gas and may demonstrate proximal dilation of the bowel. Ultrasonography, CT, and MRI may demonstrate the multilocular or unilocular nature of the cysts, which may have homogeneous or nonhomogeneous contents (Fig. 123-12). Of the three imaging modalities, ultrasonography probably yields the most information for the least expense.

FIGURE 123-12. Computed tomography scan of a large lymphatic cyst arising from the mesentery (*arrow*). (Courtesy of Luis B. Morettin, M.D., Galveston, TX.)

Surgical resection represents the definitive diagnosis and treatment for these lesions. Percutaneous aspiration and biopsy are not warranted because they are not likely to provide a definitive diagnosis and may lead to infection or rupture of the cyst. Total excision of the cystic lymphangioma requires resection of adjacent attached abdominal organs (usually segments of small bowel) in most cases, but most other types of mesenteric cysts simply can be excised.[167],[169] Rarely, the location of the cyst precludes complete resection and requires drainage or marsupialization. However, this is usually associated with a high recurrence rate.[170],[171]

Solid Tumors of the Omentum and Mesentery

Incidence and etiology. Primary tumors of the omentum and mesentery are exceedingly rare and may arise from any of the cellular elements that constitute these tissues.[155],[172] By far the most common types of tumors that involve the omentum and mesentery are malignant tumors that arise from intra-abdominal viscera, such as the ovaries, stomach, colon, or pancreas, and secondarily involve the omentum or mesentery through metastasis or direct invasive extension. In some instances, the tumor arises from the mesenchymal elements in the wall of the gut segment; for example, leiomyoma, schwannoma or gastrointestinal stromal tumors (GISTS) are derived from smooth muscle, neural sheath, or interstitial cells of Cajal, respectively.[173],[174]
Clinical manifestations. Patients may present with a constellation of nonspecific or vague complaints; however, the most consistent presenting feature of omental and mesenteric tumors is a palpable abdominal mass that is often movable, often associated with pain, and sometimes associated with ascites or vomiting.[155],[172],[175] Plain abdominal radiographs and gastrointestinal contrast studies can demonstrate intestinal displacement and are useful in excluding the intestine as the origin of the tumor. A CT scan usually identifies the location of the mass within the mesentery or omentum and can exclude other organs as the origin of the mass but is nonspecific with regard to the diagnosis.[176]
Treatment. The treatment of primary omental and mesenteric tumors is surgical excision, if possible. The malignant tumors of the mesentery and omentum spread by local invasion and by peritoneal implantation and kill by involvement of vital abdominal organs. Surgery always should be considered in patients with symptoms of bowel obstruction or ischemia. Metastatic tumors of the mesentery are more common than primary mesenteric tumors and are usually the result of enlarged lymphomatous or carcinomatous lymph nodes. In addition, malignant midgut carcinoid tumors often metastasize or spread directly to the mesentery and exhibit pronounced fibrosis causing mesenteric shortening, angulation, and fixation of the bowel, which can result in bowel obstruction and intestinal infarction.[177],[178] and[179] Surgical palliation of patients with metastatic carcinoid tumors is warranted because of the indolent behavior of these tumors. Mesenchymal tumors (e.g., leiomyomas or GISTS) of the gut wall are also treated by surgical resection. The GISTS may express gain-of-function mutations of the *c-kit* protooncogene, which encodes a tyrosine kinase receptor. If the stromal tumor stains positive for *c-kit*, the tumor appears to be responsive to the inhibitor G1eevec, and studies are underway to assess the responsiveness of these tumors to this form of chemotherapy.

CHAPTER 124

Phillip D. Smith and Edward N. Janoff

GASTROINTESTINAL COMPLICATIONS OF THE ACQUIRED IMMUNODEFICIENCY SYNDROME

The acquired immunodeficiency syndrome (AIDS) has become the greatest worldwide pandemic in history, surpassing even the bubonic plague of the 14th century in magnitude and number of deaths. Originating in chimpanzees in central Africa, [1] AIDS was first recognized in 1981 in men who have sex with men in the United States. [2], [3] and [4] The disease rapidly achieved epidemic proportions in this group and then intravenous drug users. Subsequently, human immunodeficiency virus type 1 (HIV-1), the causative agent of AIDS, spread to heterosexual populations, and, by the mid 1990s, heterosexual contact was recognized as the mode of transmission in 75% to 85% of infected people worldwide. [5]

In the 1990s, the AIDS pandemic was also recognized in developing countries throughout the world, but particularly those of sub-Saharan Africa. More than 70% of people infected with HIV-1 now live in these resource-poor nations, where in some countries, an astonishing 25% of the population is infected. [6] In these countries, vertical transmission has emerged as a major problem, and thousands of young children have been orphaned by the epidemic. In Botswana, for example, the prevalence of HIV-1 infection among pregnant women exceeds 30%. [6] By 2002, 20 million people worldwide were estimated to have died of AIDS and 40 million to be infected with the virus. The devastating impact of AIDS on the well-being of individuals and their families, societies, and national economies throughout the world is incalculable.

In the late 1990s, improved treatment options in the form of highly active antiretroviral therapy (HAART) and more effective agents for the prevention and treatment of opportunistic infections caused a decline in AIDS-related deaths in the United States and an increase in the prevalence of people living with HIV-1 infection. However, these therapeutic agents are prohibitively expensive throughout most of the world, and drug resistance is a serious potential problem. Moreover, development of an effective vaccine for HIV-1 infection has lagged far behind the development of therapeutic agents. Thus, until HIV-1 infection can be cured through antiviral therapy or prevented through an effective vaccine, clinicians throughout the world will continue to care for patients with AIDS.

The gastrointestinal tract mucosa plays a fundamental role in the pathogenesis and clinical manifestation of AIDS. Consequently, it is not surprising that gastrointestinal complications are common in patients with AIDS (Table 124-1). Infectious processes cause most of these complications and are responsible for relentless morbidity and, in some cases, mortality. [7] Among HIV-1–infected patients, diarrhea significantly diminishes the quality of life and is associated with an increased risk for death. The effective care of patients with AIDS requires a clear understanding of the gastrointestinal infections associated with HIV-1 disease and the most efficient and effective approaches for the evaluation and therapy of these infections. Therefore, this chapter focuses on the intestinal infections and key gastrointestinal syndromes associated with HIV-1 disease and presents effective approaches for their evaluation and treatment.

Diarrhea	Acute HIV-1 syndrome, infectious enteritis and colitis, drug-induced and AIDS enteropathy
Abdominal pain	Infectious organ disease, non-Hodgkin lymphoma, pancreatitis, and typhlitis
Hepatobiliary disorders	Acalculous cholecystitis, sclerosing cholangitis, and papillary stenosis
Pancreatitis	Drugs (pentamidine and dideoxyinosine), infections, and neoplasms (non-Hodgkin lymphoma and Kaposi sarcoma)
Gastrointestinal bleeding	Upper tract: infectious esophagitis, Kaposi sarcoma and lymphoma Lower tract: infectious colitis, idiopathic colonic ulcers, non-Hodgkin lymphoma and Kaposi sarcoma
Neoplasms	Non-Hodgkin lymphoma and Kaposi sarcoma
Anorectal disease	Anus: condylomata, infection, fistula, fissure and squamous cell carcinoma Rectum: nonspecific proctitis, infectious proctitis and perirectal abscess
Opportunistic infections	Inflammation, ulceration and inflammatory mass

AIDS, acquired immunodeficiency syndrome; HIV-1, human immunodeficiency virus type 1.

TABLE 124-1 Gastrointestinal Complications of AIDS

ROLE OF THE GASTROINTESTINAL MUCOSA IN HUMAN IMMUNODEFICIENCY VIRUS TYPE 1 INFECTION

All HIV-1 infections, excluding those acquired parenterally, are acquired across a mucosal surface. For heterosexual transmissions, the genital mucosa is the most common site of virus entry. In vertical transmission, HIV-1 is acquired through the upper gastrointestinal tract during the swallowing of infected amniotic fluid in utero, infected blood and secretions intrapartum, and infected breast milk postpartum. [8] Among men who have sex with men, the rectum is the portal of entry in anogenital contact and the upper tract the site of entry in orogenital contact. [9], [10]

In addition to their role in HIV-1 transmission, mucosal surfaces participate in many key events in HIV-1 pathogenesis. [11] First, mucosal cells likely are involved in selecting from the pool of inoculated viruses the phenotypically and genotypically restricted HIV-1 that is transmitted in acute infections. [12], [13] and [14] Second, lamina propria lymphocytes appear to be the initial target cells for HIV-1 infection. [15], [16] Third, HIV-1 replication occurs in the mucosa, a microenvironment containing an abundance of microorganisms and cytokines capable of enhancing HIV-1 replication in infected cells. [17], [18], [19] and [20] Fourth, the subsequent decline in the number of circulating $CD4^+$ T lymphocytes, a fundamental characteristic of AIDS, begins in the gastrointestinal mucosa. [21], [22], [23] and [24] Fifth, the local and systemic reduction in $CD4^+$ T cells predisposes the gastrointestinal tract mucosa to an array of opportunistic infections and neoplasms.

DIARRHEAL DISEASES

HIV-1-related diarrhea may first occur during the syndrome of primary HIV-1 infection 1 to 4 weeks after virus inoculation. This mononucleosis-like syndrome, characterized by fever, sore throat, rash, lymphadenopathy, fatigue, weight loss, and myalgias, occurs in up to 90% of patients acutely infected with HIV-1 and lasts 1 to 3 weeks. [10], [25], [26], [27], [28] and [29] Acute, self-limited diarrhea occurs in about one third of patients with the syndrome. [25], [29] Severe, but less common, gastrointestinal manifestations of acute HIV-1 infection include thrush and ulcerations of the oral cavity, esophagus, and rectum as well as enteropathy and profound weight loss. [29], [30] High titers of circulating virus coincide with the clinical syndrome, eventually eliciting an antibody response (seroconversion) that is followed by a rapid decline in the level of circulating virus. [27], [28] Resolution of acute HIV-1 syndrome is followed by a prolonged period of clinical latency that often lasted 8 to 10 years before the use of HAART. [31]

In addition to the diarrhea associated with acute HIV-1 syndrome and *opportunistic infections* (see later), medication-induced diarrhea is a frequent side effect of many antiretroviral and antimicrobial agents currently used to treat HIV-1 and opportunistic pathogens. [32], [33] Nucleoside analogs and protease inhibitors also may impair pancreatic function, causing steatorrhea. [32] Discontinuation, dose reduction, or accommodation to the offending drug are usually accompanied by resolution of symptoms.

Chronic diarrhea, defined as two or more loose or watery stools per day for at least 1 month, is common in patients with clinically apparent AIDS. Previously, in North America, diarrhea occurred in about 50% of HIV-1–infected patients [34], [35]; in developing African countries, the incidence of diarrhea may approach 90% of infected patients. [36], [37] HIV-1–associated diarrhea is typically chronic, often severe, and frequently associated with cramps, anorexia, fever, weight loss, and wasting. [35], [38], [39] Patients with lower CD4 $^{+}$ T-cell numbers are more likely to develop these symptoms. [35] The wasting is a consequence of the malabsorption of fat, carbohydrate, and probably protein [39], [40], [41], [42], [43] and [44] and reduced nutritional intake. [45] Tumor necrosis factor-a (TNF-a), a proinflammatory cytokine produced by activated or infected monocytes and macrophages, may be involved in the pathogenesis of AIDS-associated cachexia through its effects on lipid metabolism. [46]

Chronic diarrhea and *malabsorption* in HIV-1-infected patients cause fatigue and inanition, a marked decrease in the sense of well-being, and an impaired ability to conduct social and work-related activities of daily life. [47], [48] In African AIDS patients, diarrheal illness is more severe and accompanied by profound cachexia. [49] Referred to as *slim disease,* this severe manifestation of AIDS-associated diarrhea likely reflects limited access to medical care and the presence of opportunistic infections superimposed on traditional tropical infections. Patients with AIDS and diarrhea have lower numbers of circulating CD4 $^{+}$ T lymphocytes and a higher incidence of extraintestinal opportunistic infections, suggesting that infected patients who develop diarrhea have a greater degree of immunosuppression than those who do not. [50] Diarrhea in HIV-1–infected patients is associated with decreased survival in adults and infants. [44], [51], [52] In developed countries, the total cost of care for HIV-1–infected patients with diarrhea is 50% higher than for patients without diarrhea. [47] The increased outpatient costs reflect more office visits and diagnostic tests, and the increased inpatient costs reflect, in part, longer hospitalizations. [48] The high cost of providing health care and the related loss of ability to work are major drains on the financial resources of families and ultimately society in developed as well as developing countries.

Diagnostic Evaluation

The decision to begin an extensive evaluation of diarrhea in HIV-1–infected patients is tempered by the epidemiology and microbiology of potential enteric pathogens, the cost and feasibility of stool examination versus an invasive endoscopic procedure, the ability of the patient to undergo sedation and endoscopic evaluation, and the therapeutic implication of identifying certain pathogens. [38], [53] Because pathogen-specific therapy can often reduce the volume and frequency of the diarrhea, [50], [54] a vigorous diagnostic evaluation in HIV-1–infected patients with severe chronic diarrhea is usually justified. Increased awareness of the infectious processes involving the gastrointestinal tract (Table 124-2) and improved diagnostic techniques have led to the identification of enteric pathogens in 44% to 85% of AIDS patients with diarrhea. [50], [54], [55] and [56] A gastrointestinal pathogen is more frequently identified in symptomatic patients who also have weight loss and less than 100 CD4 $^{+}$ T cells/mm ^{3} than in those without weight loss and more than 100 CD4 $^{+}$ T cells/mm ^{3}, indicating that patients with more severe illness and greater immunosuppression are more likely to have an identifiable enteric pathogen. [56], [57] Two or more enteric pathogens may coexist in about 25% of AIDS patients with diarrhea. [58]

ORGAN	PATHOGENS
Esophagus	*Candida albicans*, herpes simplex virus, cytomegalovirus
Stomach	Cytomegalovirus, *Mycobacterium avium* complex
Biliary tract	Cytomegalovirus, *Cryptosporidium parvum*, microsporidia, *Isospora belli*
Gall bladder	Cytomegalovirus, *Crytosporidium parvum*, microsporidia, *Isospora belli*
Pancreas	Cytomegalovirus, *Mycobacterium avium* complex, herpes simplex virus
Small intestine	*Cryptosporidium parvum*, microsporidia, *Isospora belli*, *Cyclospora cayetanensis*, *Mycobacterium avium* complex, *Salmonella* species, *Campylobacter jejuni*
Colon	Cytomegalovirus, *Mycobacterium avium* complex, *Shigella* species, *Clostridium difficile*, *Campylobacter jejuni*, *Histoplasma capsulatum*, adenovirus, enteroaggregative *Escherichia coli*
Rectum	Herpes simplex virus, lymphogranuloma venereum, papilloma virus

TABLE 124-2 Sites of Infections in the Gastrointestinal Tract in Patients Infected with HIV-1

Step 1 Evaluation begins with a thorough history and physical examination. The history should include a detailed review of the patient's drugs. In North America and Europe, antimicrobial agents and antiretroviral drugs are among the most common causes of gastrointestinal symptoms and diarrhea [33] (Table 124-3). In addition, the increased use of antimicrobial agents in HIV-1–infected patients may be associated with increased rates of *Clostridium difficile*–associated diarrhea. [59], [60] Thus, a review of current medications and their temporal relationship to symptoms is an increasingly important component of the diagnostic evaluation. The geographic regions in which a patient has resided or traveled are important because some AIDS-defining pathogens are endemic or more common in certain geographic regions. For example, *Histoplasma capsulatum* is endemic in the Mississippi valley and is more common in HIV-1–infected patients who have resided in or traveled to that region. [61] *Cryptosporidium parvum* and *Isospora belli* are more common in patients in developing countries than in developed countries. [62], [63] Rotavirus, which is not a common pathogen in AIDS patients in the United States, [50], [64] /SUP>has been identified in 18% of AIDS patients with diarrhea in Australia. [65]

TABLE 124-3 Gastrointestinal Complications of Antiretroviral Therapy and Potential Interactions with other Medications used in Gastrointestinal Medicine

Step 2 After the history and physical examination, we use the following protocol to evaluate diarrhea in HIV-1–infected patients. [66], [67] Up to three fresh stool specimens are cultured for *Salmonella* species, *Shigella* species, and *Campylobacter jejuni,* the most common bacterial diarrheal pathogens identified in patients with and without HIV-1 infection. In contrast, *Aeromonas* species, *Yersinia* species, and *Escherichia coli* 0157:H7 are not more common among patients with AIDS, and therefore, stool is not routinely cultured for these bacteria. Each specimen is also examined for ova and parasites using saline, iodine, trichrome, and acid-fast preparations of direct or concentrated samples of stool. Stool is assayed for *C difficile* toxin by immunoassay, but because about 10% of non-AIDS patients with *C difficile* infection are toxin negative, stool is cultured for *C difficile* when the bacterium is suspected despite a negative toxin assay. [68] The identification of enteric pathogens by stool examination alone in 48% to 55% of HIV-1–infected patients with diarrhea [54], [69] underscores the importance and cost-effectiveness of stool examination as the initial diagnostic test. [70] When fever is present, blood cultures are obtained for *Salmonella* species, *Shigella* species, and *C jejuni* because bacteremia often accompanies enteric infection in HIV-1–infected patients.

Step 3 When stool examination does not reveal a potential pathogen or when therapy for the identified pathogen does not improve symptoms, we perform esophagogastroduodenoscopy (EGD) and colonoscopy. In addition to visual inspection of the mucosa, tissue biopsies are obtained for histopathological examination and microbiologic evaluation for the presence of bacteria, protozoa, and viruses. Because small bowel fluid from HIV-1–infected patients rarely contains parasites [71] or excessive levels of bacteria (more than 104/mL), [72] we no longer routinely aspirate fluid from the small intestine to diagnose parasitic infection or bacterial overgrowth. The use of endoscopic procedures to evaluate HIV-1–infected patients with diarrhea was previously controversial, [70] but their usefulness has been confirmed in the following studies. Among HIV-1–infected patients with diarrhea and pathogen-negative stool studies, EGD alone yielded a diagnosis in 26% of patients, [71] EGD plus sigmoidoscopy a diagnosis in 50%, [44] and EGD plus colonoscopy a diagnosis in 44%. [56] The diagnostic yield of an endoscopic procedure is significantly greater for patients whose number of CD4$^+$ T cells is less than 100 cells/mm^3 and whose diarrhea is severe. [56], [73] A lower tract endoscopic procedure provided a diagnosis in 64% of patients with weight loss of more than 10 kg but yielded no diagnosis in patients with stool volumes of less than 400 mL/day or less than 5 kg lost weight. [74] Colonoscopy is usually superior to flexible sigmoidoscopy for the detection of pathogens and neoplasms; in one study, [73] 30% of pathogens and 75% of lymphomas were detected only in the proximal colon, well beyond the reach of the flexible sigmoidoscope. Thus, endoscopic procedures are an important adjunct to the diagnostic evaluation of unexplained chronic diarrhea in HIV-1 disease, and the diagnostic yield is greater for patients with more profound immunosuppression and severe diarrhea.

Step 4 When the evaluation of tissue specimens also does not yield an identifiable pathogen and when therapy for an identified pathogen is ineffective, glutaraldehyde-fixed tissue specimens obtained during step 3 can be evaluated by electron microscopy for microsporidian (duodenal biopsies) adenovirus and enteroaggregative bacteria (colonic biopsies). The cost required to perform electron microscopy should be weighed against the low prevalence and lack of an effective therapeutic agent for these pathogens. When no treatable pathogen is identified, the therapeutic approach should emphasize reducing symptoms rather than a continuous diagnostic evaluation.

Approach to Therapy

We approach the treatment of gastrointestinal infections in HIV-1–infected patients using the following principles. [67] First, during the diagnostic evaluation of diarrhea, many patients benefit from supportive therapy with fluids, electrolytes, and antimotility agents. Second, because the array of opportunistic and nonopportunistic pathogens that cause diarrhea in HIV-1–infected patients is extensive (Table 124-4) and because drug-related side effects and drug interactions are common, specific antimicrobial therapy is preferable to empiric therapy. Third, diarrhea and often other gastrointestinal syndromes, such as AIDS cholangiopathy, may be multifactoral in etiology, and, therefore, treatment may be only partially beneficial. Fourth, many microorganisms, including cytomegalovirus (CMV), herpes simplex virus (HSV), some enteric bacteria, and *Mycobacterium avium* complex (MAC), may be resistant or develop resistance to currently used antimicrobial agents. Consequently, infections with these pathogens require close monitoring with appropriate in vitro drug sensitivity testing. Fifth, long-term suppressive therapy is often necessary for infections that reactivate or recur after treatment. Sixth, specific antimicrobial therapy and supportive care can enhance the quality of life and duration of survival in many patients. Seventh, HAART may induce remission of some gastrointestinal infections, obviating the need for antimicrobial therapy for cryptosporidiosis and microsporidiosis. However, some infectious processes, such as CMV retinitis (when the CD4$^+$ T-cell number increases to more than 200 cells/mm^3), chronic hepatitis B infection and MAC adenitis may be exacerbated by HAART. HIV-1–infected patients with these processes should be followed closely for possible flare-up of their opportunistic infection. Finally, appetite enhancers may be helpful, but the role of total parenteral nutrition and anabolic steroids is uncertain.

	OPPORTUNISTIC	NONOPPORTUNISTIC
Bacteria	*Salmonella* species *Shigella flexneri* *Campylobacter jejuni* *Mycobacterium avium* complex Enteroaggregative *Escherichia coli*	*Clostridium difficile*
Protozoa	*Cryptosporidium parvum* *Enterocytozoon bieneusi* *Septata intestinalis* *Cyclospora cayetanensis* *Isospora belli*	*Giardia lamblia* *Entamoeba dispar*
Viruses	Cytomegalovirus Herpes simplex virus Adenovirus Picobirnavirus and astrovirus[†]	Rotavirus* Norwalk virus
Fungi	*Histoplasma capsulatum* *Candida albicans*[‡]	

*Nonopportunistic in United States and Africa, but more common in HIV-1–infected patients in Australia and Europe.

†More common in HIV-1–infected patients with diarrhea; pathogenesis under investigation.

‡Esophageal disease only.

HIV-1, human immunodeficiency virus type 1.

TABLE 124-4 Opportunistic and Nonopportunistic Pathogens in the Gastrointestinal Tract in Patients Infected with HIV-1

Highly Active Antiretroviral Therapy

A major advance in the therapeutic management of HIV-1 infection has been the development of HAART. HAART combines reverse transcriptase inhibitor (RTI) and protease inhibitor (PI) drugs into a powerful and highly effective antiviral regimen. RTIs include nucleoside analogs (NRTIs), such as zidovudine, and nonnucleoside analogs (NNRTIs), such as nevirapine, which inhibit the ability of HIV-1 RNA to encode viral DNA. PIs block the cleavage of HIV-1 Gag-Pol polyprotein precursor into structural core proteins and enzymes (reverse transcriptase, integrase, and protease), causing the production of abnormal viral proteins and noninfectious virions. Current HAART regimens typically include three or more agents, usually two NRTIs and one PI, to diminish or ablate viral replication, prevent the development of resistance, enhance recovery of immunologic competence, and improve clinical status. [75], [76], [77] and [78]

HAART has dramatically reduced the rate of death among patients with HIV-1. Among patients with advanced HIV-1 disease in the United States, mortality declined between 1995 and 1997 from 29.4

to 8.8 per 100 person-years. [79] The dramatic effect of HAART on mortality has been accompanied by an equally impressive decline in the incidence of many systemic and gastrointestinal opportunistic infections, [80], [81] and [82] most likely due to the inhibition of HIV-1 replication and the resultant recovery of immune function. Because the recovery of immune function takes several months, rates of opportunistic infections decline most prominently after 2 months of antiretroviral therapy. [83] Thus, prophylactic therapy against many such infections may be discontinued in patients on HAART whose $CD4^+$ lymphocytes have increased in number to 200 cells/mm^3 for more than 12 weeks. [83], [84], [85], [86], [87] and [88]

Cryptosporidiosis was the first AIDS-associated opportunistic infection shown to improve clinically and microbiologically in response to antiretroviral therapy. [89], [90], [91], [92] and [93] Patients with microsporidiosis also improve on HAART, although parasite-associated diarrhea may recur when the patient fails to respond to antiretroviral therapy. [93] The incidence of CMV gastrointestinal disease, esophageal candidiasis, and idiopathic esophageal ulceration also declines dramatically in association with HAART. [82] HAART appears to induce sustained clinical improvement in some patients with AIDS enteropathy. [92]

A spectrum of toxicities are associated with antiretroviral drugs [33] (see Table 124-3). Nausea, vomiting, abdominal pain, and diarrhea occur early in the course of therapy and may abate over time. Gastrointestinal toxicity significantly limits the initial tolerance to protease inhibitors and necessitates dose titration and sequential addition of other medications, such as RTI nucleoside analogs. [33] Hepatic toxicity is more often associated with long-term therapy and is typically mild, although severe hepatic toxicity, particularly with the PI ritonavir, may require discontinuation of the medication. [94] Pancreatitis is a more specific complication of dideoxyinosine. Toxic reactions ascribed to each drug are often confounded by the administration of two or more drugs at the same time. Increased rates of adverse events, such as pancreatitis or hepatic toxicity, may result from simultaneous administration of medications with overlapping toxicities. Distinguishing between symptoms of drug toxicity and opportunistic infection requires careful evaluation of the timing of events and the presence of comorbid findings.

HAART toxicities occur more frequently among patients with advanced HIV-1 disease ($CD4^+$ T cells less than 200 cells/mm^3) and may limit use of the antiretroviral drugs. [33] In patients taking NRTIs, gastrointestinal symptoms include nausea, vomiting, abdominal pain, and diarrhea in more than 25% of patients. Long-term therapy may be associated with myopathic, neuropathic, hepatic, pancreatic, and hematologic complications. [94], [95] and [96] Among patients taking NNRTIs, gastrointestinal and hepatic toxicities are not common. Mild rashes are the predominant side effect. Drug interactions occur primarily with inducers of and substrates for the cytochrome P450 system. The most frequent dose-limiting toxicities with protease PIs are diarrhea, nausea, and abdominal discomfort. Hepatic toxicity is most often associated with ritonavir. The presence of chronic hepatitis B or C virus may increase the rate but not necessarily the severity of hepatic effects [94]; these infections should not limit the initiation of HAART. Metabolic complications, particularly with PI-containing regimens and less often with NRTIs, include glucose intolerance, elevations in triglycerides and cholesterol, and lipodystrophy syndrome (increased abdominal fat, loss of peripheral subcutaneous fat of the face, arms, legs, and buttocks, and the presence of a “buffalo hump”). Women receiving therapy may experience breast enlargement.

The management of HAART toxicity is complicated by the need to identify the causative agent in a multi-drug regimen. Many of the toxic effects of antiretroviral medications are dose-dependent, and dose reduction may allow the continuation of therapy. Because optimal antiretroviral activity is usually dose-dependent, particularly for PIs, changing antiretroviral agents may be preferable to lowering doses. Because the development of HIV-1 resistance may occur, clinical and virologic status should be monitored. The management of overlapping toxicities of different medications and their effects on drug metabolism may allow continuation of the most critical agents. Severe or prolonged complications and the development of hypersensitivity reactions with abacavir require discontinuation of individual agents. For gastrointestinal side effects, antidiarrheal agents, such as loperamide or diphenoxylate atropine, may be useful for drug-related diarrhea, and antiemetics may reduce drug-induced vomiting. Taking medications with or after eating can limit nausea. Histamine receptor blockers and antacids may affect absorption of some drugs and usually do not alter symptoms.

Bacterial Infections

Salmonella* species, *Shigella* species, and *Campylobacter jejuni The gram-negative bacteria *Salmonella typhimurium* (less frequently, *Salmonella enteritidis*), [97], [98], [99], [100], [101], [102] and [103] *Shigella flexneri,* [103], [104], [105], [106], [107] and [108] and *C jejuni* [109], [110] cause a similar clinical illness in HIV-1–infected patients characterized by chronic or recurrent diarrhea, abdominal cramps, and fever. During symptomatic infection, the stool frequently contains fecal leukocytes and either gross or microscopic blood. Each of these bacterial infections occurs more often, causes more prolonged or recurrent diarrhea, and is more commonly associated with bacteremia and antibiotic resistance in HIV-1–infected patients than in seronegative patients. *C jejuni* may cause visible mucosal inflammation. *Campylobacter* species other than *C jejuni* have been detected in HIV-1–infected patients with diarrhea, [111] but a causative role for these species in the diarrhea awaits confirmation.

Diagnosis. These bacteria are diagnosed by culture of the organism in a stool specimen. The blood should also be cultured when diarrhea is accompanied by fever.

Treatment. The drug of choice for infection with *Salmonella* species is ceftriaxone or ciprofloxacin; for *Shigella* species, ciprofloxacin; and for *C jejuni,* erythromycin or ciprofloxacin (Table 124-5). Because recurrence is common and drug resistance may develop, repeat culture of stool and blood (when bacteremia occurs) and drug sensitivity testing are used to monitor therapeutic response.

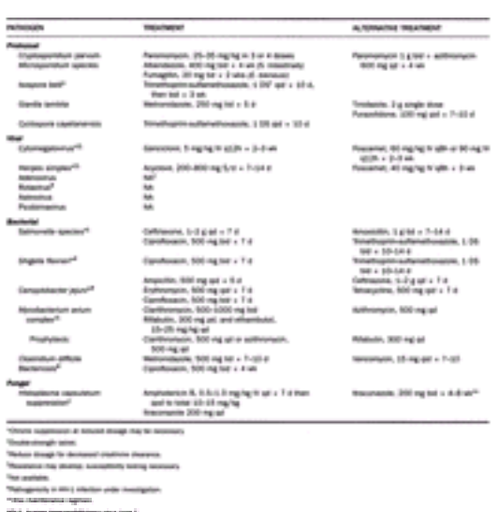

TABLE 124-5 Therapy for Intestinal Infections in HIV-1–Infected Adults

***Mycobacterium avium* Complex** MAC comprises two acid-fast, obligate, intracellular bacteria: *M avium* and *Mycobacterium intracellulare*. Exposure is common because the organisms are ubiquitous in the environment. In immunocompetent hosts, MAC is not an enteric pathogen, but immunosuppressed HIV-1–infected patients ($CD4^+$ T cells less than 100 cells/mm^3) are highly susceptible to infection. Macrophages are an important reservoir for the bacteria, and during HIV-1 infection, macrophages phagocytose, but appear unable to kill, MAC. The organism up-regulates macrophage HIV-1 production in dually infected cells [112] and alters macrophage function. [113] The gastrointestinal tract is the likely portal of entry for MAC. MAC is the most common cause of systemic bacterial infection in HIV-1–infected patients in the United States. MAC is much less common in Africa and Haiti. End-organ involvement and bacteremia usually do not occur until the number of circulating $CD4^+$ T cells declines to less than 100 cells/mm^3. Gastrointestinal tract disease, which is usually a manifestation of disseminated infection, may be associated with diarrhea, abdominal pain, malabsorption, weight loss, and fever, with or without night sweats. [114], [115] Concomitant hepatomegaly and splenomegaly with anemia due to MAC infection are often present. The numerous mycobacteria typically present in gastrointestinal tract mucosa suggest that MAC contributes to the associated gastrointestinal symptoms. Endoscopic abnormalities are nonspecific and include erythema, friability, erosions, and fine white nodules. Occasionally, an inflammatory mass, which can be mistaken for a tumor, is the major gastrointestinal manifestation. The small intestine is reported to be involved more often than the colon, [114] but this may reflect easier endoscopic access. Histological examination shows diffuse infiltration of the lamina propria by macrophages filled with bacilli. Granulomata are usually absent or poorly developed, possibly owing to the impaired chemotactic activity of monocytes in patients with AIDS. [116]

Diagnosis. The diagnosis of MAC is based on the identification of typical acid-fast organisms in stool or gastrointestinal biopsy specimens (fixed and touch preparations). [114], [115] Culture of gastrointestinal tissue may increase the positivity rate compared with acid-fast staining alone. [117] Isolation and speciation are achieved by culture of organisms from stool and biopsy specimens. Although the incidence of both pulmonary and extrapulmonary *Mycobacterium tuberculosis* infections is increased among HIV-1–infected patients, intestinal involvement is uncommon.

Treatment. Although initial trials of antituberculosis agents proved disappointing, improved results with newer multidrug regimens provide reason for cautious optimism in treating MAC. [84], [118], [119] Combination regimens have produced more sustained benefit, but such regimens are expensive, have adverse effects, and often are difficult to tolerate. The current recommended three-drug therapy is two antimycobacterial agents, including a macrolide azole agent and rifabutin, and a third agent, such as ethambutol. [120] When the $CD4^+$ T cell number falls below 50 cells/mm^3, clarithromycin or clarithromycin plus rifabutin is effective prophylactic therapy; MAC disease occurred in 9% and 7% of patients treated with clarithromycin alone or combination therapy, respectively. [121] For patients on

HAART who respond with an increase in the number of CD4 + lymphocytes to greater than 100 cells/mm 3 for more than 3 to 6 months with sustained suppression of HIV-1 plasma RNA for the same period, prophylactic therapy may be discontinued.

Clostridium difficile The gram-positive bacteria *C difficile* is an important pathogen in the differential diagnosis of diarrhea in patients with HIV-1 infection. Risk factors for *C difficile*–associated diarrhea in HIV-1–infected patients include recent antimicrobial therapy (particularly clindamycin and pyramethamine) and hospitalization, [122] risk factors similar to those in immunocompetent patients. [123] Although asymptomatic carriage occurs, *C difficile* infection in HIV-1–infected patients is commonly associated with profound watery diarrhea, abdominal pain and tenderness, fever, leukocytosis, and the presence of fecal leukocytes and occult blood. [124] However, the severity of the clinical illness, the response to therapy, and the frequency of recurrent or persistent infection in HIV-1–infected patients are similar to those of seronegative subjects. [125], [126] Thus, *C difficile* is a frequent, but nonopportunistic, pathogen associated with diarrheal illness in HIV-1–infected patients.

Diagnosis. The diagnosis of *C difficile*–associated diarrhea or colitis is based on the presence of diarrhea during antimicrobial use and the detection of either *C difficile* toxin or organisms in stool or endoscopically confirmed pseudomembranous colitis. The potential usefulness of stool culture is underscored by the higher rates of positive stool cultures (90% to 97%) compared with positive toxin assays (70% to 73%) in HIV-1–seronegative subjects with *C difficile* infection. [68], [127] Newer toxin assays show increased sensitivity for toxin A or are capable of detecting toxin A deficient strains of *C difficile*. [128]

Treatment. Metronidazole and vancomycin are highly effective for the treatment of *C difficile* infection in HIV-1–infected patients [124], [125] and [126] (see Table 124-5).

Enteroaggregative Bacteria Intestinal infection with enteroaggregative *E coli* has been reported in HIV-1–infected patients in the United States and Africa. [129], [130], [131] and [132] The bacterium adheres to enterocytes predominantly in the colon and ileum, where focal areas of epithelial cell injury (effacement, displaced microvilli, necrosis) are associated with attached bacteria. [129], [130] Accumulation of inflammatory cells in the epithelium or lamina propria is minimal or absent. Enteroaggregative *E coli* have been identified more frequently in stool from HIV-1–infected adults with diarrhea than in stool from asymptomatic seropositive subjects [132]; the mechanism of the diarrhea is not known. Therapeutic eradication of the bacteria with ciprofloxacin has been associated with restoration or improvement of diarrheal symptoms. [133]

Protozoan Infections

Cryptosporidium parvum *C parvum* is a unicellular, spore-forming coccidian protozoan taxonomically related to *Isospora, Toxoplasma, Sarcocystis,* and *Cyclospora*. [134], [135] Before the advent of HAART, cryptosporidia were present in about 20% of AIDS patients with chronic diarrhea in the United States [50], [54], [134], [136] but in as many as 55% of AIDS patients in developing countries such as Zaire and Haiti. [62], [137] Persistent infection occurs predominantly in HIV-1–infected patients with less than 200 CD4 + T cells/mm 3. [138], [139] A relatively common cause of self-limited mild diarrhea in immunocompetent people, [134], [140], [141] cryptosporidiosis can cause chronic, debilitating diarrhea in patients with AIDS. Typically, the diarrhea is voluminous, nonbloody, and watery; abdominal cramps, anorexia, malaise, and weight loss are also prominent symptoms. [142] Asymptomatic carriage may occur, [143] but symptoms of dehydration and wasting are more common. Malabsorption of both fat and carbohydrate is associated with cryptosporidiosis. Rarely, cryptosporidia may spread to the biliary tract, leading to biliary tract obstruction, [144], [145] or to the esophagus, causing distal esophagitis. [146] The parasite has been identified throughout the gastrointestinal tract, developing within a parasitophorous vacuole beneath the epithelial cell membrane but outside the cytoplasm. Despite its ability to cause severe disease, the spectrum of *Cryptosporidium* species–associated symptoms is broad, may vary over time, and is strongly influenced by the level of immunosuppression. [147], [148]

Diagnosis. Cryptosporidia are easily identified microscopically in stool with a modified acid-fast stain. Concentration of stool by zinc sulfate or sucrose flotation enhances detection of rare or infrequent oocysts during intermittent shedding. A single stool examination was sufficient to diagnose 96% of cases in one retrospective study. [149] When *Cryptosporidium* infection is suspected despite negative stool examination, hematoxylin and eosin–stained tissue specimens obtained by endoscopy can reveal the parasite; biopsy of the terminal ileum has a higher sensitivity (91%) than that of the duodenum (53%) for the detection of the parasite. [150] Organisms may also be identified on small and large intestinal brush-border biopsy specimens by electron microscopy, but this technique is rarely necessary.

Treatment. Despite reports of successful treatment of cryptosporidiosis in HIV-1–infected patients with spiramycin, [151], [152] paromomycin, [148], [153], [154] and [155] bovine colostrums, [156], [157] transfer factor, [158] somatostatin, [159], [160] and zidovudine, [89] therapy with these agents has not been consistently effective, and successful controlled clinical trials have not yet been performed. A course of paromomycin, a nonabsorbable aminoglycoside, with or without azithromycin (Table 124-5) is reasonable based on preliminary studies reporting symptomatic improvement and oocyst clearance in some patients. [148], [153], [154], [155] and [155a] Somatostatin may reduce the frequency and volume of *Cryptosporidium*–associated diarrhea; [159], [160] therapy is complicated by requirement that the drug be given parenterally, but long-acting preparations now allow once-a-day or less frequent injection. To date, HARRT is the most effective therapy for reducing the incidence, severity, and duration of AIDS-associated *Cryptosporidium* infections. [91], [92], [161], [162] and [163]

Microsporidia Microsporidia are spore-forming, obligate intracellular protozoa that infect the small intestine (*Enterocytozoon bieneusi*), small intestine with dissemination (*Septata intestinalis*), liver (*Encephalitozoon cuniculi*), and cornea (*Encephalitozoon hellem*). The parasite has distinctive ultrastructural features; many organisms at different stages of evelopment can be identified in the same enterocyte, causing cytopathic effect [164] (Fig. 124-1; Color Fig. 124-1). *E bieneusi* infects only enterocytes in the small intestine. *S intestinalis,* which is ultrastructurally distinct from *E bieneusi,* also infects epithelial cells but can penetrate into the lamina propria, infect macrophages, and disseminate to other organs such as the kidney. [165], [166], [167], [168] and [169] Microsporidia were initially identified exclusively in HIV-1–infected patients, but the parasite has now been diagnosed in seronegative liver and renal transplant recipients. [170], [171] and [172] and infrequently in immunocompetent people. [173], [174] and [175]

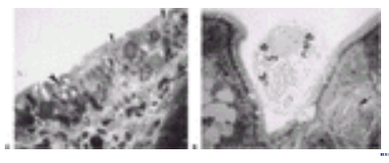

FIGURE 124-1. (See Color Fig. 124-1). **A:** Densely stained microsporidial spores are detected in the cytoplasm of several epithelial cells by light microscopic examination of an intestinal biopsy from a patient with microsporidiosis (semi-thin plastic section; methylene blue–azure II and basic fuchsin stain, original magnification × 630). **B:** Electron micrograph shows a necrotic intestinal enterocyte containing six microsporidial spores in the final stage of being sloughed into the lumen (original magnification × 10,000). (Courtesy of Dr. Jan M. Orenstein.)

Infection with the parasite is associated with chronic, watery, nonbloody diarrhea of variable severity, frequently with substantial fluid and weight loss. [176], [177] and [178] Microsporidiosis has been reported to cause 40% to 50% of the cases of unexplained diarrhea among patients with HIV-1 infection, [179], [180] but microsporidia infection is not invariably accompanied by diarrhea. [181], [182] *E bieneusi* was equally common in HIV-1–infected patients with and without diarrhea. The highest density of *E bieneusi* is located in the jejunum, [183] where the parasite infects enterocytes and may cause villous atrophy. [57] The organism has been associated with AIDS-related biliary tract disease, including acalculous cholecystitis, cholecystitis with cholelithiasis, and cholangitis, [184], [185] presumably by ascending the proximal small intestine to infect the biliary tract. *S intestinalis* also can cause biliary tract disease, including necrotizing cholangitis. [186]

Diagnosis. The diagnosis of microsporidiosis is based on the identification of the parasite in small intestinal tissue or fluid. Biopsy should be performed at the most distal site, where the parasite burden is the highest. Because of their small size, poor staining qualities, and minimal associated inflammation, microsporidia were formerly diagnosed exclusively by transmission electron microscopy. Microsporidia can be identified by light microscopy in semi-thin plastic sections of small intestinal biopsy specimens stained with methylene blue–azure II–basic fuchsin, (Fig. 124-1A; see also Color Fig. 124-1A) [171] touch preparations of mucosa stained with Giemsa, [187], [188] and stool specimens stained with a small modified trichrome (chromotrope 2R) stain. [187] One light microscopic technique appears to obviate the need for electron microscopy in more than 50% of cases, and a combination of any two techniques obviates the need in more than 75% of cases. [58] A rapid fluorescence technique based on Uvitex 2B binding to chitin, a component of the spore wall, is reportedly effective for detecting microsporidia. [180] However, because Uvitex 2B binds to any chitin-containing microorganism, morphologic evaluation may be necessary to confirm the diagnosis. Polymerase chain reaction using primers for the rRNA gene of *E bieneusi* and *S intestinalis* has been developed to identify microsporidia in tissue specimens, [189] but this diagnostic tool is not widely available.

Treatment. Curative therapy for microsporidiosis is not currently available. Albendazole, a benzimidazole derivative related to mebendazole, has been used to treat patients with both intestinal species of microsporidia. [189] (see Table 124-5). In open-label trials, [190], [191] albendazole was associated with cessation of weight loss. Albendazole appears to be more effective for *S intestinalis* than *E bieneusi* infections [192]; the drug has provided resolution or improvement in diarrheal symptoms and weight gain for patients with disseminated *S intestinalis* infections. [168], [169] Fumagillin is the

preferred drug for *E bieneusi.* 169a Patients on HAART have shown both improvement and resolution of diarrheal symptoms due to microsporidia infection. 161 , 163

Isospora belli *I belli* is an obligate, intracellular coccidian parasite that resembles *Cryptosporidium* in its life cycle and small intestinal habitat. In the early years of the AIDS epidemic, *I belli* was identified in fewer than 3% of AIDS patients in the United States but in up to 15% of patients in developing nations such as Zambia and Haiti. 63 , 193 Isosporosis is typically a chronic illness characterized by profuse, nonbloody, watery diarrhea that may be indistinguishable from the diarrheal illness associated with *Cryptosporidium* and microsporidia infections. Weight loss of at least 10% may occur during the months before diagnosis. 63 , 194 Nausea and abdominal cramps also typically accompany the illness; fever and vomiting are less frequent. Dehydration requiring hospitalization has been reported in nearly 50% of Haitian patients. 63 Steatorrhea and eosinophilia may also be present. Histology usually shows inflammation associated with some degree of villous atrophy; in contrast to *Cryptosporidium, I belli* may invade the mucosa. Although concentrated in the small intestine, *I belli* has been identified throughout the gastrointestinal tract and has been associated with biliary disease, specifically acalculous cholecystitis. 195 Rarely, the organism disseminates to extraintestinal sites, including mesenteric and tracheobronchial lymph nodes. 196

Diagnosis. The diagnosis of *I belli* is established by the identification of the typical highly refractile, spherical oocysts (containing two sporoblasts) in stool using the modified Kinyoun acid-fast stain. Stool concentration may be necessary to detect infrequent or rare oocysts.

Treatment. The most effective therapeutic agent for *I belli* is trimethoprim-sulfamethoxazole (see Table 124-5). Because infection recurs in as many as 50% of cases after treatment, prolonged or repeat therapy with this agent may be required to suppress clinical illness.

Cyclospora cayetanensis *Cyclospora* are obligate, intracellular coccidian parasites with morphologic and staining characteristics of a cyanobacterium-like organism. 197 , 198 The spherical cyst-like organisms measure 8 to 10 µm in diameter and, on modified acid-fast staining, resemble Cryptosporidia. 199 The *Cyclospora* oocyst has two sporocysts, each containing two sporozoites, distinguishing the parasite from the larger *I belli*. 199 Both sexual and asexual forms occur in small intestinal epithelial cells, suggesting the organism can complete its life cycle in a single host. 200 The organism has been identified in patients with diarrhea from Latin America (primarily Peru), the Caribbean, Southeast Asia, Eastern Europe, and the United States. In immunocompetent people, the diarrhea is typically abrupt in onset, watery, and prolonged (lasting a mean of 6 weeks) but self-limited. 201 The histopathology of the small intestine in patients with *Cyclospora*–associated diarrhea shows acute and chronic inflammation, surface epithelial disarray, and varying degrees of villous atrophy and crypt hyperplasia. 202 *Cyclospora* infection in patients with AIDS is associated with prolonged or relapsing diarrhea and weight loss as great as 10%. 203 , 204 Diffuse, cramping abdominal pain accompanies the diarrhea in more than one half of patients and fever in one third. 204 *Cyclospora* outbreaks have been associated with contaminated drinking water and imported raspberries. 205 , 206

Diagnosis. Modified Kinyoun stain is used to identify *Cyclospora* oocysts in a concentrated fresh stool sample; oocysts appear as 8- to 9-µm, acid-fast, granular spheres.

Treatment. Trimethoprim-sulfamethoxazole appears to be effective therapy for *Cyclospora* infection. 204 (see Table 124-5).

***Giardia lamblia* and *Entamoeba* species** In immunosuppressed HIV-1–infected patients, *Giardia lamblia* does not cause more frequent or severe infection than in seronegative patients and responds appropriately to antimicrobial therapy with metronidazole. 207 In addition, neither colitis nor liver abscess caused by *Entamoeba histolytica* infection appear to be more frequent or more severe in HIV-1–infected patients. The *Entamoeba* species usually detected in HIV-1–infected patients is *Entamoeba dispar,* a nonpathogenic species. 208

Viral Infections

Cytomegalovirus CMV is a double-stranded DNA virus in the herpesvirus group. After initial infection, which in immunocompetent patients is usually asymptomatic, the virus enters a latent, nonproductive phase in circulating mononuclear cells. 209 When the host becomes immunosuppressed, virus is reactivated, leading to replication and cell lysis. Replication occurs in the nuclei of permissive cells, and virus accumulates in nuclear and cytoplasmic inclusions, producing cell enlargement and the characteristic nuclear and cytoplasmic inclusions. In the immunosuppressed host, CMV has been detected in intestinal mononuclear, epithelial, endothelial, and smooth muscle cells. 210 The local inflammatory response appears to involve CMV-induced release of proinflammatory cytokines. 211 , 212 The clinical manifestations of CMV disease in the gastrointestinal tract include esophagitis, 213 gastritis, 214 small intestinal enteritis, 214 and, less frequently, acalculous cholecystitis, 214 papillary stenosis, 145 sclerosing cholangitis, 145 pancreatitis, 215 and appendicitis. 216 Colitis appears to be the most common enteric manifestation of enteric CMV disease 217 , 218 and 219 ; among AIDS patients with colitis or enteritis, CMV has been identified in biopsy specimens from 45% of patients. 218 CMV colitis is characterized by diarrhea, fever, and weight loss. Abdominal pain and hematochezia are also frequently present and help distinguish CMV colitis from the protozoan diarrheal illnesses described earlier. The colon appears to be particularly susceptible to progression to ischemic necrosis and perforation during CMV infection. 220 Regardless of whether diarrhea is present, CMV-associated disease of the biliary tract (usually without icterus or pruritus) should be included in the differential diagnosis of abdominal pain, nausea, and vomiting in patients with AIDS. Endoscopic findings that suggest CMV-induced disease range from localized hyperemia to hemorrhagic erythema to superficial or deep ulceration (Fig. 124-2; Color Fig. 124-2A).

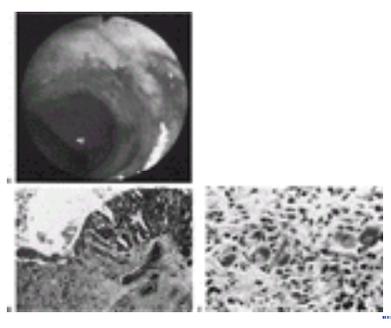

FIGURE 124-2. (See Color Fig. 124-2.) **A:** Endoscopic visualization of mucosal ulceration and inflammation in a patient with cytomegalovirus colitis. **B:** Light microscopic view of a colon biopsy from the same patient shows ulceration and hemorrhage. **C:** A higher magnification shows infiltration by inflammatory cells, many containing cytomegalic inclusions. (**B, C,** hematoxylin and eosin; **B,** original magnification × 30; **C,** original magnification × 62). (From ref. 211 .)

Diagnosis. CMV should be suspected when endoscopic or colonoscopic visualization shows discrete, often hemorrhagic, erosions or ulcerations with normal intervening mucosa in an HIV-1–infected patient. Colitis may be patchy in about 40% of cases and involve only the right colon or cecum in 18%, 220 underscoring the importance of colonoscopy in the diagnostic evaluation of colitis in an HIV-1–infected patient. The diagnosis of CMV gastrointestinal disease is established by the histopathological identification of large (cytomegalic) mononuclear, endothelial or epithelial cells containing intranuclear or cytoplasmic inclusions with surrounding inflammation 218 , 222 (see Fig. 124-2B, Fig. 124-2C; see also Color Fig. 124-2B, Color Fig. 124-2C) and confirmed by immunocytochemical staining, in situ hybridization, or DNA amplification.

Treatment. Ganciclovir and foscarnet, currently the drugs of choice (see Table 124-5), provide variable clinical responses. Because these agents are virustatic and not virucidal, recurrent CMV disease is common after the cessation of therapy. Ciclovovir is a new nucleoside analog with potent prolonged in vivo activity against CMV in patients with CMV retinitis, but the agent has not been studied in patients with gastrointestinal CMV disease.

Herpes Simplex Virus HSV is also a double-stranded DVA virus in the herpesvirus group. Latent in sensory nerve ganglia, HSV reactivation during immunosuppression leads to spread of the virus along sensory nerve pathways to mucocutaneous sites, where the virus next spreads among epithelial cells by lysis, releasing virions that infect and lyse adjacent cells. Gastrointestinal HSV disease is confined to the perianal region, rectum, and esophagus. The perianal lesions are typically chronic, cutaneous ulcers that cause localized pain but not diarrhea. 222 Involvement of the rectum (proctitis) is often associated with perianal disease. Proctitis manifests as severe anorectal pain, tenesmus, constipation, inguinal lymphadenopathy, and less often, difficulty with urination and sacral paresthesias. Such symptoms may also be associated with proctitis in seronegative homosexual men. 223 Diarrhea is not associated with typical proctitis, although the mucopurulent discharge may be misinterpreted as diarrhea. Proctocolitis, which occurs when the proctitis extends proximally into the distal sigmoid colon, can cause mild diarrhea associated with hematochezia, but the predominant symptoms are generally those of the proctitis. Overall, HSV proctocolitis is an infrequent cause of diarrhea in HIV-1–infected patients. 218

Diagnosis. Anoscopy and sigmoidoscopy are required to diagnose HSV proctitis and proctocolitis, respectively. Typical lesions begin as small vesicles and progress to erosions that often coalesce into diffuse ulcers. Diagnosis is predicated on the cytologic identification of intranuclear (Cowdry type A) inclusions in cells within the lesion and is confirmed by virus isolation.

Treatment. Acyclovir and related agents are the drugs of choice (see Table 124-5) for HSV infections. Because recurrent HSV is common, long-term suppressive therapy may be necessary.

Adenovirus In HIV-1–infected patients, adenovirus has been isolated from various body sites and may induce hepatic necrosis, 224 , 225 and 226 but intestinal involvement is rare. In the United States, adenovirus excretion is equally common in HIV-1–infected patients with and without diarrhea. 54 , 64 In contrast, 23% of Australian HIV-1–infected patients with diarrhea reportedly excrete adenovirus, compared with 5.4% without diarrhea. 65 Adenovirus has been identified with transmission electron microscopy and culture in inflamed colonic tissue of AIDS patients with chronic, watery, nonbloody,

nonmucoid diarrhea.[224, 227] Weight loss was also a prominent symptom. Endoscopically, the colonic mucosa showed areas of discrete, often raised, erythematous lesions that were several millimeters in diameter. Light microscopy showed chronic inflammation surrounding epithelial cells containing large, amphophilic intranuclear, but not cytoplasmic, inclusions. Adenovirus appeared to infect only epithelial cells, especially goblet cells, sparing lamina propria cells, which are frequent targets of CMV. At the ultrastructural level, adenovirus was associated with degeneration, death, and focal necrosis of infected epithelial cells, some of which had been extruded into the lumen (Fig. 124-3). Although adenovirus can cause pathogenic changes in the colonic mucosa, a causal relationship between adenovirus and diarrhea has not been established. Effective therapy is not available.

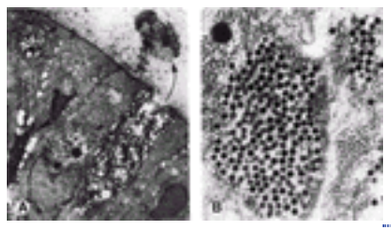

FIGURE 124-3. A: Transmission electron micrograph of a colonic biopsy specimen from a patient with adenovirus colitis shows a nucleus from a necrotic enterocyte extruded into the lumen. Adjacent cells have foci of disrupted cytoplasm containing secondary lysosomes (original magnification × 34,000). **B:** Higher magnification of a portion of the extruded nucleus in **A** shows numerous hexagonal virions characteristic of adenovirus (original magnification × 49,000). (From ref. [224].)

Astrovirus, Picobirnavirus, and Rotavirus Prospective evaluation of chronic diarrhea in HIV-1–infected patients indicated an association between the presence of astrovirus and picobirnavirus and diarrhea,[228] but further epidemiologic and clinical studies are needed to define the role of these viruses in HIV-1 disease. Rotavirus is not associated with diarrhea in HIV-1–infected patients in the United States[54, 64, 218, 228] or Africa (Zaire)[229, 230] but is the predominant virus detected in the stools of Australian HIV-1–infected homosexual men with diarrhea[65] and is present in the stool in about 14% of HIV-1–infected adults in Germany.[231] These findings suggest geographic variation in the prevalence of rotavirus-associated diarrhea in HIV-1–infected patients, but additional studies are needed.

Fungal Infections

Histoplasma capsulatum *Histoplasma capsulatum* is a dimorphic fungus that exists as a mycelial form with septate branching hyphae that contain readily airborne and infectious spores and a yeast form present in tissue macrophages. The organism is endemic in the central region of the United States and some tropical, subtropical, and temperate zone areas, where bird excrement provides microfoci of infection. Disseminated *H capsulatum* is as an important opportunistic infection in HIV-1–infected patients who reside in endemic areas.[232, 233] Gastrointestinal involvement generally reflects disseminated disease, which is due primarily to reactivation of quiescent infection. Among patients with disseminated *H capsulatum,* gastrointestinal involvement has been detected in about 70% of cases by evaluation of biopsy specimens, but gastrointestinal symptoms are present in only about 10% of patients.[234] Symptoms include diarrhea, weight loss, fever, and abdominal pain. Whether *H capsulatum* itself causes these symptoms has not been proved. Most patients with gastrointestinal manifestations of *H capsulatum* have colonic involvement. Colonoscopy in such patients may show inflammation, ulcerations, or fungating mass lesions.

Diagnosis. The histological examination of Giemsa-stained sections shows small yeast-like cells within macrophages or histiocytes. When infection is intense, the organism is not difficult to identify. However, the diagnosis of histoplasmosis is established by culture. Serologic detection of complement-fixing antibodies to *H capsulatum* mycelial antigens provides supportive evidence for infection.

Treatment. Amphotericin B is the drug of choice for disseminated histoplasmosis (see Table 124-5). The recommended therapy in HIV-1–infected patients is amphotericin B, 0.5 to 1.0 mg/kg intravenously daily for 7 days, then every other day to a total of 10–15 mg/kg followed by itraconazole 200 mg qd for chronic suppression.[235] Long-term therapy with amphotericin B, 50 to 80 mg intravenously every 2 weeks, is also highly effective in suppressing relapses after initial treatment.[233] The role of caspofungin acetate, a fungicidal echinocandin, is under evaluation.

ABDOMINAL PAIN

Abdominal pain is less common than diarrhea in HIV-1–infected patients. In two cohorts of patients with HIV-1 infection, the prevalence of severe abdominal pain was 12% among patients attending a surgical outpatient clinic and 15% among consecutive patients admitted to a hospital.[236, 237] The causes of abdominal pain in patients with HIV-1 infection are dependent on the severity of the immune suppression. Among HIV-1–infected patients with relatively preserved immune function ($CD4^+$ T cells more than 200 cells/mm^3), pain is typically due to traditional gastrointestinal disorders, such as peptic ulcer disease, biliary tract disease, inflammatory bowel disease, pancreatitis, and less commonly, appendicitis and diverticulitis. In contrast, among patients with AIDS, pain is commonly the consequence of a neoplastic process or an opportunistic infection.[236, 237, 238] and[239] The most common diseases associated with abdominal pain in patients with AIDS are *non-Hodgkin lymphoma* involving the gastrointestinal tract or abdominal cavity, CMV disease of the small intestine and colon, and *pancreatitis*. *Hepatobiliary disease* due to opportunistic infections (see later) is the leading consideration in the differential diagnosis of right upper quadrant pain in patients with AIDS. Less common causes of AIDS-associated abdominal pain include *typhlitis* or *necrotizing enterocolitis* with or without neutropenia[240, 241] and unusual manifestations of opportunistic infections, such as CMV-induced peritonitis[215] and appendicitis.[216]

AIDS-associated conditions that may present as an acute abdomen requiring emergent laparotomy include intestinal or colonic perforation due to CMV disease, intestinal obstruction or perforation caused by Kaposi sarcoma or lymphoma, intussusception associated with neoplasm or infection, and appendicitis caused by infection and neoplasm.[210, 220, 242, 243] and[244] Aside from the expanded array of causes for abdominal pain in patients with AIDS, the evaluation and management of abdominal pain in HIV-1–infected patients is otherwise similar to that in seronegative patients. Although emergent abdominal surgery was accompanied by high rates of complication and mortality early in the AIDS epidemic,[236, 242] improved awareness of the spectrum of AIDS-related abdominal complications and better surgical approaches have brought these rates into the acceptable range,[243] making emergent surgical intervention appropriate management for the acute abdomen in patients with HIV-1 infection and AIDS.

HEPATOBILIARY DISORDERS

HIV-1-infected patients and patients with AIDS may develop *cholecystitis* and *cholangitis* due to cholelithiasis and the same gram-negative bacteria that cause biliary tract disease in seronegative patients. In addition, HIV-1–infected patients are susceptible to a spectrum of biliary tract disorders related to *opportunistic pathogens* (see Table 124-2) and *lymphoma,* referred to collectively as the *AIDS cholangiopathy*. These disorders became apparent early in the AIDS epidemic when several patients with AIDS presented with right upper quadrant abdominal pain, jaundice, and fever and were shown to have acalculous cholecystitis, biliary tract obstruction due to stenosis of the distal common bile duct, and narrowing and irregularity of the intrahepatic and extrahepatic bile ducts.[144, 214] The identification of *Cryptosporidium* species infection or CMV in the gallbladder and bile ducts led to the conclusion that these pathogens had an etiologic role in the disorder. Endoscopic retrograde cholangiography further defined the underlying lesion as consistent with papillary stenosis and sclerosing cholangitis.[145] Besides *Cryptosporidium* infection and CMV, other opportunistic pathogens implicated etiologically in the syndrome include *E bieneusi, E intestinalis, I belli,* and *Pneumocystis carinii*.[144, 145, 184, 185, 195, 245, 246, 247] and[248]

Endoscopic retrograde cholangiography is the most effective diagnostic tool for evaluating the extent of the disease and excluding other processes, such as cholelithiasis, and sphincterotomy is an effective therapeutic modality for relieving the obstruction and pain.[145, 249] Rarely, HIV-1–associated non-Hodgkin lymphoma may cause sclerosing cholangitis, resulting in a similar clinical syndrome.[250] The long-term prognosis of HIV-1–infected patients with hepatobiliary cholangiopathy is similar to that of patients without the syndrome.[251, 252]

Hepatitis C virus (HCV) is the leading cause of chronic hepatitis among HIV-1–infected patients in the United States. Intravenous drug users and patients with hemophilia compose most of these co-infected patients; 40% of HCV-infected hemophiliac men are co-infected with HIV-1.[253] The natural history of patients infected with both HCV and HIV-1 differs from that of patients with HCV alone. Patients with both infections have high HCV RNA levels in blood and liver tissue, more rapid progression of liver disease, and possibly increased rates of death related to hepatic disease.[254, 255, 256] and[257] HCV viral loads are typically increased with advanced immunosuppression and are inversely proportional to $CD4^+$ T-cell number.[94, 254, 257] Despite the accelerated course of HCV replication and associated liver disease, HCV does not usually promote progression of HIV-1 disease or increase mortality.[258, 259] However, an increased risk for death and for new AIDS-defining illnesses and delayed recovery of $CD4^+$ T cells with antiretroviral therapy have been reported in some HIV-1–infected patients with HCV infection.[260] These increased risks were primarily associated

with intravenous drug use and unrelated to more progressive liver disease.

The response of HCV to antiviral therapy with interferon (IFN) in patients with HIV-1 co-infection appears to be similar to the response in HIV-1–seronegative subjects. About one fourth of patients show a sustained reduction in the level of virus 1 year after discontinuing therapy. [261], [262] and [263]; most responders have high CD4 + T-cell numbers (more than 500 cells/mm 3). Preliminary data suggest that the antiviral effects of IFN therapy plus ribavirin may be greater than with IFN alone among both HIV-1–infected and seronegative patients, [264], [265] although anemia is an important complication.

Another therapeutic option for patients with HCV and HIV-1 is HAART. In several series, [253], [266], [267], [268], [269] and [270] levels of plasma HCV and transaminases showed transient and clinically unapparent increases with HAART, whereas HCV RNA decreased to below the limits of detection, albeit in a minority of patients. Although both subclinical and severe hepatitis can occur with the initiation of HAART, [94], [270], [271] and [272] the presence of co-infection with HCV and HIV-1 should not be a primary deterrent for beginning antiretroviral therapy. The relatively infrequent “immune restoration” syndrome, characterized by deleterious inflammatory responses or even reactivation of infections (e.g., CMV and MAC) on HAART, [273], [274] and [275] appears not to affect HCV infection. Efforts to reduce the impact of HCV infection should include limiting the use of alcohol, vaccination for hepatitis A if the patient is seronegative, and therapy for HCV to eradicate infection or limit progressive liver injury in those with significant hepatic pathology.

PANCREATITIS

Pancreatitis is an important gastrointestinal complication in patients with HIV-1 infection. Autopsy studies have identified an array of *opportunistic pathogens,* including viruses (CMV and HSV), fungi (*Cryptococcus neoformans*), bacteria (*Mycobacteria* species), and protozoa (*Toxoplasma gondii*), as well as *neoplasms* (non-Hodgkin lymphoma and Kaposi sarcoma), in the pancreas. [276] Although CMV and tuberculosis may cause clinical pancreatic disease, [215], [277], [278] most infectious and neoplastic processes involving the pancreas in HIV-1–infected patients are subclinical. In contrast, *drug-induced pancreatic disease* is a common cause of clinical pancreatitis among patients with HIV-1 infection. [279] The two most common drugs implicated in HIV-1–associated pancreatitis are pentamidine and dideoxyinosine. Pentamidine-induced disease, which may occur with either inhaled or parenterally administered drug, causes mild to severe and even fatal pancreatitis. Dysregulation of glucose metabolism is common in this setting, although pentamidine itself may cause dysregulation in the absence of clinical pancreatitis. [280] Dideoxyinosine therapy may induce pancreatitis in up to 10% of patients [281], [282]; occasionally, dideoxyinosine-induced pancreatitis is fatal. Low-level hyperamylasemia (serum amylase level less than three times the upper limit of normal) may occur in patients with AIDS despite the absence of underlying pancreatic disease. [283], [284] After antiretroviral drug-induced pancreatitis has been excluded, the presentation, evaluation, and management of acute pancreatitis in HIV-1–infected patients are similar to those in seronegative patients.

GASTROINTESTINAL BLEEDING

Gastrointestinal bleeding is uncommon in HIV-1–infected patients with and without AIDS. In one prospective study, [285] upper gastrointestinal bleeding occurred in 6% of HIV-1–infected patients during a 14-month period. HIV-1–infected patients are as likely to bleed from HIV-1–related etiologies as *non–HIV-1-related causes*. The most common HIV-1–related causes are *viral esophagitis, gastroduodenal lymphoma,* and *MAC disease* of the proximal small intestine. [285], [286] and [287] Regarding viral esophagitis, HSV is the most common cause of bleeding; CMV esophagitis is rarely associated with significant bleeding. [213], [288], [289] Thrombocytopenia and other coagulopathies infrequently cause bleeding from minor lesions.

Similar to the low prevalence of bleeding in the upper gastrointestinal tract, intestinal and colonic bleeding in HIV-1–infected patients is uncommon. Although the differential for lower gastrointestinal tract bleeding includes traditional causes, such as diverticulosis, angiodysplastic lesions, and hemorrhoids, *opportunistic infectious processes* are, in our experience, the most common etiology for bleeding from the lower gastrointestinal tract in patients with HIV-1 infection. In contrast to the esophagus, however, where HSV is the most common infection associated with bleeding, lower tract bleeding is more frequently caused by CMV. [219], [220], [290] Among HIV-1–infected patients with CMV colitis, bleeding is reported to occur in up to 10%. [220] Typically, bleeding is slow and associated with abdominal pain and diarrhea; bleeding from CMV colitis is rarely severe. [291] Other HIV-1–related causes of lower gastrointestinal tract bleeding include neoplasms, such as non-Hodgkin lymphoma; unusual infections, such as *H capsulatum*; and idiopathic ulcerations. The approach to diagnosis and management of gastrointestinal bleeding in HIV-1–infected patients is similar to that of seronegative patients. Gastrointestinal bleeding is associated with reduced survival in patients with HIV-1 infection owing to the comorbidity associated with late-stage AIDS. [287]

GASTROINTESTINAL NEOPLASMS

Kaposi sarcoma and *non-Hodgkin lymphoma* are the most common gastrointestinal neoplasms associated with HIV-1 infection. Recognized formerly as a rare neoplasm of the skin in older men of Jewish or Eastern European origin, Kaposi sarcoma emerged in the 1980s as one of the most common opportunistic processes heralding the AIDS epidemic. Although the incidence of Kaposi sarcoma has declined in recent years, [292] the tumor remains an important gastrointestinal malignancy in HIV-1–infected, immunosuppressed, homosexual and bisexual men; Kaposi sarcoma occurs rarely in those who acquire HIV-1 intravenously or through heterosexual contact. Epidemiologic and molecular studies have implicated human herpesvirus type 8 (HHV-8), also termed *Kaposi sarcoma herpesvirus,* etiologically in the development of Kaposi sarcoma. [293], [294], [295], [296] and [297] Histologically, the tumor is characterized by the proliferation of spindle-shaped endothelial cells in a stroma of proliferating abnormal vessels, fibroblasts, and infiltrating leukocytes. The local presence of angiogenic growth factors, HHV-8, and impaired immunosurveillance mechanisms appear to predispose the gastrointestinal tract to Kaposi sarcoma formation.

Endoscopically, Kaposi sarcoma begins as a small hyperpigmented plaque or macule, progressing to a violaceous nodule and eventually a tumor-like mass. In the early stage of the AIDS epidemic, visible tumor was identified in the gastrointestinal tract in 40% to 50% of patients with AIDS. [298], [299] Although the tumor may be more common in the upper tract, Kaposi sarcoma occurs throughout the gastrointestinal tract. Oropharyngeal Kaposi sarcoma is highly suggestive of upper tract involvement. Most patients with enteric Kaposi sarcoma are asymptomatic; consequently, therapy for gastrointestinal lesions is rarely necessary. IFN-a and doxorubicin treatment have been associated with tumor regression. [300], [301] Unusually large tumors may cause bleeding, obstruction, or perforation and can be treated emergently with radiation therapy.

Among HIV-1–infected patients with non-Hodgkin lymphoma, the most frequently involved gastrointestinal sites are the colon (46%), ileum (39%), and stomach (23%). [302] Symptoms associated with gastrointestinal lymphoma include abdominal pain, weight loss, obstruction, and bleeding. [302] /SUP>, [303] and [304] The presence of latent and replicating Epstein-Barr virus DNA in the lymphomas of patients with AIDS suggests that lymphoproliferative lesions in the gastrointestinal tract could represent the outgrowth of Epstein-Barr virus–transformed mucosal B [305] Chemotherapy, surgery, radiotherapy, or combination therapy have not substantially improved survival of HIV-1–infected patients with gastrointestinal lymphoma.

ANORECTAL DISEASE

Anal complications associated with HIV-1 disease includ*perianal condylomata, infection, fissure, fistul*, and *squamous cell carcinom*. These complications occur predominantly in HIV-1–infected homosexual and bisexual men. Homosexual men, particularly those who are HIV-1 positive, have a high incidence of anal infection with human papillomavirus (HP[306] which has been implicated as a risk factor for anal condylomata and anal squamous cell carcino[307] The link between HPV, particularly types 16 and 18, and anal carcinoma may be through the ability of the virus to induce local dysplasia in a high proportion (15%) of immunosuppressed, HIV-1–infected homosexua[308] Perianal infection is commonly caused by HSV, but rectal involvement is rare. Rectal complications in HIV-1-infected patients include nonspecific proctitis (rectal inflammation in the absence of an identifiable patho[309] and infectious proctitis due to *Chlamydia trachomatis, Treponema pallidum, Neisseria gonorrhoea* or HSV.[310] Perirectal abscess in HIV-1–infected patients is often idiopathi[311] but may be associated with HP[312], [313] or CMV.[314]

The initial presentation of anorectal disease includes dyschezia (pain on defecation), bleeding, drainage from the anal canal, palpable mass, and sepsis syndrome (local pain and fever). Dyschezia usually results from ulcerative lesions in the anal canal due to infection, abscess, fissure, hemorrhoids, or neoplasm. A palpable mass suggests neoplasm. When the mass is tender and accompanied by fever, perirectal abscess leads the differential diagnosis. Tenesmus, urgency, and frequent small-volume stools suggest proctitis. Perianal drainage is usually caused by a fistulous tract or, less commonly, severe proctitis. Careful inspection, palpation of the perianal area and anal canal, and visualization of the rectum are mandatory components of the anorectal evaluation. Biopsy is performed for microbiologic evaluation and histological examination, and computed tomography is helpful for staging neoplasms and evaluating perirectal abscess. Symptomatic treatment, pathogen-specific antimicrobial therapy, and surgery in selected patients [315] are effective for most nonmalignant anorectal lesions. Anorectal neoplasms are treated with radiation therapy, chemotherapy, and, when localized, surgical res[316] ion.

In summary, the gastrointestinal tract plays a critical role in HIV-1 infection at virtually all stages of disease. As the largest lymphoid organ in the body, the intestinal mucosa is an important site of virologic and immunologic events that eventually lead to local immunosuppression and the gastrointestinal complications of AIDS, particularly the acquisition of opportunistic infections. New insights into the natural history of these infections, improved diagnostic modalities, new antiretroviral therapy, and more effective antimicrobial agents provide sound reasons for optimism in caring for patients with the gastrointestinal complications of AIDS.

CHAPTER 125

Ellen Li and Samuel L. Stanley, Jr.

PARASITIC DISEASES: PROTOZOA

Protozoan parasitic infections of the gastrointestinal tract are being increasingly recognized as an important public health problem in the United States. They were the most frequently identified etiologic agents in water-borne disease outbreaks in 1991 through 1994. [1] The reasons for the apparent increased prevalence of intestinal parasites in the United States include the continuing immigration of people from developing countries in southeast Asia, the Caribbean, and Central America; the expanded use of day-care facilities, which represent breeding grounds for any fecally-orally transmitted pathogens; a growing problem with fecally contaminated food and water supplies; the increased recognition of parasites as pathogens of patients with acquired immunodeficiency syndrome (AIDS); and the development of improved stool examination techniques. [2]

The intestinal protozoan pathogens include both parasites that are extracellular, such as *Giardia lamblia, Blastocystis hominis,* and *Entamoeba histolytica,* and the intracellular spore-forming coccidian parasites *Cryptosporidium parvum, Cyclospora cayetanensis,* and *Isospora belli.* This latter group of organisms has emerged as important pathogens in immunocompetent individuals as well as in patients with AIDS. The most commonly detected protozoan pathogen in stool specimens in the United States is *G lamblia* [2] (Table 125-1). *B hominis* is the next most commonly detected protozoan in stool, although its role in intestinal disease remains controversial. The reported prevalence of the coccidian organisms, such as cryptosporidia, is probably underestimated because the appropriate procedures necessary to detect them may not be routinely performed in many clinical laboratories. Conversely, the prevalence of clinically significant *E histolytica* infections may be overestimated, based on the recent recognition that organisms identified as *E histolytica* by microscopic examination could be the morphologically indistinguishable nonpathogenic *E dispar*. In some cases in which infection is suspected on clinical grounds, stool examination may not be revealing, and endoscopy may be necessary to make the diagnosis. It is important for the gastroenterologist to know what the likely organisms are, where and what to sample, and how specimens should be processed to optimize the diagnostic yield (Table 125-2).

ORGANISM	STOOL SPECIMENS CONTAINING THE ORGANISM (%)
Giardia lamblia	7.2
Blastocystis hominis	2.6
Entamoeba histolytica	0.9
Dientamoeba fragilis	0.5
Cryptosporidium species	0.2

Note: The results of 216,275 stool specimens examined for intestinal parasites by state public health laboratories in 1987 are shown. Only organisms detected at a level of more than 0.1% of the stools are listed.

Adapted from ref. 2.

TABLE 125-2 Morophology of Human Gastrointestinal Protozoan Parasites

EXTRACELLULAR PROTOZOAN PARASITES

Amebiasis: Entamoeba histolytica

E histolytica is the causative agent of human amebiasis. The clinical manifestations of human amebiasis range from asymptomatic disease to invasive disease manifested as amebic colitis or liver abscess. Although Brumpt postulated in 1925 that there were two morphologically indistinguishable species of *E histolytica*—one that could cause disease and a second that could not [3]—only in the 1990s have molecular genetic analyses confirmed data from isoenzyme studies and clearly established that there are two genetically distinct but morphologically identical species [4], [5]: *E histolytica,* which can cause invasive amebiasis, and *E dispar,* a harmless commensal.

The life cycle of *E histolytica* consists of two stages: the cyst (host infective stage) (Fig. 125-1) and the trophozoite (host tissue invasive stage) (Fig. 125-2). No host other than humans is implicated in the life cycle, although natural infection of primates has been reported. [6] The disease is most commonly acquired by ingestion of food or water contaminated with feces containing the cyst form of the parasite, but venereal transmission through fecal-oral contact also occurs. Under still undefined stimuli in the intestinal tract, the cysts excyst and then form by nuclear and cytoplasmic division a total of eight trophozoites. The trophozoites are the motile feeding form of the parasite and contain a single nucleus and pseudopodia. Trophozoites are the causative agents of invasive disease but play no role in the transmission of disease, owing to their rapid degeneration outside the body and destruction by gastric acidity. *E histolytica* trophozoites multiply by binary fission, and they encyst, producing uninucleate cysts, which then undergo two successive nuclear divisions to form the characteristic quadrinucleate cysts.

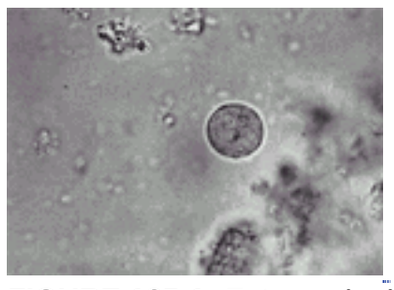

FIGURE 125-1. *Entamoeba histolytica* cyst from stool specimen stained with iodine. The cyst contains four nuclei and measures 9 to 25 µm in diameter. (Courtesy of Centers for Disease Control and Prevention, Atlanta, GA.)

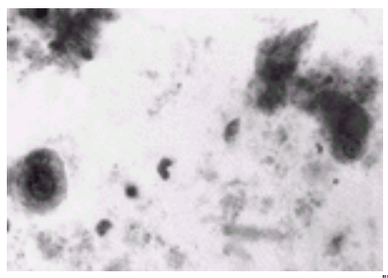

FIGURE 125-2. *Entamoeba histolytica* trophozoites in stool. Note ingested red cells and the single nucleus (trichrome stain). (Courtesy of Centers for Disease Control and Prevention, Atlanta, GA.)

Epidemiology It has been estimated that 500 million people are infected with either *E histolytica* or *E dispar.* [7] In asymptomatic individuals, the prevalence of *E dispar* infection is about 7- to 10-fold higher than *E histolytica* infection. Forty million individuals infected with *E histolytica* develop disabling colitis or extraintestinal abscesses, resulting in 50,000 deaths annually. Among parasitic diseases, only malaria and schistosomiasis result in more deaths than amebiasis. [7] High prevalence rates of amebiasis (both *E histolytica* and *E dispar*) are found in developing countries, including Central and South America, the Indian subcontinent and Indonesia, and the sub-Saharan and tropical regions of Africa. [7], [8] and [9] A recent prospective study of a cohort of almost 300 children living in a slum region of Dhaka revealed that almost 40% acquired a new *E histolytica* infection during the 12-month study period, but only 3% of the infections were associated with dysentery. [8] A serologic study of the inhabitants of Mexico City demonstrated that 8.4% had been infected with *E histolytica* in the past 5 to 10 years. [9] The prevalence of colonic disease is equal between men and women, but amebic liver abscesses and other extraintestinal disease are 3 to 10 times more common in men. Children, especially neonates, and pregnant and postpartum women have an increased risk for severe disease and death. Malignancy, malnutrition, and treatment with corticosteroids are other risk factors for more severe disease. In developed countries of Europe and North America, amebic infection is generally confined to certain high-risk groups, including recent travelers and immigrants, inmates of mental institutions, and sexually active homosexual men. [10] However, it should be noted that even in these populations, most individuals are infected with *E dispar* rather than *E histolytica*. [11], [12] There is conflicting evidence regarding naturally acquired immunity to amebiasis. In the study of Bangladeshi children, some children showed resistance to the acquisition of a new *E histolytica* infection that was associated with the presence of stool immunoglobulin A antibodies to an *E histolytica* antigen. [8] However, the effect was relatively short lived, and almost 20% of the children in the study had more than one episode of amebiasis during the 1-year study period. [8] These data, along with anecdotal reports of multiple episodes of amebic liver abscess in the same individual, suggest that naturally acquired immunity to amebiasis is, at best, short lived and may occur only in a small proportion of infected individuals. [13], [14]

Pathogenesis and Pathology Invasive disease is characterized by ulcerations of the intestinal mucosa, which extend into the submucosa. Trophozoites invading laterally through the submucosa, relatively sparing the overlying epithelium, give rise to the classic flask-shaped ulcer of amebiasis. [15], [16], [17], [18] and [19] In some cases, amebic invasion through the mucosal and submucosal layers and subsequent dissemination through the portal circulation to the liver result in the formation of liver abscesses. Adhesion of amebic trophozoites to host epithelial cells through a galactose-binding lectin, [20] release of cysteine proteases, [21], [22], [23], [24] and [25] amebic contact-dependent cytolysis of host cells through amebapore (a pore-forming protein that resembles NK-lysin from natural killer T cells), [26], [27] and amebic phagocytosis and motility have all been implicated in tissue invasion and destruction by the organism. *E histolytica* can induce severe inflammation that can be confused clinically with inflammatory bowel disease. [28] The molecular mechanisms underlying amebic induction of gut inflammation and disease have recently been delineated. [29], [30] These studies suggest that *E histolytica* cysteine proteinases play a key role in amebic invasion of intestinal tissue and may stimulate gut inflammation by activating host interleukins-1 (IL-1). [25] Recent studies using human cell lines and a murine model of amebic liver abscess indicate that *E histolytica* trophozoites can also induce apoptosis in host cells. [31], [32] This may be particularly important for the pathogenesis of amebic liver abscess. The interaction of *E histolytica* trophozoites with the intestinal mucosa has been modeled in animals, [19], [33] colonic explants, [34], [35] and [36] intestinal cell lines, [37], [38] and [39] and human intestinal xenografts. [25], [40], [41] In addition to disruption and penetration of trophozoites through the epithelium, changes in epithelial permeability may occur before morphologic disruption, which could facilitate transport of amebic toxins or secretagogues across the epithelium before direct trophozoite invasion. [39] Ultrastructural studies have shown blunting of microvilli in regions where amebas are in close proximity to the brush border. [39], [42] Neutrophils in close proximity to amebas often exhibit a variety of degenerative changes, and it has been suggested that substances released from lysed neutrophils contribute to the tissue damage. This was confirmed by recent studies in human intestinal xenografts in severe combined immunodeficient mice, in which depletion of neutrophils from mice lessened intestinal xenograft damage early in amebic infection. [41] Trophozoites also may cause diarrhea by stimulation of intestinal secretion: amebic lysate applied to the serosal but not the mucosal side of stripped colonic mucosal preparations produces a rapid increase in anion secretion. [35], [43] *E histolytica* trophozoites introduced into human intestinal xenografts induce the production of the proinflammatory mediators IL-1, IL-8, and cyclooxygenase-2 by the intestinal epithelial cells. [25], [44] Cytokine production by intestinal epithelial cells is mediated by *E histolytica* activation of the transcription factor NF-?B, and blockade of NF-?B synthesis greatly reduces inflammation and tissue damage early in amebic infection. [41] These studies suggest that the inflammatory response, although critical for controlling *E histolytica* infection, may contribute to tissue damage early in disease.

Clinical Manifestations

Intestinal disease. The clinical manifestations of intestinal amebiasis range from asymptomatic infection to mild diarrhea to classic dysentery with abdominal pain, tenesmus, and bloody stools. [45], [46] The presentation is generally subacute, with most individuals symptomatic for less than 1 month. Dysentery is a hallmark of invasive amebic infection, and stools that are not grossly bloody almost invariably contain occult blood, consistent with the invasive pathophysiology. Rarely, patients may present with a more fulminant colitis with severe bloody diarrhea and fever. [47] These patients have diffuse abdominal tenderness but usually do not present with a rigid surgical abdomen, although up to 75% of these patients may have peritonitis secondary to leakage through the severely diseased colon. Fulminant colitis is associated with a high (more than 50%) rate of mortality. The risk for developing this syndrome is higher in children, pregnant women, and patients taking corticosteroids. Toxic megacolon is a rare but often fatal complication that is associated with administration of corticosteroids to patients with intestinal amebiasis. Unusual presentations of intestinal amebiasis include chronic nondysenteric infection—in which symptoms of diarrhea, abdominal pain, and weight loss persist for years—and appendiceal involvement. The differential diagnosis of invasive intestinal amebiasis includes infection with *Shigella, Campylobacter,* and other invasive bacteria, as well as pseudomembranous colitis secondary to *Clostridium difficile,* cytomegalovirus colitis, ischemic colitis, and inflammatory bowel disease. Because of the similarities in symptoms between amebiasis and inflammatory bowel disease, [28] amebiasis should be excluded by examination of stools or amebic serology in all patients before a diagnosis of inflammatory bowel disease is made and especially before corticosteroid therapy is begun. Rarely, a localized amebic colonic infection results in a segmental mass of granulation tissue forming an ameboma. Amebomas are found, in decreasing order of frequency, in the cecum, ascending colon, rectosigmoid, transverse colon, and descending colon, and they can be detected on physical examination as a tender palpable mass. The ameboma can be mistaken for a carcinoma on barium enema. Amebic strictures are most commonly observed in the anus, rectum, or sigmoid colon and must be differentiated from those due to lymphogranuloma venereum (chlamydia) or malignancy.

Extraintestinal disease. The most common manifestation of extraintestinal amebiasis is amebic liver abscess. [48], [49], [50] and [51] Patients often present with fever and right upper quadrant pain, leukocytosis, and abnormal liver test results, with an elevated alkaline phosphatase level the most common finding (more than 75% of individuals). Hyperbilirubinemia is uncommon, and severe jaundice may indicate bacterial superinfections of the abscesses. Concurrent diarrhea occurs in only one third of the patients. In about half the patients with amebic liver abscess, hepatomegaly and point tenderness of the liver are prominent on physical examination. Most patients have a single abscess, usually in the right lobe. Multiple abscesses are observed more commonly in patients with an acute presentation. With early diagnosis and treatment, the mortality of uncomplicated liver abscess is less than 1%. Most of the complications are related to rupture of the amebic liver abscess, which occurs most commonly into the chest (10% to 20%), but also into the peritoneum (2% to 7%) or pericardium (rare, often from left lobe abscess). The development of a bronchopleural fistula presents as a cough productive of the odorless, brown anchovy paste–like necrotic contents of the liver abscess. Amebas are usually not detectable in the necrotic material. Before the availability of effective antiamebic therapy, formation of such a fistula was a good prognostic sign for a spontaneous

cure because it provided drainage of the abscess. Amebic brain abscess occurs rarely but has a high associated rate of mortality. There have been case reports describing genitourinary involvement, including perinephric abscesses, splenic abscesses, infected rectal cysts, rectovaginal fistulas, cervical ulcers, uterine involvement, and vaginal lesions. [51] Cutaneous amebiasis is a rare complication and generally involves the perineum and genitalia as a complication of intestinal disease. [52]

Diagnosis The diagnosis (see Table 125-2) of intestinal amebiasis still rests primarily on microscopic demonstration of cysts or trophozoites in the stool or in scrapings or biopsy samples obtained by sigmoidoscopy or colonoscopy. Because organisms may be excreted intermittently or may be unevenly distributed in the fecal specimen, at least three stool specimens on separate days should be examined to detect 85% to 95% of the infections. Barium studies, laxatives, bismuth-containing preparations, antidiarrheal agents, and antibiotics can interfere with detection of the organism. Problems with microscopy include the misidentification of other *Entamoeba* species and leukocytes that have ingested red cells for *E histolytica* and the inability to distinguish between *E histolytica* and *E dispar*. In patients with mild bowel complaints, whose symptoms do not appear consistent with invasive amebiasis, care must be taken in the interpretation of a positive microscopic examination for amebic cysts or trophozoites. Fecal antigen detection assays that can distinguish between *E histolytica* and *E dispar* infections have been developed for commercial use, and their efficacy has been established in areas where disease is not endemic. [53], [54] and [55] Because *E dispar* infections are not associated with seroconversion, amebic serology may be a useful adjunct in assessing the patient, especially in areas where *E histolytica* is not endemic. Sigmoidoscopy should generally be performed in patients presenting with dysentery. Endoscopy should be performed without previous bowel preparation in order to increase the chance of detecting amebas in the colonic mucus. [56] Discrete shallow-based ulcers covered with yellow or white exudate with intervening areas of edematous mucosa are often found in invasive amebic colitis. However, the endoscopic appearance of amebic colitis may be indistinguishable from inflammatory bowel disease, diffuse mucosal erythema, granularity, and friability, or from pseudomembranous colitis secondary to *C difficile* infection, with pseudomembranes. [47] Multiple biopsy samples or scrapings should be taken from the ulcer edge, exudate, and intervening mucosa. [47], [56] The diagnostic yield from endoscopic biopsy samples or scrapings is high. Trophozoites are usually easily identified in these specimens by routine light microscopy, but immunohistochemical staining for *E histolytica* may further increase the yield. [47] Serology is an important tool in the diagnosis of amebic liver abscess and can help confirm the diagnosis of intestinal amebiasis. [57] Because antiamebic antibodies may persist for months and years after the eradication of infection, a positive serology requires more rigid clinical and diagnostic correlation in endemic areas. Indirect hemagglutination is the most sensitive assay, and it yields positive results in 90% to 100% of subjects with liver abscess, 75% to 90% of subjects with symptomatic intestinal infection, and 5% to 50% of subjects with asymptomatic infection. Enzyme-linked immunosorbent assay (ELISA) kits for the serodiagnosis of amebiasis are also available. Because serologic tests may be negative early in the course of an acute infection, it is important to repeat the serology 5 to 7 days later. Recombinant antigens have been used for diagnosis and may offer improved specificity for acute infection. [58], [59] and [60] An imaging procedure should be performed in all suspected cases of amebic liver abscess. Right upper quadrant ultrasonography is usually the least expensive initial procedure. The usual appearance is a round or oval-shaped hypoechoic lesion with no wall echoes. On abdominal computed tomography, the abscesses usually appear as well-defined low-density lesions. The differential diagnosis of space-occupying lesions in the liver includes bacterial (pyogenic) liver abscess, hydatid cyst, or tumor. Amebic serology usually establishes or excludes the diagnosis of amebic liver abscess. Ultrasonographic or computed tomography–guided needle aspiration of the abscess can be performed to rule out a pyogenic abscess if the results of serology are nondiagnostic or if the clinical condition of the patient requires an immediate diagnosis. Concomitant pyogenic and amebic infections are unusual at the time of the initial presentation, but bacterial superinfection may occur after repeated aspirations or open drainage. Amebas are rarely recovered in the aspirate. Because of the risk for spillage and anaphylaxis, aspiration should be avoided if there is suspicion of a hydatid cyst.

Treatment Patients with *E histolytica* infection should receive antiamebic therapy, but there is no evidence that patients with *E dispar* infection require treatment. [46], [61] If one does not have access to assays that distinguish between infection with *E histolytica* and *E dispar,* treatment decisions must be based primarily on the clinical presentation. The goals of treatment are to cure invasive disease and eradicate intestinal carriage of the organism. Metronidazole is the drug of choice for patients with invasive intestinal disease or amebic liver abscess (Table 125-3). Metronidazole is highly efficacious (90% cure rate in many studies) and is relatively well tolerated. Despite widespread use of this drug, *E histolytica* resistance to metronidazole has not been a problem to date. Intestinal disease is generally treated for 5 to 10 days. Antibiotic therapy of liver abscess is similar; however, 2.4 g of metronidazole taken as a single dose for 2 days has been reported to be more effective in a small group of patients. [62] Common side effects of metronidazole include nausea, headache, metallic taste, and abdominal discomfort; ataxia, confusion, insomnia, and paresthesias may occasionally occur. Patients should avoid alcoholic beverages owing to metronidazole's disulfiram-like properties. The most serious side effects are central nervous system effects (psychosis, seizures), which mandate cessation of the drug. Rapid recurrence of these symptoms after readministering the drug has been reported. [63] The drug is available for intravenous administration in patients unable to take medications by the oral route. Other nitroimidazoles—tinidazole and ornidazole—may have less toxic effects but are not currently available in the United States. Tinidazole is reported to be effective as a single dose. [64]

DRUG	ADULT DOSAGE	PEDIATRIC DOSAGE
Lumenal Agents[1]		
Paromomycin (Humatin)	30 mg/kg/d orally × 7 days in 3 divided doses	25 mg/kg/d orally × 7 days in 3 divided doses (maximum, 2 g/d)
Iodoquinol (Yodoxin)	650 mg orally tid × 20 days	30–40 mg/kg/d × 20 days in 3 divided doses (maximum, 2 g/d)
Agents for Invasive Amebiasis[2]		
Metronidazole	750 mg orally tid × 5–10 days 500 mg IV every 6 h × 5–10 days	30–50 mg/kg/d × 5–10 days orally in 3 divided doses; 15 mg/kg IV load followed by 7.5 mg/kg every 6 h (maximum, 2250 mg/d)
Dehydroemetine[3] (Mebadin)	1–1.5 mg/kg/d IM × 5 days (maximum, 90 mg/d)	1–1.5 mg/kg/d IM × 5 days (maximum, 90 mg/d)

[1]Lumenal agents are used primarily for the treatment of nondysenteric amebiasis and to eradicate intestinal colonization after treatment of invasive amebiasis (colitis and liver abscess).

[2]Treatment of amebic colitis, liver abscess, and other invasive disease is followed by a complete course of a lumenal agent to eliminate intestinal colonization.

[3]Available only through the Centers for Disease Control and Prevention: telephone, 404-639-3670 or 404-639-3356; nights and emergencies, 404-639-2888.

tid, three times daily; IM, intramuscularly.

TABLE 125-3 Antibiotic Therapy for Amebiasis

In the critically ill patient with fulminant amebic colitis, there may be some advantage in adding a second agent, dehydroemetine, for the first 2 to 3 days of therapy. Although there are no controlled trials to support such combination therapy, dehydroemetine offers a rapid amebicidal effect that could be beneficial in severe disease. The short course of therapy is designed to lessen the risk for cardiotoxicity. Dehydroemetine, which is preferred to the parent compound, emetine, because it may be less toxic, is available only from the Centers for Disease Control and Prevention. Because bacterial peritonitis resulting from leakage of the diseased colon is a frequent complication of fulminant amebic colitis, antibacterial therapy should also be initiated in these patients. [46] As in other patients with dysentery, antidiarrheal agents should not be administered. After treatment of invasive intestinal or extraintestinal amebic disease is complete, a lumenal agent is generally begun to eradicate intestinal carriage of the organism. Three drugs have proven efficacy as lumenal agents: diloxanide furoate (no longer available in the United States), paromomycin, and iodoquinol (see Table 125-3). The side effects of paromomycin are diarrhea and gastrointestinal side effects. Rare dose-related neurological toxicity, including optic neuritis, has been reported with iodoquinol. It is controversial whether a lumenal agent is necessary in conjunction with treatment with metronidazole because courses of metronidazole of 10 days or longer may be effective in eradicating intestinal carriage. [65] Because about 10% to 15% of patients treated with any of these agents fail to eradicate intestinal carriage, a follow-up stool examination after completion of therapy is recommended. Most cases of colonic and extracolonic amebiasis can be managed medically. Even in cases of fulminant colitis, it is unclear whether these patients benefit from surgery unless toxic megacolon is present. [46] Further interventions are generally reserved for prevention of complications resulting from perforation of the colon and rupture of liver abscesses. Possible indications for aspiration of an amebic liver abscess as an adjunct to medical therapy include extremely large abscesses in which rupture is felt to be imminent, abscesses in the left lobe of the liver (because of the higher risk for rupture into the pericardium), and treatment failure, in which fever and pain persist after 3 to 5 days of appropriate therapy. Aspiration can generally be accomplished percutaneously. Surgical drainage should be reserved for large left lobe abscesses that cannot be reached percutaneously. It is important to note that amebic liver abscess cavity may resolve slowly and that successfully treated abscess cavities may increase in size over the first few weeks. Most abscesses resolve by 6 months, but 10% of patients may have abnormal ultrasonographic findings more than 1 year after therapy. The persistence of a cavity alone is not an indication for aspiration or for administering another course of antibiotics. Positive ameba stool examinations may be encountered in patients with minimal bowel complaints as well as in AIDS patients with diarrhea who do not have symptoms or findings consistent with invasive disease. Most of these cases represent infection with *E dispar,* rather than *E histolytica,* and do not require therapy. However, it is recommended that asymptomatic cyst passage of pathogenic strains of *E histolytica* be treated because these patients may subsequently develop invasive disease or transmit the organism to close contacts. At the present time, our recommendation is to treat all patients in areas of nonendemicity whose stool examination results are positive, particularly because stool examinations are rarely conducted in the absence of any intestinal symptoms. This practice may change after widespread acceptance of tests that can differentiate between *E histolytica* and *E dispar*. Despite legitimate concerns about administering metronidazole in pregnancy, women who develop symptomatic amebic colitis during pregnancy should receive metronidazole because of their increased risk for fulminant colitis. A long-term follow-up study of women given metronidazole for therapy of trichomonas during pregnancy reported no adverse outcomes. [66] However, in the case of the pregnant woman with a positive stool

examination result, but without evidence of invasive disease (a setting in which infection with *E dispar* is most likely), treatment with paromomycin, a nonabsorbable aminoglycoside, could be initiated with close follow-up of the patient. [67]

Giardia lamblia

Giardia lamblia (also termed *intestinalis* and *duodenalis*) is a flagellated protozoan initially described by Van Leeuwenhook in 1681 and by Lambl in 1859. The clinical spectrum of human giardiasis includes asymptomatic carriage, acute self-limiting diarrhea, and, rarely, persistent diarrhea that may fail to respond to appropriate therapy even in immunocompetent individuals. *Giardia* infection can cause intestinal malabsorption, and in children, this may be associated with retardation of growth and development.

Giardia species represent one of the most primitive of all eukaryotes. [68] The life cycle consists of two stages: the trophozoite and the cyst (Fig. 125-3). Infection is initiated by ingestion of as few as 10 to 100 cysts. [69] The cysts excyst in the proximal small intestine, releasing two trophozoites that multiply by binary fission. Trophozoites attach to the intestinal mucosa through an attachment organelle called the *ventral disk*. The life cycle is completed by encystation, an event that may be induced by exposure to intralumenal conjugated bile salts or decreasing levels of cholesterol. [70], [71]

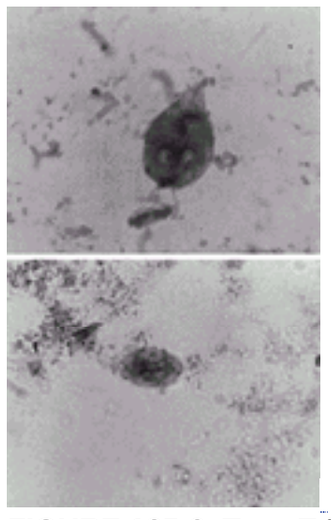

FIGURE 125-3. Top: Trichrome stain of a *Giardia lamblia* trophozoite, demonstrating the characteristic facelike image secondary to the two nuclei, each containing a prominent karyosome and four symmetrically placed flagella. **Bottom:** Trichrome stain of a *Giardia lamblia* cyst, 7 to 10 µm in length, and ovoid in shape. (Courtesy of Patrick Murray, Ph.D., St. Louis, MO.)

Epidemiology *Giardia* is cosmopolitan in distribution, and prevalence rates are estimated to be as high as 2% to 5% of populations in the industrialized world and a staggering 20% to 30% of individuals in some regions of the developing world. *Giardia* is now the most frequently identified intestinal parasite in the United States and was the most commonly implicated pathogen in water-borne disease outbreaks between 1978 and 1991. [2] Although recognized as a common pathogen, it is less well appreciated that *Giardia* can cause illness serious enough to require admission to the hospital, with the number of admissions for giardiasis rivaling that for shigellosis. [72] High-risk groups for giardiasis include infants and young children, particularly those attending day-care centers, individuals who have traveled outside the United States, people exposed to infected water sources, and homosexual men. [73] The prevalence of *Giardia* infections among children in day-care centers varies from 17% to 90%. Day-care centers are emerging in the United States as a major site of endemic *Giardia* infection and as a nidus for spread of the organism to the surrounding community. [74] *Giardia* has been implicated in multiple outbreaks of diarrheal illness associated with ingestion of contaminated drinking water and recreational water sources. [1], [75] Many of these outbreaks were associated with unfiltered water systems in which the only treatment was chlorination, a tribute to the ability of the cysts to survive in fresh water and their relative insensitivity to chlorination. Contamination of recreational water sources may occur from animals; strong epidemiologic data, and more recently genetic data, indicate that giardiasis is a zoonosis. [76], [77] This provides an immense reservoir of infection that can make disease control more difficult. Transmission of *Giardia* does not occur exclusively by ingestion of contaminated water; food-borne transmission has been described in several outbreaks.

Pathogenesis and Pathology Despite intensive investigation, the pathogenesis of human giardiasis is poorly understood. Adherence to intestinal epithelial cells is a critical step in infection. [78] Adhesion is inhibitable by drugs that block actin polymerization and microtubule formation, which interfere with attachment by the ventral sucking disk of the parasite. Adhesion is also inhibited by D-mannose and other mannose derivatives, suggesting that parasite adherence may be mediated in part by *Giardia* lectin. [79], [80] and [81] Inhibition of *Giardia* adherence to artificial substrates by human neutrophils and monocytes indicates one possible mechanism by which host innate immunity could alter infection. [82] How *Giardia* actually causes diarrhea remains unclear. Animal models suggest a secretory mechanism, with net secretion occurring by a Ca^{2+}-dependent mechanism, [83], [84] malabsorption secondary to a decrease in brush-border surface area, [85] and local zinc depletion by *Giardia* cysteine-rich proteins resulting in interference with intralumenal digestion. [86], [87] Malabsorption of fat and vitamins, including vitamin A, vitamin B_{12}, and folate, has been documented in some patients. [88] The extent of villous atrophy seen in histological sections has correlated with the severity of diarrhea and malabsorption in some reports. [89] However, in most individuals with giardiasis, minimal, if any, changes are seen in biopsy samples by light microscopy, although distortion of microvilli has been observed at the ultrastructural level. [90] It has been suggested that malabsorption associated with giardiasis may be associated with reductions in intralumenal bile salt concentration and intralumenal enzyme levels. [76] Infecting strains may differ in their virulence. [91], [92] One phenotypic difference between *Giardia* strains is their susceptibility to host intestinal proteinases, and resistance may depend on the form of variant surface protein expressed by the parasite. [93] Host factors also play a role in whether infection with *Giardia* results in disease. Killing of *Giardia* trophozoites exposed to human milk is dependent on the presence of bile salt–stimulated lipase. [94] Host macrophages can phagocytose *Giardia* trophozoites, suggesting that cellular immunity could play some role in controlling disease. [95] There is strong experimental and clinical evidence that secretory antitrophozoite antibodies are important and contribute to clearance of the parasite from the intestinal tract. [96] For example, individuals with immunoglobulin deficiencies are at significantly higher risk for chronic *Giardia* infection. [97], [98] Although recent animal studies suggest that cell-mediated immunity could play a role in host defense against *Giardia,* [99] the clinical course of giardiasis does not appear to be altered in patients infected with the human immunodeficiency virus (HIV). Ingestion of maternal antibody in breast milk appears to provide infants with protection from symptomatic disease but does not stop the establishment of *Giardia* infection. [100]

Clinical Manifestations Studies of human volunteers suggest that the incubation period for symptomatic disease is 1 to 2 weeks. [69], [92] It is important to note that the onset of symptoms may precede the excretion of cysts in stool by more than 1 week. [101] The clinical presentation is varied and can be classified in one of three syndromes: asymptomatic carrier state, acute self-limiting diarrhea, and chronic diarrhea. Asymptomatic infection is probably the most common outcome of *Giardia* infection. [102], [103] In individuals who develop symptoms, the most common presentation is that of diarrhea with watery, foul-smelling stools, often with abdominal distention, flatulence, nausea, flatus, anorexia, and vomiting. Blood and mucus in the stool are rare. Low-grade fever also may be observed, and in some individuals, fatigue and malaise or headache may be prominent. Although infection is self-limiting in most healthy individuals, a significant proportion (25% to 30%) come to medical attention because of chronic diarrhea, often with features of steatorrhea and weight loss. Malabsorption of vitamins A and B_{12}, proteins, and D-xylose is not unusual, and more than 50% of symptomatic individuals report weight loss of greater than 10 pounds. [103], [104] It is important to note that secondary lactase deficiency may persist for several weeks after eradication of *Giardia* infection, necessitating the dietary restriction of lactose. This can be confused with recurrent or relapsing infection. Protracted disease is more frequent in young children and in those individuals with an underlying humoral immunodeficiency syndrome and nodular lymphoid hyperplasia. This syndrome is most commonly associated with patients with common variable immunodeficiency and occasionally with selective immunoglobulin A deficiency. [97], [105] However, *Giardia* infection also has been associated with nodular lymphoid hyperplasia in the absence of overt humoral immunodeficiency. [106] Extraintestinal disease is rare, but there are case reports of individuals with gastritis, reactive arthritis, biliary tract disease, and urticaria. [107], [108] and [109] Gastric giardiasis may be seen in patients with achlorhydria.

Diagnosis The diagnosis of *Giardia* infection (see Table 125-2) should be considered in any patients with prolonged diarrhea, particularly if they have been exposed to children in day care, were exposed to potentially contaminated water, or report a history of recent travel. The diagnosis has been based primarily on detection of *Giardia* cysts or trophozoites in stool or of trophozoites in the upper intestine. Examination of a single stool may detect 50% to 70% of cases, and sensitivity increases to 85% when three concentrated stools collected on different days are examined. Because symptoms may precede excretion of stools by more than 1 week, one stool should be obtained 1 to 2 weeks after the initial one. Even with the examination of three stools, however, some infections may be missed owing to periodic excretion

of cysts, with as much as 20 days elapsing between positive stools. The prior use of antibiotics, antacids, and antidiarrheals may interfere with detection of the organism. Barium studies are not useful and may even hamper detection of the organism in stool. The experience of the laboratory staff in the microscopic recognition of *G lamblia* also has an important impact on the sensitivity of microscopic examination of stools. A direct fluorescent antibody test, now being used in clinical laboratories, allows for the detection of a low number of organisms in a shorter period of time and can facilitate the differentiation of *G lamblia* cysts from other cysts and cystlike bodies. [110] ELISAs for the detection of *Giardia*-specific antigens in fecal specimens appear to have specificity and sensitivity rates that compare favorably with microscopy. [111], [112] and [113] When the diagnosis cannot be made by examination of stool and the index of suspicion for *Giardia* infection is high, intestinal aspiration, intestinal biopsy, or brush cytology may be indicated. One advantage of biopsy is that it may provide additional information regarding associated bowel pathology, such as nodular lymphoid hyperplasia. An alternative approach is to treat empirically for giardial infection before subjecting the patient to more invasive tests. The nonspecificity of symptoms associated with chronic *Giardia* infection and the similarity to symptoms observed in irritable bowel syndrome may contribute to delayed and missed diagnoses. The differential diagnosis includes infection by other protozoan organisms, enteric viruses, and noninvasive bacteria. In patients with malabsorption, the differential diagnosis includes other causes of steatorrhea and malabsorption as well as inflammatory bowel disease. Serology has not proved helpful in the diagnosis of giardial infections.

Treatment Metronidazole and tinidazole (not available in the United States) are currently the drugs of choice (Table 125-4) for the treatment of giardiasis. Quinacrine exhibits similar efficacy but is no longer available within the United States. Furazolidone is somewhat less effective than metronidazole, but it is available in a liquid preparation that is widely used in children in the United States. More recently, albendazole has been shown to exhibit some efficacy in the treatment of giardiasis, and it may prove useful for administration to children in undeveloped countries for the simultaneous treatment of intestinal helminths and *Giardia.* [114] None of the above agents are recommended for use during pregnancy. Paromomycin, a nonabsorbable aminoglycoside with antigiardial activity, has been suggested as a possible drug for use in pregnant women.

	ADULT DOSAGE	PEDIATRIC DOSAGE
Metronidazole	250 mg tid × 5–7 days	5 mg/kg/d × 10 days
Tinidazole	2 g single dose	50–75 mg/kg single dose
Quinacrine	100 mg tid × 5–7 days	2 mg/kg tid × 5–7 days
Furazolidone	100 mg qid × 7–10 days	2 mg/kg tid × 7–10 days

tid, three times daily; qid, four times daily.

TABLE 125-4 Drug Treatment of Giardiasis

A major problem in treating patients with *Giardia* infection is the recurrence of symptoms after standard courses of therapy. This may be secondary to persistent infection because of resistant organisms, or may occur in patients in whom reinfection cannot be documented and in whom an immunodeficiency, such as hypogammaglobulinemia, is not present. [115], [116] One should consider secondary lactase deficiency, which may persist despite eradication of infection. Relapse of symptoms after an initial course of therapy is frequent enough that some physicians have adopted the practice of routinely prescribing a second course of therapy. Patients who have persistent symptoms after single-drug therapy may benefit from combined therapy. [117], [118] Our current approach to individuals with recurrent symptoms after treatment is to give a second course of metronidazole (250 mg three times daily for 10 to 14 days), whether or not a microbiologic diagnosis of recurrent infection can be made. If symptoms persist after this second course of treatment, and lactase deficiency is ruled out, stools are examined again for *Giardia* parasites. If parasites are detected, a search for possible immunodeficiency is made, and combination therapy with metronidazole and furazolidone is administered. Although symptomatic patients infected with *Giardia* should receive therapy, the treatment of asymptomatic carriers is not routinely recommended. This particularly pertains to control of infection within day-care centers. A longitudinal study of asymptomatic children in a day-care center indicated that excretion of *Giardia* cysts is well tolerated, and in the setting of a high rate of reinfection, treatment of asymptomatic children may lead to recurrent courses of therapy of potentially toxic drugs. [119]

Blastocystis hominis

Blastocystis hominis is a commonly detected intestinal protozoan parasite, found in 10% to 25% of stools examined [120] (see Table 125-2). The pathogenicity of *B hominis* continues to be controversial. [120], [121], [122], [123], [124] and [125] Mild diarrhea, nausea, anorexia, and fatigue may be seen in those individuals with a high parasite load. However, in a recent study, symptomatic patients with high concentrations of *Blastocystis* parasites [more than 10 organisms per high power (400×) field] were more likely to be co-infected with other enteric pathogens. [122] This may explain why the treatment of *Blastocystis* with iodoquinol and metronidazole appears to be more effective in relieving the symptoms of infected patients than in eliminating the infection. [123] Alternatively, there may be distinct strains of *B hominis* differing in their pathogenic potential, which could explain the poor correlation between infection and symptomatic disease. A recent study suggested that *Blastocystis* infection was associated with disease only in immunocompromised individuals. [124] At this point, symptomatic *Blastocystis* infection should be considered a diagnosis of exclusion, and if symptoms persist after therapy, there should be a further investigation for other causes of intestinal disease. [125] Optimum therapy has not been established, but metronidazole, iodoquinol, and furazolidone have efficacy in anecdotal reports.

Dientamoeba fragilis

Dientamoeba fragilis is a flagellated protozoan parasite that is being increasingly identified in stool samples [126] (see Table 125-2). There is no known cyst form of *D fragilis,* and recent studies suggest that it shares a common evolutionary history with trichomonads. [127] Symptoms ascribed to *D fragilis* infection include mild diarrhea, abdominal pain, anorexia, and fatigue. [128] Fever, irritability, weight loss, nausea, and vomiting are occasionally reported, and an associated eosinophilia has been described. [126] Co-infection of *D fragilis* and the pinworm, *Enterobius vermicularis,* is nine times higher than expected based on random distribution of each organism, increasing the possibility that pinworm eggs or larvae could be responsible for the transmission of *D fragilis* infection. [129] The pathogenic potential of this organism remains uncertain, but symptomatic individuals and experimentally infected volunteers become free of symptoms when it is eradicated. [128], [130] Adults should be treated with diiodohydroxyquin (650 mg three times daily for 3 weeks), or tetracycline (500 mg four times daily for 1 week) as an alternative. [130], [131] In children, metronidazole is recommended (30–50 mg/kg/day orally in three divided doses for 5 to 10 days). [131] Paromomycin (25 mg/kg/day orally in three divided doses for 5 to 7 days) is also a reasonable alternative.

Balantidium coli

Balantidium coli is a ciliated protozoan parasite and is a rare cause of intestinal disease (balantidiasis) in humans (see Table 125-2). Disease outbreaks in humans are associated with close exposure to pigs and their feces. [132] Outbreaks in institutions associated with poor hygiene or coprophagia have also been reported, [133] as have water-borne outbreaks. Humans are probably relatively resistant to *B coli* infection, but malnutrition, achlorhydria, and poor hygiene predispose to disease. The spectrum of disease ranges from asymptomatic carriage, to watery diarrhea, to active colitis with bloody, mucus-laden stools. *B coli* infection is also a rare cause of appendicitis. [134], [135] *B coli,* like *E histolytica,* can invade the colonic mucosa and spread through submucosal layers, causing colonic ulcerations. Misdiagnosis as ulcerative colitis has been reported. [136] Rarely, colonic perforation occurs with resultant peritonitis. [137] Extraintestinal disease, with lung or liver involvement, is a rare complication. [136] Diagnosis is made by observing the motile trophozoites in stool saline mounts under low-power microscopy. [132] Cysts are much less frequently seen in human infections. Optimum therapy remains uncertain, but tetracycline (500 mg four times daily for 10 days) is recommended by most authorities. Iodoquinol (650 mg three times daily for 3 weeks) is an appropriate alternative.

INTRACELLULAR PROTOZOAN PARASITES (COCCIDIA)

The AIDS epidemic has played an important role in the recognition of Coccidia (phylum Apicomplexa, class Sporozoasida, subclass Coccidiasina) as important gastrointestinal protozoal pathogens. Organisms from the genera *Cryptosporidium, Cyclospora,* and *Isospora* can cause an acute, self-limited diarrheal illness in immunocompetent hosts and a severe chronic diarrhea in patients with AIDS and other forms of immune dysfunction. The similar life cycles of these organisms may account for their similar clinical presentations. *Cryptosporidium, Cyclospora,* and *Isospora* are all intracellular pathogens that can replicate asexually within the enterocyte to produce a merozoite stage, which can autoinfect other enterocytes, leading to a rapid spread of the infection within the epithelium. All three pathogens also undergo a sexual stage that leads to the generation of cysts or spores, which are sloughed into the gut lumen and excreted in the stool. For *Cryptosporidium,* formation of the infectious sporozoite can take place within the host, which can autoinfect other enterocytes. However, for *Cyclospora* and *Isospora,* formation of the infectious sporozoite must take place outside of the host.

Of note, not all laboratories routinely include screening for coccidial organisms in their analysis of stool samples for parasites. Organisms of the three genera *Cryptosporidium, Cyclospora,* and *Isospora* possess distinct morphologic characteristics, although it may be difficult to distinguish cryptosporidia from *Cyclospora*

organisms (see Table 125-2). The modified acid-fast stain may be the most useful for distinguishing among the three genera (Fig. 125-4). The distinction is important because infections with *Cyclospora* and *Isospora,* but not *Cryptosporidium,* respond well to antibiotic treatment.

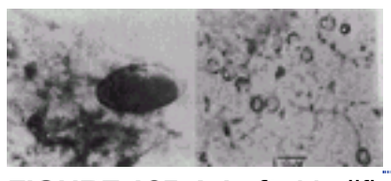

FIGURE 125-4. Left: Modified Kinyoun stain of *Isospora belli* cyst in stool. Note that the ellipsoid shapes are larger (20–33 × 12–15 µm) than the oocysts of *Cryptosporidium* or *Cyclospora* (4–10 µm). Immature oocysts contain a single sporocyst; mature oocysts contain two. (**Right**) Modified Kinyoun stain of *Cryptosporidium* oocyst in stool. (From DeHovitz JA, Pape JW, Boncy M, Johnson WD. Clinical manifestations and therapy of *Isospora belli* infection in patients with the acquired immunodeficiency syndrome. N Engl J Med 1986;315:88.)

Microsporidia are spore-forming protozoa that have been recognized as causing widespread infection in patients with AIDS (see Chapter 124). Because they do not appear to be significant pathogens in immunocompetent hosts, they are not discussed further in this chapter.

Cryptosporidium parvum

Cryptosporidium species were originally described in the stomach and intestine of asymptomatic mice by Tyzzer in 1907. [138] *C parvum* was recognized as a cause of diarrhea in animals but was not identified as a human pathogen until 1976. [139], [140] Initially, most of the reported *C parvum* infections were in patients with AIDS. [141] However, with improved methods of stool diagnosis and better understanding of the clinical disease, cryptosporidiosis has emerged as an important cause of diarrhea in normal hosts as well. The importance of *Cryptosporidium* infection as a public health problem in the United States was underscored by several recent large water-borne outbreaks of disease. *C parvum* is considered the predominant species causing disease in humans but is capable of infecting all species of mammals. [142]

Epidemiology Human cryptosporidiosis is found worldwide in both industrialized and developing countries and in both rural and urban areas. The parasite is transmitted by ingestion of oocysts that are excreted in the feces of infected humans or animals, from person-to-person spread, by ingestion of contaminated food and water, and, as a zoonosis, by contact with infected (primarily farm) animals. Direct person-to-person transmission may occur by fecal-oral spread related to sexual practices. The prevalence of *Cryptosporidium* infection is highest in young children and immunocompromised individuals. The stool positivity rate is higher in developing countries (1% to 22%) than in industrialized countries, where cryptosporidia are identified in the stool of 0.3% to 4% of individuals with diarrheal illnesses. [143], [144], [145] and [146] In developing nations, there is a high rate of asymptomatic carriage, and in some studies, the prevalence of stool positivity for *C parvum* in control patients approached or exceeded that observed in children with diarrhea. [145] Based on serologic studies, exposure to *Cryptosporidium* is relatively common even in industrialized countries, with as many as 15% to 36% of individuals seropositive. [147], [148], [149] and [150] The highest prevalence rates in these studies were seen in individuals with occupational exposures, such as dairy farmers. [150] In developing countries, the seroprevalence is even higher, with 65% to nearly 100% of individuals possessing antibodies to *C parvum* in portions of Latin America. [151], [152] Cryptosporidiosis is among the most common causes of diarrhea in patients with AIDS, with an annual incidence of 5% to 10%. [142] Severe cases of cryptosporidiosis also can be seen in individuals with other forms of immunodeficiency, such as hypogammaglobulinemia, and in those patients who are receiving immunosuppressive drugs for malignancies, autoimmune diseases, or organ transplantation. [145] The reader is referred to Chapter 124 for a more detailed discussion of *Cryptosporidium* infection in immunocompromised hosts. In developing countries, a significant portion of disease transmission may arise from person-to-person spread within families, with transmission rates comparable to those of *Shigella.* [152] In industrialized countries, day-care centers represent a source for outbreaks and sporadic infections. A cross-sectional study showed that 1.8% to 3.8% of children in day-care centers are infected, but rates are much higher (27% to 59%) among children in centers experiencing an outbreak of *C parvum* disease. [153] Infections occur primarily in diaper-aged children, who serve as a potential nidus for secondary infection of the surrounding community. The risk for secondary transmission within a household is low (5%) when the index case involves an adult. [154] Person-to-person spread within the hospital setting also has been reported. [155] Water-borne outbreaks of *C parvum* are a major threat to public health. *Cryptosporidium* was identified as the agent responsible for eight water-borne disease outbreaks involving drinking water between 1991 and 1994. [1], [156], [157] In 1993, an estimated 403,000 people in the Milwaukee area became infected with *C parvum* due to a failure in water treatment and purification. [157] This represents the largest community outbreak of diarrhea due to any defined organism ever reported in the United States. [154], [157] *C parvum* also has been identified as the causative agent in water-borne outbreaks associated with swimming pool water. [158], [159] These outbreaks underscore the resistance of *C parvum* oocysts to chlorination and the difficulties in removing the organism by filtration. Food-borne outbreaks of cryptosporidiosis have been reported; in several instances, the outbreaks were associated with ingesting unpasteurized apple cider. [160], [161]

Pathogenesis and Pathology The mechanisms by which cryptosporidia cause intestinal disease are still poorly defined and include disruption of the epithelial barrier, [162], [163] resulting in malabsorption, [164] induction of inflammatory mediators, or release of parasite enterotoxins that stimulate intestinal secretion. [165], [166] However, no product of *C parvum* has yet been identified that possesses enterotoxic or cytotoxic activity. On histological examination of intestinal biopsy specimens from individuals with *C parvum* infection, a variety of nonspecific changes can be seen, including villous atrophy (partial or complete) and crypt hyperplasia with increased numbers of lymphocytes, macrophages, plasma cells, and, less commonly, neutrophils in the lamina propria. [167] However, many patients show normal duodenal biopsy specimens, despite chronic diarrhea. [167] There appears to be an association between the extent of malabsorption and intestinal injury and the intensity of the infection (based on oocyst excretion). [168] Recent studies in a human intestinal xenograft model of disease and in human volunteers have shown that *C parvum* infection induces production of tumor necrosis factor-a from intestinal cells, but the contribution of cytokine production to disease remains unclear. [169], [170] and [171] The prolonged infection in immunocompromised patients and in animal models suggest that CD4 (helper) T cells and interferon are critical to the control of infection. [172], [173] and [174] One of the remarkable consequences of the availability of highly active antiretroviral therapy has been a significant reduction in the cases of cryptosporidiosis seen in HIV-infected individuals. [175]

Clinical Manifestations The clinical spectrum of the disease is wide and includes asymptomatic carriage, a self-limited diarrheal illness in immunocompetent individuals, and a relentless, severe, watery diarrhea in some immunocompromised individuals. In a study of 29 healthy volunteers, the median infective dose was estimated to be 132 oocysts, with a mean incubation period of 9 days (range, 5 to 22 days). [148] As few as 30 oocysts caused infection in some subjects. The infectivity was therefore comparable to the infectivity of *Giardia* cysts. Subjects with diarrhea excreted more oocysts over the course of the infection than did subjects without diarrhea. [176] The predominant symptom in intestinal cryptosporidiosis is diarrhea, which is often accompanied by abdominal cramps and varies greatly in severity from individual to individual. Some patients have scant, intermittent diarrhea, whereas others (more often, immunocompromised individuals) experience voluminous watery diarrhea that can approach the quantities seen with cholera (more than 10 L/day). Mucus may be present in stools, but bloody diarrhea is rare, and white blood cells are usually not found in stools from patients with cryptosporidiosis. Accompanying symptoms may include nausea, fatigue, general malaise, anorexia, vomiting, and low-grade fever. The duration of illness in immunocompetent individuals ranged from 2 to 26 days in one study, [177] with a mean of 12 days, but more prolonged illness is not unusual. [152] Transient relapse of watery diarrhea has been observed in immunocompetent hosts, particularly in the massive outbreak of water-borne *Cryptosporidium* infection that occurred in Milwaukee. [154] Extraintestinal disease is rare in immunocompetent individuals, but pancreatitis and cases of reactive arthritis have been reported in previously healthy adults. [178], [179] Cholecystitis is seen in as many as 10% of patients with cryptosporidiosis and AIDS but is rare in immunocompetent patients. The differential diagnosis for cryptosporidiosis in immunocompetent hosts includes other protozoan infections (e.g., *C cayetanensis, G lamblia,* and *I belli*), bacterial infection (e.g., *Salmonella, Shigella, Campylobacter, Yersinia, C difficile,* and enterotoxigenic *E coli* in patients with a history of travel to developing countries), and viral infections (e.g., rotavirus and Norwalk viruses).

Diagnosis The diagnosis of *Cryptosporidium* infection should be suspected in individuals with diarrhea lasting longer than 3 days and currently rests primarily on the identification of the oocysts in stool samples [180] (see Table 125-2 and Fig. 125-4). It is important to make a diagnosis in the interest of public health, although disease is generally self-limiting in immunocompetent hosts. Patients should be questioned with respect to recent travel, exposure to children in day care, their drinking water, ingestion of unpasteurized milk or fruit juices, exposure to recreational water, and exposure to animals, particularly cattle. Stool specimens from individuals suspected of having cryptosporidiosis should be preserved in formalin as soon as possible and should be concentrated by either a sugar flotation or formalin-ethyl acetate method. At least three different stool concentrates and five or six acid-fast stained samples should be examined before the diagnosis of cryptosporidiosis is excluded. There are now immunology-based tests that may facilitate the diagnosis, especially in settings in which skilled microscopists are not available [146], [181] (see Table 125-2). In most patients with diarrhea and suspected cryptosporidiosis, stool examination, as outlined earlier, is probably as sensitive as small intestinal biopsy and is the diagnostic procedure of choice. [182], [183] For those unusual cases in which *Cryptosporidium* infection is suspected, but the major symptoms are abdominal cramps or

abdominal pain without significant diarrhea, stool specimens are more likely to be negative, and a duodenal aspirate with biopsy, combined with lower endoscopy and terminal ileum biopsy, may have a higher diagnostic yield. [183]

Treatment Effective treatment for cryptosporidiosis remains an elusive goal. For immunocompetent individuals, the disease is self-limiting, and symptomatic treatment (replacement of lost fluids) is the cornerstone of therapy. Nonspecific antidiarrheal therapies, such as antimotility agents, may provide some relief for individual patients. A recent study in patients with AIDS suggested that combination oral therapy with azithromycin (600 mg daily) and paromomycin (1 g twice daily) may have some efficacy, but not all patients responded. [184]

Cyclospora cayetanensis

In the early 1990s, diarrhea associated with an organism variously described as a large *Cryptosporidium,* blue-green algae, cyanobacterium-like body, or coccidian-like body was reported. [185], [186], [187], [188] and [189] The organism was identified as a *Cyclospora* species by Ortega and colleagues, [190] who successfully induced sporulation and excystation of oocysts obtained from individuals with diarrhea. Electron microscopic studies of the organisms in enterocytes revealed that they possessed morphologic features of coccidians of the phylum Apicomplexa, [191] and a molecular phylogenetic analysis confirmed that *Cyclospora* is a coccidian parasite closely related to protozoa of the *Eimeria* genus, a known pathogen of birds. [192]

Epidemiology *Cyclospora* species are distributed widely—the organism has been implicated as the causative agent in diarrheal illnesses in the Americas, Southeast Asia, the Indian subcontinent, the Caribbean, Africa, Australia, and Europe. [1] Originally, disease was described primarily in travelers to endemic areas, [188], [193], [194] but with greater awareness of the parasite, indigenous disease in endemic areas and outbreaks in areas of low endemicity are being more widely recognized. [195], [196] and [197] Prevalence rates as high as 11% have been reported in nonnative residents of an endemic area, and 18% of young children (1 month to 2 years of age) in poor regions of Peru had oocysts in their stool. [196], [198] In the United States, surveys of stool specimens suggest a low prevalence of only 0.3% to 0.5%. [199], [200] and [201] The ingestion of water containing sporulated oocysts of *Cyclospora* is the major mode of transmission, [185], [197], [202], [203] but food-borne outbreaks also have been described. [204], [205] In the United States and Canada, a major outbreak of *Cyclospora* infection (1500 cases involving 20 states, the District of Columbia, and two provinces) was associated with the consumption of raspberries harvested in Guatemala. [206] *Cyclospora* may be a relatively common cause of diarrhea (11%) in patients with AIDS in developing countries but is relatively rare in patients with AIDS in the United States, possibly because of widespread use of trimethoprim-sulfamethoxazole (TMP-SMX) as prophylaxis against *Pneumocystis carinii.* [207]

Pathogenesis and Pathology Limited information is available on how *Cyclospora* causes disease in humans. Disease appears to involve primarily the small intestine, and documented impaired D-xylose absorption suggests that the proximal small intestine may be an important target for infection. [188], [208] Electron microscopic studies of jejunal biopsy samples have demonstrated that the sporozoite, trophozoite, schizont, and merozoite stages of the organism are present within parasitophorous vacuoles in the cytoplasm of infected enterocytes. [191], [194] Histological findings on examination of biopsy specimens from patients with active *Cyclospora* infection are similar to those seen with cryptosporidiosis and with tropical sprue. [194]

Clinical Manifestations Prolonged, nonbloody diarrhea (99%), associated with loss of appetite, fatigue, and weight loss (90%), are the major manifestations of *Cyclospora* infection and are similar to those observed for cryptosporidia. [206] The incubation period is estimated to be 7 to 10 days, but shorter (1-day) incubation periods have been reported. [185], [197] The diarrhea can be prolonged, with a mean duration of illness of 14 days (1 to 60 days) reported in the 1996 outbreak, but other series have reported a mean duration of as long as 56 days. [198], [200], [206], [207], [208] and [209] The mean duration of oocyst shedding was 23 days. [190] Symptoms of diarrhea and fatigue may persist after organisms are no longer detectable in stool samples; conversely, individuals may continue to shed oocysts after symptoms have disappeared. Although cyclosporiasis can be prolonged and frequent relapses are common, disease appears to be self-limited in immunocompetent hosts. In contrast, in immunosuppressed hosts, cessation of infection may not occur without drug therapy. [207] Extraintestinal manifestations of *Cyclospora* infection appear to be rare, but acalculous cholecystitis has been reported in patients with AIDS. [209]

Diagnosis *Cyclospora* infection should be suspected in patients with prolonged diarrhea, particularly those with a recent history of travel. Diagnosis depends on the detection of oocysts by the microscopic examination of stool samples (Fig. 125-5; see Table 125-2). Because excretion of oocysts may be intermittent, multiple stool samples should probably be examined before excluding the diagnosis of *Cyclospora* infection. The diameter of oocysts in stained specimens can distinguish *Cryptosporidium* oocysts (4 to 6 µm) from the larger (8 to 10 µm) *Cyclospora* oocysts.

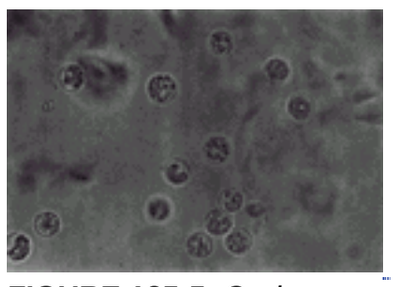

FIGURE 125-5. *Cyclospora cayetanensis* oocysts (saline, wet preparation). Note 8- to 10-µm diameter spheres containing numerous refractile globules. (Courtesy of Earl G. Long.)

Diagnosis of cyclosporiasis also has been made by light microscopic examination of duodenal and jejunal aspirates obtained during endoscopy and examined as wet mounts, or, probably more efficiently, as acid-fast–stained samples. Smears also can be examined under ultraviolet fluorescence microscopy looking for the characteristic blue fluorescence. Identification of the parasite by light microscopy in a duodenal biopsy specimen has been reported, but in general, this has not been a high-yield approach for diagnosis, and electron microscopy probably offers a more sensitive method in biopsy specimens. [191]

Treatment Immunocompetent patients can be treated successfully with few or no relapses with TMP-SMX (160 mg TMP/800 mg SMX) twice daily for 7 to 10 days. [207], [210] Individuals seropositive for HIV with cyclosporiasis were treated with TMP-SMX (160/800 mg) taken orally four times daily for 10 days and had cessation of diarrhea within 1 to 5 days (mean, 2.5 days) of initiation of therapy and negative stools at day 10. [207] About 40% of the patients developed recurrence of cyclosporiasis and required retreatment with TMP-SMX. Continued prophylactic therapy with TMP-SMX orally three times weekly prevented further relapse in all but one of these patients. Few data are available on potential alternatives to TMP-SMX in sulfa-allergic patients, but pyrimethamine and the newer macrolides may be effective.

Isospora belli

Isospora belli is a coccidian protozoan that was first recognized as an intestinal parasite of humans more than 80 years ago in military forces stationed overseas and in outbreaks of diarrhea in institutionalized individuals. [211], [212] *Isospora* infection is more common in individuals residing in developing countries and is relatively rare in immunocompetent individuals in the United States. Sporadic small-scale outbreaks of *Isospora* infection have been seen in mental institutions and day-care centers within the United States, but more widespread outbreaks, as have been seen with *Cryptosporidium* and *Cyclospora,* have not been reported. [211], [213], [214] Isospora is an important cause of diarrhea (about 15%) in individuals with AIDS in developing countries [215], [216], [217], [218], [219] and [220] but accounts for only 0.2% of diarrhea cases in AIDS patients within the United States. [221] Isospora is sensitive to TMP-SMX, and one reason for the lower prevalence of isosporiasis in AIDS patients within the United States may be the widespread use of TMP-SMX as prophylaxis for *P carinii* infection.

The manifestations of *Isospora* infection are similar to those seen with both *Cyclospora* infection and cryptosporidiosis: watery, nonbloody, noninflammatory diarrhea that is often accompanied by abdominal cramps, fatigue, weight loss, anorexia, and occasionally fever. [212], [214], [222], [223] and [224] The incubation period is relatively short (2 to 3 days), and infection is generally self-limited but may be quite prolonged in immunocompetent hosts. [223], [224] In contrast to cryptosporidiosis and cyclosporiasis, a peripheral eosinophilia may be seen in individuals with isosporiasis. [223] In immunosuppressed hosts, most prominently those with AIDS, disease is more severe, and recurrent episodes of profuse watery diarrhea are common. [216], [225], [226] Signs and symptoms of malabsorption may be prominent. [224] Extraintestinal disease is rare, but acalculous cholecystitis, reactive arthritis, and disseminated infection have been described in individuals with AIDS. [227], [228] and [229]

Diagnosis is made by detection of the *Isospora* oocysts in feces using light microscopy (see Table 125-2). Shedding of oocysts is intermittent, and multiple stool samples may need to be examined. Charcot-Leyden crystals and eosinophils are occasionally seen in stool samples from individuals with isosporiasis. [223], [224] There are case reports of individuals who had negative stool tests but had organisms detected by histological examination of small intestinal biopsy specimens. [224]

The drug of choice for the treatment of *Isospora* infection is TMP-SMX (160/800 mg four times daily for 7 days, followed by 10 days of 160/800 mg twice daily).

Patients with AIDS may require more prolonged initial therapy; once infection has been eradicated, they should be placed on prophylactic TMP-SMX (160/800 mg three times weekly) or sulfadoxine-pyrimethamine (500 mg sulfadoxine/25 mg pyrimethamine given once weekly) to prevent relapses. [215], [225] Alternative agents in the sulfa-allergic patient include pyrimethamine alone, nitrofurantoin, and furazolidone.

CHAPTER 126

Richard D. Pearson

PARASITIC DISEASES: HELMINTHS

Intestinal helminths are prevalent throughout the world in areas where sanitation and public health measures are poor. Although many infested persons are asymptomatic, the impact of helminthic infections on health and childhood development in endemic areas is substantial. In industrialized countries, *Enterobius vermicularis,* the pinworm, is common among children, and other intestinal helminths are encountered among immigrants, returning travelers, and occasionally local residents.

The pathogenic intestinal helminths (Table 126-1) are divided into the roundworms (Nemathelminthes of the class Nematoda) and the flatworms (Platyhelminthes), which are subdivided into the Cestoda, or tapeworms, and the Trematoda, or flukes. [1], [2] This classification system is useful clinically because members of these groups tend to have similar life cycles, metabolic pathways, and susceptibilities to chemotherapeutic agents. Photographs of adult helminths and eggs are available in the *Atlas of Gastroenterology* (see Chapter 80).

TABLE 126-1 Helminthic Infections Involving the Human Gastrointestinal Tract and Their Treatment

The degree to which intestinal helminths compromise health depends on multiple factors, including their pathogenicity, environmental factors, and the genetically determined susceptibility and immune responses of their hosts. In general, tissue damage correlates with the magnitude of the parasite burden, which varies widely among persons, even in areas of intense transmission. In a study of *Ascaris lumbricoides* in Nepal, genetic components accounted for between 30% and 50% of the variability in worm burden and environmental factors between 3% and 13%. [3] In some instances a single worm or a limited number of worms or larvae produce life-threatening disease.

Helminths typically have complex life cycles. Most cannot multiply in their hosts and have finite life spans. The common intestinal nematodes usually die after several years, although some of the flukes, such as *Clonorchis sinensis,* can survive for decades. In the case of *Strongyloides stercoralis, Capillaria philippinensis,* and *Hymenolepis nana,* autoinfection can result in large parasite burdens and persistent infection.

The mechanisms of immunity to intestinal helminths in humans are poorly understood. Data from animal models suggest that $CD4^+$ lymphocytes and their cytokines are important. In general $CD4^+$ Th2-type cytokine responses (Il-4, Il-5, Il-9, and Il-13) are associated with expulsion of worms from the gastrointestinal tract, while Th1-type responses (Il-12 and interferon-?) are found in chronic infections. [4] The precise interplay among these cytokines, the effector mechanisms, and the role of eosinophils and immunoglobulin E (IgE)-mediated responses remain to be defined.

Exposure in an endemic area along with clinical evidence of disease should alert the clinician to the possibility of a helminthic infection. Eosinophilia may be present, but it is neither a sensitive nor a specific test for helminths. A species-specific diagnosis usually depends on identification of adult worms, larvae, or ova in stool or tissue. Serologic tests provide presumptive evidence of infection in many situations. A number of effective drugs are available for the treatment of helminthic infections (see Table 126-1). [5], [6]

INTESTINAL NEMATODES (ROUNDWORMS)

Intestinal nematodes, or roundworms, are prevalent in areas of the world where sanitation is poor and indiscriminate defecation occurs. It is not uncommon for residents of endemic areas to be infected with more than one helminthic species. The intensities of these infections vary depending on genetically determined, but poorly understood, host factors and micro-environmental variables. [3], [4] Children tend to have the highest worm burdens.

The life cycles of intestinal nematodes can be divided into three general patterns. In many cases infection follows ingestion of ova (Fig. 126-1), which excyst

releasing larvae in the gastrointestinal tract. *Trichuris trichiura* and *E vermicularis* develop to adulthood within the lumen of the bowel, whereas *Ascaris lumbricoides* larvae invade the intestinal wall, pass through the venous circulation to the lungs, migrate into the alveoli, ascend to the pharynx, are swallowed, and then reach maturity in the intestinal tract. Hookworms and *S stercoralis* invade the skin, pass through the venous circulation to the lungs, and then follow a pattern comparable to that of *Ascaris*.

FIGURE 126-1. Relative sizes and shapes of helminth ova. (Adapted from Smith JW, Ash LR, Thompson JH Jr, et al. Intestinal helminths. In: Atlas of diagnostic medical parasitology series. Chicago: American Society of Clinical Pathologists, 1984.)

The clinical manifestations of these helminthic infections generally depend on the organ systems involved and the magnitude of the worm burden. Children living in endemic areas have demonstrated improved growth and activity following treatment of roundworms. [7], [8] and [9] The disability-adjusted life years lost to helminthic diseases has been estimated to be 39 million. [10] This has led to the implementation of mass treatment programs with the broad-spectrum anthelmintic albendazole in areas of high prevalence.

Trichuris trichiura (Whipworm)

The whipworm, *T trichiura,* is prevalent in developing areas in tropical and temperate climates. [11] Humans become infected when they ingest embryonated ova. After excystation, larvae penetrate the intestinal mucosa with their threadlike anterior ends, molt, mature, and reattach as adults to the mucosa of the cecum and the rest of the colon. Mature female worms release 2000 to 6000 eggs (see Fig. 126-1) per day into the feces. Maturation requires a period of 10 to 14 days in the soil. About 3 months elapse between the ingestion of eggs and the production of ova by mature whipworms. Adults can persist in the colon for several years.

Epidemiology *T trichiura* has a worldwide distribution. Various *Trichuris* species infect animals, but only *T trichiura* is found in humans. Ova require warm, moist, shaded soil for development. Infection is most frequent in areas without latrines and in communities where untreated human fecal material is used for fertilizer. The severity of infestation also varies within a community resulting in an aggregated, or clumped, distribution. The subset of people with heavy infections is more likely to show manifestations of disease.

Clinical Manifestations Mild *T trichiura* infections are often asymptomatic. [11] Heavy infections are most common in children between 2 and 10 years of age and may be associated with diarrhea, anemia, and growth retardation. [12] A small percentage of those infected present with a dysentery syndrome. [13] Rectal prolapse is a rare but potentially serious consequence of heavy infection [11] (see Fig. 126-2, Color Fig. 126-2). Cases of colonic obstruction and perforation have been reported. [14] Eosinophilia is frequently present, even in light infections.

FIGURE 126-2. (See Color Fig. 126-2.) *Trichuris trichiura* associated with rectal prolapse in a child. Adult *T trichiura* are seen as white threads on the mucosal surface. (From Smith JW, Ash LR, Thompson JH Jr, et al. Intestinal helminths. In: Atlas of diagnostic medical parasitology series. Chicago: American Society of Clinical Pathologists, 1984.)

Diagnosis, Treatment, and Prevention The diagnosis of trichuriasis is confirmed by identifying ova in the stool or adult worms in the colonic mucosa. Mebendazole or albendazole are recommended for therapy (see Table 126-1). A single 400-mg dose of albendazole is used in mass treatment programs in endemic communities, [7], [8] but in persons with heavy infections, it is advisable to administer it daily for 3 days. [5], [6] A single dose of albendazole combined with ivermectin has been reported to be more effective than albendazole alone. *T trichiura* infection can be prevented by adequate sanitary disposal of human feces, hand washing, and proper preparation of food.

Enterobius vermicularis (Pinworm)

E vermicularis is endemic in both temperate and tropical climates. [11], [15] It is encountered most frequently among school-age children living in areas of high population density. People become infected when ingested ova hatch in their upper small bowel, and larvae mature as they migrate to the ileum. Adults live 7 weeks (males) to 13 weeks (females). The earliest that eggs appear in the stool is 5 weeks. An infected person may harbor anywhere from a few to several hundred adult pinworms.

At the time of oviposition, the adult female (Fig. 126-3) migrates out through the anus to lay her eggs on the perianal or perineal skin. Eggs (see Fig. 126-1) are expelled by uterine contraction, by death and disintegration of the adult worm, or by disruption of worms during scratching. The shell of the ovum has a thick outer albuminous layer, which plays a role in adherence to objects in the environment.

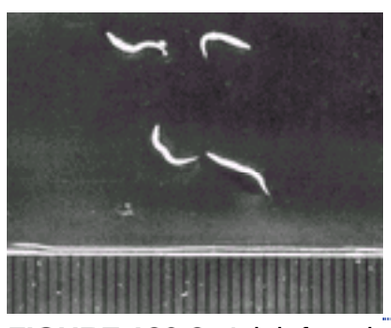

FIGURE 126-3. Adult female *Enterobius vermicularis* (pinworms) may be found on the perianal skin or occasionally on the surface of stools. Adult female pinworms are 8 to 13 mm long and 0.3 to 0.5 mm wide. (The scale is in millimeters.) (From Smith JW, Ash LR, Thompson JH Jr, et al. Intestinal helminths. Atlas of diagnostic medical parasitology series. Chicago: American Society of Clinical Pathologists, 1984.)

Epidemiology *E vermicularis* can infect people of all ages, but it is most prevalent among children between the ages of 5 to 10 years. [11], [15], [16] Finger sucking, [17] poor personal hygiene, and exposure to infected family members or peers in schools or orphanages are contributing factors. Although one time as many as 30% of elementary school students in the United States were infected, the prevalence has probably decreased in recent decades. [18] Enterobiasis also has been reported

among male homosexuals, who become infected through anilinction.

Clinical Manifestations The most important consequence of *E vermicularis* infection is irritation of the perianal or perineal skin, [11], [15], [16] although many infected persons are asymptomatic. Scratching, self-induced trauma to the skin, and, in some persons, secondary bacterial dermatitis may result. Vulvovaginitis may develop in prepubertal girls when adult pinworms migrate to the vagina, [19] and may result in secondary enuresis [20] or introital colonization leading to bacterial urinary tract nfection. [21] Adult pinworms occasionally are found in the appendix after surgical excision. Although they have been associated with abdominal pain, they do not appear to cause acute appendicitis. Eosinophilic ileocolitis has been associated with *E vermicularis* in persons presenting with abdominal pain, melena, and diarrhea. [22], [23] On rare occasions, adult female pinworms reach the peritoneum by traversing the female genital tract or by migrating through a perforation in the bowel associated with appendicitis, diverticulitis, or intestinal malignancy to produce ectopic peritoneal disease. [24], [25] Granulomatous reactions to dead worms or eggs may result in small peritoneal nodules, which can be confused grossly with metastatic carcinoma. Granulomatous inflammation in response to worms or eggs also has been observed in the vulva, vaginal wall, cervix, endometrium, salpinx, and ovaries, as well as in the liver and epididymis. [26]

Diagnosis, Treatment, and Prevention The discovery of ova (Fig. 126-2 and Color Fig. 126-2) or pinlike adult female worms on the perianal skin (Fig. 126-3) is indicative of enterobiasis. The most successful diagnostic approach uses a strip of transparent tape that is held with the adhesive side out affixed to a tongue depressor. [16] When a person first arises in the morning, before bathing or defecation, the buttocks are spread and the tape is pressed against the perianal skin several times. The strip then is transferred to a microscope slide with the adhesive side down. Eggs are prominent at low power. A single smear detects about 50% of those infected; 90% can be detected with three swabs. Stool examination for ova and parasites is positive in only 10% to 15% of cases. On rare occasions, ova are found in vaginal smears treated with Pap stain or in the urine sediment. *E vermicularis* is susceptible to a number of anthelmintic drugs (see Table 126-1). Pyrantel pamoate, administered as a dose of 11 mg/kg body weight (maximum, 1 g) and repeated in 2 weeks, is available over the counter in the United States. Albendazole and mebendazole are also effective. Spread of *E vermicularis* can be reduced by hand washing and by treating infected children. Because the home environment is often contaminated with viable ova, it is advisable to launder clothes and linen; to vacuum around beds, curtains, and other potentially contaminated areas; and to cover food to avoid dust-borne eggs. Anthelmintic treatment of the entire household may be necessary to interrupt transmission.

Capillaria philippinensis

C philippinensis, a small intestinal nematode, causes severe diarrhea and malabsorption. [11], [27], [28] It was initially described among residents of the Philippines, but cases also have been reported from Thailand, Indonesia, Japan, Taiwan, Korea, India, Egypt, Iran, and Colombia. Infection follows ingestion of raw or inadequately cooked freshwater or brackish fish, the intermediate host, containing infectious larvae. Fish-eating birds are the usual definitive hosts.

Adult *C philippinensis* invade the mucosa of the small intestine of humans causing inflammatory changes in the lamina propria. [27], [28] Symptoms include watery diarrhea (often severe), abdominal pain, borborygmus, constitutional complaints, malabsorption, and weight loss. Infection also has been associated with jejunal stricture and chronic intestinal pseudoobstruction. Some ova are passed in the stool; others excyst in the intestine and complete the life cycle resulting in autoinfection and a large worm burden. Deaths occur as a result of malnutrition, electrolyte imbalance, and secondary infections in debilitated patients.

The diagnosis of *C philippinensis* is made by identifying ova, larvae, or adult worms. Multiple stool examinations often are necessary because ova are shed sporadically and in low numbers. Albendazole (see Table 126-1) is the treatment of choice; mebendazole is an alternative. Supportive care with fluid, electrolytes, and nutritional replacement is often necessary. Thorough cooking of fish prevents infection.

Capillaria hepatica, a common hepatic pathogen of rodents and other animals, has been associated with hepatomegaly, fever, and eosinophilia in a very limited number of persons, primarily children, around the world. [29], [30] The pathology is characterized by prominent granulomatous reactions to eggs in the liver. The diagnosis usually is made by liver biopsy. Albendazole has been used for treatment.

Trichostrongylus Species

Trichostrongylus species are common parasites of herbivorous animals such as sheep, horses, and goats. [1] Human infections occur most prevalently in the Middle East and Asia. Ova are passed in the feces of animals, hatch in 1 or 2 days under favorable conditions, and pass through 3 free-living stages before becoming infective after approximately 3 days. Although larvae can invade through the skin, human infection usually occurs when they are ingested in contaminated food or water. Larval migration through the lungs is not necessary for maturation. Adult worms reside in the duodenum or upper jejunum with their heads embedded in the mucosa.

Most human infections are asymptomatic, but epigastric pain, diarrhea, and flatulence have been reported. Rarely, anemia or emaciation develops. Eosinophilia is present in some cases. The diagnosis is made by identifying *Trichostrongylus* ova in stool. *Trichostrongylus* ova are larger and more pointed on the ends than hookworm ova. Albendazole, mebendazole, or pyrantel pamoate can be used for treatment (see Table 126-1). Vegetables should be cooked thoroughly and water boiled before ingestion in endemic areas.

Ascaris lumbricoides

A lumbricoides is the most prevalent and the largest of the intestinal nematodes that infect humans; [31] it is the only nematode that truly looks like a “worm.” Adult female ascarids can grow to a length of 40 cm. They produce a prodigious number of ova—up to 200,000 each day (see Fig. 126-1). Fertilized eggs develop in moist, warm, shaded soil and become infectious in 2 to 4 weeks. After ingestion in contaminated food or water, eggs hatch in the duodenum. Larvae subsequently penetrate the intestinal wall, enter the venous circulation, and migrate to the lungs. They break into the alveoli, ascend to the trachea, are swallowed, and complete their development in the small intestine. The time from ingestion of ova to the production of eggs by mature females is 10 to 12 weeks.

Epidemiology An estimated 1.3 billion people are infected with *Ascaris* worldwide, resulting in 12 million cases of acute illness and 10,000 deaths each year. [32] Only cold, arid climates are spared. Transmission of *Ascaris* is continuous in the tropics and intermittent in temperate areas. While the majority of the population may be infected in areas of poor hygiene, only a subset, usually children younger than 10 years of age, harbor a large number of adult worms at any given time. [33] Genetic and shared environmental factors account for the variation. [3]

Clinical Manifestations The clinical manifestations of ascariasis can be divided into those associated with the migration of larvae through the lungs and those associated with adult worms in the gastrointestinal tract. [31] Migrating larvae in the lungs can elicit pulmonary hypersensitivity reactions, including bronchospasm, hypersecretion of mucus, and bronchiolar inflammation. Sputum may contain Charcot-Leyden crystals and, on occasion, larvae. The presence of eosinophilia with pulmonary infiltrates leads to the clinical diagnosis of Löffler syndrome. Urticaria and other manifestations of hypersensitivity may also be present during the pulmonary phase. *Ascaris* antigens are among the most potent allergens. Hypersensitivity reactions have been a major problem for investigators working with *Ascaris* in vitro. Accurate characterization of the gastrointestinal manifestations of *Ascaris* infection is confounded by the high frequency of concurrent infestations with other intestinal parasites and enteropathogenic bacteria. Patients harboring *Ascaris* have reported abdominal pain, nausea, anorexia, and diarrhea, but it has been difficult to determine how frequently *Ascaris* is responsible for these symptoms. The precise impact of Ascaris infection on nutrition is difficult to quantify in people harboring multiple enteric pathogens, [34], [35] but children infected with *Ascaris* and other common intestinal nematodes have demonstrated gains in growth and activity after treatment with albendazole. [7], [8] and [9] One of the most serious complications with *Ascaris* occurs when a large number of worms become intertwined to form a bolus that causes partial or complete intestinal obstruction in young children (Fig. 126-4; see also Color Fig. 126-4). [36] It has been estimated to occur in as many as 2 per 1000 children infected with *Ascaris* per year. [37] Those affected present with nausea, vomiting, abdominal pain, and occasionally a palpable abdominal mass. [36], [37] and [38] The presentation may mimic an acute abdomen. Rarely, a mass of worms results in intussusception or volvulus of the small bowel. Bowel perforations with peritonitis and localized abscesses have been reported, but the role of *Ascaris* in these cases remains uncertain. Intestinal pseudoobstruction has been reported with *Ascaris*-associated inflammatory lesions. [39] Adult *Ascaris* have also been found in the appendices of persons presenting with of acute appendicitis. [40]

FIGURE 126-4. (See Color Fig. 126-4.) Intestinal obstruction caused by a mass of adult *Ascaris lumbricoides* is seen in this autopsy specimen. Intestinal obstruction is an unusual complication of heavy *Ascaris* infection. (From Smith JW, Ash LR, Thompson JH Jr, et al. Intestinal helminths. In: Atlas of diagnostic medical parasitology series. Chicago: American Society of Clinical Pathologists, 1984.)

On occasion, adult *Ascaris* migrate to the oropharynx or nasopharynx, much to the consternation of the host or parents, or more importantly, they may enter the common bile duct, producing biliary colic, acute cholecystitis, ascending bacterial cholangitis, secondary liver abscess, perforation of the bile duct, intrahepatic or bile duct calculi, [41], [42] or acute pancreatitis. [43], [44]

Diagnosis, Treatment, and Prevention Embryonated or unembryonated ova in feces are indicative of *A lumbricoides* infection (see Fig. 126-1). On occasion, migrating adult worms, which range from 10 to 40 cm in length, are found in feces; are detected radiographically or sonographically in the gastrointestinal tract, bile duct, pancreatic duct, or intestine; [41], [42], [43] and [44] or emerge from the oropharynx or nose. By ultrasound they produce echogenic, nonshadowing images that appear as single or multiple strips. The digestive tract of the worm appears as an anechoic inner tube. *Ascaris* can also be visualized by computed tomography. On contrast-enhanced radiographic studies, they appear as cylindrical filling defects; the intestinal tract of the worm may be seen as a thin thread of contrast material within a tubular filling defect. Albendazole, 400 mg as a single dose, mebendazole, or pyrantel pamoate are effective in the treatment of *Ascaris* (see Table 126-1). Therapy for the complications of *Ascaris* depends on the organs involved. Intestinal obstruction may require surgery, but most patients are treated successfully with rehydration and anthelmintic drugs. Endoscopic extraction and sphincteroplasty have been used to remove adult worms from the biliary tract, but chemotherapy and supportive therapy are effective in many cases. In principle, ascariasis can be prevented by the sanitary disposal of human feces and good personal hygiene. In practice, this is difficult to achieve. *Ascaris* eggs are relatively stable in the environment and can persist for years. Community-based mass treatment programs are effective, but treatment must be repeated, usually at 3- to 4-month intervals, due to re-infection. [45]

Trichinella spiralis

Trichinella spiralis is cosmopolitan in its distribution. [46] Humans become infected when they ingest inadequately cooked meat containing infective larvae. The encysted larvae are released in the small intestine and molt 4 times within 36 hours to become adults. After mating, females remain embedded in the mucosa. In about 5 days, viviparous females begin to deposit larvae, which invade the mucosa, enter the lymphatics or bloodstream, and ultimately encyst in skeletal muscle cells. They remain there until ingested by another carnivore or until their death from senescence after several years. A single female worm produces approximately 1500 larvae during her life.

Epidemiology *T spiralis* is responsible for the majority of cases of trichinosis, but some are caused by *T britovi, T pseudospiralis, T nativa* in arctic regions, and *T nelsoni* in Africa. Approximately 50 cases of trichinosis occur in the United States annually. [47] Trichinosis can follow ingestion of contaminated pork or sausage from domestic pigs that have had access to garbage or wildlife carcasses, or from inadequately cooked meat from wild boar, bear, walrus, cougar, horse, or other animals. [48], [49], [50] and [51] Horses have become infected from protein supplements made from contaminated meat. [51] As the number of cases of trichinosis due to commercial pork has decreased in the United States and other developed countries, the proportion of cases due to wild game has risen. Cases of trichinosis are often sporadic, but small outbreaks are not uncommon. Infections in North America have been reported among immigrants from Southeast Asia who prefer rare or undercooked pork; trichinosis has also been reported among international travelers who have eaten inadequately cooked pork or other infested meat. [52]

Clinical Manifestations During the initial phase of trichinosis, nausea, vomiting, abdominal pain, or diarrhea may occur as the result of larval invasion of the intestinal mucosa. The systemic phase, which typically begins 1 to 3 weeks after ingestion of contaminated meat, is characterized by fever, myalgia, facial or periorbital edema, headache, conjunctivitis, and occasionally a rash. [46], [47], [48], [49], [50], [51] and [52] Extraocular muscles are frequently affected. Cardiac and central nervous system involvement occur in a minority of cases, and can be life threatening. Trichinosis among native Inuits living in northern Canada differs in that prolonged diarrhea is the dominant symptom in previously infected people who become re-infected. [50]

Diagnosis, Treatment, and Prevention The diagnosis of trichinosis is suggested by the constellation of fever, myalgia, eosinophilia, and a history of eating raw or inadequately cooked, potentially contaminated meat. Creatine phosphokinase or aldolase is elevated in about half of the cases. The clinical diagnosis is eventually supported by serologic evidence. This includes a positive enzyme-linked immunosorbent assay (ELISA), bentonite flocculation test, or indirect immunofluorescence test. However, anti- *Trichinella* antibodies are usually not detectable until the third week of infection or later. [46] The diagnosis can be confirmed by muscle biopsy, but that is seldom necessary. Either albendazole [53] or mebendazole [5] can be used for the treatment of acute trichinosis, along with corticosteroids when symptoms are severe (see Table 126-1). Bed rest is prescribed and nonsteroidal antiinflammatory agents are administered for symptomatic relief of fever and myalgias. Trichinosis can be prevented by cooking pork or other potentially contaminated meat to at least 76.6°C (170°F). Meat less than 6 inches thick can be rendered safe if frozen at -15°C (5°F) for 20 days, unless it is infected with *Trichinella nativa,* which is resistant to freezing. [50]

Hookworms

The hookworms, *Ancylostoma duodenale* and *Necator americanus,* rank among the major causes of iron deficiency anemia in the world. Adult hookworms are small, creamy white nematodes. [11], [54] The anterior portion of *N americanus* is sharply curved in the direction opposite the curve of the body, producing a hooklike appearance. Fourth-stage larvae and adults anchor themselves in the mucosa of the small intestine and employ complementary strategies to inhibit the coagulation of the host's blood. They secrete *Ancylostoma* anticoagulant peptide, which inhibits factor Xa, a factor(s) that inhibits platelet aggregation and adhesion, and fibrinogenolytic enzymes. [55], [56] and [57] Hookworms periodically change their location. Bleeding from the former site of attachment contributes to the total blood loss. *N americanus* infection results in the loss of approximately 0.03 mL/d of blood per adult hookworm, and *A duodenale* infections results in the loss of 0.15 to 0.26 mL/d. [58], [59]

Ova (see Figure 126-1) are released into the intestine and excreted in feces. They excyst in the soil liberating rhabditiform larvae, which feed actively on organic debris and bacteria. After increasing in size, they molt twice to become infectious filariform larvae, which migrate in response to pressure, carbon dioxide, or warmth and invade the epidermis through fissures or hair follicles, most commonly between the toes or on the dorsum of the feet. Infection also may be acquired through the interdigital spaces of the hands. Invading larvae exsheath as they enter the host and pass through the venous circulation to the lungs. There they break out of the alveoli, ascend to the pharynx, and are swallowed. Although invasion is principally through the skin, filariform larvae of *A duodenale* occasionally are ingested and complete their life cycle in the gut. In addition, data from animal models suggest that larvae can enter a developmentally arrested state in somatic tissues, including mammary glands, and could infect breast-feeding infants after resuming development.

Epidemiology *A duodenale* and *N americanus* are widely distributed in tropical and subtropical areas. Hookworm infections are limited to areas where the climate allows development of larvae in the soil. They are readily killed by desiccation or freezing. *A duodenale* is found in the Middle East, North Africa, India, and China. *N americanus* frequently overlaps *A duodenale* in Africa, India, and China and is the dominant hookworm in sub-Saharan Africa, southern China, southern India, and Southeast Asia. *N americanus* is the predominant species in the New World, where there are also focal sites of *A duodenale*. *N americanus* infections were once common in the southeastern region of the United States, but treatment and control measures resulted in a dramatic lowering of prevalence by 1965. [60] Human infection with *A ceylonicum* has been reported from Southeast Asia and India. In general the prevalence and intensity of hookworm infection increases through childhood, reaching a plateau in young adults. Several factors favor the spread of hookworms: poor sanitation and agrarian practices; walking barefoot; and the use of human excrement as fertilizer.

Clinical Manifestations The clinical manifestations of hookworm infection correlate with the life cycle of the organism and the intensity of infection. [11], [54] Penetration of the skin by filariform larvae can produce a papular eruption with intense pruritus, vesiculation, and local edema (“ground itch” or “dew itch”). As larvae pass through the lungs, they can elicit hypersensitivity reactions with cough, wheezing, infiltrates, and eosinophilia (Löffler syndrome). Epigastric pain, flatulence, and abdominal tenderness accompany the early intestinal phase of infection in some. Humans experimentally infected with *N americanus* [61] experienced abdominal pain and flatulence 35 to 40 days after exposure to filariform larvae, eosinophilia peaked between 38 and 64 days, and eggs first appeared in the stool during the sixth week. At times, abdominal pain was severe enough to suggest peptic ulcer disease and occasionally was accompanied by diarrhea with mucus or blood in the stool. In young children with heavy primary hookworm infections, massive invasion by filariform larvae can result in acute gastrointestinal hemorrhage, a condition that is rare but potentially life threatening. [62] The hallmark of chronic hookworm disease is iron deficiency anemia. [11], [54], [63] The infecting species of hookworm; the parasite burden;

the age, sex, diet, iron requirements, and iron reserves of the host; and concurrent malaria are important variables. Hookworm disease with severe anemia is common in young children, potentially stunting growth and intellectual development, and in women during pregnancy, increasing the risk of maternal and neonatal mortality. [64] Hypoalbuminemia is often present and generally correlates with the degree of anemia. In areas of high iron intake and bioavailability, even heavy hookworm infections may not produce anemia.

Diagnosis, Treatment, and Prevention Hookworm disease should be considered in any person from an endemic area who presents with the clinical and laboratory findings of iron deficiency anemia. Eosinophilia frequently accompanies hookworm infection. [65] Direct fecal examination for ova is adequate to detect clinically significant infections, except in the case of the naive host who presents with eosinophilia or abdominal symptoms in the prepatent stage of infection prior to the onset of ova production. It is not easy or necessary clinically to differentiate between the eggs of *N americanus* and *A duodenale*. Hookworm ova can hatch in stool specimens that have been allowed to stand at warm temperature, and it is occasionally necessary to differentiate the rhabditiform larvae of hookworms from those of *S stercoralis*. Hookworm larvae have a long buccal tube, in contrast to the short buccal tube of *S stercoralis*. The treatment of hookworm disease includes iron repletion as well as anthelmintic therapy (see Table 126-1) with albendazole, mebendazole, or pyrantel pamoate. [66] During pregnancy, iron deficiency anemia is treated with ferrous sulfate alone, and anthelmintic therapy, which is potentially teratogenic, is administered after delivery. Empirical therapy is occasionally administered to returning travelers who present with eosinophilia and abdominal symptoms after a recent exposure who may be in the prepatent period. The transmission of hookworm infection can be interrupted by sanitary disposal of human feces, use of footwear, and treatment of infected people.

Strongyloides stercoralis

S stercoralis is in an important cause of morbidity and mortality, but it is less prevalent than *A lumbricoides* or the hookworms. It differs from them in its ability to complete its life cycle in the soil and in its capacity to produce autoinfection, which can result in infections that last for decades and may progress to life-threatening hyperinfection in immunocompromised hosts. [67] Like the hookworms, *S stercoralis* enters the skin from soil contaminated by feces, migrates through the venous circulation to the lungs, penetrates alveoli, ascends the trachea, is swallowed, and ultimately reaches maturity in the small bowel. Adults reside in the superficial mucosa of the duodenum or jejunum and produce ova, which quickly hatch releasing rhabditiform larvae. Autoinfection occurs when a subset of rhabditiform larvae converts to filariform larvae in the gut or on the skin. Filariform larvae can penetrate the intestinal mucosa or skin and go on to complete the life cycle. *Strongyloides* infections can persist for decades because of autoinfection. The conversion of rhabditiform to filariform larvae is enhanced in immunocompromised person and those receiving corticosteroids. [67] Rhabditiform larvae are excreted in fluctuating numbers in the stool. After reaching the soil, they convert to infectious filariform larvae or to free-living adults, which in turn produce rhabditiform larvae that convert to filariform larvae. *S stercoralis* is the only human geohelminthic pathogen that can complete its life cycle entirely in the soil.

Epidemiology *S stercoralis* is endemic in tropical areas of Africa, Asia, and Latin America as well as the southern part of the United States and Eastern Europe. Prevalence rates of 3% to 21% have been reported from Nigeria. Autochthonous cases are reported from Appalachian regions of West Virginia, Virginia, and Tennessee. [68], [69] and [70] A number of U.S. military personnel who were exposed in Southeast Asia during World War II or the Vietnam War remained infected decades later. [71], [72] and [73] *Strongyloides fülleborni,* primarily a pathogen of infrahuman primates, is recognized as an occasional cause of human strongyloidiasis in Papua, New Guinea and Africa. [74] An unexpectedly high prevalence of *S stercoralis* and increased severity of disease has been observed in persons concurrently infected with human T-cell lymphotrophic virus type 1 (HTLV-1). [75], [76] and [77] The interactions between the two pathogens are complex. It is thought that the spontaneous secretion of high levels of interferon-? by HTLV-1- infected mononuclear cells may suppress potentially protective Th2 responses. [77] In addition, chronic infection with *S stercoralis* may hasten the development of T-cell lymphoma or leukemia in persons infected with HTLV-1. [78] *S stercoralis* can produce life-threatening hyperinfection in persons with suppressed immunity and those receiving steroids. [67] The syndrome had been reported in association with HTLV-1, organ transplantation, malignancies (especially lymphoma and leukemia), corticosteroid and other immunosuppressive therapy, protein-calorie malnutrition, visceral leishmaniasis, lepromatous leprosy, and other debilitating conditions. Hyperinfection has been associated with human immuno- deficiency virus infection, [79] but it has not been as frequent as originally predicted. Exogenous steroids appear to be homologs of molecules that stimulate conversion of filariform to rhabditiform larvae. No cases of hyperinfection have been reported among transplant recipients receiving cyclosporin, which has been demonstrated in animals to have anti- *Strongyloides* activity.

Clinical Manifestations Most people are asymptomatic at the time of cutaneous penetration by larvae, although some develop a maculopapular rash or linear urticaria, called larva currens, [67], [80] which also may be seen as a consequence of external autoinfection. Eosinophilia is common. On rare occasions infected persons may present with generalized, chronic prurigo nodularis or lichen simplex chronicus. The pulmonary phase of strongyloidiasis can be associated with cough, shortness of breath, wheezing, fever, transient pulmonary infiltrates, and eosinophilia. [81] Once *S stercoralis* reaches the gut, it can produce epigastric or diffuse abdominal pain or diarrhea. [67], [82] With heavy infections of the upper small bowel, vomiting, malabsorption, steatorrhea, and weight loss can occur. In some cases the symptom complex may be confused with inflammatory bowel disease. [83] Eosinophilic granulomatous enterocolitis and inflammatory mass lesions have also been reported. [84] Rarely, intestinal obstruction develops. [85] Of note, about one third of chronically infected World War II veterans diagnosed with *S stercoralis* decades after exposure were asymptomatic; the other two thirds reported recurrent larva currens, gastrointestinal complaints, or pulmonary symptoms. *Strongyloides* hyperinfection is characterized by multisystem involvement and the presentation varies. [67] Some patients present with pulmonary symptoms including cough, shortness of breath, wheezing, and hemoptysis. They may progress to the acute respiratory distress syndrome. Infiltrates are seen on chest radiograph. Others have intestinal symptoms. Concurrent polymicrobial bacterial infections often occur as a result of bacteria on the surface of invading filariform larvae. Sepsis, meningitis, peritonitis, and endocarditis have been reported. The mortality rate with *S stercoralis* hyperinfection exceeds 50%.

Diagnosis, Treatment, and Prevention The diagnosis of strongyloidiasis is confirmed by identifying larvae in stool, tissues, or secretions. Eosinophilia is frequently present in immunocompetent patients, but it may be absent in immunocompromised hosts. The agar plate method is the most sensitive way to identify larvae in stool. It has replaced the Baermann funnel and other techniques. [86] In people with the hyperinfection syndrome, larvae are also frequently found in sputum or tissue. Several serologic tests, including ELISA, have been developed and provide presumptive evidence of infection. [87] Ivermectin has emerged as the treatment of choice for uncomplicated strongyloidiasis (see Table 126-1). [5], [88] Thiabendazole, once the drug of choice, was associated with frequent side effects and is no longer manufactured in the United States, but some physicians prefer it for the treatment of patients with hyperinfection. Relapses have been reported with both drugs. Albendazole, 400 mg daily for 3 days, cures about half of those treated. [89] Prevention of strongyloidiasis depends on improved standards of living and personal hygiene. It is advisable to screen immunocompromised persons, particularly those receiving corticosteroid therapy, who may have been exposed to *S stercoralis* in endemic areas.

Other Syndromes Caused by Intestinal Nematodes

Cutaneous Larva Migrans Also known as *creeping eruption,* this is a distinctive form of parasite-induced dermatitis characterized by serpiginous, papulovesicular, erythematous, pruritic lesions. [90] It is a consequence of migrating larvae of intestinal nematodes of animals that cannot complete their life cycle in humans (i.e., hookworms of dogs and cats, primarily *A braziliense* and less commonly *A caninum,* and other nematodes). Cutaneous larva migrans is prevalent in tropical and subtropical areas of the Caribbean, Africa, Latin America, and the southern Atlantic and Gulf of Mexico coasts of North America. Infection is acquired when people come in contact with infected soil in playgrounds, beaches, or crawl spaces under houses. A single 12 mg dose of ivermectin, or alternatively, albendazole, 400 mg daily for 3 days, can be used as treatment.

Eosinophilic Enteritis *A caninum,* the dog hookworm, has been identified as a cause of eosinophilic enteritis, generally a rare condition but quite common in northeastern Australia. [92], [93] The findings include eosinophilic infiltration of the wall of the intestine, aphthous ulceration of the ileum, regional lymphadenopathy, and in some patients peripheral blood eosinophilia. Many of those infected are asymptomatic, whereas others experience abdominal pain. The diagnosis is made by finding a sexually immature adult worm at endoscopy or by serological evidence of *A caninum* infection. Although optimal chemotherapy has not been identified, albendazole or mebendazole are likely to be effective.

Visceral Larva Migrans and Ocular Toxocariasis Visceral larva migrans is a systemic syndrome resulting from invasion of human organs by larvae of the dog ascarid, *Toxocara canis,* the cat ascarid, *Toxocara cati,* [94], [95] or less commonly, other nematodes of animals. Infection follows ingestion of ova originating in animal feces. The syndrome is encountered most commonly in children with a history of pica, but on occasion it is seen in adults, some of whom have a history of eating clay. Larvae are released and penetrate the intestine. Because these helminths are unable to complete their life cycle in humans, they wander through various organs. *Toxocara* species are common throughout tropical and temperate areas. The clinical course of visceral larva migrans is highly variable, ranging from no symptoms to fever, cough, abdominal pain, arthralgia, oligoarticular arthritis, urticarial skin rash, or neurological abnormalities. Physical examination may reveal hepatomegaly, pneumonitis, dermatitis, or encephalitis. Persons with ocular toxocariasis may present with an intraocular mass lesion suggestive of a retinoblastoma. Eosinophilia is common and often pronounced. Hypergammaglobulinemia and high levels of IgE are also observed. These findings have been attributed to the dynamic nature of the larval membrane and the release of antigens that stimulate Th2 responses. The characteristic pathological lesion consists of a granulomatous inflammatory response with eosinophils. The triad of hepatomegaly, eosinophilia, and hypergammaglobulinemia suggests visceral larva migrans. Ultrasound or magnetic resonance imaging can be used to identify hepatic granulomas. An ELISA is available to detect anti- *Toxocara* antibodies. High levels of isohemagglutinins against A and B blood group antigens are also frequently observed. Diethylcarbamazine is used for treatment (see Table 124-1); [5] albendazole is an alternative. Corticosteroids are also administered in severe cases. Control measures include worming dogs, covering sandboxes, and preventing promiscuous defecation of dogs in other areas where

children play.

Anisakiasis Also known as anisakidosis, this syndrome is caused by members of the family Anisakidae, which are nematode parasites of sea mammals. The common intermediate hosts include codfish, herring, rockfish, sardine, anchovy, salmon, tuna, mackerel, Pacific pollock, Pacific red snapper, and squid. [96], [97], [98] and [99] Anisakine larvae normally reside in the viscera of fish, but they migrate to muscle if fish are not promptly filleted after being caught. Anisakiasis occurs after contaminated fish are eaten raw or inadequately cooked. It is most common in Japan and Europe, areas where fish is consumed raw as sushi or sashimi. Sporadic cases occur in the United States. Anisakine larvae are prevalent in susceptible types of fish along the California coast and in the northern Atlantic Ocean. People who ingest infested fish may be asymptomatic, but the presentation can be dramatic when anisakine larvae attempt to invade the mucosa. In acute gastric anisakiasis, severe abdominal pain, chest pain, nausea, vomiting, and occasionally gastric bleeding develop 12 to 24 hours after contaminated fish is ingested. [97] Involvement of the greater curvature of the stomach is most common. In intestinal anisakiasis, symptoms mimicking acute appendicitis, regional enteritis, or small bowel obstruction or perforation develop several days after ingestion. Eosinophilic inflammatory responses develop at the site of attempted larval penetration, but peripheral eosinophilia is not common. Intestinal inflammation and edema may result in luminal narrowing, thumbprinting, or mass effect and may be confused with a neoplasm. Symptoms can persist for weeks to months in chronic cases. The allergic consequences of exposure to *Anisakis* species, which include urticaria, angioedema, erythema, bronchospasm, and anaphylaxis, have been increasingly recognized in recent years. They have been reported in persons ingesting contaminated fish, either raw or cooked, as well as among fisherman and fishmongers. [99], [100] Allergic symptoms can develop up to a day after contaminated fish is ingested. Since the life cycle cannot be completed in humans, neither anisakine larvae nor ova are passed in the stool. Visualizing worms at endoscopy typically leads to a diagnosis of anisakiasis. Larvae have been extracted successfully from the stomach and duodenum by using biopsy forceps. [96], [97] and [98] Surgical resection is occasionally necessary to relieve intestinal obstruction, to repair a perforation of the bowel, or to rule out malignancy, but most patients can be managed conservatively. Anisakiasis can be prevented by filleting freshly caught fish before larvae have a chance to penetrate muscle, by cooking fish to 60°C (140°F) for at least 10 minutes, or by freezing for 24 hours at -20°C (-4°F). Allergic symptoms can occur in patients ingesting properly cooked as well as frozen fish and correlate with the presence of IgE antibodies to *Anisakis simplex.*

Gastrointestinal Angiostrongyliasis *Angiostrongylus costaricensis* is endemic among rodents from California to South America. Adult worms reside in mesenteric arteries in the ileocecal region of rodents. They occasionally infect the same site in humans. Human disease is typically sporadic and observed among children in Central America. Rare cases have been reported in the United States, and an outbreak occurred among adults who ate contaminated mint. [101], [102] Humans and rodents acquire infection by ingesting infected slugs or their slime in vegetation. Adult worms and ova elicit a granulomatous arteritis with eosinophilic infiltration in the ileocecal region that can result in thrombosis, local infarction, and bowel perforation. The clinical manifestations vary from a visceral larva migrans-like syndrome to those of an acute abdomen. Nausea, vomiting, right lower quadrant pain, and fever are common. A right lower quadrant mass may be palpable, suggesting acute appendicitis or malignancy. Radiographic studies may document a mass lesion in the ileocecal region. Eosinophilia and leukocytosis are common. Neither ova nor larvae are found in the stools of humans. Surgery is often necessary, and the diagnosis is made when adult worms or ova are identified in surgical specimens. Cooking slug-infested vegetables and hand washing can prevent infection.

CESTODES (TAPEWORMS)

The major pathogenic cestodes are *Taenia solium* (pork tapeworm), *Taenia saginata* (beef tapeworm), *Diphyllobothrium latum* (fish tapeworm), *Hymenolepis nana* (dwarf tapeworm), *Echinococcus granulosus,* and *Echinococcus multilocularis*. [103], [104] Cestodes have complex life cycles, living as adults in the gastrointestinal tract of their definitive mammalian hosts and as solid or bladder larvae in tissues of vertebrate or invertebrate intermediate hosts. Adult tapeworms are ribbonlike, with a scolex at the anterior end that is responsible for attachment in the small intestine, a connecting neck region, and the strobila, which is a chain of progressively developing segments known as proglottids. The number of proglottids ranges from 3 to 4000, depending on the cestode species, and the total length of adult tapeworms varies from several millimeters in the case of *E granulosus* to several meters in the case of *T saginata*.

Humans are the definitive host for *T saginata, T solium, H nana,* and *D latum,* and adult tapeworms are found in their gastrointestinal tract. On rare occasions, humans serve as a definitive host for *Hymenolepis diminuta,* which is primarily a parasite of rats and mice, and *Dipylidium caninum,* a dog tapeworm. Both of the latter infections are uncommon, light, and usually of little consequence. Humans serve as intermediate hosts for *E granulosus, E multilocularis,* and *T solium,* and cysts are found in liver, lung, brain, or other organs. In general, adult tapeworms produce little evidence of disease in their human hosts, although *D latum* can result in vitamin B_{12} deficiency. In contrast, cestodes can produce severe, life-threatening disease when humans serve as intermediate hosts.

Taenia saginata

The beef tapeworm, *T saginata,* is renowned for its length, up to 4 to 6 meters, and the occasional finding of strobila up to several feet long in the stool. [103], [104] Humans become infected when they ingest inadequately cooked beef or meat from other herbivores, such as camels, that contains the bladder or cysticercus stage. As the meat is digested, the cysticercus breaks down, releasing a scolex that typically attaches in the upper jejunum. Development of the adult worm is followed by the appearance of proglottids and ova in the stool. Cattle become infected when they ingest ova from human feces. Larvae are released in the intestine of the cow, penetrate the mucosa, and find their way to muscle, where they develop into cysticerci, completing the life cycle.

Although nonspecific symptoms such as abdominal discomfort, epigastric pain, nausea, vomiting, diarrhea, and weight loss have been attributed to *T saginata,* most infected persons are asymptomatic. There is usually no evidence of weight loss or malnutrition. The diagnosis of *Taenia* infection is made by finding ova or proglottids in the stool. The ova of *T saginata* are indistinguishable from those of *T solium* (see Fig. 126-1), and a species-specific diagnosis requires examination of the proglottids (see *Atlas,* Chapter 80). Praziquantel is the treatment of choice (see Table 126-1). [5] Niclosamide is an alternative, but resistance has been reported.

Taenia solium

Humans can serve as both the definitive host and as an intermediate host for the pork tapeworm, *T solium.* [103], [104] Infection is endemic in areas of Latin America, Africa, and Asia where hogs are raised and sanitary conditions are poor. People become infected as the definitive host when they ingest inadequately cooked pork containing infective cysticerci cellulosae. The scolex is released and attaches to the small intestine. Adult worms usually cause few, if any, symptoms, although a number of nonspecific gastrointestinal complaints have been attributed to them. Eosinophilia may be present. Mature proglottids and ova of *T solium* are released in the stool. Pigs, the normal intermediate host, become infected when they ingest ova from human feces.

The major risk with *T solium* is cysticercosis, [105], [106], [107] and [108] which develops when humans ingest ova from human feces or, theoretically, if internal autoinfection occurs in persons harboring adult worms. Ova excyst in the human or pig intestine. Larvae invade the mucosa, disseminate, and form cysticerci in the brain, subcutaneous tissue, skeletal muscle, eye, or other organs. Neurocysticercosis is the most common parasitic disease of the central nervous system in the world. It is prevalent in many Latin American countries where it is a leading cause of epilepsy and hydrocephalus. It is increasingly encountered in the United States and other industrialized countries among immigrants from endemic areas, and on rare occasion, in international travelers. Autochthonous cases of neurocysticercosis also have occurred among residents of the United States who have neither traveled internationally nor been exposed to pigs, but who have had close contact with immigrants harboring adult tapeworms. [107]

Intestinal infection is documented by finding *Taenia* ova (see Fig. 126-1) or proglottids (see *Atlas,* Chapter 80) in the stool. The ova of *T solium* and *T saginata* are indistinguishable from one another by conventional microscopy. The diagnosis of neurocysticercosis usually is based on a history of exposure in an endemic area, the clinical presentation, and computed tomographic and magnetic resonance findings. The identification of antibodies in serum or cerebrospinal fluid provides further support for the diagnosis. [108]

Praziquantel is recommended for the treatment of intestinal *T solium* infection (see Table 126-1). Niclosamide can be used, but it is associated with disintegration of the adult worm, [103] raising the theoretic possibility of autoinfection. Some physicians recommend a purge after therapy to expedite expulsion of proglottids, but there are no data to prove that it is necessary.

The guidelines for the treatment of neurocysticercosis are controversial. Both albendazole and praziquantel are effective in killing parenchymal cysticerci in the brain. [108] They have been used to treat patients with multiple, non-enhancing cysticerci. Corticosteroids are usually given concurrently to prevent cerebral edema, which may develop in response to parasite antigens released from dying cysticerci. It is important to note that corticosteroids reduce the concentration of praziquantel in the cerebrospinal fluid while increasing that of albendazole. For that reason most physicians favor the latter drug. Anticonvulsants are used in patients with seizures. The results of anthelmintic therapy in patients with extraparenchymal neurocysticercosis have been disappointing. Surgical procedures are necessary to remove intraventricular cysts and to divert cerebrospinal fluid in those who develop hydrocephalus. Albendazole and praziquantel are contraindicated in persons with

cysticerci in the spinal cord or eye.

Infection with *T solium* can be prevented by the proper disposal of human feces, treatment of infected people, inspection of pork, and thorough cooking of pork to at least 50°C before it is eaten. Freezing below -12°C (10°F) is an effective way to kill cysticerci, but they can remain viable for as long as 2 months in meat frozen at 0°C or F to -2°C (30°F). [109] Attempts are underway to develop a vaccine that would reduce or eliminate cysticercosis in pigs.

Diphyllobothrium latum

The fish tapeworm, *D latum,* is known for its ability to compete with its human host for vitamin B_{12}. [104], [110] The parasite has a complex life cycle. Adult worms reside in the human gastrointestinal tract. Ova are passed in feces. Free-swimming coracidia are released in fresh water and infect small crustaceans (copepods). When freshwater fish ingest infected copepods, procercoid larvae are released and penetrate into them. Humans become infected when they ingest raw or inadequately cooked fish, including pike, salmon, trout, whitefish, or turbot. *D latum* is found in regions of northern Europe, northern Asia, northern North America, and temperate areas of South America, such as Chile and Argentina. Some people have become infected while preparing gefilte fish, as they sampled the raw fish while adding condiments.

A number of minor gastrointestinal complaints have been associated with *D latum,* [104], [110] but most infected people are asymptomatic. Some present with macrocytic anemia due to vitamin B_{12} deficiency. The diagnosis of *D latum* is made by identifying ova or the typical broad, rectangular proglottids in the stool. The treatment of choice is praziquantel; niclosamide is an alternative (see Table 126-1). Thorough cooking or freezing of fish (-10°C [14°F] for 24 hours) prevents infection.

Hymenolepis nana

The dwarf tapeworm, *H nana,* infects as many as 20 million people worldwide. It has been diagnosed among immigrants to the United States from a number of endemic areas, including Southeast Asia. Natural hosts include humans, mice, and rats. [103], [104]

Infection with *H nana* follows ingestion of ova (see Fig. 126-1). Transmission is often hand to mouth, particularly among children, or by ingestion of food or water contaminated by feces. An oncosphere is liberated from each ova in the intestine. It penetrates a villus and develops into a cercocystis. At maturity, the cercocystis ruptures, releasing a scolex, which becomes anchored in the small intestine. Some eggs are passed in the stool. Others excyst in the lumen of the small intestine and invade villi to produce internal autoinfection.

Light *H nana* infections are usually asymptomatic or associated with vague abdominal complaints. Heavy infections may be associated with loss of appetite, abdominal pain with or without diarrhea, anorexia, flatulence, or weight loss. [104], [111] The diagnosis is made by identifying eggs in the feces (see Fig. 126-1). Praziquantel is the treatment of choice (see Table 126-1). [5], [6] Spread of *H nana* could be interrupted by improved sanitation.

***Echinococcus* Species**

Echinococcus granulosus Echinococcosis is endemic in scattered areas around the world. Adult *E granulosus* reside in the intestine of canines, their definitive hosts, and as hydatid cysts in sheep, humans, or other mammals that ingest ova from the feces of infected dogs. [104], [112] *E granulosus* is found in areas where dogs, sheep, and humans live in close proximity under conditions of poor sanitation. Infection is found in areas of Australia, New Zealand, North Africa, the Middle East, and South America. Scattered autochthonous cases have been reported from the western part of the United States. In some areas of Canada, moose and caribou serve as intermediate hosts, and the wolf is the predominant definitive host. Humans become infected with *E granulosus* when they ingest ova. Transmission is often hand to mouth from the fur of infected dogs or by way of food or water contaminated with dog feces. Ova excyst in the human intestine. The embryo invades through the intestinal wall and is carried to the liver, lung, or other organs though the portal system or lymphatics. Approximately two thirds of the cysts develop in the liver (Fig. 126-5), one fifth in the lung, and the remainder in bone, brain, muscle, eye, heart, or other organs. The typical *E granulosus* cyst contains an external hyaline cuticula, an inner germinal membrane with brood capsules, protoscoleces, which are known as hydatid sand, and daughter cysts that are replicas of the mother cyst.

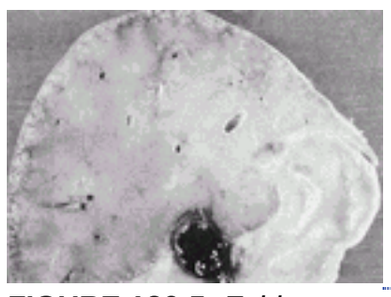

FIGURE 126-5. *Echinococcus granulosus* (hydatid) liver cysts have well-defined capsules, each with an irregular lining. These capsules contain a semi-opaque, tan liquid with hydatid sand composed of protoscoleces, each of which can mature to one adult worm. (From Smith JW, Ash LR, Thompson JH Jr, et al. Intestinal helminths. In: Atlas of diagnostic medical parasitology series. Chicago: American Society of Clinical Pathologists, 1984.)

The natural history of *E granulosus* in humans has not been defined fully. Hydatid cysts followed prospectively may shrink, remain stable, or grow slowly at a rate of approximately 0.3 cm per year. They usually do not cause symptoms until they are 10 cm or larger. Many cysts are silent or associated with vague abdominal pain. Tissue damage occurs secondary to pressure from the enlarging hydatid cyst or rupture into the biliary tract, [112] peritoneum, or lung. Obstructive jaundice, cholangitis, or biliary pain occur on rare occasions. Intra-abdominal spillage of cyst contents following spontaneous rupture can result in anaphylaxis or the seeding of the peritoneal surface. Cysts outside the liver often pose diagnostic dilemmas. The findings may be suggestive of neoplasm, particularly when cysts occur in the testes, ovary, urinary bladder, retroperitoneum, heart, or eye. The diagnosis of *E granulosus* is based on a history of exposure in an endemic area and identification of a typical hydatid cyst by ultrasound, computed tomography, or magnetic resonance imaging. [113], [114] Various serologic tests are available to detect antibodies, but they are negative in a substantial number of cases, and the specificity varies. [115] The diagnosis is confirmed histopathologically by identification of cysts or cyst contents. The World Health Organization (WHO) Informal Working Group on *Echinococcosis* recommends surgery as the treatment of choice for *E granulosus* cysts. [116], [117] Percutaneous, ultrasound-guided, cyst puncture with drainage and instillation of a scolicidal agent, such as hypertonic saline or alcohol, followed by aspiration has been advocated as an alternative for simple, uncomplicated cysts. [118], [119] Anaphylaxis has been reported as a result of leaked cyst material, but it is uncommon. [120] Laparoscopic approaches [121] have also been used. Injection of formalin into cysts should be avoided as it has been associated with sclerosing cholangitis and death. [122] Of major concern with any drainage procedure is spillage of cyst contents, resulting in anaphylactic shock or peritoneal implantation. Treatment with high doses of albendazole or mebendazole before surgery or percutaneous drainage reduces the risk of peritoneal implants. [123] Albendazole, administered at high doses for several months, is an alternative to surgery or percutaneous drainage. It suppresses cyst growth in the majority of cases and cures approximately one fourth of cases. It is the treatment of choice for patients with inoperable lesions. [116], [124] Mebendazole also has activity, but it is less well absorbed than albendazole. Liver transplantation has been performed successfully in rare cases. Progress has been made in controlling transmission of *E granulosus* in endemic sheep-raising areas by treating intestinal infections in dogs and keeping them from eating the uncooked viscera of sheep or carrion. *E granulosus* has a relatively low reproductive rate in its domestic life cycle, and it is thought to be relatively unstable and potentially susceptible to eradication. [125]

Echinococcus multilocularis This *Echinococcus* species is endemic in northern regions of North America, Central Europe, northern Asia, and Japan, and has a life cycle involving foxes, sled dogs, and other canines as definitive hosts, and mice, voles, and other rodents as natural intermediate hosts. [104], [112] Humans, who serve as intermediate hosts become infected by eating wild plants or berries contaminated with canine feces or by hand-to-mouth spread from the fur of infected dogs. *E multilocularis* has been recognized as an emerging zoonosis in Central Europe where infection has been documented among foxes, which are increasing in number, as well as domestic dogs and cats. [126] In humans, *E multilocularis* is typically found as an alveolar hepatic cyst, a spongy mass of fibrous tissue and small cysts with a jellylike matrix. These cysts resemble neoplasms in their ability to spread locally, metastasize, and invade bile ducts and vessels. The initial symptoms of *E multilocularis* are often vague. Hepatomegaly, abdominal pain, obstructive jaundice, and focal necrosis follow. Allergic complications are rare. Late complications include secondary bacterial infections, biliary cirrhosis, chronic Budd-Chiari syndrome, and portal thrombosis. The diagnosis is based on a history of exposure in an endemic area and ultrasonographic, computed tomographic, or magnetic resonance findings. The presence of anti- *Echinococcus* antibodies is suggestive of the diagnosis, but a negative serologic test does not exclude the diagnosis. [127] Surgical resection is the only reliable means of curing *E multilocularis* infections. [116] Prolonged albendazole treatment usually is administered to those who undergo surgery as well as to those who have inoperable lesions (see Table 126-1). [116] Liver

transplantation has been necessary in rare cases. *E multilocularis* can be prevented by avoiding uncooked, potentially contaminated wild fruits, by worming sled dogs, and by washing hands after exposure to potentially infected domestic animals.
Other *Echinococcus* Species A limited number of cases of polycystic hydatid disease resulting from *Echinococcus vogeli* and *Echinococcus oligarthus* have been reported from Central and South America. [128] *E vogeli* is a zoonotic parasite that infects wild canines and rodents in rural areas. Surgical resection of cysts is the only proven therapy.

TREMATODES (FLUKES)

Trematodes have complex life cycles with humans, and in some instances other animals, serving as the definitive host. Fresh-water snails are the primary intermediate hosts. *Schistosoma* species, which are often referred to as blood flukes, are among the most prevalent of the trematodes that infect humans. *Schistosoma mansoni* and *Schistosoma japonicum,* which live in mesenteric venules, are major causes of intestinal and liver pathology. Less prevalent are *Schistosoma intercalatum* and *Schistosoma mekongi*. *Schistosoma haematobium* primarily affects the urinary tract, although it occasionally involves the appendix or bowel. *Schistosoma* species enter the skin when humans come in contact with fresh water. Other pathogenic trematodes live in the biliary tract or the small intestine. They include the liver flukes *Clonorchis sinensis, Opisthorchis viverrini, Fasciola hepatica,* and *Metorchis conjunctus,* and the intestinal flukes *Fasciolopsis buski, Heterophyes heterophyes,* and *Metagonimus yokogawai*. They are acquired by eating the second intermediate hosts, fresh water fish, or in the case of *F hepatica* and *F buski,* water plants.

Schistosoma Species

As many as 200 million persons are infected with schistosomiasis worldwide. [129] *Schistosoma* species have complex life cycles. The delicate adult worms live as pairs within mesenteric venules in their definitive human host (see *Atlas,* Chapter 80). The adult female spends her life in the gynecophoric canal of the male. From 300 eggs in the case of *S mansoni* to 3500 in the case of *S japonicum* are produced daily. Lytic enzymes secreted by the ova allow them to penetrate the wall of the vessel to reach the lumen of the intestine. They are excreted in the stool. Miracidia are released when ova hatch in fresh water.

The next phase of infection begins when miracidia penetrate snails of the appropriate genera. After asexual development, fork-tailed cercariae emerge. They enter human skin when contact is made with fresh water during bathing, fishing, or other water-related activities. The tails of the cercariae are lost, and the resulting schistosomulae make their way through the vasculature to the portal circulation. Approximately 3 weeks later, *S mansoni* migrates predominantly to the superior mesenteric veins and *S japonicum* to the inferior mesenteric veins. Adult worms can live as long as 30 years in humans. [130]

Epidemiology *S mansoni* is endemic in Africa and many areas of Latin America. Transmission frequently is associated with dams, reservoirs, and irrigation systems. Scattered foci are present in the Middle East. *S intercalatum* is found in areas of Western and Central Africa. *S japonicum* is endemic in the Far East, China, coastal river valleys in Japan, numerous islands in the Philippines, and Indochina. Its epidemiology differs from other *Schistosoma* species in that it has a number of nonhuman hosts, including cows, dogs, and pigs. [131], [132] *S mekongi* is found along the Mekong River in Indochina and is similar to *S japonicum*.
Clinical Manifestations Invasion of skin by cercariae is usually asymptomatic, but a mild, pruritic dermatitis may result. Acute schistosomiasis, or Katayama fever, was first described among people with primary *S japonicum* infections. It can occur, however, with *S mansoni* and other *Schistosoma* species. [133] The time from invasion by cercariae to onset of systemic symptoms ranges from 6 to 8 weeks with *S japonicum* to 3 to 8 weeks with *S mansoni* and coincides with the start of egg production. Katayama fever is a serum sickness–like syndrome characterized by fever, malaise, urticaria, abdominal discomfort, diarrhea, weight loss, cough, mild hepatosplenomegaly, lymphadenopathy, and eosinophilia. Symptoms can persist for several months. Chronic schistosomiasis develops as a consequence of the inflammatory response directed against schistosome eggs that are deposited in mesenteric vessels, carried to the liver through the portal circulation, or reach the lungs or other sites by way of the systemic circulation. The degree of pathology depends on the worm burden and the host's genetically determined immune response to the eggs, a complex mix of Th1 and Th2 cytokines that result in varying degrees of inflammation and fibrosis. [134] Inflammation, hypertrophy, and ulceration of the mucosa characterize intestinal disease caused by *Schistosoma*. It is often asymptomatic, but infected persons may experience abdominal pain, diarrhea, and occult or gross blood in their stools. Intestinal polyps and strictures may be encountered late in disease. [135] Eggs that are swept to the liver through the portal circulation elicit a granulomatous inflammatory response and “Symmers” periportal fibrosis, which varies in intensity. [136] A subset of persons progress to severe “pipe-stem” portal fibrosis with presinusoidal portal hypertension. [137] Hepatomegaly and splenomegaly are common in heavily infected persons. The pathology in the liver is predominantly mesenchymal; the parenchyma and liver function are preserved until late in the disease. Bleeding from esophageal varices and ascites are complications of advanced hepatosplenic schistosomiasis. Heavy infections in children can be associated with malnutrition and growth retardation. [138], [139] Portosystemic anastomoses in persons with hepatosplenic schistosomiasis can result in shunting of eggs to the pulmonary vasculature, where granulomas and fibrosis may progress to chronic obliterative arteritis, pulmonary hypertension, and eventually cor pulmonale. [140] Granulomatous responses to eggs occasionally are encountered in other organs, including the gallbladder, where they have been associated with cholecystitis and cholelithiasis. Ectopic *S mansoni* egg-related granuloma have been identified in the spinal cord, [141], [142] and *S japonicum*-related granuloma in the central nervous system. [143] A small subset of patients infected with *S mansoni* develop immune complex glomerulonephritis that can progress to the nephrotic syndrome. This complication is seldom observed with *S japonicum.* Schistosomiasis also has been associated with prolonged or relapsing *Salmonella* bacteremia. The bacteria apparently colonize adult worms and are thus protect them from the effects of systemically administered antibiotics. [144] *S haematobium* resides primarily in venules of the vesical plexus, but on occasion it too involves the gastrointestinal tract. *S haematobium* has been found in association with acute appendicitis, although its role in pathogenesis is uncertain, [145], [146] and it has been reported as a cause of asymptomatic appendiceal calcification. [147]
Diagnosis, Treatment, and Prevention The diagnosis of schistosomiasis is confirmed by identifying ova in feces or biopsy material. Direct smears of stool are of relatively low sensitivity; Kato thick smears using 20 to 50 mg of fecal material are more sensitive. [148] Diffuse or patchy mucosal hyperemia, friability, and occasionally schistosomal polyps may be observed at colonoscopy. [149] A rectal biopsy may be necessary to document light infections. Ultrasonography has been widely used to assess hepatosplenic involvement and responses to chemotherapy. [150], [151] Several serologic assays are available and provide suggestive evidence of schistosomiasis, [152] but they are of no help in determining the severity or duration of infection. Praziquantel is recommended for the treatment of all *Schistosoma* species (see Table 126-1). [5], [6] It is effective in killing the parasite and can decrease periportal fibrosis, hepatomegaly, and splenomegaly, [150], [151] but treatment does not reverse all of the effects of chronic schistosomiasis. Concern has been raised about the possible emergence of resistance to praziquantel. [153] Oxamniquine is an alternative for the treatment of *S mansoni*. Endoscopic sclerotherapy or surgical decompression have been used successfully to treat bleeding esophageal varices due to portal hypertension. [154], [155] Control measures in endemic areas include improved sanitation and disposal of human feces, avoidance of contaminated fresh water, use of molluscacides, and mass treatment programs. [132] Despite these efforts, schistosomiasis remains prevalent in many endemic areas. There is hope that an effective vaccine can be developed, but one is not currently available.

Liver Flukes

The liver flukes, *Clonorchis sinensis* and *Opisthorchis viverrini,* are found in Japan, China, Indochina, South Korea, and Taiwan among those who eat raw freshwater fish. [156], [157] and [158] It has been estimated that 6 to 7 million people are infected in northeastern Thailand alone. Adult liver flukes live in the biliary tract. Eggs are released into the bile and passed in the stool. Snails are the first intermediate host, and freshwater fish are the second. Humans become infected when they eat raw or incompletely cooked fish. Freed larvae enter the common bile duct from the duodenum. These flukes have life spans of 10 to 30 years. In the United States, *C sinensis* and *O viverrini* are periodically encountered among immigrants from Southeast Asia.

Slight liver enlargement and tenderness may be observed at the onset of infection. The major pathological changes of chronic infection are in the bile ducts. Initially, there is desquamation of the biliary epithelium, followed by hyperplasia and eventually adenomatous proliferation. Fibrosis and stricture of the bile ducts may follow.

The precise relationship of infection to gastrointestinal symptoms is uncertain. Light infections are usually asymptomatic. In heavy infections, dyspepsia, abdominal pain, anorexia, hepatomegaly, icterus, edema, or diarrhea may occur. Pyogenic cholangitis, cholelithiasis, chronic cholecystitis, pancreatitis, and cholangiocarcinoma are potential long-term complications. [159], [160]

The diagnosis is confirmed by identifying ova in the stool or bile (see Fig. 126-1). Ultrasonographic examination may reveal liver enlargement; dilation, sludge, and thickening of the wall of the gallbladder; dilation of intrahepatic bile ducts; or evidence of cholangiocarcinoma. [161] Endoscopic retrograde cholangiopancreatography may show small, irregular filling defects in the common bile duct, tortuosity and irregular dilation of the intrahepatic ducts, or blunting of the terminal branches of the biliary tree. [162] Praziquantel is the drug of choice for the treatment of *C sinensis* and *O viverrini* (see Table 126-1).

Fasciola hepatica, which is responsible for “liver rot” in sheep and other herbivorous mammals, including humans, is cosmopolitan in sheep- and cattle-raising areas of the world. [156] Snails are intermediate hosts. Humans become infected when they eat wild watercress contaminated with encysted metacercariae. Larvae excyst in the small intestine, penetrate the gut wall, migrate through the peritoneal cavity, and enter the liver through the capsule. They may wander through the human liver for periods of 6 to 9 weeks before finally penetrating into the bile ducts, where they spend their adult lives. Acutely infected people may experience fever, hepatomegaly, abdominal pain, weight loss, anemia, and eosinophilia. [163] Jaundice and biliary colic are manifestations of chronic disease. Serologic assays provide presumptive evidence of infection. The diagnosis is confirmed by identifying ova in bile, duodenal aspirates, or stool. Multiple low-density areas may be observed in the liver by computed tomography. They are often subcapsular in location, arrayed in a tractlike fashion, and evolve slowly. [164] Unlike the other liver flukes, therapeutic failures are common in patients with *F hepatica* treated with praziquantel. Bithionol is used for treatment (see Table 126-1); [5], [6], [165] triclabendazole, a benzimidazole used for veterinary infections, is also effective.

On rare occasion, *Opisthorchis felineus* or other liver flukes that primarily infect animals are found in humans. *Dicrocoelium dendriticum,* a liver fluke of sheep and cattle, has been reported in humans who have ingested infected field ants, the second intermediate host. Most infections are asymptomatic, but hepatobiliary disease and eosinophilia can result. A common-source outbreak of acute infection caused by the North American liver fluke, *Metorchis conjunctus,* occurred in Montreal, Canada, among persons who ate raw fish (sashimi) prepared from white suckers. [166] The illness was characterized by persistent upper abdominal pain, low-grade fever, eosinophilia, and elevated liver enzymes. Ova were present in the stool. The symptoms resolved after treatment with praziquantel.

Intestinal Flukes

The intestinal fluke, *Fasciolopsis buski,* has as its definitive hosts humans, hogs, and occasionally dogs. [167] It is endemic in Asia. The adult flukes attach to the mucosa of the upper small intestine and release ova into the feces. Snails are the intermediate host. Cercariae encyst on water plants such as the water caltrop, water hyacinth, water chestnut, or water bamboo, which are ingested raw by humans. Inflammation, ulceration, and mucosal abscesses may develop in the small intestine. Epigastric pain, nausea, and diarrhea of varying severity are reported, but many people are asymptomatic. The diagnosis is made by identifying ova in the stool. Praziquantel is recommended for treatment (see Table 126-1). [5], [6]

Many species of the trematode family Heterophyidae, including *Heterophyes heterophyes* and *Metagonimus yokogawai,* are parasites of humans and other fish-eating mammals. The first intermediate hosts are snails, and the second intermediate hosts are freshwater or brackish-water fish. Humans become infected from eating raw or inadequately cooked fish. *H heterophyes* is encountered in Egypt, the Middle East, and Asia. It does relatively little damage to the intestine. Colicky pain, abdominal tenderness, and diarrhea are experienced by some, particularly those with heavy infections. Eosinophilia may be present. A case of *Heterophyes* infection was reported in the United States in a woman who ate sushi imported from the Orient. [168] *M yokogawai* is found primarily in the Far East, where it has infected American travelers, causing diarrhea. [169] *M yokogawai* on rare occasions is associated with the formation of egg-related granuloma at distant foci, such as the heart or central nervous system. Intestinal fluke infections are typically diagnosed by finding ova in the feces. Praziquantel is the treatment of choice (see Table 126-1). [5], [6] Infection can be prevented by eating only thoroughly cooked fish.

On rare occasions, people living in the Pacific Northwest or Siberia become infected with *Nanophyetus salmincola* when they ingest raw or inadequately cooked salmonid fish. Abdominal pain, diarrhea, nausea, and vomiting may result, along with eosinophilia. [170] Praziquantel has been used for therapy (see Table 126-1). Infection with one of many *Echinostoma* species may also occur after ingestion of raw, infected snails, fish, or amphibians, but symptoms, when present, are usually mild. [171]

CHAPTER 127

Elizabeth M. Petty

GASTROINTESTINAL AND HEPATIC MANIFESTATIONS OF SPECIFIC GENETIC DISORDERS

Genetic factors contribute to the pathogenesis of many gastrointestinal (GI) and hepatic disorders. Additionally, many inherited multisystemic conditions and syndromes are associated with specific GI or hepatic pathology. While the impact of genetic contributions to these conditions varies, genetic and nongenetic factors (e.g., environmental, epigenetic) interact at least to some degree to influence phenotypic expression of most conditions with GI or hepatic manifestations. Clinicians need to be aware of genetic contributions to these conditions. Recognition of a highly penetrant well-understood genetic contribution to a disease could impact clinical management of the patient and often has significant implications for other family members. To help recognize genetic contributions to GI or hepatic disorders, it is helpful to review a comprehensive family history, relevant medical records (including pathology reports, laboratory studies, and clinical summaries) of the patient, and, in some cases, medical records of other affected family members.

As discussed in Chapter 54, the family history may reveal a specific Mendelian inheritance pattern (e.g., autosomal dominant, autosomal recessive, X-linked recessive, or X-linked dominant) or non-Mendelian mode of inheritance (mitochondrial/maternal/cytoplasmic or imprinted) that suggests a discrete inherited genetic contribution. It is sometimes difficult to recognize genetic contributions when there is a small family, genetic heterogeneity, common phenocopies (sporadic conditions that mimic inherited disorders), variable expressivity of manifestations, or incomplete penetrance. Determining the genetic contribution to a GI or hepatic disease that is multifactorial (e.g., where significant environmental or epigenetic factors interact with an individual's underlying genetic constitution) or polygenic (e.g., where several genetic factors, including modifying genes, interact to contribute to the disease) is even more challenging. Despite these challenges, it is clinically relevant to assess genetic contributions to the disease process.

The purposes of this chapter are to:

Provide a basic framework as to when, how, and why to consider genetic factors.
Review several well-known genetic syndromes that may present with significant GI or hepatic manifestations, most of which are highly penetrant single-gene disorders with Mendelian patterns of inheritance that have additional non-GI manifestations.

Some of these syndromes present early in life (e.g., inborn errors of malabsorption), while others are characterized by their adult-onset presentation (e.g., dominant colon cancer syndromes). It is important to be aware of these syndromes to ensure that patients are appropriately diagnosed and offered the most appropriate medical management. For example, in an adult with Ehlers-Danlos syndrome (EDS) type IV (often referred to as the "vascular type" of EDS), an autosomal dominant syndrome characterized by type III collagen abnormalities, who presents with acute severe abdominal pain, rupture of the bowel and dissection of an abdominal artery must be immediately suspected to reduce disease-associated morbidity and early mortality.

Most of the diseases presented in this chapter are summarized in an abbreviated table format for easy reference. More comprehensive discussions of the pathophysiology and treatment for common GI and hepatic diseases mentioned in this chapter are covered in more detail elsewhere in this text (see the references for each topic, Chapter 128, and the). For more information about less common genetic conditions several excellent genetic textbooks and on-line genetic databases are referenced for additional, more detailed, information about the particular syndromes and diseases. [1], [2], [3], [4] and [5] Specifically, the *Online Mendelian Inheritance of Man* (OMIM) (http://www3.ncbi.nlm.nih.gov/Omim/), GeneTests-GeneClinics Web site (http://www.geneclinics.org/), and the Center for Disease Control's HuGE Net (http://www.cdc.gov/genetics/hugenet/reviews.htm) are excellent on-line database references that provide regularly updated information about many genetic syndromes and include more detailed up-to-date reference lists. All information for this chapter was obtained through these on-line searches of these databases with review of their listed references and genetic textbooks. [4], [5] Genetic contributions to common GI and hepatic conditions that have complex multifactorial or polygenic etiologies (e.g., inflammatory bowel disease, cirrhosis) are covered in other disease-specific chapters throughout this text (see).

PRACTICING GENETIC MEDICINE (See Also Chapter 54)

Basic genetic principles must be well understood by the clinician in order to provide accurate diagnostic, prognostic, and therapeutic services for individuals with genetic conditions and other at-risk family members. Once the genetic basis of a disease is recognized, preventive screening, medical or surgical management, genetic counseling, patient and family education, and referrals can be implemented as appropriate. DNA testing is now available for dozens of conditions that have prominent GI or hepatic manifestations and the list will continue to grow. With completion of the Human Genome Project and identification of the genetic codes for all of our estimated 30,000 to 35,000 human genes, genetic discoveries relevant to gastroenterologists and hepatologists will continue to be revealed at an unprecedented pace. Genetic testing can serve various purposes, from molecular confirmation of a suspected disease to facilitate more appropriate medical management and accurate recurrence risk counseling as in the case of hemochromatosis, or, predictively, to more accurately predict one's own risk of developing colon cancer. Thus, this new era of molecular medicine has already made an undeniable impact in medicine, especially as related to predictive genetic testing.

An example of this is seen in familial adenomatous polyposis (FAP), classically a highly penetrant, autosomal dominant condition caused by deleterious mutations in the adenomatous polyposis coli gene (*APC*) located on the long arm of chromosome 5 (see Chapter 90). In its classic form, individuals with one copy of a mutated *APC* gene will develop colon cancer in early to mid-adulthood after having hundreds to thousands of polyps that began developing in adolescence. At-risk individuals benefit from genetic counseling, education, and testing to better understand their risks of developing cancer. In over 80% of affected individuals, causative *APC* mutations can be detected, allowing robust and reliable predictive testing for at-risk family members. Specific preventive management strategies (e.g., serial colonoscopies, colectomies) can greatly reduce the risk of colon cancer in mutation carriers. Individuals lacking the mutation that segregates in affected family members, are spared the high risk of developing early-onset colon cancer and do not need the surveillance and surgical interventions recommended for mutation carriers. Thus, it is both clinically and economically desirable to offer predictive genetic testing to individuals at risk for a highly penetrant, late adolescent/early adult-onset disorder such as FAP, where interventional management can significantly reduce morbidity and early mortality. In contrast to highly penetrant *APC* mutations responsible for classic FAP, recognition of a relatively common polymorphism associated with a hypermutable tract of DNA in the *APC* gene in Ashkenazi Jews confers only a mildly increased risk of colon cancer in individuals with the polymorphism. Thus, understanding the relative risks for colon cancer associated with various mutations is critical for patients as it may have profound effects on their clinical management. With a better understanding of genetic mechanisms in health and disease, the number and use of genetic tests available will continue to grow and, ultimately, individually targeted molecular-based therapies may become a therapeutic reality for many GI and hepatic disorders.

Issues in genetic counseling, education, and testing will be raised throughout this chapter. As discussed more fully in Chapter 54, genetic counseling involves discussing diagnostic, prognostic, recurrence risk and medical management strategies, genetic testing issues, and related psychosocial concerns with referral to

appropriate support systems and educational resources. Although board-certified geneticists and genetic counselors currently provide genetic counseling, the growth of genetic knowledge will require that virtually all health care professionals will need to provide some basic level of genetic counseling in the future. For complex cases and rare genetic conditions specialized genetic services are available through most academic medical centers.

Since genetic testing evolves with laboratory methods becoming increasingly more sensitive, specific, and cost-effective, detailed discussion of specific genetic tests will not be addressed here. It is important to remember, however, that each test has its own strengths and weaknesses, and the specificity and sensitivity will vary considerably depending on the particular genetic test. For some disorders, such as hereditary nonpolyposis colorectal cancer (HNPCC), an adult-onset, autosomal dominant disease where genetic heterogeneity exists, clinicians must now choose between a number of different kinds of available genetic tests to identify the most appropriate, sensitive, specific, and cost-effective test for any one individual or family. On-line genetic testing laboratory databases, such as GeneTests, for health care professionals, provide up-to-date information on laboratories that offer research or clinical genetic testing for diseases with a genetic component. [2] Individuals needing more information should consult with local genetic centers and gather up-to-date information provided by national disease-associated organizations.

While DNA tests may be the most appropriate diagnostic test to offer an individual being evaluated for a genetic condition, this is not always the case. Consider, for instance, a disease like neurofibromatosis type 1 (NF1), an autosomal dominant, neurocutaneous disorder that may be associated with GI symptoms caused by the mass effect of internal plexiform neurofibromas or by episodes of vascular ischemia caused by vascular lesions in the intestinal bed. Close to 100% of older children and adults with NF1 have a clinically recognizable diagnosis while current molecular testing for NF1 is only about 70% sensitive for identifying mutations in affected individuals—much less than a good clinical genetics examination. DNA testing in a clinically diagnosed individual who presents for management of their GI symptoms currently offers no benefit to the patient as there are relevant genotype/phenotype correlations that would offer insight into their prognosis or management. Molecular testing for NF1, however, may be quite useful if the same individual is interested in prenatal testing or if the patient has very young children and the diagnosis cannot be firmly established by clinical examination.

In all cases, genetic testing encompasses more than a simple laboratory analysis and generally includes pretest counseling and education, provision of informed consent, accurate interpretation and discussion of implications, follow-up after test results, and post-test education, management, and support (Table 127-1). This is especially true when molecular testing is used to more accurately determine a healthy individual's genetic risk for developing a disease, as in predictive testing of an asymptomatic individual who, by virtue of their family history or their ethnicity, is at risk of having inherited a particular mutation. Such testing is currently employed in the evaluation of inherited colon cancers, as described previously.

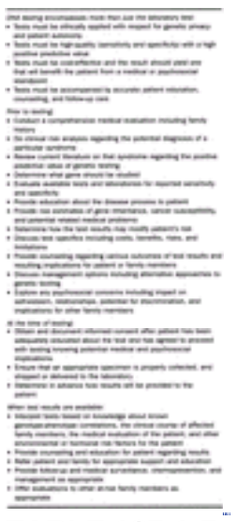

TABLE 127-1 Foundations for the Appropriate Use of Genetic Tests

WELL-DEFINED GENETIC DISORDERS WITH PROMINENT GASTROINTESTINAL OR HEPATIC PRESENTATIONS

Malabsorption Disorders (See Also Chapter 77)

Some genetic syndromes involve defects of intestinal absorption (Table 127-2). Most are disorders of brush border enzymes or transport proteins that transfer sugars, amino acids, electrolytes, lipids, vitamins, and minerals from the lumen of the gut into our circulation. They may involve malabsorption of a singular, specific substance, such as in lactase deficiency, or general malabsorption of several substances, such as in Hartnup disease. The other large group of genetic malabsorption syndromes involves disorders of the exocrine pancreas. Cystic fibrosis is most common, followed in frequency by the Shwachman-Bodian syndrome and the much rarer Johanson-Blizzard syndrome.

Download image in PDF format

TABLE 127-2 Genetic Disorders of Intestinal Malabsorption

Defects in Carbohydrate Metabolism

Congenital lactase deficiency. Patients with congenital lactase deficiency (i.e., disaccharide intolerance II) present with watery diarrhea, usually after the first milk feeding. Lactase, an enzyme with lactase and phlorizin hydrolase activity, appears to be absent in the duodenal mucosa of affected infants, but the duodenum is otherwise histologically and enzymatically normal. The DNA sequence of the human lactase-phlorizin hydrolase gene, *LCT,* maps to chromosome 2q21.

Later onset lactase deficiency. Lactase activity is generally around 10% of maximal activity in adults with lactase deficiency. Approximately three fourths of non-Caucasian adults are lactase-deficient and 5% to 30% of Caucasians, depending on their ethnicity, have some degree of lactase deficiency. In ethnic groups where late-onset lactase deficiency is common (e.g., >50% prevalence), affected individuals between 1 and 5 years of age often present with diarrhea and crampy abdominal pain after the ingestion of lactose-containing foods. In Caucasians with hypolactasia, symptoms generally arise during adolescence. The diagnosis is most often confirmed by the noninvasive techniques of oral lactose tolerance tests or breath tests. Since adult lactase activity variation in different ethnic groups is independent of lactose intake, the differences are largely genetic. The molecular defect is a decreased amount of active brush border lactase protein, which is probably regulated at the level of gene expression. Two phenotypes have been described: type I is characterized by a decrease in mRNA coding for lactase-phlorizin hydrolase; type II is characterized by abnormal posttranslational processing of lactase-phlorizin hydrolase, with retention of the molecule in the endoplasmic reticulum. Since hypolactasia is autosomal recessive it would be expected that only siblings would be affected in families. However, parents are commonly affected due to the high prevalence of the gene for hypolactasia in the population, which results in homozygotes marrying heterozygous carriers.

Congenital lactose intolerance. Congenital lactose intolerance is a serious autosomal dominant disorder characterized by vomiting, failure to thrive, dehydration, renal tubular acidosis, disaccharidiuria, aminoaciduria, liver damage, cataracts, and brain damage in infants. Unlike congenital lactase deficiency, it can be fatal unless diagnosed and managed promptly. The disease is caused by the abnormal absorption of lactose in the stomach rather than the duodenum. Lactose is hypothesized to be toxic to the liver and brain, analogous to the toxicity of galactose-1-phosphate in galactosemia. Treatment consists of lactose avoidance. The disorder spontaneously resolves between 12 and 18 months of age.

Sucrose isomaltose malabsorption/disaccharide intolerance I. The autosomal recessive sucrose-isomaltose malabsorption disorder (i.e., sucrase– *a*-dextrinase deficiency) presents with symptoms similar to lactase deficiency, except that they are evoked by sugar, not milk. Symptoms range from severe diarrhea in infants to

occasional stomach upset in adults. Ingestion of sweetened foods and fruits provokes symptoms but tolerance to the sugars increases with age. Starch is generally well tolerated. In general, homozygotes have severe enzyme deficiency with lifelong symptoms, but heterozygotes with intermediate enzymatic activity may have mild symptoms as infants and no symptoms as adults. The disorder affects 10% of the Inuit of Greenland but only 0.2% of North Americans. The diagnosis is made using the same techniques as used in lactase deficiency. Ingesting live yeast (fresh baker's yeast has sucrase activity), preferably on a full stomach, can ameliorate the symptoms after sucrose ingestion. Studies suggest that the primary defect is in the sucrase with secondary effects in isomaltase. Defects in intracellular processing of the enzyme complex have been demonstrated: accumulation in the endoplasmic reticulum, blocked transport in the Golgi, and transport of a catalytically altered enzyme to the cell surface, illustrating the heterogeneity of this relatively uncommon, single-gene disorder. The sucrase-isomaltase gene (*SI*) maps to chromosome 3q25-26.

Glucose-galactose malabsorption. The autosomal recessive condition of intestinal monosaccharide transport deficiency presents similarly to intestinal disaccharidase deficiency. In glucose-galactose malabsorption, diarrhea and dehydration occur after ingestion of carbohydrates containing one or more of these sugars. Tolerance to these sugars improves with age. Acidic stools, containing glucose and galactose, suggest the diagnosis. Some patients also have a mild defect in renal tubular reabsorption of glucose. It is clinically distinguished from disaccharidase deficiency as there is no significant rise in plasma glucose during a glucose-galactose oral tolerance test. Treatment consists of substituting fructose for other dietary carbohydrates. The transport mechanism in the small intestine is dysfunctional where the mucosa is unable to take up glucose and galactose. Mutations in the glucose-galactose transporter gene (*SGLT1,* also known as *SLCA5A1*—solute carrier family 5) which maps to chromosome 22q13 are responsible for the condition.

Trehalase deficiency. Trehalase deficiency, an autosomal recessive disorder characterized by diarrhea and vomiting after ingestion of trehalose-containing foods, is rare in Caucasian Americans but is found in 10% to 15% of the Inuit of Greenland. Trehalose is a disaccharide found in insects and mushrooms. Deficiency can be detected by oral tolerance tests. The gene encoding human renal trehalase (*TREH*) encodes a brush border membrane glycoprotein and maps to 11q23.

Defects in Amino Acid Transport Proteins are normally absorbed by two major mechanisms: transport of liberated free amino acids by group-specific, sodium-dependent amino acid transport systems and uptake of unhydrolyzed peptides independent of the specific entry mechanisms. At least three major group-specific active transport systems exist: monoamine monocarboxylic (neutral) amino acids; dibasic amino acids and cystine; and dicarboxylic (acidic) amino acids. The genetic disorders of amino acid absorption involve deficiencies in one or more of these transport mechanisms.

Iminoglycinuria. Iminoglycinuria is due to benign autosomal recessive inborn errors of imino acids (i.e., proline and hydroxyproline) and glycine absorption in the kidneys and consists of five subtypes. Two subtypes also involve the intestine. This autosomal recessive malabsorption condition is often asymptomatic but has been associated with mental retardation and gyrate atrophy of choroid and retina. When any of the three amino acids is ingested, excretion of the other two increases, indicating a group-specific membrane transport defect. Heterogeneity in the disorder is suggested by the fact that some homozygotes show no proline transport defect. Obligate heterozygotes may be hyperglycinuric or not. At least four alleles for the disorder are suspected, but it is not known whether they are all at the same locus. They occur most often in Ashkenazi Jews and the frequency among Caucasians is about 1 in 15,000, giving a heterozygote frequency of about 2%. The existence of an autosomal dominant form of glycinuria with oxalate nephrolithiasis, seen most often in Ashkenazi Jews, may be a particular heterozygote form of iminoglycinuria that predisposes some persons to urolithiasis.

Hartnup disease. Hartnup disease is a rare heterogenous autosomal recessive disorder with an incidence of 5 cases per 100,000 individuals. It causes virtually no symptoms in more than 90% of affected persons in the United States, probably reflecting the adequate diet that most of this population consumes. In symptomatic individuals, an intermittent, red, scaly, pellagra-like rash after sun exposure and attacks of cerebellar ataxia, sometimes accompanied by psychiatric disorders and seizures, develop in childhood. Low-normal or subnormal intelligence has also been reported. The main feature, and the only diagnostic test, is massive aminoaciduria involving neutral and aromatic monoamine monocarboxylic amino acids sharing a common renal reabsorption mechanism in the proximal tubule. Patients have diminished capacity for jejunal absorption of these amino acids because of a brush border transport defect, causing retention of the amino acids in the intestine for abnormally long periods which allows intestinal bacteria to convert them into dipeptide decomposition products, some of which are absorbed. There is inadequate nicotinamide synthesis because of diminished tryptophan absorption, which causes pellagra. The decomposition is toxic to the central nervous system, and coupled with pellagra, produces the cerebellar and psychiatric manifestations. A general nutritional deficiency results from the diminished availability of essential amino acids. Liver biopsy shows extensive fatty liver without infiltration of inflammatory cells or fibrosis. Patients are treated by the administration of niacin. The gene, *HND,* maps to chromosome 5p15 based on the isolation of the mouse gene hyperphenylalaninemia (*hph2*) that produces a murine disorder similar to human Hartnup disease.

Cystinuria. Cystinuria is an autosomal recessive disorder characterized by cystine, lysine, ornithine, and arginine transport abnormalities in the renal tubule and intestinal epithelium. The clinical manifestations are confined to nephrolithiasis resulting from the insolubility of cystine in the urine, and expression of the disease peaks in the second and third decades. Men are more severely affected than women. It is relatively rare, with an incidence in the United States of 1 in 15,000 individuals (based on newborn screening studies) but has an incidence of 1 in 2500 among Israeli Jews of Libyan origin. Three forms of cystinuria are recognized, and investigation of the radiopaque stones that present as hexagonal cystine crystals in the urine in all types leads to the diagnosis. Classification is based on excretion rates of amino acids in obligate heterozygotes. In type I, heterozygotes excrete no excess amino acids, in type III, excretion of up to twice the normal amount is noted, and in type II, the rarest form of the disease, excretion of 9 to 15 times the normal amount is noted. Type I cystinuria maps to chromosome 2p16 where the culprit gene, *SLC3A1,* was identified. The type II and III cystinuria gene, *SLC7A9,* maps to chromosome 19q13. Treatment is directed at reducing the concentration of cystine in urine by increasing urine volume, increasing solubility by alkalinization, and, as needed, reducing free cystine excretion by medical therapy, historically D-penicillamine.

Lysinuric protein intolerance/dibasic aminoaciduria II. Lysinuric protein intolerance, or dibasic aminoaciduria II, is a rare serious autosomal recessive disorder beginning in infancy when cow's milk is introduced. It is characterized by abnormal transport of dibasic amino acids across the basolateral membranes of intestinal and renal tubular cells. Symptoms include vomiting, diarrhea, failure to thrive, severe growth retardation, hepatosplenomegaly with ultimate cirrhosis, lens opacities, mental retardation, sparse and brittle hair, osteopenia, attacks of stupor, and sometimes hyperextensible skin and joints. It is caused by the malabsorption of arginine, lysine, and ornithine as demonstrated after oral protein loading. Reduced tubular reabsorption of these amino acids also occurs in the kidney with demonstrable lysinuria. Some heterozygotes manifest partial intestinal malabsorption after an oral protein load. Quantitative plasma amino acids reveal low levels of arginine, lysine, ornithine, leucine, and tyrosine; normal serine and citrulline levels; and elevated glutamine and alanine levels. Dibasic aminoaciduria without cystinuria, impaired intestinal absorption of basic amino acids, and protein intolerance are diagnostic features. Hyperammonemia results from deficient hepatic uptake of the amino acids producing a deficiency of some intermediate products of the urea cycle. Treatment consists of protein restriction with citrulline and lysine supplements. Some of the abnormalities resolve on this therapy. It is caused by mutations in the amino acid transporter gene, *SLC7A7,* which maps to chromosome 14q11.

Blue diaper syndrome. Blue diaper syndrome is a rare autosomal or X-linked recessive disorder of intestinal, but not renal, tryptophan malabsorption. Infants present with failure to thrive, recurrent fever, infections, irritability, and constipation in addition to the bluish discoloration of the diapers. Hypercalcemia and nephrocalcinosis also occur because of increased absorption of calcium. The unabsorbed tryptophan is converted to indoles in the intestine by bacteria. The indoles are absorbed and converted in the liver to indican, which, when oxidized, becomes indigo blue in the urine. Included in the differential diagnosis is the blue-green discoloration that can occur from a pigment elaborated by *Pseudomonas aeruginosa*.

Methionine malabsorption syndrome (oasthouse urine disease). This autosomal recessive condition of methionine absorption is often called oasthouse urine disease because affected patients excrete urine containing *a*-hydroxybutyric acid, a product of bacterial metabolism of methionine that has the odor of an oasthouse, a kiln for drying hops. The clinical features include white hair, hyperpnea, convulsions, diarrhea, and mental retardation. Individuals will have a positive ferric chloride test on analysis of their urine in addition to a-hydroxybutyric aciduria. A methionine-free diet improves the symptoms.

Disorders of Electrolyte Absorption Four genetic causes of intestinal electrolyte and water are well characterized: microvillus inclusion disease, congenital chloride diarrhea, congenital sodium diarrhea, and disorders of aldosterone metabolism causing significant salt wasting.

Congenital chloride diarrhea. Congenital chloride diarrhea is an autosomal recessive disorder that may present in utero with polyhydramnios, presumably caused by in utero diarrhea. The infant may be premature and exhibit abdominal distention. Voluminous, watery, high-chloride–containing stools are produced, leading to a hypocholuria, hypokalemia, and metabolic alkalosis. The secretory diarrhea in this condition results from a deficiency in intestinal brush border chloride-bicarbonate exchange. With later presentations, or inadequate replacement therapy, growth failure is noted. The high volume of diarrhea can be illustrated by the family of one young boy with the disorder who required donations of disposable diapers by a diaper manufacturer as this was the boy's largest non-reimbursable "medical" expense. Affected adults have a history of watery diarrhea since birth with numerous hospital admissions for dehydration and electrolyte abnormalities. Additional adult-onset features included glucose intolerance, gout, proteinuria, and mild renal function impairment. The chloride content of the stools and characteristic serum electrolyte changes are diagnostic. Treatment consists of administering prostaglandin inhibitors and potassium chloride. The gene for this condition, *DRA,* maps to chromosome 7q22-q31.

Congenital sodium diarrhea. Congenital sodium diarrhea is an autosomal recessive disorder that presents similarly to congenital chloride diarrhea with polyhydramnios, prematurity, and voluminous, watery, high sodium and bicarbonate-containing stools in the first days of life. Treatment consists of replacement of sodium bicarbonate. Perfusion studies show that the jejunum is in a net secretory state, with intact hexose transport but with abnormal intestinal sodium-hydrogen exchange activity.

Microvillus inclusion disease. Microvillus inclusion disease is an autosomal recessive disorder involving the brush border membrane which results in severe congenital fluid and electrolyte malabsorption and causes severe refractory diarrhea in early infancy. Unlike sodium and chloride diarrheas, polyhydramnios is not present prenatally. Microvillus inclusion disease likely results from either defective brush border assembly and differentiation or from an error of intracellular transport. Localization of the cytoplasmic inclusions to the microvillus membrane in villus cells is revealed by electron microscope examination. Rectal biopsy is used for early diagnosis. Therapies such as octreotide, clonidine, and epidermal growth factor have had limited success. It has been suggested that the only therapy to reduce fluid losses may be enterectomy. Survival is unusual after 2 years of age. Small bowel transplantation may become the best available treatment.

Intestinal Defects in Protein Absorption Many genetic syndromes demonstrate selective protein malabsorption as outlined in Table 127-2. Most involve

abnormalities of the intestinal lymphatic system with intestinal lymphangiectasia, protein-losing enteropathy, and vascular hyalinosis. A rare association of protein-losing enteropathy with neurofibromatosis has been described. This patient had massive protein loss from a localized segment of small intestine with possible neurofibromatosis involvement of the mesenteric vessels.

Intestinal Defects in Lipid Absorption Several important genetic disorders may present in adults with lipid malabsorption. Many are caused by inborn errors of apolipoprotein or lipid metabolism. Familial amyloidosis polyneuropathy is also an important disorder with onset in adulthood that may present with lipid malabsorption. The clinical features common to most of these syndromes are caused by the deficiency of fat-soluble vitamins. Neurological symptoms may be present because of a deficiency of vitamin E, and a coagulopathy may be caused by vitamin K deficiency.

Familial amyloidosis polyneuropathy. The amyloid protein in familial amyloidosis polyneuropathy type 1 is composed of abnormal transthyretin molecules. Transthyretin is a plasma protein that transports thyroid- and retinol-binding proteins. Systemic deposition of this abnormal protein causes a progressive stocking sensorimotor neuropathy that usually begins in the lower limbs. The autonomic nervous system may also be involved, causing orthostatic hypotension, impotence, and abnormal GI motility presenting as initial constipation followed by episodic diarrhea. Malabsorption of bile acids is common and appears to be the result of GI motility dysfunction from the autonomic neuropathy, with resultant bacterial overgrowth, rather than from the amyloid deposits in the intestinal mucosa. This is an autosomal dominant condition that can be presymptomatically diagnosed by looking for mutations in the transthyretin gene, *TTR,* on chromosome 18q11-12.

Abetalipoproteinemia. The principal GI symptom of abetalipoproteinemia, an autosomal recessive disorder, is malabsorption of fat, often beginning in infancy with steatorrhea and poor weight gain. The disorder is often misdiagnosed as celiac disease. Impaired absorption of fat-soluble vitamins is responsible for many of the clinical features. Histopathological analysis of the small bowel shows normally formed villi with lipid-engorged enterocytes. Treatment consists of avoidance of fat and the administration of fat-soluble vitamins. Neurological symptoms usually begin in the second decade and include peripheral neuropathy and cerebellar ataxia. Decreased night and color vision, caused by an atypical retinitis pigmentosa, may also develop as does mild to moderate anemia, usually with hemolysis where most circulating red cells are acanthocytes. There may be an iron or folate deficiency because of malabsorption and there usually is a coagulopathy caused by decreased vitamin K stores. The total cholesterol values are in the range of 20 to 50 mg/dL and triglyceride values are also very low, with little postprandial increase. There are no chylomicrons, very-low-density lipoproteins, low-density lipoproteins, or apolipoprotein B particles, the major structural apolipoprotein for these lipids. Heterozygotes are asymptomatic with normal plasma lipids. The genetic defect is not in the apolipoprotein B gene itself but instead in the microsomal triglyceride transfer protein gene, *MTP,* on chromosome 4q22-24 that mediates the intracellular transport of membrane-associated lipids. *MTP* mutations cause defects in the ability of the liver and intestines to assemble or secrete apolipoprotein B.

Anderson disease/lipid transport defect of the intestine. Individuals with Anderson disease, an autosomal recessive lipid transport defect of the intestine characterized by hypobetalipoproteinemia with accumulation of apolipoprotein B-like protein in intestinal cells, present with fat malabsorption with steatorrhea and growth retardation, but without the significant acanthocytosis and the neuroocular symptoms of abetalipoproteinemia. Low-density lipoprotein particles are present in the plasma, but there is a failure of chylomicron formation. Enterocytes from intestinal biopsies show numerous fat droplets, and monoclonal antibody staining reveals the presence of apolipoprotein B48, the form produced by the intestine. Defective glycosylation of apolipoprotein B48 has been observed, which may underlie the absence of formation and secretion of chylomicrons.

Familial hypobetalipoproteinemia. Familial hypobetalipoproteinemia is thought to be an autosomal dominant disorder caused by low levels of apolipoprotein-ß. Truncated versions of the normal apolipoprotein B gene, *APOB,* on chromosome 2p24 have been reported in some families where affected individuals have low levels of low-density lipoproteins, normal amounts of triglycerides, low levels of high-density lipoproteins, mild fat malabsorption, and a defect in chylomicron clearance. There were no reports of neuroocular abnormalities. In other families with similar clinical presentations linkage to *APOB* has been excluded. Linkage analysis suggests that another locus (*FHBL2*) may map to 3p22-p21, confirming the genetic heterogeneity of this condition.

Wolman disease and cholesterol ester storage disease/lysosomal acid lipase deficiency. Wolman disease is a severe autosomal recessive disorder that is often fatal in infancy. Cholesterol esters and triglycerides accumulate in the liver, adrenal gland, spleen, lymph nodes, bone marrow, small intestine, lungs, and thymus because of lysosomal acid lipase deficiency. Death is thought to be the result of intestinal malabsorption. Cholesterol ester storage disease is a late-onset disorder with milder manifestations. It also involves lysosomal acid lipase deficiency and is allelic with Wolman disease. The culprit lysosomal acid lipase gene (*LIPA*) maps to chromosome 10q24-25. Prenatal diagnosis has been performed by enzyme assay in cultured amniocytes. DNA-based testing may be available soon.

Exocrine Pancreas Abnormalities (See Also Chapter 98) Defects in protein and fat absorption are more commonly caused by abnormalities of the exocrine pancreas. Examples include deficiencies of specific pancreatic exocrine enzymes, cystic fibrosis, the Shwachman-Bodian syndrome, and the Johanson-Blizzard syndrome. Table 127-2 lists genetic syndromes manifesting with exocrine pancreas insufficiency.

Cystic fibrosis. Cystic fibrosis (CF) is the most common lethal autosomal recessive disorder in the Caucasian population, occurring with a frequency of about 1 in 2500 births. The disorder is characterized by viscous secretions and dysfunction of multiple exocrine glands, leading to pancreatic insufficiency, malabsorption, chronic pulmonary infection with emphysema, and a high chloride concentration in sweat. Milder mutations of the gene, *CFTR,* result in male infertility owing to congenital bilateral absence of the vas deferens or chronic pancreatitis. Only the GI manifestations of CF are reviewed here. Because of the often life-threatening nature of the pulmonary complications of classic CF, less emphasis is sometimes paid to the GI complications, but their importance is underscored by the fact that CF remains a leading cause of malabsorption in Caucasian children in developed countries. More than one third of patients with CF survive to adulthood and develop many of the GI complications with time. In fact, the majority of patients with classic CF have some degree of pancreatic insufficiency leading to achylia. Many are born with insufficiency and require enzyme replacement therapy by their first birthdays. Because the pancreatic secretions are abnormal, the pancreatic ducts become plugged, leading to destruction of distal ducts. Proximal to these clogged ducts, autodigestion and inflammation lead to fibrosis and ultimately to exocrine insufficiency. The result is malabsorption, primarily of fats and fat-soluble vitamins, which causes malnutrition, susceptibility to hemorrhage caused by lack of vitamin K, tetany caused by hypocalcemia from losses in the stool, and neurological problems caused by vitamin E deficiency. Treatment consists of pancreatic enzyme replacement. The islets of Langerhans may become secondarily affected by fibrosis of the pancreas, leading to glucose intolerance or clinical diabetes that is similar to non–insulin-dependent diabetes in approximately 50% of patients with CF. Approximately 25% to 30% of CF patients also develop focal biliary cirrhosis. In 2% to 5% of these cases, multilobular biliary cirrhosis with portal hypertension may develop. Thick secretions plug the bile ducts, leading to inflammation and fibrosis. There usually is a history of pancreatic insufficiency in these cases. The earliest clinical manifestation of CF may be meconium ileus, occurring in approximately 10% to 15% of patients, caused by the lack of fluid in the small intestine because of a lack of pancreatic secretion or defective intestinal epithelial secretion. Gastrografin enema or oral *N*-acetylcysteine may resolve the obstruction; if not, surgery is necessary. A similar abnormality occurring later in life, called the distal intestinal obstruction syndrome, may occur in 10% to 20% of CF patients, causing symptoms of colicky pain and constipation. These symptoms may be relieved with Golytely, mineral oil, an increase in pancreatic enzymes, or *N*-acetylcysteine. Rectal prolapse occurs in approximately one fourth of patients before 2 years of age, but it usually does not occur in patients receiving pancreatic enzyme replacement therapy. The mechanism for the prolapse is unknown. The responsible gene, *CFTR,* was mapped to chromosome 7q31 by positional cloning strategies. The putative protein product for the gene, called the cystic fibrosis transmembrane regulator protein, forms a cAMP-regulated chloride channel. More than 500 *CFTR* mutations have been described, which account for over 90% of all recognised mutant chromosomes detected by linkage analysis. The sensitivity of mutation testing varies depending on an individual's ethnicity, however, with up to 96% of mutant chromosomes detectable in affected Ashkenazi Jews and less than 70% of mutant chromosomes detected in African Americans with most commercially available mutation testing products. The most common mutation in Caucasians of Northern European descent is dF508, a deletion of the amino acid residue phenylalanine at codon 508, occurring in 70% of CF patients. The dF508 deletion is located near an apparent binding site for ATP, and it may interfere with the phosphorylation of the CF protein or with some other need for energy provided by ATP. Most of the non-dF508 mutations are relatively rare, affecting less than 1% to 10% of CF patients. Some *CFTR* genotypes are associated with pancreatic sufficiency or insufficiency, suggesting that the genotype at the *CFTR* locus is responsible for susceptibility to pancreatic insufficiency. *d*F508 and the common mutation among Ashkenazi Jews, *W1282X,* are examples of pancreatic insufficiency alleles. Preconceptual and prenatal testing are readily available. As of 2001 the American Colleges of Medical Genetics and Obstetrics and Gynecology recommend that all Caucasian couples considering children and pregnant women be routinely offered DNA carrier testing.

Shwachman-Diamond/Shwachman-Bodian syndrome. The Shwachman-Diamond/Shwachman-Bodian syndrome, also called congenital lipomatosis of the pancreas, is an autosomal recessive disorder and the second most frequent pancreatic cause of malabsorption in childhood. It has an incidence of 1 in 250,000 births. Symptoms include poor growth, intestinal malabsorption, steatorrhea, and recurrent respiratory infections, which present within the first few years of life. Dysplastic changes in the metaphyses of long bones lead to a moderate dwarfism. Patients may suffer from a pancytopenia caused by bone marrow dysfunction and are at increased risk for hematologic malignancies. The pancreatic enzyme replacement required in infancy may not be necessary later. The locus for this condition maps to the centromeric region of chromosome 7.

Johanson-Blizzard syndrome. In addition to pancreatic insufficiency with malabsorption, Johanson-Blizzard syndrome, an autosomal recessive syndrome, is characterized by multiple anomalies including aplasia or hypoplasia of the nasal alae, upswept frontal hair, widely spaced teeth, congenital deafness, hypothyroidism, postnatal growth retardation, mental retardation, midline ectodermal scalp defects, and absent permanent teeth. Genitourinary and anorectal abnormalities have also been described. Autopsy findings have shown almost complete replacement of the pancreas with fat and a paucity of islet cells. Death usually occurs in childhood from malabsorption-related complications. Survival to adulthood is rare but possible if continuous enzyme replacement is instituted. Insulin-requiring diabetes is a feature in adulthood, similar to the situation for CF patients, presumably because of the loss of ß-cells.

Cartilage-hair hypoplasia/metaphyseal chondrodysplasia, McKusick type. Cartilage-hair hypoplasia (i.e., metaphyseal chondrodysplasia, McKusick type) is an incompletely penetrant autosomal recessive dwarfing syndrome (average adult height is 107–157 cm) with radiologic changes called metaphyseal dysostosis. Other features include fine, sparse, light-colored hair, anemia, malabsorption caused by pancreatic insufficiency, Hirschsprung disease, and a susceptibility to chicken pox. Malignancies, specifically lymphoma, are more frequent in affected individuals. The *CHH* gene maps to chromosome 9p13.

Asphyxiating thoracic dystrophy/Jeune syndrome. Asphyxiating thoracic dystrophy, also called Jeune syndrome, is an autosomal recessive skeletal dysplasia that is often lethal in the perinatal period caused by involvement of the rib cage leading to severe asphyxia. Mildly affected individuals survive to adulthood. Other features include polydactyly, chronic nephritis, and intestinal malabsorption because of pancreatic insufficiency. Cystic changes occur in the kidney, liver, and

pancreas. This syndrome shares clinical features seen in two other genetic syndromes, Ellis-van Creveld and renal-hepatic-pancreatic dysplasia syndromes.

Disorders of Vitamin and Mineral Assimilation This heterogeneous group of disorders displays widely variable manifestations dependent on the specific vitamin or mineral involved. Some disorders of vitamin and mineral metabolism can be appropriately treated by adequate replacement therapy.

Imerslünd-Grasbeck syndrome (see also Chapter 77). Imerslünd-Grasbeck syndrome is an autosomal recessive disorder of chronic relapsing megaloblastic anemia caused by malabsorption of vitamin B_{12}, which is not corrected with exogenous intrinsic factor. No antibodies to intrinsic factor or gastric parietal cells are detected. The defect appears to be located between the attachment of B_{12} to the surface of the ileal cell and the binding to transcobalamin II. In some cases, the defect is a selective failure of intrinsic factor transcytosis; in others, it may be the absence of an ileal receptor; and in others, the defect is unknown. Associated features include proteinuria and malformations of the urinary tract and persistent proteinuria. The gene for this disorder, *MGA1,* maps to 10p12.2. This syndrome should be differentiated from intrinsic factor deficiency and transcobalamin II deficiency. The disease does not respond to administration of intrinsic factor. Treatment consists of monthly intramuscular doses of 250 µg of hydroxycobalamin or intramuscular doses every 2 to 3 months of 1000 µg of hydroxycobalamin. The proteinuria does not usually respond. Because mental retardation may ensue from delay or lack of treatment, the siblings of an affected person should be screened.

Menkes syndrome (see also Chapter 77). Menkes syndrome, also called kinky hair disease, is an X-linked recessive disorder of copper metabolism caused by a defect in the intestinal absorption of copper owing to mutations in the *ATP7A* gene on chromosome Xq12-13. This affects copper-dependent enzymes in the body, producing a phenotype characterized by light-colored and kinky hair, growth retardation, severe neurological impairment with focal cerebral and cerebellar degeneration, changes in the metaphyses of the long bones, tortuosity of vessels, and bladder diverticula. Most patients die between 6 months and 3 years of age but mildly affected patients with presumably allelic forms of the disease have survived to adolescence. Low serum copper levels in the appropriate clinical setting is a simple and reliable diagnostic method. Heterozygotes may be detected by the finding of pili torti (i.e., kinky hair).

X-linked cutis laxa/occipital horn syndrome. X-linked cutis laxa/occipital horn syndrome mutations are caused by mutations in *ATP7A,* on chromosome Xq12-13, making the syndrome allelic with Menkes syndrome. The syndrome is characterized by occipital bony prominences (occipital horns), short broad clavicles, fused carpal bones, pectus deformities, a hooked nose with a long philtrum, multiple large diverticula of the bladder, varicosities, inguinal hernias, joint laxity, and diarrhea. Serum levels of copper and ceruloplasmin are low, similar to Menkes syndrome.

Acrodermatitis enteropathica (see also Chapter 76). Acrodermatitis enteropathica is an autosomal recessive disorder of zinc malabsorption and presents with intermittent diarrhea, dermatitis, and failure to thrive. Additional features include alopecia of the scalp, eyebrows, and eyelashes. At autopsy islet cell hyperplasia, absence of the thymus, and absence of germinal centers with plasmacytosis of the lymph nodes and spleen are noted. Laboratory findings include low serum and urinary levels of zinc and serum alkaline phosphatase (i.e., a zinc metalloenzyme). Oral zinc therapy has been successful in ameliorating symptoms. Low serum zinc levels are helpful, but not 100% sensitive, in making the diagnosis. Ultrastructural abnormalities of the Paneth cells of the small intestine (i.e., cells that usually contain high concentrations of zinc) or a trial of oral zinc supplementation with good clinical response may provide evidence for the diagnosis in cases with normal serum zinc levels. The locus has been mapped to chromosome 8q24.

Hemochromatosis (see also Chapter 112). Hemochromatosis is one of the most common autosomal recessive disorders with a carrier frequency of 1 in 10 individuals and affecting between 1 in 200 to 400 individuals of Northern European descent. An entire chapter, Chapter 112, is devoted to this condition. In homozygotes, increased absorption of iron in the small intestine results in an excess of iron deposited in many organs, ultimately resulting in organ failure in some individuals. Serious manifestations of hemochromatosis include cirrhosis, diabetes, cardiomyopathy, arthritis, hepatomas, and hypogonadotropic hypogonadism. Symptoms vary considerably among individuals. These may be minimal in individuals with chronic or episodic blood loss (e.g., menstruating women) and more severe in men with a high content of iron in their diet. Generally, symptoms begin in adulthood, after several years of increase in iron absorption. The gene, *HFE,* maps to the human leukocyte antigen (HLA) region of chromosome 6p21, and has been cloned. One predominant mutation, Cys282Tyr, accounts for between 80% to 90% of mutant chromosomes, making DNA testing relatively straightforward. Homozygotes diagnosed early or when asymptomatic can be closely monitored and managed to prevent symptoms of iron overload. In addition to DNA diagnosis, liver biopsy along with serum iron, total iron-binding capacity, and ferritin levels may be helpful in the diagnosis. Treatment continues to include phlebotomy for individuals with increased iron levels. Other forms of hemochromatosis, caused by other factors, likely exist.

Chronic Diarrhea Syndromes Not Characterized by Malabsorption (See Also Chapter 42)

Several genetic disorders featuring chronic, recurrent diarrhea are not associated with a specific malabsorption syndrome. Many of the inherited immunodeficiency disorders involving T-cell antigens, T-cell antigen receptors, B cells, and immunoglobulin and complement deficiencies are characterized by a chronic diarrhea. Inherited colitis syndromes, neurological disorders, and endocrinopathies may also feature chronic or recurrent diarrhea as a common manifestation. Many of the polyposis syndromes may present with complaints of chronic diarrhea. Table 127-3 briefly summarizes those disorders that may be more commonly encountered by the clinician.

TABLE 127-3 Diarrhea Syndromes

Recurrent Gastrointestinal Bleeding Syndromes (See Also Chapter 130)

Recurrent acute or occult GI hemorrhage should raise suspicion for a variety of genetic disorders (Table 127-4). These include structural abnormalities, such as the polyposis syndromes (e.g., Peutz-Jeghers syndrome, Gardner syndrome); vascular abnormalities, such as those that occur in vascular malformation syndromes and connective tissue disorders (e.g., hereditary hemorrhagic telangiectasia syndrome, Ehlers-Danlos syndrome); and disorders of the hematologic system that may involve platelets, clotting factors, or abnormalities in fibrinolysis. The polyposis syndromes are reviewed elsewhere (see Chapter 90).

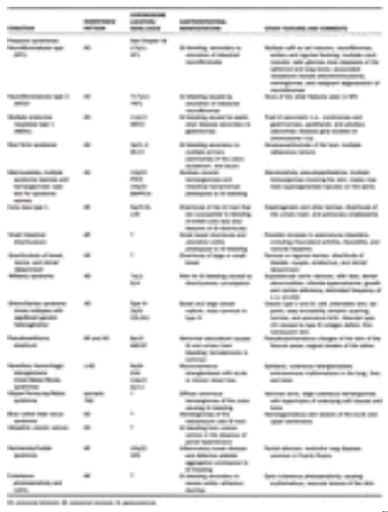

TABLE 127-4 Recurrent Gastrointestinal Bleeding Syndromes

Many of the structural and vascular abnormality syndromes that cause GI bleeding belong to a group of disorders called the phakomatoses or genodermatoses, including neurofibromatosis type I, basal cell nevus syndrome, Gardner syndrome, hereditary hemorrhagic telangiectasia, Klippel-Trenaunay-Weber syndrome, and Peutz-Jeghers syndrome. *Phakos* means spots, and these disorders have characteristic spotty or patchy cutaneous lesions. Other common features include a major vascular component to some lesions, involvement of the skin and central nervous system, and autosomal dominant inheritance patterns, often with significant variable expressivity and a high new mutation rate.

Many genetic hematologic disorders predispose to GI bleeding. Deficiencies of clotting factors may result in a bleeding diathesis. von Willebrand disease and combined deficiency of factor VII and VIII are autosomal dominant disorders that may present with recurrent GI bleeding. The most common factor deficiency is factor VIII deficiency, better known as hemophilia A, an X-linked condition occurring with a frequency of 1 in 10,000. This disorder usually presents with hemarthroses that result in a chronic arthropathy, deep muscle hematomas, frank hematuria, and spontaneous intracranial bleeds. GI bleeding is not a common complication.

Abnormalities in fibrinolysis may also predispose to GI bleeding. Deficiencies of the anticlotting factors, protein C, protein S, and antithrombin III, can cause portal vein thrombosis, which can be complicated by ruptured esophageal varices.

Several genetic disorders are associated with abnormal platelet number or function predisposing to increased GI bleeding. Glanzmann thrombasthenia (i.e., platelet glycoprotein IIb-IIIa deficiency) is an autosomal recessive bleeding diathesis with deficient clot retraction and abnormal platelet morphology. Mucosal bleeding is typical, and gingival bleeding, epistaxis, and laryngeal bleeding are common features. An autosomal dominant form of Glanzmann thrombasthenia has similar features. Bernard-Soulier syndrome (i.e., platelet glycoprotein Ib deficiency) is an autosomal recessive bleeding disorder characterized by unusually large platelets and a prolonged bleeding time. The platelet membrane is abnormal and lacks a receptor, glycoprotein Ib, involved in the adhesion of platelets to subendothelium and von Willebrand factor; patients are susceptible to mucosal bleeding. Thromboxane synthase deficiency, leading to platelet aggregation abnormalities, is an autosomal recessive disorder that may present with petechiae, bruising, epistaxis, hematuria, or massive GI bleeding. The Hermansky-Pudlak syndrome is also characterized by abnormal platelets and is discussed in a later section of this chapter.

Neurofibromatosis (See Also Chapter 73) There are two major types of neurofibromatosis (NF): NF type 1 (NF1) and NF type 2 (NF2). NF2 is not typically associated with significant GI manifestations. NF1 and a probable allelic variant of NF1, previously called NF3, known as familial intestinal neurofibromatosis, can be associated with GI hemorrhage because of ulceration of neurofibromas in the lumen of the bowel. Major characteristics of NF1 include multiple cutaneous café au lait macules, multiple neurofibromas or plexiform neurofibromas, axillary or inguinal freckling, optic gliomas, multiple Lisch nodules (i.e., iris hamartomas), and bony dysplasia of the sphenoid or long bones. Occasionally, an individual with NF1 may present with obstructive GI symptoms secondary to having large internal plexiform neurofibromas extending throughout their thoracoabdominal cavity. Arterial occlusive disease also has been reported in NF and may be the underlying etiology of GI complaints in affected individuals. NF1 is an autosomal dominant disorder displaying significant intrafamilial and interfamilial variability and occurs in 1 per 4000 persons of all ethnic groups. New mutations are thought to account for up to 50% of affected individuals. The large NF1 gene maps to chromosome 17q12. DNA-based diagnostic testing relies on a protein truncation assay, which detects approximately 70% of mutations, or on linkage analysis when multiple family members are available to set the appropriate phase. The National Neurofibromatosis Foundation (and its local chapters) provides educational materials, support, and newsletters to families and physicians.

Hereditary Hemorrhagic Telangiectasia (HHT)/Osler-Weber-Rendu Syndrome Hereditary hemorrhagic telangiectasia (HHT) is a genetically heterogeneous autosomal dominant disorder of high penetrance characterized by mucocutaneous telangiectases. Two major genetic forms are recognized. The usual presenting feature is epistaxis occurring at puberty. The cutaneous telangiectases appear later, usually between 5 and 20 years of age. Blood loss from the mucosal lesions in the gut can be chronic or acute. Larger vessel involvement is common. Pulmonary arteriovenous malformations occur in approximately 15% to 20% of individuals, especially in those families with HHT1 whose disease is caused by mutations in the endoglin gene, *ENG,* on chromosome 9q34, and may lead to embolic complications or high-output cardiac failure. HHT2 maps to 12q13 where mutations have been identified in *ALK-1*. Arteriovenous malformations occur less often, in the cerebral and hepatic vessels.

Klippel-Trenaunay-Weber Syndrome The Klippel-Trenaunay-Weber syndrome is a sporadic, but presumably autosomal dominant, disorder that features varicose veins and large, cutaneous hemangiomas with hypertrophy of the underlying bones and soft tissues. Diffuse cavernous hemangiomas of the colon are found in 1% to 12.5% of patients and can sometimes cause significant GI bleeding. Partial colectomy and endoscopic laser ablation of residual abnormal colonic mucosa has been successful in the management of this complication.

Blue Rubber Bleb Nevus Syndrome The blue rubber bleb nevus syndrome is an autosomal dominant disorder characterized by the presence of easily compressible bladderlike hemangiomatosis skin lesions that refill quickly after compression and have the look and feel of rubber nipples. The sites most commonly involved are the trunk and upper extremities, but the mucosa of the nasopharynx and GI tract, particularly the small bowel, can be affected. Bleeding is an important complication of these lesions. Nocturnal pain and regional hyperhidrosis may also be features of this disorder.

Ehlers-Danlos Syndrome Connective tissue disorders in which the integrity of structural tissues is impaired may predispose to GI bleeding. Ehlers-Danlos syndromes (EDS) are a heterogenous group of connective tissue disorders affecting the skin, ligaments, joints, blood vessels, and internal organs, depending on the structural protein or modifying enzyme affected. There are six major subtypes of EDS that have been described, most of which are autosomal dominant, although the dermatospraxis and kyphoscoliosis forms are autosomal recessive. The nomenclature for EDS subtypes has been revised to define the “classic” forms, EDS I and EDS II (where EDS II is a milder form) as characterized by soft, velvety, hyperextensible skin, lax joints, easily bruised skin, atrophic scarring, venous varicosities, hernias, and prematurity caused by rupture of fetal membranes. GI bleeding caused by hollow organ (i.e., bowel) and arterial rupture is not a usual manifestation but may occur. Some cases of EDS I and II (a milder variant similar to EDS I) have demonstrated to alterations in the type V collagen gene, *COL5AI,* which maps to chromosome 9q. The “vascular” form of EDS, EDS IV, is associated with increased morbidity and early mortality caused by bowel and large vessel ruptures. Individuals most often have very thin, fragile skin with easily visible veins and friable tissues. They bruise easily, have tight skin over the fingers, face, and ears (acrogeria), and hyperextensible distal interphalangeal joints. Defects in the type III collagen gene, *COL3A1,* which maps to chromosome 2q31, are responsible for the phenotype. Unfortunately, no specific treatment is available for EDS IV and it is not uncommon for individuals to die during late adolescence or early adulthood owing to rupture of the bowel, large arterial vessels, or uterus during pregnancy. Cases have been reported where the ruptured bowel could not be appropriately repaired at surgery owing to the extensive friability of the tissue that was unable to adequately hold sutures. For most disorders in the EDS family of syndromes, analysis of skin fibroblasts for collagen synthesis and secretion are the diagnostic methods of choice. Once a specific DNA mutation is identified in a family, sensitive DNA-based mutation testing can easily be done. Unfortunately, even with early diagnosis of type III collagen abnormalities, no specific therapy is available to prevent rupture of hollow organs and vessels. However, appropriate genetic counseling about risks and strategies to minimize catastrophic complications, especially during pregnancy, can be offered to individuals.

Pseudoxanthoma Elasticum Pseudoxanthoma elasticum primarily affects the skin of the neck, axillae, and other flexural areas; the Bruch membrane of the eye, resulting in angioid streaks on funduscopic examination; and the arteries, producing GI and urinary tract hemorrhage, precocious calcification, and occlusive vascular changes. Recurrent, severe hematemesis was the presenting feature of one of the first reported cases. Hematemesis is much more common than melena; superficial hemorrhages and erosions may be seen in the stomach. Bleeding tends to occur as early as the first decade of life, before the skin and eye changes are evident. Pregnant women are more susceptible to bleeding. The diagnosis is made on the basis of clinical examination but there is wide variable expressivity. Allelic autosomal dominant and autosomal recessive forms have been reported. The dominant types are characterized by *peau d’orange* skin changes, severe vascular complications, severe choroiditis, angioid streaks, retinal detachment, macular or focal changes in the skin which may be very stretchy, myopia, a high-arched palate, blue sclerae, and loose joints. The recessive types may be clinically similar. Patients have been reported with generalized skin changes with no ocular or vascular abnormalities. Mutations in the multidrug resistance gene, *ABCC6* (ATP-binding cassette, sub-family C, member 6), on chromosome 6p13 have been identified in

individuals with both autosomal dominant and autosomal recessive forms of the disease.

Syndromes Characterized by Hamartomas, Macrocephaly, Multiple Lipomas, and/or Hemangiomas (See Also Chapter 90) A collection of several autosomal dominant syndromes, including Bannayan-Zonana syndrome, Bannayan-Riley-Ruvalcaba syndrome, Cowden syndrome, Riley-Smith syndrome, and Ruvalcaba-Myhre-Smith syndrome, present with similar features but exhibit genetic variability and, likely, both allelic and locus heterogeneity. Typical features include macrocephaly, pseudopapilledema, multiple lipomas, multiple hemangiomas involving the skin and viscera, thyroid nodules, and intestinal hamartomatous polyposis. The latter two features create a susceptibility to GI hemorrhage. Men may have hyperpigmented macules on the penis. High birth weight and length is typical, but growth levels off at 6 to 7 years of age. There may be delayed motor development, autistic features, cognitive delays, and lifelong problems with coordination. Seizures have been reported from intracranial hemorrhage caused by arteriovenous malformations. Arteriovenous malformations may also lead to extremity overgrowth, necessitating amputation. In adults a higher incidence of breast, thyroid, colon, renal, endometrial, and skin cancer have been reported, making this a cancer predisposition syndrome for which preventive screening and management should be employed. Mutations in the *PTEN* gene, a tumor suppressor gene first identified in association with Cowden syndrome, which maps to chromosome 10q23, have also been demonstrated in individuals with Bannayan-Riley-Ruvalcaba, Bannayan-Zonana, Riley-Smith, and Ruvalcaba-Myhre-Smith syndromes, demonstrating that these are indeed, allelic conditions. Mutations in the *BMPR1A/ALK3* gene, a member of the transforming growth factor-ß/ *BMP* superfamily, on 10q22, have been identified in some families with these conditions. They have also been noted in some kindreds with the inherited juvenile polyposis syndrome, a similar but distinct hamartoma syndrome with an increased predisposition to colon cancer. Mutations in the *MAD4/DPC4* gene located on 18q21 have also been associated with familial juvenile polyposis and some reports have suggested that juvenile polyposis can be caused by mutations in the *PTEN* gene. Atypical juvenile polyps with mixed features of hamartomas and adenomas are characterized by a variant of the juvenile polyposis syndrome known as the hereditary mixed polyposis syndrome. This form maps to chromosome 6q16. Further molecular characterization of the hamartomatous syndromes is needed to more precisely clarify the relationships between these conditions. It has been suggested that if *PTEN* mutations are identified in a patient that the most useful diagnosis may be the " *PTEN* hamartoma syndrome" to reduce the confusion associated with the multiple syndromes that have been associated with *PTEN* alterations.

Cutis Laxa Several forms of cutis laxa have been described and the relationship between these forms at a molecular level is not yet understood. Cutis laxa type I is an autosomal recessive disorder characterized by abnormalities of the elastic tissue and features diaphragmatic and other hernias; diverticula of the GI and urinary tract, which are susceptible to bleeding; and pulmonary emphysema, which may lead to cor pulmonale. Death usually occurs in the first year of life. Cutis laxa I has been mapped to the long arm of chromosome 5. The second less severe form is characterized by prenatal and postnatal growth deficiency, large fontanels with delayed closure, congenital hip dislocation, and lax joints. Diminished elastin production has been verified in these patients, and quantitation reveals decreased elastin mRNA, perhaps caused by decreased rates of transcription or degradation of unstable transcripts. A dominant form of cutis laxa does not have the visceral manifestations characteristic of the recessive forms. X-linked cutis laxa is discussed in "Disorders of Vitamin and Mineral Assimilation" as it is associated with copper abnormalities. The syndrome also features diverticular disease of the GI tract, increasing the possible risk for GI hemorrhage.

Hermansky-Pudlak Syndrome Hermansky-Pudlak syndrome is an autosomal recessive disease that occurs most frequently in Puerto Rico, where the prevalence is 1 in 2000 individuals. It is a storage disorder of a ceroidlike substance and is associated with features of partial albinism, restrictive lung disease, and a platelet abnormality. There is a deficiency of the granule storage pool in platelets, causing defective ADP release, which leads to a prolonged bleeding time and defective platelet aggregation. Inflammatory bowel disease with an onset between the ages of 12 and 30 years is also common in the Puerto Rican patients. The combination of inflammatory bowel disease and defective platelets contributes to the occurrence of GI bleeding in these patients. The gene for this disorder, *HPS,* maps to chromosome 10q23.

Intestinal Motility or Pseudoobstruction Disorders (See Also Chapter 41, Chapter 73)

Intestinal pseudoobstruction may result from intrinsic enteric myopathies and neuropathies or from generalized muscular and neurological disorders. This section reviews the genetic disorders that feature abnormal intestinal motility or pseudoobstruction in each of these categories. These disorders are summarized in Table 127-5.

TABLE 127-5 Intestinal Motility and Pseudoobstruction Disorders

Intestinal pseudoobstruction is suggested clinically by recurrent signs and symptoms of intestinal obstruction in the absence of mechanical obstruction, as proven by appropriate radiologic, endoscopic, or surgical investigations. The presence and severity of complications depend on the individual's age (i.e., infant or adult), site of involvement, and degree of functional impairment. In the adult, a long-standing history of symptoms suggesting GI motility dysfunction—such as dysphagia, early satiety, and constipation or diarrhea—may precede the onset of acute symptoms. Patients usually present in the second to fourth decades of life with complaints of abdominal pain, distention, and sometimes vomiting. Malnutrition is common and results from decreased food intake, impaired digestion, or malabsorption. Infants with these disorders usually present with acute, severe, obstructive symptoms of abdominal pain and distention after feeding. Reflux esophagitis and aspiration pneumonia caused by impaired gastroesophageal motility is also common in infants.

After mechanical obstruction has been ruled out, diagnostic studies to evaluate pseudoobstruction include esophageal and intestinal manometry, gastric emptying studies, and full-thickness biopsy with silver stains. Esophageal manometry shows aperistalsis and incomplete relaxation of the lower esophageal sphincter. Intestinal manometry usually shows a hypomotile pattern. Gastric emptying studies show a delay for solids and a variable pattern for liquids. Silver stains delineate neuropathic from myopathic forms. Detection of subclinically affected family members at risk can be accomplished with these diagnostic techniques.

Visceral Myopathy Syndromes Clinical GI manifestations of the visceral myopathic and neuropathic forms of intestinal pseudoobstruction are similar. In the myopathic form, there may be other evidence of myopathy, such as megacystis, vesicoureteral reflux, ophthalmoplegia, ptosis, and small intestine diverticulosis. Pathogenetic mechanisms of GI manifestations include degenerative changes and thinning of intestinal smooth muscle, especially of the longitudinal layers; the enteric neurons are normal. A mitochondrial myopathy associated with intestinal pseudoobstruction caused by a visceral myopathy has been described. Some forms of visceral myopathy may be mitochondrial myopathies. Diagnosis of a mitochondrial myopathy can often be made by a Gomori trichome–stained skeletal muscle biopsy, which shows the characteristic ragged, red fibers, or by analysis of respiratory chain enzymes. There are no well-documented reports of a mitochondrial DNA mutation responsible for intestinal pseudoobstruction. The reported familial cases are autosomal dominant or recessive, lacking the maternal pattern of transmission seen with mitochondrial DNA mutations. If a mitochondrial myopathy is involved, it is likely that the disease gene responsible in most cases resides in the nucleus.

Duchenne muscular dystrophy. Duchenne muscular dystrophy is an X-linked disorder characterized by skeletal muscle degeneration causing atrophy and weakness. The incidence in male births is about 1 in 3500. Onset of symptoms usually begins before 5 years of age, with progressive symptoms of muscle weakness, toe walking, and difficulty in rising from sitting and in climbing stairs. Affected boys have a waddling gait, and pseudohypertrophy of the calves is typical. By puberty, most require use of a wheelchair; joint contractures and scoliosis then develop. Death usually occurs in the late teens or early 20s from respiratory infections or heart failure. Laboratory studies show elevated serum levels of aldolase, lactate dehydrogenase, and creatine kinase. Common GI symptoms include abdominal pain and distention, delayed gastric emptying, acute gastric dilation, and chronic intestinal pseudoobstruction. The large disease gene, encompassing over 2 Mb of DNA, responsible for Duchenne muscular dystrophy maps to Xp21 and encodes a protein found in skeletal muscle called dystrophin, which helps stabilize the cytoskeleton of skeletal muscle. This gene is lacking in affected boys and partially deficient in female carriers. DNA diagnosis is readily available. The majority of mutations are large deletions that can be easily detected by polymerase chain reaction-based DNA diagnostic methods. Prenatal DNA diagnosis, followed by pregnancy termination if the fetus is affected, is therefore an option for families wishing to prevent the birth of an affected child. Obviously, improved treatments are desperately needed and many hope that efforts in gene therapy in mouse models will lead to human trials in the near future.

Myotonic dystrophy. Myotonic dystrophy is an autosomal dominant disorder characterized by delayed muscular relaxation, facial weakness and muscle atrophy, ptosis, cataracts, gonadal atrophy, cardiac conduction abnormalities, and male pattern baldness. Significant GI complications are caused by abnormal functioning at all levels of the GI tract, from the pharynx to the anal sphincters; this results from degenerative changes in smooth muscle and fatty infiltration, causing problems with swallowing, aspiration, and constipation. The more severe phenotype of congenital myotonic dystrophy only occurs with alleles of maternal origin. The congenital form, often inherited from a mildly affected mother, features mental retardation, hypotonia, facial diplegia, gastroparesis, subacute intestinal obstruction, megacolon, and constipation. The disease gene maps to 19q13 and involves a CTG trinucleotide repeat in the three untranslated regions of the gene. Unaffected individuals have

5 to 27 copies of the repeat, whereas affected individuals have minimally 50 or more repeats with severity increasing as the repeat copy number increases to several kilobases. Expansion of the repeat can occur in subsequent generations, providing a molecular basis for the clinical phenomenon of anticipation (i.e., earlier clinical onset of disease in subsequent generations) in this disorder. DNA testing is sensitive, specific, and relatively easy to perform, thereby providing a specific way to confirm a suspected clinical diagnosis noninvasively. Other disorders presenting with myotonia caused by different genetic alterations can present with GI symptoms similar to those previously described.

Kearns-Sayre syndrome. Kearns-Sayre syndrome is a mitochondrial disorder characterized by progressive external ophthalmoplegia, pigmentary retinopathy, cardiomyopathy, and cardiac conduction defects; weakness of facial, trunk, and extremity muscles; and deafness, small stature, electroencephalographic changes, and increased cerebrospinal fluid protein. GI symptoms relate to the pharyngeal muscle weakness experienced by affected individuals, causing swallowing difficulties and dysphagia. The mitochondrial mutations characteristic of this disorder are deletions ranging in size from 2 to 7 kb and can be easily detected by analysis of mitochondrial DNA.

Visceral neuropathy syndromes. The visceral neuropathic forms of intestinal pseudoobstruction are characterized by abnormal pupillary reflexes, ataxia, and dysarthria; peripheral nervous system abnormalities, including absent deep tendon reflexes and impaired vibratory and position sense; and autonomic neurological abnormalities such as inappropriate blood pressure responses to phenylephrine, Valsalva maneuver, upright posture, and lack of sweating on warming. One type is also associated with basal ganglia calcification and mental retardation. Histological sections of tissues stained with a silver stain reveal degenerative changes of myenteric plexus neurons.

Hirschsprung disease (see also Chapter 82). Hirschsprung disease is probably a multifactorial disorder that usually occurs as an isolated congenital anomaly but may be a syndromic association of several genetic conditions (see Table 127-4). With isolated Hirschsprung disease, the risk to family members increases with severity (i.e., length of GI tract involved) and the number of affected relatives, especially female relatives. Empiric risk estimates are 7.2% for the siblings of affected women and 2.6% for the siblings of affected men. Complex segregation analysis demonstrated Mendelian inheritance patterns when the length of affected bowel was considered. Cases with aganglionosis beyond the sigmoid colon had a mode of inheritance that was compatible with an autosomal dominant trait with incomplete penetrance. Cases with aganglionosis no more proximal than the sigmoid colon had inheritance patterns consistent with multifactorial inheritance or autosomal recessive inheritance with very low penetrance. Isolated, nonsyndromic familial forms of the disease have demonstrated mutations in the *RET* protooncogene, which maps to chromosome 10q11.

Familial achalasia and diffuse esophageal spasm. Familial occurrence of achalasia, an autosomal recessive disorder, involves the esophagus, causing symptoms of progressive dysphagia, retrosternal discomfort, and intermittent regurgitation. The cause of achalasia is unknown. Diverticulosis of the esophagus may also occur. The severity of the disorder exhibits intrafamilial variability. Esophageal ganglion cells and dorsal motoneurons of the vagal nucleus are decreased, and there is the wallerian degeneration of the vagus nerve.

Familial dysautonomia. Familial dysautonomia, also called Riley-Day syndrome, is an autosomal recessive disorder, involving the autonomic nervous system, that is most prevalent in the Ashkenazi Jewish population, with an incidence of about 1 in 3500 individuals. It is characterized by autonomic instability, including lack of tearing, emotional lability, paroxysmal hypertension, increased sweating, cold hands and feet, corneal anesthesia, red blotching of the skin, and drooling. GI manifestations include oropharyngeal incoordination, abnormal esophageal motility and decreased lower esophageal sphincter pressure, prolonged gastric emptying, and gastroesophageal reflux, all of which result in dysphagia, emesis, and aspiration pneumonia. Affected individuals are reluctant to eat and suffer from dehydration and failure to thrive. Fundoplication and gastrostomy has some documented benefit in these cases. Diagnosis is determined by a lack of axon flare after intradermal injection of histamine, absence of fungiform papillae on the tongue, miosis of the pupil after instillation of methacholine chloride (2.5%), absent deep tendon reflexes, and diminished tear flow. The disease gene, *IKBKAP,* maps to chromosome 9q31 and linkage disequilibrium is present within Ashkenazi Jews, with a high-risk haplotype recognized.

Mechanical Obstruction and Malformation Syndromes

Most genetic disorders that cause mechanical obstruction are related to congenital malformations, and in general they have more importance in the pediatric population than they do for adults. However, as noted earlier in this chapter, some disorders with potential mass effects, such as large abdominal plexiform neurofibromas in NF1, may cause mechanical obstructive symptoms in rare instances. Another more common genetic cause for mechanical obstruction not caused by malformation is meconium ileus seen in 10% to 15% of cystic fibrosis patients. The anatomic site or sites of developmental malformation in these syndromes is usually restricted to derivatives of the embryologic foregut, midgut, and hindgut. In a rostral to caudal distribution, Table 127-6 reviews genetic malformation syndromes that may present with symptoms secondary to a mechanical obstruction.

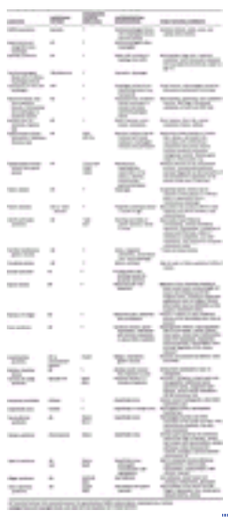

TABLE 127-6 Mechanical Obstruction and Malformation Syndromes

Chronic Abdominal Pain Syndromes (See Also Chapter 128)

Many genetic syndromes can present with recurrent bouts of abdominal pain, including familial Mediterranean fever (FMF), Fabry disease, hereditary angioneurotic edema, hereditary fructose intolerance, and the hereditary pancreatitis syndromes (Table 127-7). Although these syndromes (except for FMF) are relatively rare; making the correct diagnosis in a symptomatic individual may prevent unnecessary and invasive procedures and may similarly benefit other family members. The porphyrias are also associated with significant recurrent abdominal pain as discussed in Chapter 49.

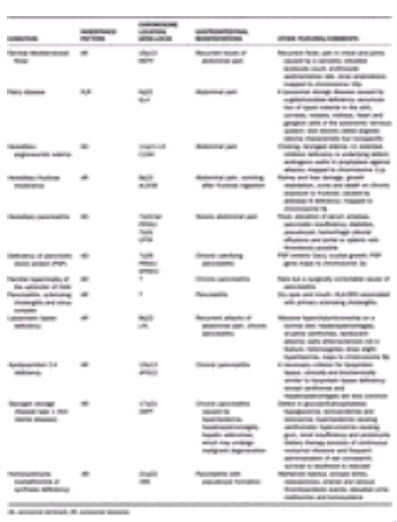

TABLE 127-7 Chronic or Recurrent Abdominal Pain Syndromes

Familial Mediterranean Fever FMF is an autosomal recessive disorder with protean manifestations and an obscure cause that has a frequency of approximately 1 in 2700 in Israel, a country in which it has been studied intensively. Half of affected individuals are of Sephardic Jewish descent, about 20% are Armenian, 20% are Turkish or Arabic, and the remainder are Italian, Greek, or Ashkenazi Jews. FMF occurs rarely in Northern Europeans. Approximately 50% of patients do not have a positive family history. Manifestations usually appear during childhood or adolescence and are characterized by brief episodic febrile attacks, recurring in varying intervals and associated with painful inflammation involving a variety of serosal surfaces, including the abdomen, chest, joints, and skin, lending the alternative name of recurrent familial polyserositis. Attacks last typically for 1 to 2 days and occur once or twice each month. The natural history of the attacks can vary considerably, even in an individual patient. Clinical features include fever, abdominal pain, and signs of peritonitis in most patients. Because the peritonitis is nonspecific, other acute febrile conditions must be considered, such as appendicitis, cholecystitis, pancreatitis, and intestinal obstruction. Less constant features include pleuritic pain, mild arthritis of the large joints, and a transient erysipelas-like skin lesion on the lower extremities. In 1% of patients, meningitis also occurs. Arthritis is an episodic monarthritis or oligoarthritis of the large joints, mimicking oligoarthritic forms of juvenile rheumatoid arthritis with attacks usually lasting days to weeks. They may last for months and can be associated with radiographic changes of periarticular osteopenia without erosions. Laboratory test results are nonspecific during the attacks of pain and fever. The leukocyte count averages 16,000 cells/μL but may be as high as 40,000 cells/μL. The erythrocyte sedimentation rate increases, as do other acute-phase reactants. Albuminuria and microscopic hematuria also occur. Radiographic studies may show bowel edema and air-fluid levels in the small bowel, causing confusion with obstruction. The diagnosis is made in patients with the appropriate ethnic background, who have typical, self-limited, and recurrent attacks of fever and abdominal pain. The most severe feature of this disease is the progressive accumulation of a specific protein known as amyloid fibrillar protein, AA, in the kidney, which manifests clinically as a nephropathy. There is considerable ethnic variation in the incidence of amyloidosis in FMF. Amyloidosis occurs least frequently in Armenians with the disorder, even though FMF occurs most commonly in Armenians (1 in 400). Amyloidosis occurs commonly in non-Ashkenazi Jews (1 in 2400) and is most common in Moroccan Jews in Israel (up to 30%). In some patients, the amyloid develops before any other clinical sign. The genetic or environmental factors that account for these differences in the incidence of amyloidosis are not clear. The amyloidosis appears to be a phenomenon secondary to the periodic inflammation, because its occurrence is reduced by colchicine therapy. Colchicine (0.6 mg), administered orally, two to three times per day, is an effective treatment in the prevention of the acute febrile attacks of the disease. A low-fat diet (20 g/d) may also prevent the attacks. Colchicine does not allay symptoms if taken during attacks. Some patients use it intermittently to forestall attacks when they recognize that one is imminent. The cause of FMF is unknown. It seems to involve a genetically determined defect in the regulation of inflammatory responses. Research into the cause of FMF has included studies of suppressor T cells, leukocyte chemotaxis, lysosome release from neutrophils, and immunoglobulins, all without a definitive identification of the pathophysiological defect. The FMF susceptibility gene, *MEFV* or the pyrin gene, maps to chromosome 16p13, and both diagnostic and predictive testing of at-risk family members is possible. Although clinical heterogeneity exists, as reflected by the different prevalence rates of renal amyloid in different ethnic groups, there is no evidence for locus heterogeneity, because the FMF gene is linked to the same locus in the non-Ashkenazi Jewish and Armenian populations.

Fabry Disease/Diffuse Angiokeratoma Fabry disease, also called diffuse angiokeratoma, is an X-linked recessive lysosomal storage disorder caused by a deficiency of a-galactosidase. Deposition of lipoid material in several tissues is responsible for the characteristic findings. These include: attacks of pain in the abdomen and extremities (probably caused by lipid changes in ganglion cells of the autonomic nervous system), vascular lesions in the fundi of the eye and the kidney, corneal opacities, a hypertrophic cardiomyopathy, and characteristic skin lesions of a vascular nature called angiokeratoma. Symptoms may present in adulthood, and death usually occurs after renal failure in mid-adulthood. Female heterozygotes may have renal insufficiency and proteinuria, and rarely have skin lesions. a-Galactosidase activity is deficient in the leukocytes of male patients, and carrier females can be identified because of decreased activity. Several mutations in the a-galactosidase gene, *GLA,* at Xq22 in patients with Fabry disease have provided the definitive evidence to indicate that this is the gene for Fabry disease. Enzyme replacement therapy is now available to treat affected individuals.

Hereditary Angioneurotic Edema Hereditary angioneurotic edema is an autosomal dominant disorder that affects the respiratory and GI tracts. Symptoms of choking occur because of airway edema that can be precipitated by acts of trauma, such as tracheal intubation. GI symptoms include abdominal pain, nausea, vomiting, and diarrhea. Barium studies during an acute attack show bowel wall edema. Associated findings include an increased incidence of autoimmune disorders. Deficiency of C1 esterase inhibitor is the underlying pathophysiological defect in these patients. This protein regulates the first component of complement (C1) by inhibition of the proteolytic activity of its subcomponents C1r and C1s, preventing activation of C4 and C2 by C1s and inhibiting other serine proteases, including plasmin, kallikrein, and the coagulation factors XIa and XIIa. Low levels of C4 and normal levels of C1 are characteristic of hereditary angioneurotic edema. These low levels of C4 are responsible for the increased incidence of systemic lupus erythematosus, glomerulonephritis, and vasculitis among these patients. Heterozygotes have about 10% to 20% of the normal levels of C1 inhibitor rather than the expected 50%, possibly because of complex formation of the activated C1 inhibitor and activated C1 or because of increased catabolism of the protein. Androgens are effective in stimulating increased synthesis of C1 inhibitor from the normal allele and are useful for prophylaxis against attacks. Concentrates of C1 inhibitor are useful in acute attacks. The C1 inhibitor gene, *C1NH,* maps to chromosome 11q11-q13. Two clinically indistinguishable types of hereditary angioneurotic edema are described. Type 1 patients have a deletion of the C1 inhibitor gene or a truncated transcript, and type 2 patients have a single base substitution.

Hereditary Fructose Intolerance Hereditary fructose intolerance (HFI) is an autosomal recessive disorder caused by a deficiency of aldolase B (i.e., fructose-1-phosphate aldolase). This enzyme is expressed in tissues that metabolize fructose: the liver, kidney, and small intestine. It catalyzes the reversible cleavage of fructose-1-phosphate into dihydroxyacetone phosphate and glyceraldehyde. After fructose, sorbitol, or sucrose ingestion, patients with HFI present with severe abdominal pain, vomiting, and hypoglycemia. Liver and kidney damage, growth retardation, coma, and even death may result from chronic ingestion of fructose. Most patients with HFI learn to avoid fructose-containing foods. Problems arise when they are unable to avoid them, as during infancy, or if given intravenous fructose- or sorbitol-containing infusions for dehydration resulting from diarrhea and vomiting associated with illness, a practice carried out in some European countries. Intravenous fructose loading tests and measurement of aldolase B activity in liver biopsy specimens are methods used for the diagnosis of HFI. The aldolase B gene, *ALDOB,* maps to chromosome 9q22. It consists of nine exons that code for 363 amino acids. At least 10 mutations have been described; three missense mutations of *A149P, A147D,* and *N334K* account for 87% of alleles in the European HFI population and 68% in the North American population. The *A149P* mutation is the most common and widespread, accounting for 58% of HFI alleles in Europe and 55% in North America. Linkage studies suggest that the *A149P* allele arose once during evolution and spread through the mechanism of genetic drift, rather than occurring several times in different populations. Testing for the common mutations with amplified DNA specimens against a panel of allele-specific oligonucleotides would be an appropriate initial diagnostic approach that could identify most patients in a noninvasive manner.

Hereditary Pancreatitis Syndromes (See Also Chapter 98) Hereditary pancreatitis is an autosomal dominant disorder that is similar clinically to nonfamilial chronic pancreatitis. Steatorrhea and recurrent attacks of severe abdominal pain, fever, and marked elevation of serum amylase levels are characteristic. The elevated amylase level differentiates the disorder from FMF. The mean age at onset is 13 years. Between 5% and 10% of affected persons have pancreatic insufficiency, diabetes, and pseudocysts. As in nonsyndromic pancreatitis, emotional stress, alcohol, or a diet rich in fat can precipitate an attack. The disorder exhibits 80% penetrance. The gene for hereditary pancreatitis is the cationic trypsinogen gene, *PRSS1,* which maps to chromosome 7q32-qter. One predominant mutation in codon 117 results in an arginine to a histidine substitution that can easily be detected by restriction digestion. Codon 117 is a trypsin-sensitive site and when the arginine 117 cleavage site is replaced by histidine, trypsin continues to activate trypsinogen and other zymogens, ultimately leading to pancreatitis secondary to autodigestion of the pancreas. Mutations in the cystic fibrosis gene, *CFTR,* have also been associated with chronic pancreatitis when present in heterozygotes in association with the variable number of thymidines in intron 8, specifically the *5T* allele. Other genetic syndromes involving obstruction of the pancreatic duct, such as secretory pancreatic stone protein deficiency, familial hypertrophy of the sphincter of Oddi, or sclerosing cholangitis, pancreatitis, and sicca complex, can present as cases of familial or recurrent pancreatitis. Recurrent pancreatitis caused by a submucosal ampullary tumor has also been described in a patient with neurofibromatosis. Cases of hereditary or recurrent pancreatitis may be caused by genetic disorders of triglyceride metabolism, leading to hypertriglyceridemia, such as lipoprotein lipase deficiency, apolipoprotein C-II deficiency, and familial hypertriglyceridemia.

Gastrointestinal Neoplasm Syndromes (See Also Chapter 34, Chapter 62, Chapter 69, Chapter 80, Chapter 90, and Chapter 91)

Exciting and important applications of genetics to oncology and gastroenterology has led to the elucidation of genetic contributions to many GI malignancies. Details about GI and hepatic malignancies are further described in Chapter 62, Chapter 69, Chapter 80, and Chapter 91. Genetic disorders have been associated with malignancies in the esophagus, stomach, small and large bowel, pancreas and rectum as summarized in Table 127-8A and the general features that suggest an inherited predisposition to cancer are presented in Table 127-8B. Although most cancers are sporadic, approximately 10% are caused by the inheritance of an autosomal dominant germline mutation in a tumor suppressor or DNA recognition and repair gene leading to a significantly increased risk of developing cancer at a relatively early age. The clinical features of GI malignancies are covered in many other chapters of this volume and will not be discussed further here. An outline of genetic syndromes that are associated with increased risks for GI tract neoplasms are listed in Table 127-9. Predictive genetic testing and early preventive management may be useful for several of these conditions as illustrated by examples in Table 127-10. Increasingly, prognostic genetic tests will be used in oncology to help direct clinical management of patients.

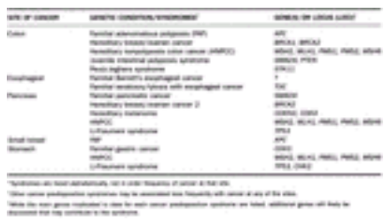

TABLE 127-8A Specific Cancer Sites in the Gastrointestinal Tract of the Hereditary Cancer Predisposition Syndromes*

- A clear inheritance pattern is suggested in the family history
- One particular type of cancer, or a limited number of different cancers, segregates in the family
- Cancer diagnoses occur at earlier ages when compared to the onset in the general population
- Family member has an identified genetic mutation associated with a cancer predisposition syndrome
- There is an unusual constellation of tumor(s)
  - —Multiple primaries in a single individual
  - —Bilateral cancers in paired organs of an individual
- Occurrence of relatively rare cancers not commonly seen in the general population clustering within a family
- Multiple recognized precursor lesions are present in the individual or family members
- Cancers are associated with other nonmalignant physical features or medical problems
- Constellation of cancers or other features that are part of a known cancer predisposition syndrome

TABLE 127-8B Findings Suggestive of an Inherited Cancer Predisposition Syndrome

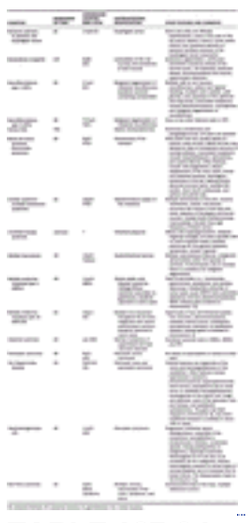

TABLE 127-9 Intestinal Neoplasm Syndromes

TABLE 127-10 Examples of the Use of DNA Testing and Ancillary Studies in the Evaluation of Cancer Predisposition Syndromes

Syndromes Associated With Benign Hepatic Masses and/or Cysts

Many genetic conditions are associated with benign hepatic masses and/or cysts. While oftentimes the hepatic manifestations do not result in significant clinical symptoms, recognition of the hepatic manifestations may be helpful in making the diagnosis of the genetic syndrome. Of the many multisystemic genetic syndromes that may be associated with benign hepatic lesions, the autosomal dominant disorders polycystic kidney disease, tuberous sclerosis complex, and von Hippel-Lindau syndrome are three conditions where clinical recognition is of paramount importance to insure that affected patients receive appropriate medical management. Von Hippel-Lindau syndrome is presented in Table 127-9.

Polycystic Kidney Disease There are both autosomal dominant and autosomal recessive polycystic kidney diseases. In general, autosomal recessive polycystic kidney diseases present very early in life, whereas the autosomal dominant forms generally present later with progression to end-stage renal disease around the fifth decade of life. While the main manifestations of polycystic kidney disease involve multiple cysts in the kidneys bilaterally with renal failure, hepatic cysts and colon diverticula may also develop. In addition, patients with the autosomal dominant form of adult polycystic kidney disease may have vascular complications including a high risk of intercranial aneurysms and an increased prevalence of cardiac valve disease. In general, the hepatic cysts are asymptomatic but the kidney cysts progress to end-stage renal disease in later adulthood. There is locus heterogeneity for autosomal dominant polycystic kidney disease with mutations in the *PKD1* gene at chromosome 16p13 and *PKD2* gene at chromosome 4q21-q23. In addition, there have been some families reported that do not map to either the chromosome 16 or chromosome 4 locus suggesting that there is at least one additional gene that predisposes to autosomal dominant polycystic kidney disease. In general, management of the disease consists of management of the renal complications with dialysis and kidney transplants.

Tuberous Sclerosis Complex Tuberous sclerosis (TS) complex is a multisystemic autosomal dominant disease with significant variable expression among affected individuals, even those within the same family. Several cutaneous features, including facial angiofibromas, hypopigmented macules, Shagreen patches, subcutaneous nodules, café au lait spots, and subungual fibromas, suggest the diagnosis. Retinal patches and astrocytomas can be identified on ophthalmology examinations. Dental examinations reveal pitted dental enamel and gingival fibromas. More serious complications include cardiac rhabdomyoma which may present early in childhood or infancy and neurological problems due to subependymal nodules, cortical tubers, and intracranial calcification that can be detected with head imaging studies and may lead to infantile spasms, seizures, and mental retardation in a significant number of patients. Cysts and angiomyolipomas are often seen in the kidneys and may also be identified in the liver of patients. The lesions in the liver are usually asymptomatic. In addition, lymphangiomyomatosis can also be identified in the lung and are important to identify in women of childbearing age. Patients are at increased risk for renal carcinoma. There is locus heterogeneity for this autosomal dominant condition with mutations in the *TSC1* gene on chromosome 9q34 and mutations in the *TSC2* gene at chromosome 16p13 accounting for the vast majority of cases. Although this condition is autosomal dominant, many patients are thought to possess new mutations and, therefore, there may be no family history of this disease. The *TSC* genes encode proteins that function as tumor suppressors.

Disorders of Bile Pigment Metabolism (See Also Chapter 44)

Several genetic disorders of bile pigment metabolism have been described. Although they vary in severity and clinical symptoms, most present with some degree of jaundice. The most commonly observed disorders are presented in Table 127-11.

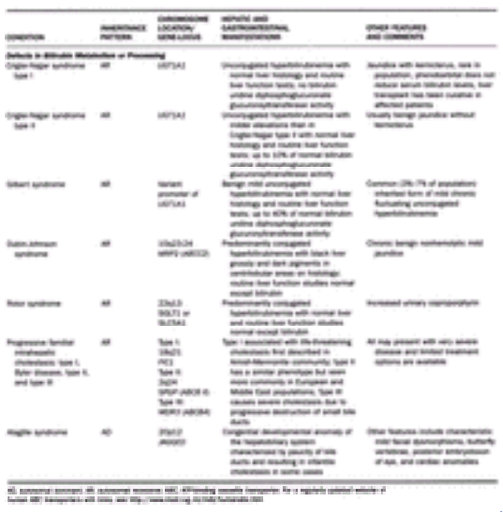

TABLE 127-11 Genetic Disorders of Bile Pigment Metabolism

Examples of Inborn Errors of Metabolism With Hepatic Manifestations (See Also Chapter 113)

Most of the inborn errors of metabolism are autosomal recessive or X-linked recessive disorders that present with multisystemic complications. Many are associated with a variety of hepatic findings including storage of precursor metabolic products, cirrhosis, and/or hepatomegaly. Discussion of classic metabolic diseases involving the GI tract and the liver are presented in Chapter 113. Many so-called metabolic disorders have been presented earlier in this chapter (i.e., hereditary fructose intolerance, Fabry's disease, hemochromatosis, etc.). A few additional diseases will be discussed subsequently to further illustrate the scope of different hepatic and GI manifestations that may be associated with inborn errors of metabolism. Although many inborn errors of metabolism present early in infancy or childhood, some do not present until later years.

Wilson Disease Wilson disease is an autosomal dominant disorder caused by mutations in the ATPase Cu $^{++}$ transporting ß-polypeptide gene (*ATP7b*) which is associated with high non–ceruloplasmin-bound serum copper levels. High urinary copper levels are also seen, as well as a low serum ceruloplasmin. Patients present with a variety of neurological and abdominal complaints. Often the onset of symptoms is in late childhood, adolescence, or early adulthood. Neurological symptoms include dementia, poor motor coordination, personality changes, dystonia, dysarthria, tremors, dysphagia, and decreased concentration. The main abdominal findings that can occur involve the liver and may include atypical hepatitis, cirrhosis, hepatomegaly, hepatic coma, and high liver copper levels. Esophageal varices can also arise. Renal tubular dysfunction and kidney stones may be seen. Loss of protein, amino acids, glucose, uric acid, phosphates, and calcium is often identified in the urine. Hypoparathyroidism and hemolytic anemia may also be observed. One characteristic ophthalmologic finding is Kayser-Fleischer rings. The diagnosis is based on analyzing serum copper levels and ceruloplasmin. *ATP7b* gene mutations lead to a dramatic build up of intracellular hepatic copper with subsequent and significant hepatic and neurological abnormalities. The gene maps to 13q14-q21. Treatment involves reducing serum copper levels. Agents including penicillamine and zinc have been successful in decreasing plasma copper levels.

Medium-Chain Acyl-Coenzyme A Dehydrogenase (MCAD) Deficiency MCAD is a relatively common autosomal recessive inborn error of fatty acid metabolism frequently seen in populations with the homozygote frequency estimated to be 1 in 6500 to 1 in 20,000, depending on ethnic background. Caucasians of Northern European descent exhibit the highest frequency of MCAD-deficient genotypes. MCAD-deficient patients are at high risk of hypoglycemia, vomiting, lethargy, encephalopathy, cardiorespiratory arrest, hepatomegaly, seizures, apnea, and sudden death in infancy. In fact, patients with this condition often die unrecognized with sudden infant death syndrome. Long-term outcomes may include developmental and behavior abnormalities, muscle weakness, cerebral palsy, and attention deficit disorder. Most often, infants are born healthy but present with symptoms after a fast or illness. It is in these times of metabolic stress caused by fasting or infection when the demands for fatty acid oxidation are high and patients may present with progressive symptoms. The MCAD gene is located on chromosome 1p31 and encodes an enzyme responsible for the metabolism of meaty enchained fatty acids. Newborn screening for this condition is now offered in several states, as recognition of the condition at the time of birth may allow for prevention of symptoms and sudden infant death syndrome by treating infections promptly and avoiding fasting conditions. Supplemental treatment including carnitine therapy may also be beneficial.

Tyrosinemia Tyrosinemia type 1 is an autosomal recessive condition due to mutations in the fumarylacetoacetate hydrolase (*FAH*) gene, which maps to chromosome 15q23-q25 and is required for the metabolism of tyrosine. Build up of tyrosine in the body can create multiple problems including failure to thrive, hypertrophic cardiomyopathy, renal Fanconi syndrome, renal failure, kidney stones, rickets, muscle weakness, episodic paralysis and peripheral neuropathy, abnormal blood coagulation studies, and a variety of abdominal problems. Hepatic problems that may occur include hepatomegaly, liver failure, cirrhosis, and associated ascites. Pancreatic islet-cell hypertrophy may also occur, as may splenomegaly. Gastrointestinal bleeding and paralytic ileus may also occur. Analysis of plasma amino acids is diagnostic. In addition, elevated a-fetoprotein, hypoglycemia, and hypophosphatemia can also be detected. Symptoms are highly variable and patients may have a progressive course that rapidly leads to hepatic failure while others may have acute and chronic hepatic crises. Hepatocellular carcinomas occur at high frequency in affected patients. The highest incidence of this condition is in the Saguenay-Lac St. Jean region of Quebec, Canada and northern Europe. Patients with this condition are often described as having an unusual "cabbage-like" odor.

Alpha-1-Antitrypsin (AAT) Deficiency AAT is an autosomal recessive condition with multiple allelic forms. Homozygotes for the PiZ form and some other much rarer variants are at a high risk of developing emphysema, particularly if they smoke, in early adulthood. These patients account for approximately 1% of all patients with emphysema. About 10% of the ZZ homozygotes develop liver failure that often leads to fatal childhood cirrhosis. This is due to an abnormal polymerization of the Z antitrypsin where the abnormal molecule has been poorly secreted in forms insoluble intracellular inclusions that are presumably toxic. In general, the infantile liver abnormalities occur when there is a less than 20% deficiency of the enzyme. Laboratory findings include a low serum a-1-antitrypsin (Pi) deficiency and abnormal liver function tests. Mutations in the protease inhibitor 1 gene on chromosome 14q32 are responsible for the phenotype. Again, multiple different mutations have been identified and different alleles are associated with different degrees of severity of disease. In the most severe form with hepatic failure in infancy, liver transplant has been used to treat this condition.

COMMON GASTROINTESTINAL AND HEPATIC DISORDERS WITH COMPLEX GENETIC CAUSES

In addition to the many monogenic, mendelian genetic disorders with GI and hepatic manifestations previously reviewed in this chapter, there are several common disorders whose genetic susceptibilities are inherited in a more complex or multifactorial mode. These disorders include conditions such as pernicious anemia, celiac disease (Chapter 76), inflammatory bowel disease (Chapter 83), cirrhosis (Chapter 116), gallstone disease (Chapter 100), peptic ulcer (Chapter 66), and sporadic colon cancer (Chapter 91). Common diseases often show familial aggregation caused by genetic factors or the combination of genetic and environmental factors. They also exhibit associations with certain genetic markers, often with specific HLA genotypes. Studies of family aggregation, twin data, subclinical markers, and genetic markers have been essential in demonstrating the importance of genetic determinants in the development of these common diseases. Many of the common complex gastrointestinal conditions are seen more frequently in specific genetic syndromes. For example, inflammatory bowel disease has been reported in individuals with Turner syndrome, Hermansky-Pudlak syndrome, glycogen storage disease type Ib, various immunodeficiency disorders, secretory immunoglobulin deficiency, gammaglobulinemia and hypogammaglobulinemia, selective immunoglobulin A deficiency, Chédiak-Higashi syndrome, deficiency of C2, hereditary angioedema, and chronic granulomatous disease. Further elucidation of genetic contributions to common non-mendelian GI and hepatic conditions will undoubtedly improve our understanding of their pathophysiology and may ultimately lead to susceptibility testing and preventive management for some of these conditions, at least in some populations in the near future. All of these common complex GI and hepatic conditions are discussed in great detail in other chapters of this text (see) and will not be further discussed here.

Acknowledgments

The author wishes to gratefully acknowledge the significant contributions of Drs. Maren Scheuner, Huiying Yang, and Jerome I. Rotter, whose related chapter in the second edition of this text formed the foundation for the current revision. The original words and tables of that chapter continue to live on in part of this revised chapter.

REFERENCES

The following on-line genetic databases and comprehensive genetic textbooks were used as the sources for all information contained in this overview chapter that summarizes salient features. Specific detailed references for each disease are found in these sources with the OMIM database being most comprehensive and up-to-date. Information from OMIM and its links were used to generate all tables.

CHAPTER 128

Joel S. Levine

GASTROINTESTINAL MANIFESTATIONS OF SYSTEMIC DISEASES

Systemic diseases are commonly manifested by gastrointestinal signs or symptoms. The liver or gut may be the principal targets of the disease process or simply indirectly affected; in either case, the gastrointestinal manifestations may be the cause for seeking medical attention. The purpose of this chapter is to examine the systemic disorders that have well-recognized gastrointestinal manifestations and to stress their more important effects on the digestive system.

CARDIOVASCULAR DISEASES

Aortic Stenosis

Aortic stenosis, a relatively common condition affecting predominantly men in middle to late life [1], has been associated with an increased incidence of gastrointestinal bleeding, [2] often attributed to angiodysplasias of the gut (Heyde syndrome). [3], [4] Although case series suggest that 15% to 41% of patients with bleeding angiodysplasias also have hemodynamically significant aortic stenosis, no such relationship is found when aortic stenosis is sought in patients with nonbleeding colonic angiodysplasias. [5] Thus, the validity of the association between the two conditions has been questioned, [6] and probably lies more with the now recognized changes in blood coagulation associated with the abnormal valve that makes the angiodysplasias bleed in older adult patients.

Although most bleeding angiodysplasias in patients with aortic stenosis are found in the right colon, gastric and small bowel lesions also have been described. [7], [8] Lesions identified by angiography or endoscopy can be incriminated as the bleeding source if active hemorrhage is observed. [9] Endoscopic cautery, angiographic embolization, and intestinal resection remain standard therapy for active bleeding. [9] Aortic valve replacement has resulted in the cessation of bleeding in some cases, [10], [11] but the angiodysplasias persist. [12] A probable mechanism is that aortic stenosis can be complicated by a deficiency of the largest multimers of von Willebrand factor and impaired shear-induced platelet aggregation, and this is corrected by porcine valve replacement. [13], [14] The use of oral contraceptives has been suggested as an effective medical alternative to surgery. [15] These latter approaches to management need validation.

Congestive Heart Failure

Impairment of the heart's ability to fill or empty the left ventricle results in inadequate perfusion of tissues and a consequent inability to maintain tissue metabolic demands. Prevalent causes include hypertension, valvular heart disease, cardiomyopathies, anemia, and hypermetabolic states (e.g., thyrotoxicosis and sepsis). [16] Heart failure leads to congestion of the splanchnic venous bed, causing anorexia, nausea, bloating, and abdominal pain. Mesenteric ischemia of the bowel due to low flow states is not uncommon in such patients. [17] Rarely, venous congestion is sufficiently severe to produce weight loss, diarrhea, malabsorption, protein-losing enteropathy, [18], [19], [20] and [21] and the clinical picture of cardiac cachexia. Hepatic congestion secondary to right heart failure (Fig. 128-1) may mimic biliary tract disease or hepatitis because of jaundice, right upper quadrant pain, hepatomegaly, abnormal liver enzyme levels, low protein ascites, and prolongation of the prothrombin time. [22] Prolonged congestion rarely progresses to cardiac cirrhosis. [23]

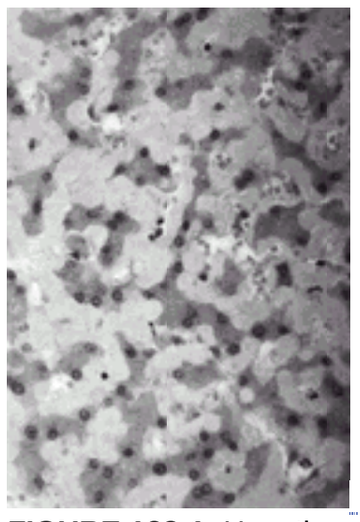

FIGURE 128-1. Hepatic congestion and cirrhosis secondary to congestive heart failure. (Hematoxylin and eosin stain; original magnification ×100.)

The medical therapy of heart failure can produce gastrointestinal side effects (Table 128-1). Digoxin causes anorexia, nausea, and vomiting in many patients. [24] Digoxin-associated constriction of splanchnic vessels may contribute to intestinal ischemia. [25] Quinidine and other agents used to control arrhythmias may produce nausea, anorexia, and diarrhea. Constipation or pseudoobstruction can result from diuretic-induced hypokalemia and hypomagnesemia. Severe pancreatitis has been attributed to a variety of diuretics, including thiazides, furosemide, and ethacrynic acid. [26] Oral potassium supplements have been implicated in esophagitis, ulcers,

and, rarely, intestinal strictures. [27] Angiotensin-converting enzyme (ACE) inhibitors are generally well tolerated, but may cause mild diarrhea. Rarely, ACE inhibitors have been associated with bowel obstruction and ascites due to angioedema of the intestine, as well as pancreatitis. [28]

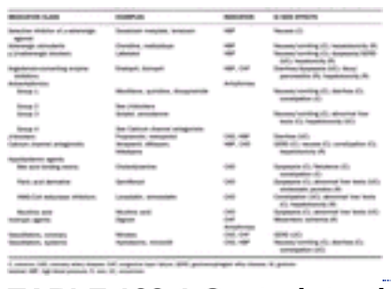

TABLE 128-1 Gastrointestinal Side Effects of Drugs for Cardiovascular Disease

The differential diagnosis of many of these complaints is long, and many patients are subjected to prolonged, fruitless investigation before the actual cause is discovered. Treatment is aimed at improving cardiac function. Cardiac medications should be changed or the dosage reduced when drug toxicity is suspected.

Coronary Artery Disease

Although the incidence of coronary artery disease (CAD) has decreased markedly since 1990, it remains the most prevalent cause of death in the United States. It is not uncommon for the initial presenting symptoms of angina or infarction to mimic gastrointestinal disease (epigastric pain or pressure, heartburn), which at times is confusing to both patient and physician. Once the diagnosis of CAD is certain, its treatments may lead to gastrointestinal problems.

Smooth muscle relaxants (calcium channel antagonists, nitrates) improve coronary blood flow but also relax the lower esophageal sphincter. Some suggest that the epidemic of esophagitis and esophageal carcinoma over the past two decades of the 20th century may relate to the common use of anti-anginal as well as other medications. [29] Constipation is also particularly prevalent with the calcium channel antagonists, and attention to bowel function is important. Lipid-lowering medications also are associated with constipation and elevations of transaminases, but most have mild and transient gastrointestinal symptoms that only rarely require discontinuation of the medication.

Large prospective trials have demonstrated the efficacy of low-dose aspirin in the secondary [30] and primary prevention [31] of myocardial infarction. In all trials, there is a small but consistent increase in the risk of gastrointestinal bleeding in the aspirin-treated groups. Although the risk of gastrointestinal bleeding is dose-related, even daily doses below 100 mg/d cause irreversible inactivation of platelet prostaglandin synthetase for 7 to 10 days. [32] Epidemiologic studies suggest that the concurrent use of nitrovasodilators reduce this risk substantially. [33] /SUP>Ticlopidine and clopidogrel, other antiplatelet agents, appear to be more effective than aspirin, are effective in preventing restenosis of coronary stents, are used with increasing frequency, and have a lower risk of gastrointestinal bleeding. [34]

More than 600,000 cardiac surgeries are now performed each year in the United States. Complications of cardiac surgery include acalculous cholecystitis, acute pancreatitis, mesenteric ischemia, hepatic necrosis, and others. [35] Gastrointestinal complications are recognized more frequently as management of these patients becomes more aggressive, as attested by reports of gastrointestinal bleeding after transesophageal echocardiography [36] and acute ischemic hepatic failure after malposition of an intraaortic balloon pump. [37]

CHROMOSOMAL ABNORMALITIES AND OTHER GENETIC DISORDERS

Abetalipoproteinemia

Abetalipoproteinemia is an autosomal recessive condition that causes severe hypolipidemia, diarrhea, fat malabsorption, growth failure, retinitis pigmentosa, acanthocytosis, and cerebellar ataxia. The growth failure and diarrhea can be improved with a diet modified to contain medium-chain triglycerides. Children with the disease can develop severe neurological disease from vitamin E deficiency, and fat-soluble vitamins must be monitored and replaced. [38] The disorder is a result of mutations of the microsomal triglyceride transfer protein, [39] and with current molecular technology it can be differentiated from a variety of hypobetalipoproteinemias caused by truncation producing mutations of the apolipoprotein B-100 gene [40] and from chylomicron retention disease.

Anderson-Fabry Disease

Anderson-Fabry disease, an X-linked glycosphingolipidosis, is caused by mutations in the gene encoding the lysosomal exoglycosidase, a-galactosidase A, with the resulting deposition of ceramide trihexose in the lysosomes of endothelial, neural, and smooth muscle cells. Diagnosis is made by skin biopsy, measurement of a-galactosidase in leukocytes, and genetic studies. [41] Gastrointestinal manifestations are present in most affected men and in 29% of female carriers and include episodic constipation, diarrhea, nausea and vomiting, and abdominal pain, and, rarely, intestinal ischemia and perforation. The cause of these symptoms may be related, in part, to impaired autonomic function and vascular insufficiency. [42]

Down Syndrome

Down syndrome (chromosome 21 trisomy) can be associated with multiple gastrointestinal anomalies, the presence of which predicts higher mortality. [43] Infants with duodenal stenosis and atresia present with vomiting, abdominal distention, and the “double-bubble” sign on abdominal radiography. Less complete obstructions from fenestrated duodenal membranes may present later in life as a cause of vomiting. [44] Esophageal abnormalities include tracheoesophageal fistula, esophageal stenosis, and gastroesophageal reflux. Imperforate anus, Hirschsprung disease, and malrotation of the intestine have been described. Celiac disease has a relatively high prevalence in these patients. [45] The high incidence of hepatitis A and B infection in patients with Down syndrome should be reduced with early vaccination.

Familial Mediterranean Fever

Familial Mediterranean fever (recurrent polyserositis) is a recessive disease that is common in populations of Eastern Mediterranean origin. The gene responsible for familial Mediterranean fever has been cloned and designated *MEFV*. Three missense mutations have been identified and can be screened for using an amplification refractory mutation system assay. [46] The target organ appears to be the blood vessel, and vasculitis can be present. Clinical manifestations begin in childhood and include self-limited attacks of fever, synovitis, peritonitis, or pleurisy. [47]

The diagnosis is suspected when patients of Mediterranean extraction with a positive family history present with recurrent episodes of chest or abdominal pain, peritoneal signs, arthritis, fevers, and leukocytosis. The patient may have undergone previous fruitless diagnostic workups, including laparotomy. Frequent complications include amyloidosis, degenerative arthritis, renal vein thrombosis, and narcotic addiction. [47] Treatment with colchicine has been beneficial in preventing and ameliorating acute attacks. [48]

Gaucher Disease

Type 1 (nonneuronopathic or “adult”) Gaucher disease is a rare autosomal recessive disease caused by a deficiency of glucocerebrosidase and resulting in the amassing of an insoluble glucocerebroside in the lysosomes of macrophages. Adults present with hepatosplenomegaly, thrombocytopenia, and pathological bone fractures. Ascites or esophageal varices, which occasionally may bleed massively, have been described (Fig. 128-2; see also Color Fig. 128-2). Definitive diagnosis relies on assaying ß-glucocerebrosidase activity. [49] Enzyme replacement therapy with small doses of mannose-terminated glucocerebrosidase (alglucerase) or the recombinant form of glucocerebrosidase imiglucerase can offer the hope of a productive life for many patients. [50]

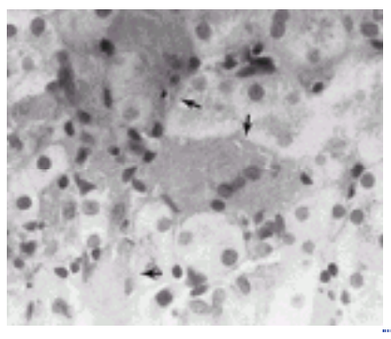

FIGURE 128-2. (See Color Fig. 128-2.) Gaucher disease of the liver. Multinucleated Gaucher cells (*arrows*) are present. (Hematoxylin and eosin stain; original magnification × 400.)

Hepatic Porphyrias

The hepatic porphyrias are a group of inherited metabolic disorders of heme synthesis. The acute hepatic porphyrias include acute intermittent porphyria, variegate porphyria, hereditary coproporphyria, and d-aminolevulinic acid (ALA) dehydratase deficiency. They are characterized by attacks of abdominal pain (commonly with vomiting and constipation) associated with hypertension, neuropathy, and neuropsychiatric disturbance that may last days to months. The abdominal pain is severe, may be associated by signs of peritoneal inflammation on physical examination, and can lead to unnecessary abdominal surgery. The peripheral neuropathy is manifest as pain in the extremities but may progress to a motor neuropathy. Photosensitivity only occurs in variegate and coproporphyria. Attacks can be precipitated by medicines (barbiturates, Dilantin, alcohol), menstruation, malnutrition, or other medical or surgical illnesses. [51], [52]

Sequence analyses of the genes for the enzymes of heme biosynthesis have revealed the porphyrias as highly heterogeneous, with multiple mutations underlying each type. All but ALA dehydratase deficiency are inherited as an autosomal dominant trait and are associated with increased urinary excretion of porphobilinogen (PBG) and ALA (Table 128-2). ALA dehydratase deficiency has normal excretion of PBG with elevated ALA. [53] Once the diagnosis is made, genetic counseling should be undertaken; patients are told to avoid precipitating factors and are placed on a high carbohydrate diet. Acute attacks may be ameliorated by infusion of glucose, hematin (being replaced by heme arginate), [54] and cimetidine 400 mg twice daily, [55] which suppress ALA synthetase. Treatment of seizures has been difficult because many anti-epileptic medications increase the hepatic metabolism of heme and can precipitate attacks. Gabapentin does not have this effect and seems to be safe and effective as a treatment of seizures in this setting. [56]

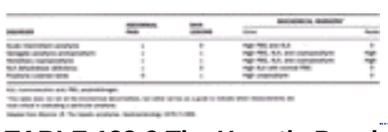

TABLE 128-2 The Hepatic Porphyrias

Porphyria cutanea tarda (PCT) is the hepatic porphyria inherited as an autosomal dominant trait, but its clinical presentation as a disease may depend on a number of other genetic and environmental factors. Characteristics include prominent photodermal and mechanical dermal sensitivity without abdominal pain. It is associated with alcoholic liver disease, hemochromatosis (or other disorders of iron overload), and hepatitis B and C. PCT has normal urinary excretion of PBG and is differentiated from variegate and coproporphyria by the increased urinary excretion of uroporphyrins. Abstention from alcohol, phlebotomy or desferrioxamine to reduce iron overload, low-dose chloroquine, and interferon-ribavirin treatment of hepatitis C all have reduced symptoms. [57]

Hereditary Angioedema

Hereditary angioedema is a rare autosomal dominant inherited deficiency of activated C1 inhibitor, a plasma protein that prevents uncontrolled intravascular activation of complement. Measurement of serum C4 screens for the disease, and an assay showing low serum C1 inhibitor confirms the diagnosis. [58]

The major clinical feature is episodic, self-limited, nonpitting, swelling of the orofacial region, larynx, extremities, and gastrointestinal tract. Angioedema is distinguished from urticaria in that it is asymmetric and burns rather than itches. Edema in the cervical region can compromise the upper airway. Abdominal attacks are characterized by colic, bloating, and nausea and vomiting secondary to enteric mucosal edema and can occur in the absence of peripheral or orofacial angioedema. Barium studies have demonstrated “thumbprinting” and other signs of mucosal edema. [59] Bradykinin is believed to be the main, if not the sole, mediator responsible for the edema. Treatment with synthetic androgens (e.g., danazol or methyltestosterone) increases the levels of C1 esterase inhibitor and can ameliorate or prevent attacks. Where available, infusions of C1 inhibitor concentrates are the treatment of choice for emergent attacks. [58] Premedication with C1 inhibitor concentrate or antifibrinolytic agents (e.g., e-amino caproic acid, tranexamic acid) should be considered before oropharyngeal manipulations such as upper endoscopy. [60]

Hyperlipidemias

The familial hyperlipidemias are a collection of inherited disorders of lipid metabolism, characterized by elevated plasma lipid levels. The epidemiologic association with atherosclerotic vascular disease is clear. Types I (hyperchylomicronemia) and V (hyperlipoproteinemia) are also associated with recurrent episodes of pancreatitis, as are patients with a deficiency of lipoprotein lipase. Patients with type IV hyperlipidemia also may be subject to an increased incidence of gallstones. Only disorders that predispose to high levels of triglycerides (>1000 mg/dL but usually >2000 mg/dL) are associated with acute pancreatitis. [60], [61] Many of these patients, particularly if overweight or diabetic, will develop fatty liver associated with abnormal serum liver enzyme levels, and will have nonalcoholic steatonecrosis on biopsy. The third trimester of pregnancy and the use of oral contraceptives are associated with an increased risk of developing severe hypertriglyceridemia. [62]

In the past 5 years multiple studies have demonstrated the beneficial effect of lipid lowering medication on the secondary prevention of coronary disease and stroke, with increasing evidence of benefit from primary prevention in patients with multiple risk factors. Statins (3-hydroxy-3-methylglutaric acid [HMG-CoA] reductase inhibitors) are commonly employed, and are associated with benign transaminase elevations in less than 1% of patients on higher doses. Hepatotoxicity is more common in patients who are also receiving drugs metabolized by the cytochrome P-450 enzyme systems, such as clarithromycin, fluconazole, fluoxetine, and cyclosporin. The symptoms of hepatitis are usually mild fatigue, anorexia, and weight loss. Aminotransferases are usually elevated two to three times the upper limit of normal. Although symptoms subside almost immediately on discontinuation of the statin, the liver tests make take several weeks to return to normal. Asymptomatic elevations of aminotransferases to 1.5 times the upper limit of normal can just be followed without stopping medication. Tests of liver function should be performed within the first 1 to 2 months of initiating therapy and every 6 months thereafter. [63]

Bile acid binding resins such as cholestyramine cause abdominal fullness, flatulence, and constipation in 30% of patients. These symptoms usually respond to dose reductions or the addition of psyllium or prune juice. Nicotinic acid, especially at doses more than 2000 mg/d, has been implicated in more common hepatotoxic reactions than statins. Gemfibrozil may cause severe abdominal pain, and is associated with increased frequency of gallstones. [63]

Niemann-Pick Disease

Niemann-Pick disease is a rare, inherited lipid storage disease that principally afflicts people of Jewish ethnicity. The enzyme sphingomyelinase is absent or nonfunctional, leading to the accumulation of sphingomyelin in the lysosomes of reticuloendothelial cells. Affected infants manifest severe neurological disease, hepatosplenomegaly, and hepatic failure and do not survive to adulthood. Survival of patients with type B Niemann-Pick disease to adulthood is common but may be associated with cirrhosis and portal hypertension. [64]

Tangier Disease

Tangier disease is a rare codominant inherited deficiency of plasma a-lipoprotein. The genetic defect has been localized to chromosome 9q31. Affected patients exhibit reduced total cholesterol, low

high-density lipoproteins, and elevated plasma triglycerides. Accumulation of cholesterol in the reticuloendothelial system results in enlarged orange or red tonsils, lymphadenopathy, peripheral neuropathy, hepatosplenomegaly, and yellow-orange patches in the colonic mucosa. [65]

Turner Syndrome

Turner syndrome (X chromosome monosomy) occurs in 1:2000 live female births and presents with a variety of external somatic features of which short stature and gonadal dysgenesis are almost invariably present. Gastrointestinal hemorrhage resulting from intestinal vascular malformations, an increased incidence of inflammatory bowel disease, and a greater risk of anorexia nervosa have been described. [66] Mild elevation of alkaline phosphatase may be seen. This cholestasis is not related to the chronic use of estrogens for the gonadal dysgenesis. [67]

Von Hippel-Lindau Disease

Von Hippel-Lindau (VHL) disease is an autosomal dominant inherited disorder characterized by hemangioblastomas of the retina and central nervous system, renal cell carcinoma, pheochromocytoma, and endolymphatic sac tumors with marked phenotypic variability. Heterogeneous germline mutations lead to the absence of the VHL protein resulting in uncontrolled production of vascular endothelial growth protein and the formation of blood vessels. [68] Pancreatic disease is found in three fourths of the affected individuals. The most common lesions found were cysts, serous cystadenomas, and neuroendocrine tumors. These lesions rarely cause symptoms and only require surgical intervention when very large. [69]

CONNECTIVE TISSUE DISEASES

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome (EDS) is a collection of inherited diseases affecting collagen synthesis. Nine different subtypes are described, although gastrointestinal involvement is common only in types I (gravis) and IV (arterial). Patients with type I EDS have fragile, hyperelastic skin and hyperextensible joints. They often complain of bleeding gums and easy bruising after even minor trauma. Severe gastrointestinal bleeding from mucosal lesions occasionally occurs. [70]

EDS type IV is unique in that hyperelastic skin is lacking and joint hyperextensibility is less prominent. Ecchymoses, thin skin with visible vessels, and “cigarette paper” scars are common, however. Cultured fibroblasts that synthesize abnormal type III procollagen molecules or the identification of a mutation in the gene for type III procollagen (*COL3A1*) confirms the diagnosis. Most complications occur after age 20. The defect in type III collagen synthesis leads to multiple aneurysms, including in the arteries of the splanchnic system. Rupture of these aneurysms results in intra-abdominal bleeding. Spontaneous perforation of the bowel, particularly the sigmoid colon, is common and a cause of death. Tissue fragility and poor wound healing with dehiscence contributes to surgical mortality. Repeated perforations are seen. [71]

Mixed Connective Tissue Disease

Mixed connective tissue (MCT) disease, or overlap syndrome, is a heterogeneous autoimmune disorder that may present with clinical features of lupus, scleroderma, and polymyositis. Gastrointestinal manifestations may resemble any of those described (see below) for the aforementioned rheumatoid diseases. Esophageal symptoms of heartburn and dysphagia are most common, however, with either proximal or distal esophageal motility distorted. Treatment with corticosteroids may improve the swallowing abnormality. [72]

Polymyositis and Dermatomyositis

Polymyositis and dermatomyositis are rheumatologic diseases characterized by inflammation of striated and, to a lesser extent, smooth muscle. Muscle biopsy is needed for diagnosis. A characteristic skin rash accompanies dermatomyositis. The gastrointestinal tract may be affected throughout its entire length, but the proximal esophagus usually is involved. Gastric and esophageal emptying is compromised in many patients, who may complain of dysphagia, aspiration, regurgitation, early satiety, and bloating. [73]

Colonic pseudodiverticula and pneumatosis intestinalis also may develop. Constipation is a common complaint. Suggested contributing causes include neurological dysfunction and diminished smooth muscle contractility as a consequence of muscle atrophy, fibrosis, or inflammation. Acute inflammation of smooth muscle may result in gut wall edema, ulceration, or perforation. An association of dermatomyositis and malignancy has long been postulated. In older adult patients colon cancer seems to be prevalent, and colonoscopic screening is appropriate. [74]

Progressive Systemic Sclerosis

Progressive systemic sclerosis (PSS) or scleroderma is characterized by vasculitis of small arteries and fibrosis of skin and other organs. Gastrointestinal manifestations are found in most patients. Tightening of the perioral skin with restricted ability to open the mouth and impaired taste sensation may contribute to malnutrition. Esophageal involvement, present in 70% to 80% of patients, is associated with more severe Raynaud’s phenomenon, skin abnormalities, and autonomic dysfunction. [75], [76] Smooth muscle atrophy leads to absent or low-amplitude esophageal contractions that are most prominent in the mid- and distal esophagus and weakening of the lower esophageal sphincter, leading to both reflux of acid and retarded clearance of the refluxed material. In addition, gastric emptying is commonly delayed, further increasing acid reflux. [77] The result is the most severe type of symptomatic reflux and erosive esophagitis. Evaluation of dysphagia may be difficult in advanced cases because it may be impossible to distinguish primary dysmotility from stricture. Endoscopy should be the primary diagnostic modality. Dilation of a stricture can substantially improve swallowing. The risk of developing strictures is high, and patients should be maintained on a proton pump inhibitor at a dose sufficient to suppress heartburn. Use of the more potent esomeprazole (40 mg/d) may be cost-effective in this setting.

Gastrointestinal hemorrhage is not particularly more common in PSS patients. In those with upper gastrointestinal bleeding, endoscopy may reveal telangiectasia [78] or gastric antral vascular ectasia (watermelon stomach). Chronic iron deficiency anemia, persistent occult blood in the stool, or recurrent melena and hematemesis are common manifestations. Cautery with heater probe or laser may reduce recurrent bleeding. [79]

The small intestine frequently is involved, causing severe morbidity. Hypomotility, dilation, pseudodiverticula, and thickening of the bowel are common. Stasis, pseudoobstruction, and bacterial overgrowth may produce anorexia, abdominal distention, postprandial periumbilical pain, malabsorption, diarrhea, steatorrhea, and weight loss. The bacterial overgrowth may be worsened by the need for effective inhibition of acid secretion because of concomitant gastroesophageal reflux. Erythromycin, cycled antibiotics, and octreotide [80] may reduce symptoms, but many patients require home parenteral nutrition.

Delayed colonic transit and impaired anal sphincter function have been demonstrated in patients with PSS. [81] Pseudodiverticula (Fig. 128-3) and telangiectasias are common. Constipation, pseudoobstruction, and volvulus may develop. Fecal incontinence and rectal prolapse are particularly disabling symptoms. Pneumatosis cystoides intestinalis may be found and is probably due to excessive hydrogen production by intestinal bacteria altering the partial pressure of nitrogen in the intestinal wall. [80], [82] Careful attention to bowel function has an important role in extending the patient’s functionality. Patients with the CREST (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, telangiectasia) variant of PSS are at risk for the development of primary biliary cirrhosis.

FIGURE 128-3. Wide-mouthed pseudodiverticula are present in a patient with scleroderma.

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum is a rare inherited disorder of connective tissue synthesis, characterized by plaques resembling xanthoma on the skin and angioid streaks on the fundus. Degeneration of elastic fibers in visceral blood vessels results in ineffectual vasoconstriction and vessel retraction after injury, predisposing to gastrointestinal bleeding. [83] Yellow raised plaques similar in appearance to the skin lesions have been identified in the stomach during endoscopy. [84] The best therapy for bleeding is uncertain, but arterial embolization has successfully controlled hemorrhage. [85]

Rheumatoid Arthritis

Rheumatoid arthritis is a chronic systemic disease characterized by a deforming symmetric polyarthritis and the presence of serum rheumatoid factors. It most commonly afflicts women between the 3rd and 7th decades of life and has a prevalence of about 1% in the United States. [86] Gastrointestinal manifestations are common and protean. Involvement of the temporomandibular joint impedes chewing. Sicca syndrome, when present, is accompanied by stomatitis and gingivitis. Heartburn and dysphagia are not as common as in PSS or MCT disease. Secondary amyloidosis may occur in patients with long-standing rheumatoid arthritis, may involve any portion of the gastrointestinal tract, may be manifest by chronic diarrhea, and can be diagnosed by endoscopic gastroduodenal biopsies. [87]

Vasculitis is less common than in other rheumatic diseases; however, both small and large vessels may be involved in the setting of severe arthritis, subcutaneous nodules, high titers of rheumatoid factor, and depressed serum complement levels. Necrotizing vasculitis of the mesenteric vessels may result in intestinal ischemia, bleeding, and infarction. [88] Cholecystitis, appendicitis, [89] perisplenitis, splenic infarction, pancreatitis, and hepatic arteritis have been described. [90]

Iatrogenic illness results in the most common gastrointestinal manifestations in rheumatoid arthritics. Chronic administration of salicylates or nonsteroidal antiinflammatory drugs (NSAIDs) that inhibit both cyclooxygenase 1 and 2 (COX-1 and COX-2) produce gastroduodenal erosions and ulcers, as well as hypocoagulability. COX-2 is an inducible enzyme that is associated with joint inflammation; its suppression leads to decreased pain, inflammation, and fever. COX-1 is a constitutive enzyme in the gastric mucosa, where it is necessary for the maintenance of normal mucosal integrity, and in platelets, where it is needed for normal aggregation. Although these lesions can be associated with anorexia, nausea, and abdominal pain, many patients are asymptomatic. [91] Larger, chronic ulcers of the stomach and duodenum will cause significant gastrointestinal bleeding or perforation in about 1% to 2% of patients each year. [92] The risk of bleeding is increased substantially (up to 9%–10%) in frail older patients who

- are taking certain NSAIDs (e.g., piroxicam)
- are taking higher doses of any NSAID
- have a previous history of gastrointestinal bleeding or ulcers
- are using steroids or aspirin with an NSAID
- have concomitant cardiopulmonary disease. [93]

Under ideal circumstances the patient with rheumatoid arthritis would be treated with joint-sparing immunotherapy alone (e.g., methotrexate) and not require chronic NSAIDs. In practice, however, many continue to have pain and inflammation that only responds to NSAIDs. For these individuals, the use of selective COX-2 inhibitors (celocoxib, rofecoxib) has been associated with decreased dyspepsia and bleeding. [94] Only patients who have multiple risk factors and who cannot use the selective COX-2 inhibitors should be considered for expensive prophylactic therapy with proton-pump inhibitors, or misoprostol. [95] Any of these approaches, however, can heal active ulcers if nonselective NSAIDs must be continued.

Methotrexate is commonly used to modify the disease progression of rheumatoid arthritis. Nausea and vomiting are common side effects during the first year of therapy and limit the use of this efficacious medication. Decreased renal function (either because of kidney disease or aging) increases the risk of side effects, and low-dose folic acid supplementation may be protective. [96] Although chronic therapy with low-dose methotrexate can result in hepatic fibrosis, when liver biochemistries are monitored the risk of developing cirrhosis is small in younger patients who do not drink alcohol. Hence, the clinical value of obtaining periodic liver biopsies is controversial. [97], [98] The toxic effects of gold preparations are discussed in the section on “Heavy Metal Toxicity.” Patients with Felty syndrome (rheumatoid arthritis, splenomegaly, and leukopenia) can develop intra-abdominal sepsis for reasons that are undefined as well as portal hypertension and variceal hemorrhage. [99]

Seronegative Spondyloarthropathies

The seronegative spondyloarthropathies are a collection of rheumatic diseases including ankylosing spondylitis, psoriatic arthritis, the reactive arthritides (e.g., Reiter syndrome), the arthritis associated with inflammatory bowel disease, and Whipple disease. Serum rheumatoid factor is lacking, but most patients are human leukocyte antigen (HLA) B27-positive, and many have recurrent oral and genital ulcers. [100] Patients with reactive arthritis frequently have an antecedent gram-negative enteric or chlamydial infection. [101] Many have chronic gastrointestinal symptoms (e.g., mild diarrhea, abdominal cramps), and most patients have endoscopic or histological evidence of ileocolonic inflammation that sometimes resembles Crohn’s disease. [102]

Sjögren Syndrome

Sjögren syndrome results from immune-mediated destruction of exocrine glands and is characterized by keratoconjunctivitis sicca (dry eyes and mouth). Atrophy of the salivary glands leads to a lack of saliva, which can, in turn, impair swallowing. In addition, esophageal dysmotility and mucosal webs are found. [103] Gastric atrophy and celiac disease [104] are reported with higher frequency in these patients than in age-matched controls. There is a strong association with the development of primary biliary cirrhosis. [105] Pancreatic acinar atrophy may result in pancreatic insufficiency and steatorrhea in some patients. [103]

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease that is most common among young and middle-aged women. Its characteristics include arthritis, myalgias, fever, rash, lymphadenopathy, renal disease, polyserositis, and central nervous system involvement. SLE is associated with abdominal pain of multiple causes. Inflammation of serosal surfaces may produce lupus peritonitis, [106] which usually is self-limited but may be associated with ascites. Self-limited peritonitis is difficult to distinguish from intestinal ischemia or perforation secondary to mesenteric vasculitis. [107] Pancreatitis, sometimes severe, perhaps related to vasculitis, has been associated with SLE. Intussusception, enteritis, and pneumatosis intestinalis may be seen. In particular, SLE may present with terminal ileitis, and it can be confused with Crohn’s disease. [108] Such vasculitis is usually associated with active disease in other organs. Malabsorption and protein-losing enteropathy with lymphangiectasia are documented. [109] Although clinically significant liver disease is uncommon in SLE, many patients have hepatomegaly and abnormal liver enzyme levels. Drug-induced hepatotoxicity is probably the most common underlying cause. [110] Abnormal liver enzyme levels and hepatocellular necrosis have been attributed to aspirin therapy, even when salicylate levels are within the therapeutic range. [111] Stopping aspirin therapy usually results in prompt regression of this syndrome. Other drugs, such as azathioprine, may produce similar abnormalities. Hepatic vasculitis is a rare cause of liver disease, which in extreme cases has resulted in liver rupture. [112]

DERMATOLOGIC DISEASES

Ataxia-Telangiectasia

Ataxia-telangiectasia is an autosomal recessive disorder that is characterized by progressive ataxia, telangiectasia on the bulbar conjunctiva and sun-exposed regions, sinopulmonary infections, immunodeficiency, and a propensity for lymphoreticular and other malignancies. [113] Rarely, hepatic venoocclusive disease has been reported in the absence of bone marrow transplantation or coincidental hepatitis infection. [114]

Blue Rubber Bleb Nevus Syndrome

Blue rubber bleb nevus syndrome is characterized by rubbery, blue nevi on the skin and gastrointestinal hemangiomas. The gastrointestinal hemangiomas can result in hemorrhage and iron deficiency anemia, may be the lead point of intestinal intussusceptions, and are commonly identifiable at the time of upper or lower endoscopy. Actively bleeding lesions can be cauterized, or the vessel can be occluded during angiography. [115], [116] and [117]

Cowden Syndrome

Cowden syndrome is an autosomal dominant disease characterized by ectodermal, mesodermal, and endodermal hamartomatous neoplasms. Patients manifest small papular lesions on the skin and oral mucosa. Diffuse esophageal glycogenic acanthosis may be characteristic of the syndrome. [118] There is a strong propensity for thyroid goiter, thyroid cancer, and, in women, breast cancer. Other organ systems may be involved. [119] Multiple hamartomatous polyps of various sizes can develop from the esophagus to the colon, but have a low potential for malignant degeneration. The hamartomas can cause chronic gastrointestinal blood loss and partial intestinal obstruction [120] (see Chapter 90).

Epidermolysis Bullosa

Epidermolysis bullosa is a group of diseases in which minor trauma disrupts the cohesion between epidermis and dermis, resulting in the formation of vesicles or bullae. Epidermolysis bullosa lethalis is an autosomal recessive disorder of the newborn period associated with extensive bullae formation and congenital pyloric atresia. [121] Other forms of this entity include epidermolysis dystrophica with either dominant or recessive inheritance and epidermolysis simplex of dominant inheritance.

Lingual adhesions and microstomia occur as a consequence of injury to the oropharyngeal mucosa during the eating of solid foods. [122] Clinically significant esophageal disease is seen more commonly in recessive epidermolysis dystrophica. Odynophagia and dysphagia are common because esophageal bullae lead to erosions, ulcers, pseudodiverticula, shortened esophagus, webs, strictures, and obstruction, most commonly in the cervical esophagus. Eating a soft or pureed diet may limit mechanical injury to the esophagus, but endoscopic placement of a gastrostomy tube may be needed. Strictures respond to frequent dilation with inflatable balloons. Bougienage probably should be avoided because the shearing forces could perpetuate injury. [123], [124]

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease) is an autosomal dominant condition found in 1 to 2 per 100,000 people. It is associated with the formation of telangiectasias, aneurysms, and arteriovenous malformations throughout the body. Cutaneous telangiectasia usually appears after the second or third decade of life and is located most frequently on the face, lips, nares, tongue, ears, and hands. The most prominent clinical feature of this disease is recurrent bleeding from mucosal telangiectasias. [125]

Epistaxis is the most common form of bleeding, with gastrointestinal hemorrhage developing in 10% to 40% of patients. Genitourinary, pulmonary, and intracerebral bleeding also may occur. [126] Hepatic vascular malformations cause arterioportal and intrahepatic portosystemic shunts, resulting in high-output congestive heart failure. Hepatomegaly, hemobilia, portal hypertension, esophageal varices, hepatic encephalopathy, bruit, and cardiomegaly have been noted. Elevated alkaline phosphatase and bile duct lesions similar to Caroli disease or sclerosing cholangitis can be encountered. [127]

Iron deficiency anemia is common and may require continuing oral or parenteral iron replacement or even transfusions. Endoscopic coagulation can effectively control life-threatening hemorrhage from a visible intestinal vascular malformation. In many cases, however, the bleeding site cannot be localized, and chronic hormonal therapy is initiated. If possible all antiplatelet medications (e.g., aspirin, NSAIDs) should be returned to the physician, as in such patients, estrogen-progesterone therapy can reduce the need for repetitive transfusions. [15] When large intrahepatic arteriovenous fistulae result in high-output congestive failure, embolization of these vessels or ligation of select branches of the hepatic artery may result in improvement of the failure, but infarction of the liver. [128]

Neurofibromatosis

Neurofibromatosis (von Recklinghausen disease) is an autosomal dominant inherited disease. The gene frequency is 1 in 3000 births. Cutaneous café au lait spots and neurofibromas rarely transform into sarcoma. [129] Polypoid neurofibromas can be present throughout the gastrointestinal tract, and it has been suggested that the Auerbach myenteric plexus may be the source of the tumors. [130] Rarely, the liver and gallbladder also are affected. [131]

Neurofibromas occasionally cause gastrointestinal bleeding and obstruction presenting as melena and abdominal pain. Gastrointestinal leiomyomas, sarcomas, and neurogenic neoplasms also are reported; [131] a somatostatin-rich carcinoid tumor of the periampullary region of the duodenum containing psammoma bodies also has been reported. [132]

Pemphigus

Pemphigus is a group of diseases characterized histologically by acantholysis resulting in bullae formation. Onset is usually between the 5th and 7th decade of life. D-Penicillamine, which is used in the management of Wilson disease, can cause pemphigus, although this is rare. Pemphigus vulgaris can involve the esophagus. Endoscopy shows blisters or erosions in the upper esophagus and linear red streaks along the entire organ, but clinically significant disease is uncommon. [133]

Psoriasis

Psoriasis is not associated with gastrointestinal disease; however, difficult psoriasis often is controlled by prolonged methotrexate administration. At the doses used, this drug carries the risk of potentially serious hepatotoxicity, including fatty liver, hepatic fibrosis, and cirrhosis. [134], [135] Serial liver biopsies are required to detect early hepatic damage because biochemical changes poorly reflect the extent of liver injury.

Stevens-Johnson Syndrome

Stevens-Johnson syndrome is an uncommon, but severe, hypersensitivity reaction characterized by a diffuse rash (erythema multiforme) that may progress to an exfoliative dermatitis. It is fatal in about 5% of cases. [136] This syndrome often is accompanied by fever and mucositis of both the gut and the respiratory tract. Etiologic agents include drugs (e.g., sulfonamides, allopurinol, anticonvulsants, NSAID) and infectious agents. The oropharyngeal mucosa frequently exhibits erosions and mucosal sloughing, although the entire gut may be involved in severe cases. Oropharyngeal pain may be severe enough to limit oral intake. Mucosal injury may result in dysphagia, odynophagia, abdominal pain, and gastrointestinal bleeding. [137] Esophageal stricture has been reported as a sequela of the Stevens-Johnson syndrome. [138] The syndrome is commonly associated with abnormal liver tests and hepatotoxicity.

Management is similar to that provided for major burns, and patients with extensive loss of skin should be managed in intensive care. Treatment includes identification and elimination of the inciting factors, rehydration, nutritional support, antibiotics, and vigilance for respiratory problems and secondary infections. Complete recovery may take several weeks. [136], [137] and [138]

Sweet Syndrome

Sweet syndrome is an uncommon condition, seen in women more than men, characterized by the acute eruption of tender, erythematous, non-ulcerating plaques and nodules. Nodules on the legs can mimic erythema nodosum. Diagnosis is defined by the histological presence of neutrophilic infiltration and leukocytoclasis on skin biopsy. The latter findings also are found in pyoderma gangrenosum, which, in contradistinction, is represented clinically by ulcerating plaques with violaceous edges. As with pyoderma, a strong association of Sweet syndrome with both ulcerative colitis and Crohn's

disease has been noted. Also reported are mouth ulcerations and an association with myeloma, myeloid leukemia, and adenocarcinoma of the colon. [139]

Tylosis

Tylosis is a rare autosomal dominant disorder characterized by thickening of the skin on the palms and soles (focal non-epidermolytic palmoplantar keratoderma) (Fig. 128-4; see also Color Fig. 128-4). Late onset tylosis (type A) is associated with squamous cell carcinoma of the esophagus. The causative locus, located on chromosome 17q25.1, has been termed the tylosis esophageal cancer (TOC) gene, [140] and has also been associated with sporadic esophageal cancer. [141] The esophageal mucosa forms papillomas. Affected persons have about a 90% probability of developing esophageal carcinoma by the age of 65 years, and should be screened with endoscopy and biopsies. [142]

FIGURE 128-4. (See Color Fig. 128-4.) Hyperkeratosis of the palm and leg may be indicative of tylosis.

Urticaria

Urticaria is a reactive inflammatory vascular dermatosis characterized by vasodilation, increased vascular permeability, and extravasation of protein and fluids into the dermis, resulting in the characteristic peau d'orange wheals. Urticaria of less than 6 weeks' duration usually is related to inciting factors, such as contact allergy, medications, or food allergy. Chronic cases are usually idiopathic. Only a minority of patients with chronic urticaria will have systemic mastocytosis, which may be signaled by the more classic urticaria pigmentosa, flushing, and diarrhea. [143] Initial reports of an association with *Helicobacter pylori* infection appear unfounded. [144] Implicated in the pathophysiology of both acute and chronic urticaria is the release of histamine and other inflammatory mediators. Gastrointestinal manifestations have been reported in a number of patients suffering from chronic urticaria and include abdominal pain, gastroduodenitis, peptic ulcer, and enteric mucosal "hives." [143]

Urticarial vasculitis is a distinct entity in which the cutaneous lesions resemble urticaria but histologically show vasculitis. The persistence of urticaria longer than 24 hours and the presence of residual bruising suggest its diagnosis. It may accompany a collagen vascular disease, a familial complement deficiency, or an infection. Involvement of the gastrointestinal tract produces transient crampy abdominal pain, nausea and vomiting, and diarrhea. These symptoms may appear with cutaneous urticaria and are more in keeping with mucosal edema than with ischemia. Hypocomplementemia is frequently evident during the acute attack. [145]

ENDOCRINOLOGIC DISORDERS

Acromegaly

Acromegaly is a disorder whose clinical manifestations result from excessive growth hormone (GH) and insulin-like growth factor-1 production, usually a result of a pituitary adenoma. Rarely, carcinoid and pancreatic islet cell tumors can secrete a GH releasing factor that leads to acromegaly. Although patients manifest enlargement of the tongue, enlargement of the other organs of the digestive system is unusual, and hepatosplenomegaly thus would warrant further investigation. [146] It is generally accepted that patients with acromegaly are at greater risk for colorectal neoplasia, although this idea is controversial, and therefore should undergo screening by colonoscopy after the age of 50. [147], [148]

When GH secretion cannot be normalized by ablation of the adenoma, octreotide can control symptoms. As a consequence of the chronic use of the somatostatin analog, patients are at increased risk of developing gallstones; for this reason, reducing the lithogenicity of the bile with ursodeoxycholic acid may be considered. [149]

Addison Disease

Addison disease results from insufficient production of both mineralosteroids and corticosteroids by the adrenals. Gastrointestinal symptoms are common in untreated Addison disease. The prominent clinical features include anorexia, vomiting, weight loss, abdominal pain, apathy, hypotension, hyponatremia, and hyperkalemia. [150] Mucosal and cutaneous pigmentation occur in primary adrenal failure. Addison disease of autoimmune etiology is associated with atrophic gastritis, antibodies against K^+-H^+-ATPase and intrinsic factor, and uncommonly achlorhydria and pernicious anemia. Subclinical Addison disease may present with increased transaminase levels. [151]

Cushing Syndrome

Overproduction of adrenal corticosteroids caused by oversecretion of corticotropin from a pituitary adenoma, or ectopically produced in small cell lung cancers, leads to the typical redistribution of fat (buffalo hump, central obesity, cushingoid facies) that identify Cushing syndrome. Gastrointestinal manifestations, other than transaminase elevations from hepatic steatosis, are unusual. However, an uncommon type of a corticotropin-independent, food-dependent Cushing syndrome deserves comment. Hypercortisolism in these patients is induced by an overexpression of gastric-inhibitory polypeptide (GIP) receptors in adrenal adenomas and adrenal hyperplasia. Eating stimulates GIP secretion, GIP binds to the receptors in the adrenal gland, and abnormal cortisol synthesis and secretion are initiated. [152]

Diabetes Mellitus

Diabetes mellitus is a common metabolic disease resulting in primary hyperglycemia. Insulin-dependent diabetes mellitus (IDDM) is caused by a genetically mediated immune destruction of the pancreatic ß-cells, whereas the eight times more common non–insulin-dependent diabetes mellitus (NIDDM) is caused by insulin-resistance at the effector cell. NIDDM is more prevalent in minority groups, particularly Hispanic groups of Mexican origin, Native Americans, and some Asian-Pacific Islander groups. [153] Diabetics are always at risk of acute complications resulting from uncontrolled hyperglycemia, such as ketoacidosis or hyperosmotic coma and infections. After one or two decades of overt disease, complications often develop. Arteriosclerosis may result in myocardial infarction, stroke, or vascular compromise of the extremities. Other frequent complications include nephropathy with resulting renal failure, retinopathy progressing to blindness, and various sensory or motor neuropathies. For a variety of inadequately understood social, genetic, and cultural reasons, diabetes-related morbidity and mortality are also more common among minorities. [153] Abdominal complaints (Table 128-3) are common, nonspecific to diabetes, and may not relate directly to the diabetes. [154]

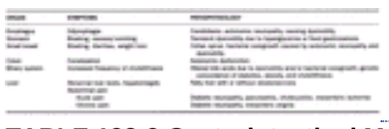

TABLE 128-3 Gastrointestinal Manifestations of Diabetes Mellitus

Acute abdominal pain associated with nausea and vomiting is a frequent accompaniment of acute diabetic ketoacidosis and resolves with normalization of blood sugar. Persistent, severe abdominal pain may signal that the ketoacidosis is the consequence of some other serious intra-abdominal process. Acute pancreatitis, cholecystitis, intestinal ischemia, appendicitis, and diverticulitis always must be considered.

Later stages of the disease may entail gastrointestinal symptoms of a chronic and irreversible nature. Many of the chronic symptoms are believed to result from visceral autonomic neuropathy, which is thought to be a consequence of a metabolic dysfunction of peripheral nerves caused by prolonged hyperglycemia. [155] Studies in which blood sugar is maintained within a normal range by using frequent daily administration of insulin demonstrated a delay in the onset of neuropathy and improvement of established neuropathy. [156]

Although clinical manifestations of esophageal dysfunction, often mild pyrosis, and dysphagia are unusual, abnormal esophageal motor function is common in both IDDM and NIDDM. [157], [158] Esophageal dilation, reflux, and delayed esophageal emptying may be seen radiographically. Changes demonstrated manometrically may include feeble peristaltic pressure waves that are at times multipeaked or multiphasic, increased frequency of nonperistaltic contractions, and decreased lower esophageal sphincter pressure.

New-onset odynophagia in the diabetic patient should suggest the presence of *Candida* esophagitis. Oral thrush accompanies *Candida* esophagitis in no more than 50% of patients, but when present it is an indication for an empirical trial of an antifungal agent such as fluconazole. If odynophagia persists, or if oral thrush is not present, diagnostic upper endoscopy should be undertaken. The most common visual finding is that of cream-colored plaques scattered throughout the esophagus. The diagnosis is made through endoscopic biopsy and brushing of the plaques. Other causes of odynophagia in the diabetic patient include herpes simplex esophagitis and esophageal spasm. Rarely, severe gastroesophageal reflux disease (GERD) secondary to decreased lower esophageal sphincter (LES) pressure can present with odynophagia.

Nausea and vomiting are common in patients with uncontrolled hyperglycemia and do not necessarily mean that the patient has the fixed vagal autonomic neuropathy seen in IDDM patients with gastroparesis diabeticorum. [158] Hyperglycemia, even in healthy volunteers using the glucose clamp technique, disrupts normal myoelectric activity in the stomach. There is an inverse relationship between gastric emptying and blood glucose concentration. [159] These alterations in gastric myoelectric activity result in gastric dilation, slow peristalsis, and delayed gastric emptying. Increased pyloric resistance and small intestinal dysmotility [160] also slow transpyloric flow. The patient's diabetes must be under optimal control before investigations are undertaken for gastroparesis.

Symptoms of gastroparesis include early satiety, bloating, heartburn, persistent nausea, and paroxysmal vomiting. Typically, the vomiting occurs 3 to 4 hours after meals and includes undigested food. Physical examination may demonstrate a succussion splash as well as findings of peripheral neuropathy. Patients are also predisposed to the formation of gastric bezoars from indigestible food. Yet most diabetic patients who have diabetes with abnormalities of gastric emptying have no symptoms. [161] Typical gastroparesis is defined by finding more than 1000 mL of gastric contents after awakening in the morning or by demonstrating a massively dilated stomach on routine abdominal radiographs or upper gastrointestinal series. Endoscopy supports the diagnosis by confirming the absence of structural gastric outlet obstruction and revealing a substantial gastric residual after an overnight fast. Other causes of gastroparesis that may be more treatable, such as hypocalcemia, hypothyroidism, or medications (e.g., narcotics, tricyclic antidepressants), must be excluded. Subtle gastric emptying dysfunction can be documented by gastroscintiscanning but must be interpreted with caution as abnormalities are found commonly in asymptomatic diabetics. [161]

Central to the treatment of diabetic gastric emptying disorders is the optimal normalization of blood glucose with appropriate diet, insulin, or hypoglycemic agents. Modification of concomitantly prescribed medications and correction of any electrolyte abnormalities are also important. In young women with IDDM eating disorders are common, and are associated with noncompliance, underdosing of insulin to achieve weight loss, and poor metabolic control. Symptoms can mimic gastroparesis. If the eating disorder is not treated progression of microvascular complications is more common. [162]

Therapy with prokinetic agents can be disappointing in advanced gastroparesis. The central dopaminergic and peripheral cholinergic effects of metoclopramide to accelerate gastric emptying may be short-lived because of tachyphylaxis. Although not available in the U.S., domperidone (up to 20 mg four times daily) can have longer-lasting improvement in symptoms despite a variable effect on tests of emptying, without the risk of the parkinsonian side effects of metoclopramide. [163] Although erythromycin improves gastric emptying in diabetic patients, [164] it has not been helpful in the long-term management of gastroparesis. Part of the unimpressive response to oral prokinetic agents may be due to the necessity for drugs to empty into the small intestine in a timely manner to achieve adequate blood levels. Surgery to improve gastric drainage should not be considered. Repeated measurements of gastric emptying are not useful because they do not discriminate well between symptomatic and asymptomatic patients and do not predict the response to treatment. [165]

Diarrhea and fecal incontinence are common complaints in advanced IDDM. [166] The diarrhea is watery, painless, and commonly nocturnal. It can remit after days or months, but recurrence is frequent. Although intestinal autonomic neuropathy may be the cause in as many as 50% of cases, other, more treatable, causes must be excluded. If steatorrhea is present, celiac disease, which is found more commonly in patients with IDDM, can be screened for with antiendomysial antibodies. [167] Pancreatic insufficiency and bacterial overgrowth also should be considered in the differential diagnosis. Fecal incontinence is commonly due to anal sphincter dysfunction and decreased rectal sensation, [168] but a flexible sigmoidoscopy will exclude proctitis.

Once other causes have been cleared, idiopathic diabetic diarrhea is treated with good glucose control, opiates, and bulk-forming agents containing psyllium. Some patients may improve with clonidine hydrochloride, an a_2-adrenergic agonist, which possibly stimulates an increase in intestinal fluid absorption by enhancing adrenergic activity; [169] however, this medication may induce hypotension. Other patients with suspected bacterial overgrowth may respond to cycled antibiotic therapy. Diarrhea control and biofeedback training [170] may provide complete or partial relief of fecal incontinence.

Severe constipation associated with colonic motor abnormalities [171] occurs in 20% of patients with diabetes and neuropathy. The onset of constipation is often insidious. Management includes the use of a variety of nonstimulant laxatives.

Diabetics can develop chronic abdominal pain secondary to thoracic radiculopathy. The pain is present constantly, is unilateral, and may or may not be associated with paresthesia or hypesthesia. Electromyographic examination may provide evidence of impairment of thoracic or lumbar nerve roots. Antidepressant drugs such as amitriptyline or desipramine may help control painful diabetic neuropathy. [172]

Diabetes may lead to a large, poorly functioning gallbladder that has a predilection for cholelithiasis. [173] Contrary to previous assumptions, patients with diabetes with acute cholecystitis may not have a substantially increased risk of complications compared with the general population. [174] Thus, diabetes mellitus is not an indication for prophylactic cholecystectomy.

Hepatomegaly and fatty liver are frequent findings, especially in diabetics with poorly controlled blood sugar, hyperlipidemia, and obesity. In a minority of such patients nonalcoholic steatonecrosis can develop, presenting with mild elevation of transaminases. Progression to cirrhosis is recognized, but weight reduction and diabetes control can normalize liver tests. [175]

Endometriosis

Endometriosis is defined as the presence of endometrial glands and stroma outside of the uterine cavity and musculature. The disorder is common to women during the years they menstruate, and it is associated with severe perimenstrual lower abdominal pains and infertility. Since bowel function is commonly abnormal around the menstrual period, the pains can be difficult to distinguish from irritable bowel syndrome or diverticulitis. Implants of endometrial tissue on the gastrointestinal tract are uncommon and usually asymptomatic. Most endometriosis takes the form of plaques of tissues on the serosal surface of the bowel lying in the pelvis in close proximity to the uterus and ovaries.

When intestinal endometriosis does cause symptoms, the symptoms can mimic a diversity of gastrointestinal illness. [176], [177] Deeper infiltration of the bowel wall can lead to obstruction of either the small or large bowel. Penetration of the mucosa can cause lower gastrointestinal bleeding, which may occur only during menstruation, but most patients do not characterize symptoms as cyclic. Rarely, perforation is reported. Radiographic and endoscopic findings may be difficult to distinguish from inflammatory bowel disease, diverticulitis, or colorectal cancer. Treatment is surgical and may

require bowel resection if implants are deep. [176], [177]

Hyperparathyroidism

Hyperparathyroidism is a disorder of calcium and phosphate metabolism due to the excess secretion of parathyroid hormone. Primary hyperparathyroidism is caused by adenomatous or hyperplastic change in the parathyroid gland and may be associated with inherited multiple endocrine adenopathies (see " Multiple Neoplasia Syndromes"). Rarely, carcinomas secrete a parathyroid-like hormone that can induce a similar syndrome. Primary hepatic tumors have been reported to do this more commonly. [178] Secondary forms of the diseases occur when there is a tendency toward hypocalcemia, such as chronic renal failure. Symptoms that are probably consequences of high serum calcium concentrations include anorexia, nausea, vomiting, constipation, and abdominal pain. Hypercalcemia induces gastric hypersecretion, and likely predisposes to peptic ulcer formation. [179] Pancreatitis can develop when hypercalcemia is moderate to severe. [180]

Hypoparathyroidism

Hypoparathyroidism, or low serum ionized calcium from whatever cause, can lead to neuromuscular irritability. Gastrointestinal manifestations can include abdominal pain, intestinal tetany, diarrhea, steatorrhea, and intestinal pseudoobstruction. [181] The steatorrhea may be secondary to pancreatic insufficiency due to insufficient endogenous cholecystokinin release following a meal. Hypoparathyroidism is present in most patients with the autosomal recessively inherited autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome. Associated manifestations include adrenocortical failure, gonadal failure, gastric parietal cell atrophy and pernicious anemia, and malabsorption with steatorrhea. [182]

Hyperthyroidism

Excessive circulating thyroid hormone causes hyperthyroidism. Although several disorders can induce this syndrome, 60% to 80% of the cases are a consequence of Graves disease, which is of autoimmune etiology. The symptoms of hyperthyroidism include nervousness, palpitations, heat intolerance, excessive perspiration, fatigue, weakness, dyspnea, and eye complaints. Despite having an enhanced appetite and hyperphagia, patients usually have weight loss because of their hypermetabolic state. [183] The most common physiological effect on the gastrointestinal system is an alteration in intestinal, but not gastric, motility, resulting in shortened small bowel and colonic transit time. This, as well as the increased consumption of fat, may result in steatorrhea and increased stool frequency, but rarely frank watery diarrhea. [184] Because of the higher prevalence of hyperthyroidism and irritable bowel syndrome in women than in men, the diagnosis of hyperthyroidism should receive strong consideration when a new diagnosis of irritable bowel syndrome is contemplated, especially in female patients. There is also a high incidence of atrophic gastritis and hypochlorhydria or achlorhydria. [185] Approximately 30% of patients have autoantibodies to the gastric parietal cell.

Moderate to severe hyperthyroidism can be associated with hepatic dysfunction. Increases in blood alkaline phosphatase, transaminases, and bilirubin have been attributed to liver injury. In many cases, passive congestion of the liver secondary to heart failure could be the underlying mechanism. [186] Autoimmune-type thyroid diseases can flare up when chronic hepatitis is treated with interferon. [187] Propylthiouracil, used in the treatment of thyrotoxicosis, can induce serious liver damage. [188]

Hypothyroidism

Hypothyroidism results from a deficiency of thyroid hormone. Most cases are a consequence of thyroid gland dysfunction resulting from Hashimoto thyroiditis or therapy of hyperthyroidism. Symptoms include weakness, dry skin, swelling of the extremities, mental aberrations, coarse voice, paresthesias, and muscle cramps. Patients have a decrease in metabolism and experience anorexia with moderate weight gain. Motility is slowed throughout the gastrointestinal tract. Dysphagia and heartburn may develop related to decreased esophageal peristalsis and diminished lower esophageal sphincter pressure. [189] Intestinal transit is slowed; it usually manifests as constipation and abdominal distention. Rarely, intestinal pseudoobstruction or megacolon results. [190] The gallbladder also may dilate and contract poorly. Other gastrointestinal manifestations include impairment in salivary, gastric, intestinal, and pancreatic secretion. [191]

Ascites, usually having a high protein concentration, is a rare complication of myxedema. It can be associated with histological changes in liver architecture suggestive of central congestive fibrosis, without congestive heart failure. [192] The ascites resolves after appropriate thyroid replacement therapy. [193]

GRANULOMATOUS DISEASES

Granulomas are dynamic, usually focal inflammatory processes composed of macrophages and other inflammatory cell types. Many factors such as infectious agents, silica, metals complexed to macromolecules, and immune complexes can evoke a granulomatous response. Even when there is a known nidus, the cause of a granuloma is not always evident on histological examination. Granulomas caused by an antigen that induces a delayed hypersensitivity reaction are called hypersensitivity granulomas. Diseases such as schistosomiasis, leprosy, tuberculosis, histoplasmosis, and berylliosis are hypersensitivity granulomas. Lesions evoked by substances that do not stimulate a hypersensitivity response are termed foreign body granulomas; examples are granulomas that develop in response to mineral oil and talc.

Many infectious and noninfectious diseases are associated with granuloma formation in the liver and intestines (Table 128-4). [194], [195] The significance of these associations is complicated by the observation that granulomas are present in 3% to 10% of liver specimens obtained at abdominal surgery or autopsy. The etiology of granulomas can, at times, be ascertained when bacteria, ova, or mineral crystals are identified within individual lesions. Some granulomas have distinctive morphology, such as the ring granuloma that is commonly found in hepatic Q fever, although ring granulomas have been described in other conditions rarely. [196], [197] Serologic testing, culture of the involved tissue, or clinical presentation may provide the diagnosis in other circumstances.

TABLE 128-4 Some Conditions Associated with Granulomatous Inflammation of the Liver (L) or Intestines (I)

In industrialized societies, the illnesses most commonly associated with hepatic granulomas are sarcoidosis and tuberculosis (discussed subsequently) (Table 128-5). Primary biliary cirrhosis, drug-induced liver disease, and occasionally other primary liver diseases account for some of the remaining cases. In many patients, it is not possible to identify an etiologic factor or an associated disease. Patients may be asymptomatic or may present with fever, fatigue, hepatosplenomegaly, and jaundice. Granulomatous hepatitis is suggested by a disproportionately high alkaline phosphatase with a normal biliary system on ultrasound. Diagnosis requires a liver biopsy that is cultured and examined histologically. The process rarely progresses to extensive hepatic fibrosis and cirrhosis, although sarcoidosis can lead to portal hypertension.

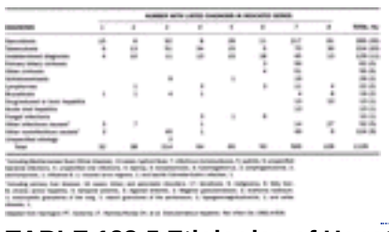

TABLE 128-5 Etiologies of Hepatic Granulomas in Several Reported Series from Around the World

Causes of granulomatous inflammation of the intestines are less well characterized (see Table 128-4). In the United States, Crohn's disease and lymphoma are overwhelmingly the most frequent diagnoses, but a rare case of intestinal tuberculosis may be encountered. All these diseases can have a chronic course, presenting with abdominal pain, fever, fatigue, weight loss, diarrhea, and gastrointestinal bleeding. All have a predilection for the terminal ileum and can result in intestinal strictures. [198]

When a specific cause of the granulomatous inflammation is defined, treatment is directed at eliminating the offending agent. Lesions that defy diagnosis or that are of unknown cause present special problems. Many patients are asymptomatic and require no therapy. Unusual conditions such as idiopathic granulomatous hepatitis frequently respond to corticosteroid administration.

Sarcoidosis

Sarcoidosis is a systemic disorder that is characterized by noncaseating granulomas in pathological specimens. The age-adjusted annual incidence of sarcoidosis in the United States is 10.9/100,000 for Caucasians and over three times more common in African Americans. In addition the disease affects blacks more acutely and more severely than people of other races. Although the cause of sarcoidosis is unknown, clustering of cases has suggested exposure to a common infectious or environmental agent. Genetic factors appear to play a part in the pathogenesis as it is likely that the host develops an exaggerated cellular immune response and the formation of granulomas when exposed to a variety of antigenic stimuli. [199]

Although the most common sites of involvement are the lungs and the intrathoracic lymphatic system, evidence of the disease will be found elsewhere in 40% to 70% of cases. Hepatic sarcoidosis is usually manifest by fever, hepatomegaly, and elevated alkaline phosphatase, and may be the most obvious clinical manifestation when pulmonary disease is subtle. [199], [200] Typically the noncaseating granulomas are scattered throughout the liver, but confluent granulomas may be present. In the patient with severe hepatic sarcoidosis and confluent granulomas scarring, portal hypertension, and hepatic dysfunction can result. A chronic cholestatic syndrome mimicking primary biliary cirrhosis is due to a granulomatous cholangiopathy with consequent ductopenia. Imaging studies may be normal, show a diffuse hepatopathy, demonstrate nodular lesions that can be mistaken for malignancy, and rarely show extrahepatic biliary obstruction due to lymphadenopathy or bile duct strictures. [201], [202] Treatment commonly includes steroids, but progression to cirrhosis and liver failure many ensue. Liver transplantation can be considered, but recurrence of sarcoidosis in the allograft is the norm. [203]

Although symptomatic disease in the liver, spleen, and abdominal lymphatics is common in sarcoidosis, involvement of the gastrointestinal tract is rare. The stomach is the most common site and may be defined by thickened gastric folds, nodularity, ulcers, or erosions. [204] As small bowel and colon disease is so rare, the demonstration of typical granulomatous ileocolitis in a patient with known sarcoidosis should still be followed and treated as presumed Crohn's disease.

Tuberculosis

Approximately one third of the world's population is infected with the causative organism of tuberculosis (TB), *Mycobacterium tuberculosis,* with over 8 million new cases reported annually. Despite an average annual decline in incidence in the United States of 5.8% per year from 1953 to 1985, the number of new cases of tuberculosis increased 20% over the next 7 years as a result of the human immunodeficiency virus/ acquired immunodeficiency syndrome (HIV/AIDS) epidemic, increased immigration, and diminished TB control. [205] Although extrapulmonary TB occurs in about 20% of cases, in the United Stated the gastrointestinal tract is involved in only 2%. [206]

TB may involve any portion of the gastrointestinal tract. At presentation abdominal pain, fever, and weight loss are the most common symptoms, and have usually been present for months. A mass is palpable in the right lower quadrant in 25% of cases. In the United States Crohn's disease, colon cancer, lymphoma, and even amebiasis will be considered before TB. The diagnosis of tuberculosis should be considered if:

- the disease has been documented elsewhere in more typical locations (e.g., the chest radiograph shows characteristic lesions, exudative ascites and peritoneal disease are recognized, tubercular tuboovarian disease is present)
- the patient is considered high risk (e.g., malnourished, immigrant from a developing country, patient with AIDS, alcoholic patient).

Tubercular granulomas may have distinct histological features: they tend to coalesce; they often contain giant cells that are numerous and large; and caseation, although rare in the liver and intestine, should suggest tuberculosis. In the unusual case, histological staining, polymerase chain reaction, or culture may identify acid-fast bacilli. Treatment follows accepted protocols. [207], [208] and [209]

Peritoneal disease with ascites is common in countries in which TB is endemic. In the United States TB peritonitis is associated with poverty, homelessness, alcoholism, and malnutrition. Abdominal distention, fever, weight loss, and abdominal pain in a patient with the appropriate risk factors should raise the suspicion for the disease. The chest x-ray will be abnormal in 50%, but active pulmonary TB will be present in only 15%. Paracentesis will usually show a high protein (>2.5 g/dL) fluid with a low albumin gradient (<1.1g/dL). Examination of the fluid for acid-fast bacilli is positive in less than 3% of cases, and cultures are positive in 20%. Adenosine deaminase activity greater than 33 U/L has excellent sensitivity and specificity. In nonendemic countries laparoscopy with peritoneal biopsies may be needed for diagnosis, whereas a therapeutic trial is commonly employed in areas with a higher prevalence of TB. [210]

HEAVY METAL TOXICITY

Lead Poisoning

Lead poisoning remains the most common form of heavy metal intoxication, often producing vague, nonspecific, and transient symptoms. Inner-city children in major metropolitan areas are at particularly high risk because of lead-based paint ingestion. The diagnosis should be considered in patients with abdominal complaints and a history of occupational or environmental exposure, such as ingestion or removal of lead-based paints, manufacture of batteries or jewelry, welding, automobile radiator repair, and eating from painted dishes acquired abroad. [211]

Common symptoms include recurrent severe abdominal pain (lead colic), oral ulcers, constipation, stocking-glove paresthesias, psychiatric symptoms, and a metallic taste in the mouth. Physical findings include a gingival lead line (absent in edentulous patients) and peripheral neuropathy. Anemia and renal dysfunction also may be evident at presentation. [212] Mild acute hepatitis that responds to chelation therapy has been described in the setting of lead intoxication. [213] Lead inhibits enzymes involved in the synthesis of heme, and secondary porphyria, characterized by elevated ALA and other porphyrin metabolites in the urine, may result.

Blood lead concentrations are an unreliable predictor of body lead stores, as they reflect only recent exposure. The diagnosis of lead intoxication is best established by measuring 72-hour urine lead levels after administration of calcium disodium edetate. [212] Treatment of lead poisoning with parenteral [204] or oral [214] chelating agents is usually successful if the diagnosis is made in time.

Arsenic Poisoning

Arsenic poisoning is endemic in many parts of the world, including North America, as a result of environmental contamination. Arsenic compounds continue to be used commercially, particularly in the preservation of wood and the manufacture of glass and metal. [215]

Acute arsenic poisoning results in a reversible inactivation of sulfhydryl-containing enzymes. Cellular oxidative processes are blocked and tissue hypoxia ensues. Patients present with severe colicky abdominal pain, nausea, vomiting, profuse diarrhea, malodorous ("garlicky") breath, dysphagia, hepatomegaly, jaundice, and circulatory collapse. Quantities of 100 to 300 mg may be fatal in an adult.

Quantitative measurement of 24-hour urinary arsenic excretion is the only reliable test to confirm arsenic poisoning. Treatment includes gastric lavage, chelation therapy (e.g., British anti-Lewisite [BAL, dimercaprol] or D-penicillamine), and cardiorespiratory support. [216], [217]

Chronic arsenic toxicity often manifests as nonspecific symptoms, including weakness, nausea, diarrhea, or constipation. Macular skin pigmentation, leukoderma, keratotic lesions of the palms and soles, pancytopenia, edema, peripheral vascular disease, neuropathy, cirrhosis and accompanying presinusoidal portal hypertension may appear alone or in combination. [218] The diagnosis of chronic arsenic intoxication is made by Gutzeit or Reinsch tests or by measuring arsenic levels in tissue samples (e.g., hair, nails). An association with cutaneous, hematologic, respiratory, and hepatic malignancies (angiosarcoma) also has been suggested. [219]

Gold

Gold preparations (e.g., gold sodium thimalate, auranofin) have long been used as disease-modifying treatment of rheumatoid arthritis. Adverse effects include aplastic anemia, proteinuria, rash, stomatitis, and diarrhea. [220] The last effect is particularly common with auranofin, an oral preparation that increases intestinal permeability and decreases intestinal transit time.

Rarely, gold can induce a severe enterocolitis, with markedly ulcerated small and large intestinal mucosa. The clinical picture can mimic ulcerative jejunoileitis seen in celiac sprue, or small intestinal lymphoma. The clinical course may be protracted, and if the relationship to gold therapy is not appreciated, a need for laparotomy. Gold should be withdrawn as soon as the condition is recognized. Corticosteroid therapy is of uncertain benefit. [221] Reversible cholestatic hepatitis also has been reported. [222]

HEMATOLOGIC DISORDERS

Hemoglobinopathies

Sickle cell anemia is an autosomal recessive disease of hemoglobin synthesis (hemoglobin SS). Eight percent of the African-American population of the United States are heterozygotes; hence, as many as 15 of every 100,000 African Americans may be affected. Under conditions of low oxygen tension, erythrocytes containing hemoglobin S-S deform (sickle), and become lodged in capillary beds, causing widespread venous congestion, thrombosis, and microinfarction and leading to the clinical vasoocclusive “crisis.” [223]

In addition to diffuse pains throughout the long bones of the body, abdominal pain and intestinal ileus are common during the acute crisis. It is often difficult to distinguish a sickle cell crisis from other gastrointestinal emergencies such as cholecystitis, appendicitis, bowel infarction, and bowel obstruction. Moreover, these intra-abdominal illnesses themselves may provoke a sickle cell crisis. The absence of bone or pleuritic pain is suggestive of a primary intra-abdominal cause. Sickle cell crises often resolve in less than 4 days. Hence, abdominal symptoms of longer duration also should raise the possibility of a primary abdominal illness. [224] Endoscopy and computed tomography (CT) scan of the abdomen can be helpful in distinguishing between the many potential causes of pain. [225]

The liver and spleen are frequently involved in sickle cell anemia. Acute crisis can selectively affect the liver with hepatic infarcts, causing pain, fever, and transaminase elevation. Chronic sickling causes cholelithiasis, cholecystitis, and chronic passive congestion. The common use of hypertransfusion programs to lower the risk of recurrent stroke places these patients at high risk of chronic hepatitis C and hemosiderosis. [226] A combination of these factors can lead to progressive liver injury, with significant fibrosis and cirrhosis developing by adulthood. [227] Splenomegaly is frequent in the early stages of the disease, but “autosplenectomy” caused by repeated splenic infarctions often results in a shrunken, fibrotic, or calcified spleen. Hyposplenism will be documented by the presence of Howell-Jolly bodies in the peripheral blood smear and signals an increased risk from encapsulated organisms, such as pneumococci and *Bacteroides.* [223]

Compared with hemoglobin S, patients with hemoglobinopathy C may have similar but milder attacks. In this disease, autosplenectomy is less common, and splenomegaly usually persists into adulthood. The risk for hepatobiliary disease remains high.

Patients with ß-thalassemia are characterized by a relative overproduction of a-globulin chains, consequent ineffective hematopoiesis, and severe anemia. Current therapy has depended on transfusion therapy. Iron overload of tissue, which is fatal if not treated, is the most important complication of this disease. In patients not receiving transfusions the enormous erythroid expansion leads to abnormally regulated iron absorption and increases in body iron burden ranging from 2 to 5 g/y. Regular transfusions may double this burden. [228] In the absence of chelating therapy iron progressively accumulates in the liver, heart, and endocrine organs, with resulting dysfunction. Iron-induced liver disease, often aggravated by chronic hepatitis C, is a common cause of death in adults. This can be delayed by adequate desferrioxamine therapy monitored by frequent quantitative measurement of liver iron stores with liver biopsy. [229]

Hemolytic Uremic Syndrome/Thrombotic Thrombocytopenic Purpura

The hallmarks of the hemolytic uremic syndrome (HUS) are hemolysis, thrombocytopenia, and acute renal failure. Although most common in children, all age groups are affected. Indeed, thrombotic thrombocytopenic purpura (TTP) is likely the same illness manifesting with fever and central nervous system sequelae in patients over 40 years of age. Both are now grouped under the thrombotic microangiopathies. Antecedent gram-negative enteric infections with *Salmonella, Shigella,* and *Campylobacter* species have been associated with HUS/TTP. [230], [231] In the past decade, verotoxin-producing strains of *Escherichia coli,* especially serotype O157:H7, appear to be responsible for most reported cases. It must be remembered that only a small minority (5% of patients with symptomatic enteritis in a recent outbreak) of patients with these food-borne illnesses develop HUS/TTP. [232] TTP has also been reported in patients undergoing solid organ transplantation, associated with the use of cyclosporin or tacrolimus. [233]

The pathophysiology connecting these enteric infections with the hematologic consequences is poorly understood. Endothelial cell injury (perhaps mediated by endotoxins or cytokines) followed by intravascular coagulation and, finally, thrombotic microangiopathy in the glomerulus and the gastrointestinal mucosa are consistent features (Fig. 128-5) [234], [235] Similar thrombotic angiopathy has been reported in gastric antral vascular ectasia (GAVE) syndrome (see Chapter 130). Thus, TTP should be included in the differential diagnosis of cases with endoscopic changes of GAVE and in whom biopsies show microscopic thromboses. [236]

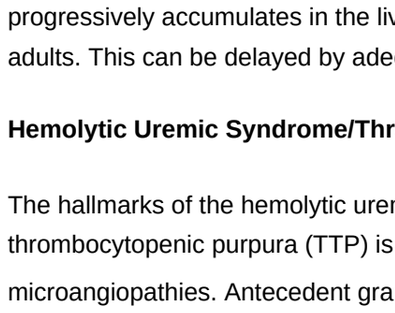

FIGURE 128-5. Colonic biopsy specimen from a patient with hemolytic uremic syndrome shows intravascular coagulation and thrombotic microangiopathy. (Hematoxylin and eosin stain; original magnification ×16.)

The spectrum of gastroenterologic symptoms ranges from gastroenteritis, to segmental colitis mimicking Crohn’s disease or ischemia, to fulminant colitis with toxic megacolon or colonic perforation. Bowel disease almost always precedes the development of HUS. [235] The disease is usually self-limited, although the course may be prolonged, and fatalities occur. There is now evidence that early treatment of the enteric infection with antibiotics increases the risk of developing HUS/TTP, and should be avoided. [237] Treatment focuses on general support and dialysis when needed. In adults with neurological changes (e.g., TTP) plasmapheresis can be life-saving. [234], [235]

Hereditary Spherocytosis

Hereditary spherocytosis is a disease of autosomal dominant inheritance characterized by small, fragile, spherical erythrocytes. Hemolysis leads to indirect hyperbilirubinemia, jaundice, and

splenomegaly in infancy. Pigment gallstones may be evident even in childhood. Splenectomy has been advocated for children and young adults, but it is of doubtful benefit to older, well-compensated patients. [238]

Hypercoagulable States

Hypercoagulability is an important cause of gastrointestinal morbidity. Spontaneous thrombosis of the mesenteric veins can cause intestinal ischemia and infarction (see Chapter 131) of the portal vein can lead to portal hypertension and variceal hemorrhage (see Chapter 33 and Chapter 147). Infarction of the hepatic veins can result in ascites and the Budd-Chiari syndrome (see Chapter 46). Oral contraceptives, pregnancy, SLE, myeloproliferative disorders (discussed later in the chapter), cancer, and surgery [239] all are associated with a hypercoagulable state and a consequent propensity for venous thrombosis. Antithrombin III deficiency [240] and protein C deficiency are inherited (autosomal dominant) disorders associated with recurrent venous thrombosis. Factor V Leiden mutation resulting in thrombophilia attributable to activated protein C resistance is a common genetic difference that has been associated with small bowel infarctions, [241] hepatic vein occlusion during pregnancy, [242] and an increased risk of venous thrombosis in patients with inflammatory bowel disease. [243] Once the cause is identified, most affected patients require lifelong therapy with warfarin to prevent recurrent vascular catastrophe.

Hypocoagulable States

Deficits of Coagulation Factors Deficiencies of coagulation factors may be inherited or acquired and when severe are associated with bleeding tendencies. The best known of the inherited factor deficits is hemophilia A, an X-linked disorder of factor VIII synthesis. Other inherited forms include hemophilia B (Christmas disease or factor IX deficiency) and factor XI deficiency. Gastrointestinal bleeding occurs in all these diseases. It may be mucosal, intramural, or intra-abdominal and may involve virtually any part of the gastrointestinal tract. Bleeding can be spontaneous or follow trauma or surgery. Upper gastrointestinal hemorrhage has multiple potential causes in these patients, including varices, because of the increasing incidence of chronic liver disease from blood-borne hepatitis viruses. Endoscopy can be undertaken safely in hemophiliac patients after correction of factor VIII level to 0.4 U/mL. [244, 245] Acquired or iatrogenic coagulation factor deficiencies are seen commonly as a consequence of vitamin K deficiency, heparin or warfarin therapy, or liver disease. Another cause is disseminated intravascular coagulation. In conditions such as SLE and cancer, circulating anticoagulants of endogenous origin can appear and interfere with normal coagulation.

Platelet Abnormalities Platelet defects also may result in severe bleeding diatheses that manifest as gastrointestinal bleeding. von Willebrand disease, the Bernard-Soulier syndrome, and Glanzmann thrombasthenia are inherited diseases of platelet adhesion and aggregation associated with prolonged bleeding times. Aspirin and other drugs (e.g., penicillins, cephalosporins) interfere with platelet function by irreversibly inhibiting COX-1 activity and prolong the bleeding time for up to 5 to 7 days. [246] Patients should be instructed to avoid the use of these drugs before and after elective endoscopic surgery and liver biopsy. In contrast, the effect of other NSAIDs on platelet function is reversible in 1 to 2 days, and endoscopic surgery can be performed safely shortly after discontinuing the drug.

Plummer-Vinson-Kelly Syndrome

Dysphagia, esophageal webs, and iron deficiency anemia are characteristic of Plummer-Vinson-Kelly syndrome. Middle-aged women are most commonly affected. Glossitis, dyspepsia, atrophic gastritis, diarrhea, hoarseness, and paresthesias are frequently present. [247] An association with postcricoid esophageal cancer has been reported. [248] The syndrome is uncommonly seen, which may reflect the improved identification and treatment of iron deficiency anemia.

Hypopharyngeal or esophageal webs of squamous epithelium cause the dysphagia. Inflammation is frequently present in the submucosa and may contribute to the dysphagia by producing fibrosis. The webs usually are thin (less than 2 mm thick) and will only be visualized when the esophagus is fully distended during esophageal cineradiography or endoscopy.

Although the significance of iron deficiency anemia with regard to the pathogenesis of Plummer-Vinson-Kelly syndrome is uncertain, iron and vitamin supplementation is indicated. Therapy includes dilation of the webs and fibrous tissue to alleviate the dysphagia. A careful endoscopic evaluation of the hypopharynx and upper esophagus also should be undertaken to exclude cancer.

METABOLIC DISORDERS

Capillary Leak Syndrome

Capillary leak syndrome is an episodic illness of variable severity characterized by increased small vessel permeability and fluid shifts. [249] Its association with systemic toxicity, sepsis, and administration of a number of recombinant protein medications, including interleukin-2 and granulocyte-macrophage colony-stimulating factor (GM-CSF), supports the contention that it is mediated directly by cytokines. [249, 250] In addition to hemoconcentration, hypotension, and a monoclonal gammopathy, patients can experience severe nausea, vomiting, and diarrhea secondary to impaired fluid absorption in the gastrointestinal tract. Therapy with aminophylline and terbutaline has been reported to ameliorate the syndrome in some patients. [251]

Systemic Amyloidoses

The systemic amyloidoses are a group of diseases characterized by the widespread extracellular deposition of insoluble fibrillar proteins. Classification of amyloidosis is based on the precursor plasma proteins that form the fibril deposits. Two types of primary systemic amyloidosis are recognized; AL (immunoglobulin-light-chain–related in patients with plasma cell dyscrasia) and ATTR (familial transthyretin-associated). Secondary amyloidosis is formed from serum amyloid A, an acute-phase reactant formed in response to inflammation. It is termed AA and caused by chronic infectious or inflammatory diseases, such as tuberculosis and rheumatoid arthritis. [252]

AL amyloidosis has the widest spectrum of organs infiltrated, with the kidney and heart most commonly involved. The gastrointestinal tract may be involved at any site. Infiltration of the tongue results in macroglossia in as many as 20% of cases, a feature that is uncommon in ATTR and AA forms of the disease. The esophagus is infiltrated in two thirds of patients, but clinical symptoms are uncommon. [253] Gastric infiltration can produce prominent gastric folds, but resulting gastric outlet obstruction, ulcer, and bleeding are uncommon. [254]

Amyloid can accumulate between the muscle layers of the intestine, causing coarsening of the valvulae conniventes (Fig. 128-6; see also Color Fig. 128-6). Mesenteric retraction and intestinal obstruction also can result from amyloid infiltration. Pseudoobstruction and autonomic dysfunction can lead to stasis, bacterial overgrowth, and malabsorption in some patients. [255] This is also a common feature of the ATTR type. Intestinal ischemia resulting in pain, enterocolitis, bleeding, and infarction also has been reported. [256]

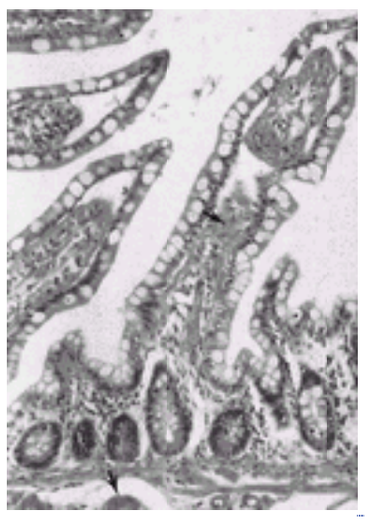

FIGURE 128-6. (See Color Fig. 128-6.) Amyloid infiltration of the small intestine (*arrows*). (Congo red stain; original magnification ×200.)

Hepatomegaly is common in AL amyloidosis but not splenomegaly. Hepatosplenomegaly is more common in AA amyloidosis, but liver failure and portal hypertension are uncommon. [257] Ascites may result from nephrotic syndrome-induced hypoproteinemia. Pancreatic involvement occasionally produces exocrine pancreatic insufficiency and steatorrhea.

The diagnosis of amyloidosis is based upon clinical suspicion and tissue biopsy of the affected organ. A safe and simple procedure, obtaining a sample of subcutaneous fat, has replaced the blind rectal biopsy recommended in the past. [252] Treatment of the underlying disease process, if present, may result in amyloid regression, but this is not the rule. [258]

NEOPLASTIC DISORDERS

Cancer Cachexia

Cancer cachexia, a common manifestation of a variety of advanced neoplastic diseases, is characterized by marasmus with anorexia, early satiety, weight loss, anemia, and edema. [259] Nutritional evaluations find an elevated basal metabolic rate and increased energy expenditure associated with systemic catabolism of muscle and adipose tissue. [260] Such tumor-induced, treatment-related malnutrition is the proximate cause of death in 20% to 30% of patients with cancer, but it also complicates the delivery of adequate antineoplastic therapy and markedly impairs the quality of life.

In exploring the cellular mediators of cancer cachexia, two groups of compounds have been suggested. Materials with hormonelike properties that result in the direct catabolism of host tissues such as endogenous corticosteroids or a lipid-mobilizing factor produced by tumors form one group. [261] The second group is the proinflammatory cytokines such as tumor necrosis factor-a, interleukin-6 (and 1), and interferon-?. [262] Since cytokines are also cellular growth factors, they may also increase tumor proliferation. Treatments aimed at these compounds might slow tumor growth as well as reduce cachexia.

Beneficial outcomes of the treatment of cancer cachexia could be just weight gain, but treatment would be more helpful if there was also an improved state of well being, improved function (Karnowsky index) and perception of quality of life, or improved survival. Simply replacing nutrients via gastrostomy or parenterally has not been helpful. The literature regarding the efficacy of nutrition support in patients with cancer has been critically reviewed, and no clear benefit was found. [263] Megestrol acetate has been shown to improve appetite and modestly increase weight. [264] In a trial both indomethacin and prednisone stabilized weight and the Karnowsky index, while patients treated with placebo worsened. Of interest was an increased survival (510 vs. 250 days) and decreased pain in the indomethacin group compared to both prednisone and placebo. [265] Such trials raise the hope that improving cachexia may not only offer palliative support, but also impact survival.

Consequences of Chemotherapy

Constipation Patients with cancer commonly develop constipation as a consequence of factors such as decreased physical activity, reduced fluid intake, depression, drugs used in treatment, and changes in diet. [266] Effective pain management may lead to the use of potent narcotics, all of which lead to constipation. Close attention to bowel function as opioids are being started will reduce the number of later problems with obstipated and impacted patients, who occasionally require hospital admission. [267] Although attention to diet is important, there are limitations to the amount of fibrous food the cancer patient will tolerate. Reversal of established opioid constipation requires agents that increase peristalsis, such as senna derivatives (see Chapter 43). Metabolic disorders and intestinal lumenal narrowing secondary to tumor growth or radiotherapy also can cause constipation. Constipation may result from hypercalcemia related to ectopic production of parathyroid-like hormone by neoplasms. Rarely, malignancy, particularly small cell carcinoma of the lung, produces a paraneoplastic visceral neuropathy that results in aberrant motor activity throughout the gastrointestinal system. [268]

Diarrhea Diarrhea is common immediately after potent chemotherapy. In adults, diarrhea may be a self-limited consequence of mucositis, but other causes need to be considered. *Clostridium difficile* colitis is a common cause. The spore-forming organism is found on the environmental surfaces of oncology units, [269] and antibiotics are ubiquitous. Because sigmoidoscopy is avoided in neutropenic patients, identification of the toxin forming *C difficile* in stools should lead to treatment with metronidazole or vancomycin. Several uncommon tumors are associated with the development of chronic diarrhea and, at times, steatorrhea that may be difficult to distinguish from chemotherapy-induced symptoms. [270] They release one or more of a variety of agents into the circulation that affect gastrointestinal function. These include carcinoid tumors, gastrinomas, glucagonomas, somatostatinomas, medullary thyroid carcinomas, pheochromocytomas, and vasoactive intestinal polypeptide (VIP) tumors. Diarrhea can be a rare consequence of some more common tumors, such as bronchogenic carcinoma.

Nausea and Vomiting

Nausea and vomiting, common after chemotherapy, exacerbate inanition and malnutrition. Inadequate management of these symptoms is a common reason for discontinuation of potentially effective chemotherapy or the unwanted conversion of outpatient to inpatient chemotherapy. [271] Cancer chemotherapy causes two main phases of vomiting: an intense, acute phase of emesis that occurs almost immediately following administration of anticancer drugs; and a milder, delayed phase of nausea and vomiting of longer duration. [272] It appears that the acute vomiting is mediated by serotonin (5-hydroxytryptamine, 5-HT) binding to 5-HT3 receptors in the central nervous system, triggering emesis. High doses of intravenous metoclopramide and the 5-HT3 receptor antagonists (e.g., ondansetron, granisetron) are most effective in treating acute-phase vomiting. [273] A wide variety of antiemetics of differing effects and costs is available to the clinician. [274], [275] and [276] Because the cost of newer pharmaceuticals needs to be matched against the increased total cost of therapy when a patient is admitted to the hospital with dehydration and intractable vomiting, clinicians may find an approach to acute and delayed emesis valuable (Table 128-6).

TABLE 128-6 Graduated Approach to Treatment of Chemotherapy-Associated Emesis*

Anticipatory vomiting can be difficult to control once initiated. The development of emesis induced by the sights and sounds of the setting in which chemotherapy is provided is more likely to occur in patients with pretreatment anxiety, posttreatment dizziness, delayed nausea and vomiting, and severe nausea and vomiting. [277] Behavioral therapy has been shown to be effective once anticipatory vomiting has developed. [278]

Hematologic Malignancies

Heavy Chain Diseases The heavy chain diseases are related neoplastic disorders of B cells. The neoplastic B cells produce abnormal monoclonal heavy chains. a-Heavy chain disease (Mediterranean lymphoma), the most common of these entities, is seen in two forms: pulmonary and enteric. The former is more common in the United States, and it rarely exhibits gastrointestinal manifestations. [279] The latter is found principally in the Mediterranean region in countries with poor sanitation. Infiltration of the small intestine and abdominal lymph nodes by malignant B cells and a-heavy chains produces abdominal pain and masses, vomiting, weight loss, malabsorption, steatorrhea, and hypocalcemia. [280] Additional complications include obstruction, intussusception, and intestinal perforation. Diagnosis is established by small bowel biopsy. Treatment includes initial staging laparotomy and debulking of tumor load if appropriate, followed by chemotherapy or radiotherapy. [281]

Leukemias Both acute and chronic leukemias can involve the gastrointestinal tract. The gastrointestinal manifestations result chiefly from leukemic infiltration of the lumenal gut and liver, or they are a consequence of therapy. Gingivitis is caused by leukemic invasion of the gums and causes oral pain and bleeding. Massively enlarged tonsils in acute lymphocytic leukemia rarely result in oropharyngeal dysphagia. Leukemic infiltration of the esophagus, stomach, intestine, or colon produces mucosal or intramural lesions that may cause dysmotility, obstruction, bleeding, or enterocolitis. [282], [283] Hepatosplenomegaly and portal hypertension are additional complications of leukemic infiltration. Rarely, an illness indistinguishable from fulminant hepatitis occurs. [284] Subcapsular splenic hemorrhage and splenic rupture have been reported, particularly in acute lymphoblastic leukemia. [285] Induction chemotherapy for leukemia can induce an often fatal syndrome characterized by acute

abdomen, paralytic ileus, diarrhea, and gastrointestinal bleeding. [286] Development of this syndrome often is attributed to necrotizing enterocolitis or typhlitis, a severe inflammatory process that involves the distal small bowel, cecum, or appendix (Fig. 128-7). [284], [285] It is seen most often in the setting of postchemotherapy neutropenia, but similar lesions have been described in other immunocompromised states. The etiology of the disease is unknown. Diarrhea (sometimes bloody), right lower quadrant pain or tenderness, nausea, and vomiting are the usual presenting features, developing over hours to days. The differential diagnosis includes infectious colitis caused by *C difficile,* Cytomegalovirus, and other organisms, appendicitis, Ogilvie syndrome, and bowel obstruction. Patients at risk must be observed carefully for evidence of perforation.

FIGURE 128-7. Typhlitis involves terminal ileum and cecum in a patient with acute myelogenous leukemia.

Lymphoma As many as 10% of patients with non-Hodgkin lymphoma originating from a nongastrointestinal site develop involvement of the gastrointestinal tract. [287] Obstruction, bleeding, abdominal masses, and perforation are among the more frequently recognized clinical features. Invasion of the liver and spleen is frequent, commonly presenting with fever and elevated alkaline phosphatase. Lymphoma in the liver can mimic acute hepatitis [288] and fulminant hepatic failure. [289] Mantle cell lymphomas can present as multiple lymphomatous polyposis and resemble the familial adenoma syndromes until biopsy is obtained. [290] Primary digestive tract lymphoma of the stomach (see Chapter 69) and the intestine (see Chapter 80) are discussed elsewhere. Clinically evident gastrointestinal involvement in Hodgkin disease is infrequent, although a substantial proportion of patients who die from this illness are found at autopsy to have hepatic involvement [291] (Fig. 128-8). Presinusoidal portal hypertension can result from either increased intrahepatic blood flow as a consequence of splenomegaly or intrahepatic infiltration with malignant cells. When the lumenal gut is involved, thickened mucosal folds are common (Fig. 128-9).

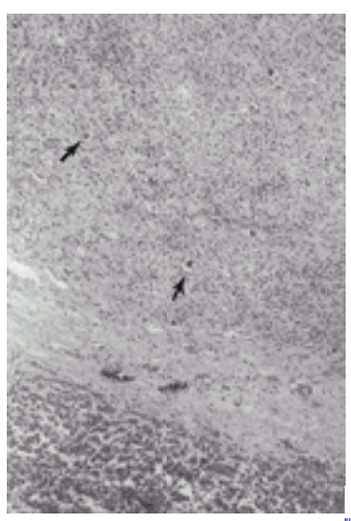

FIGURE 128-8. Hodgkin's disease infiltrating the liver. Reed-Sternberg cells are present (*arrows*). (Hematoxylin and eosin stain; original magnification × 25.)

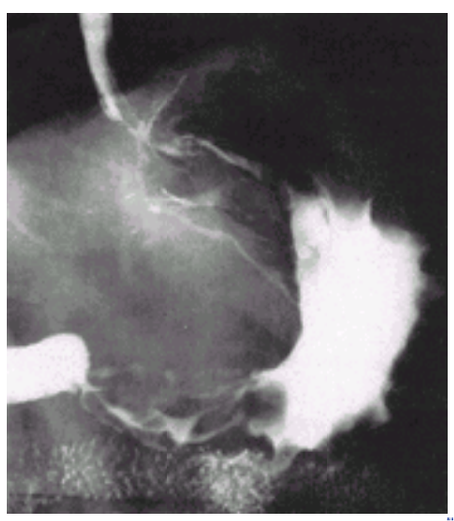

FIGURE 128-9. Hodgkin disease infiltrating the stomach. Thick folds in antrum and fundus.

Multiple Myeloma Multiple myeloma results from a monoclonal neoplastic proliferation of plasma cells and usually affects middle-aged and older people. Osteolytic lesions of the skeleton, hypercalcemia, anemia, monoclonal gammopathy, and renal disease are characteristic findings. [292] When the gastrointestinal tract is invaded, plasmacytomas form, with attendant abdominal pain, ulceration, bleeding, or obstruction. The lesions can be detected radiographically or endoscopically [293] and may look like peptic ulcer disease or colon cancer. Some patients have hyperviscosity syndromes as a result of elevated serum immunoglobulin. Visceral ischemia and thrombosis may result. Amyloidosis is a well-recognized complication of myeloma (see section " Metabolic Disorders"). Involvement of the liver and spleen results in hepatosplenomegaly and, rarely, portal hypertension. Jaundice can be caused by infiltration of the liver parenchyma or obstruction of the biliary tree secondary to myeloma in the pancreatic head. [294]

Myeloproliferative Disorders Myelofibrosis with myeloid metaplasia is characterized by ineffective erythropoiesis, dysplastic megakaryocyte hyperplasia, and an increase in the ratio of immature granulocytes to total granulocytes. This myeloproliferative disorder is associated with bone marrow fibrosis and extramedullary hematopoiesis in the spleen and liver, and presents with marked splenomegaly and progressive anemia. Portal hypertension, associated with ascites or variceal hemorrhage, occurs in about 7% of patients. The portal hypertension can be due to the increased portal flow through the enlarged spleen and obliteration of small portal venules, and is resolved with splenectomy. Patients can also develop acute left upper quadrant abdominal pain due to splenic infarction. [295] Paroxysmal nocturnal hemoglobinuria is a myeloproliferative disorder characterized by intravascular hemolysis that is manifest by episodes of hemoglobinuria and life-threatening venous thrombosis. In a large cohort of such patients seen over a 30-year period at one hospital, [296] the most common sites of venous thrombosis were the hepatic and mesenteric veins. This was also the most common cause of death. All such patients should be on long-term anticoagulation. Polycythemia vera is a myeloproliferative disorder that affects middle-aged people and is characterized by an increased red cell mass. Many patients have associated thrombocytosis. The erythrocytosis and hyperviscosity syndrome lead to plethora, headache, vertigo, dizziness, visual disturbances, vascular ischemia, and venous thrombosis. [297] Budd-Chiari syndrome may develop as a consequence of hepatic vein thrombosis. [298] Hepatosplenomegaly resulting from extramedullary hematopoiesis produces upper abdominal fullness in some patients. Bleeding esophageal varices are secondary to portal vein thrombosis and increased blood flow through the giant spleen. Primary or essential thrombocytosis is a myeloproliferative disorder characterized by platelet counts greater than $10^6/mm^3$ but without an increase in the red cell mass. This condition must be differentiated

from the secondary thrombocytosis that accompanies inflammation and iron deficiency. Platelet aggregation defects predispose to gastrointestinal bleeding or thrombosis. Hepatosplenomegaly is evident in many patients [299] and is caused by extramedullary hematopoiesis or Budd-Chiari syndrome.

Waldenström Macroglobulinemia Waldenström macroglobulinemia is an immunoglobulin M (IgM)-secreting variant of multiple myeloma characterized by the presence of macroglobulin (monoclonal IgM) in the serum. Osteolytic lesions are seen less commonly than in myeloma, whereas lymphadenopathy and hyperviscosity are more prominent. Massive hepatosplenomegaly results from infiltration by plasma cells. The deposition of large amounts of IgM in the intestinal lamina propria and mesenteric lymph nodes can impair absorption, [300] resulting in diarrhea and steatorrhea.

Nonhematologic Malignancies

Gynecologic Malignancies The treatment of cancer of the cervix, depending on stage of disease, usually involves a combination of a hysterectomy, chemotherapy, and radiation therapy. Because any invasion of the bowel can abort attempts at exenteration procedures, [301] a change in bowel habit or blood in the stool should lead to a colonoscopy before operation. Most gastrointestinal consequences of cervical cancer relate to the sequelae of radiation therapy. The risk of more severe radiation-induced bowel complications, such as obstruction or fistula formation, are doubled when adjuvant radiotherapy follows, rather than precedes, hysterectomy. [302] Although most radiation-induced bowel disease occurs in the first two years after radiotherapy, illness can occur at any time in the next several decades (see Chapter 132). Ovarian cancer can produce gastrointestinal complications by local extension and frequently encases the abdominal viscera. Intestinal obstruction, either because of direct invasion of bowel by peritoneal metastases or as a consequence of radiotherapy, is a common and disabling clinical complication. [303] In many terminally ill patients, palliation of vomiting can be a distressing management problem that is beyond the capabilities of reconstructive surgery. Octreotide at doses of 0.3 to 0.6 mg/d, in a small group of patients, rapidly relieved symptoms, and allowed removal of the nasogastric tube. [304] Refractory malignant ascites also can be an important cause of ovarian cancer morbidity, requiring repeated paracentesis or the placement of a peritoneovenous shunt for palliation. [305] Metastases to the ovary from gastrointestinal malignancies (Krukenberg tumors) may be difficult to distinguish from primary ovarian cancer by noninvasive imaging modalities. Typically, these tumors are bilateral, asymmetrically large, and solid. Almost all are mucinous signet-ring tumors from the stomach and colon, all with poor prognosis. [306]

Malignant Melanoma Malignant melanoma is a common malignancy whose prevalence is increasing. Although metastases to the gastrointestinal tract are commonly revealed at autopsy, fewer than 9% of patients with melanoma are diagnosed with gastrointestinal involvement while alive. [307] The small intestine, stomach, and colon are most commonly involved, but the liver, pancreas, and gallbladder also can be affected. Although most patients remain asymptomatic, complications include abdominal pain, anorexia, gastrointestinal hemorrhage, and intestinal perforation. In appropriate circumstances, surgical intervention to alleviate significant gastrointestinal complications is warranted and may prolong survival. [308]

Mastocytosis Mastocytosis is a rare disorder characterized by the proliferation of mast cells into the skin (urticaria pigmentosa) and other organs, including the intestines and liver. Common symptoms are headache, pruritus, flushing, dizziness, wheezing, and tachycardia. Urinary histamine excretion often is elevated. Gastrointestinal dysfunction develops more commonly than previously thought, resulting in abdominal pain, nausea, diarrhea, fecal urgency, malabsorption, gastritis, and peptic ulcers. [309] Rubbing cutaneous lesions or drinking alcohol may precipitate symptoms. Symptoms probably develop secondary to the release of many mast cell products, such as histamine, leukotrienes, and platelet-activating factor. [310] Many patients have liver disease, manifested by hepatosplenomegaly, portal hypertension with ascites, and abnormal liver tests. Liver biopsy shows portal fibrosis, nodular regeneration, and venoocclusive disease. Infiltration with mast cells is common but is seen only when special stains (toluidine blue and chloracetate esterase) are used. [311] Treatment with cromoglycate, or histamine receptor antagonists provides relief in some patients. [312]

Metastatic Disease to the Gastrointestinal Tract Intestinal metastasis from tumors originating in locations outside the gastrointestinal system can induce significant symptoms. Abdominal pain, obstruction, and bleeding are common consequences. Other than melanoma, malignancies derived from organs such as the breast, lung, and thyroid [313] can metastasize to the intestines and on occasion are diagnosed by endoscopic biopsies. In approximately half of the patients with Kaposi sarcoma, a frequent accompaniment of AIDS, intra-oral or intestinal involvement develops [314] (Fig. 128-10; see also Color Fig. 128-10).

FIGURE 128-10. (See Color Fig. 128-10.) Kaposi sarcoma of the lower extremities.

Multiple Endocrine Neoplasia Syndromes Two main types of multiple endocrine neoplasia (MEN) are distinguished. MEN-1 is characterized by the combined occurrence of tumors of the pituitary gland, pancreatic islets, and parathyroid. Islet tumors may secrete gastrin, insulin, glucagon, VIP, and corticotropin. Resulting clinical syndromes will depend on the hormone that is pathologically secreted. [315] Inactivation of the MEN-1 gene locus is associated with the development of multifocal gastric carcinoids. [316] Treatment of such patients with somatostatin analogs (octreotide) is associated with the regression of the gastric carcinoids. [317] MEN-2A is characterized by pheochromocytoma, medullary thyroid carcinoma, and hyperparathyroidism. [315] MEN-2B is similar to type 2A but without involvement of the parathyroid glands. It is associated with the development of alimentary tract ganglioneuromas throughout the gastrointestinal tract and a characteristic facial appearance consisting of patulous lips and thickened tarsal plates of the eyelids. Gastrointestinal symptoms are common, particularly severe obstipation with megacolon that may be mistaken for Hirschsprung's disease. [318] Both MEN-2A and 2B have been associated with a mutation in codon 664 of the *RET* protooncogene. [319] Octreotide is used as a radiolabeled tracer to localize these tumors and for symptomatic therapy by reducing the release of secretory products from the tumors. [320] The use of octreotide is associated with an increase in gallstone formation.

Renal Cell Carcinoma Renal cell carcinoma (hypernephroma) can directly invade into, or metastasize to, the intestinal tract, causing bleeding [321] and obstruction. Resection of the primary tumor has been associated with regression of metastatic lesions. Nonmetastatic hepatic dysfunction (Stauffer syndrome) is common, usually manifested by abnormal alkaline phosphatase and prolongation of the prothrombin time, [322] and it is associated with hepatic sinusoidal dilation. [323] It is possible that in some cases the elevated phosphatase derives from the tumor itself and does not denote hepatic dysfunction.

NEUROMUSCULAR DISORDERS (Table 128-7)

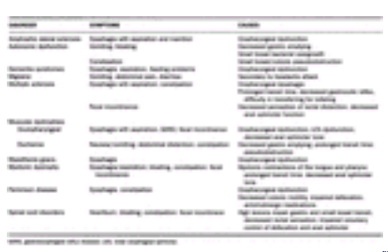

TABLE 128-7 Gastrointestinal Manifestations of Neuromuscular Disorders

Autonomic Dysfunction

The autonomic nervous system supplies every organ in the body, and dysfunction is associated with orthostatic hypotension, erectile problems, urinary retention, and temperature deregulation. Abnormal gastrointestinal function of the sympathetic and parasympathetic pathways in primary neurological disorders such as Parkinson disease, pandysautonomia, [324] or paraneoplastic syndrome [325] are manifested by vomiting, small bowel bacterial overgrowth, intestinal pseudoobstruction, fecal incontinence, and constipation. A number of gastrointestinal diseases can develop dysautonomic symptoms, particularly advanced liver disease. [326] Antibodies to ganglionic acetylcholine receptors have been found in a group of patients with idiopathic dysautonomia, suggesting an autoimmune etiology for some. [327]

A common association with the neurological diseases characterized by autonomic dysfunction is postprandial hypotension. Marked reduction in blood pressure after a meal may result in syncope, weakness, angina pectoris, nausea, and falls. The pathophysiology is complex and includes inadequate sympathetic nervous system compensation for meal-induced splanchnic pooling of blood, impaired baroreflex function, and peripheral vasodilation secondary to vasodilatory gastrointestinal peptides and insulin secretion. Similar symptoms are also seen in older adults without more global dysautonomia. [328]

Dementia Syndromes

Dementia syndromes, such as Alzheimer disease, multi-infarct dementia, and Huntington disease, demonstrate gastrointestinal symptoms related to oropharyngeal dysfunction, with dysphagia for solids and liquids and an increased risk of aspiration and progressive inanition and malnutrition. Diminished recent memory and disorientation impede rapid diagnosis of common and often easily recognized medical problems.

In advanced terminal neurological diseases, difficult decisions must be made pertaining to providing or withholding enteral feedings that must be delivered by nasogastric tube, gastrostomy, or jejunostomy. These techniques of enteral alimentation permit more effective, longer administration of defined enteral diets that can prolong the end stage of patients in a severely demented or “vegetative” state. Enteral support through feeding tubes is a form of medical treatment that is not necessarily mandatory for all patients in such condition, and indeed would not be the choice of most competent patients living in a nursing home. [329], [330] and [331] Percutaneous endoscopic gastrostomy is an easily applied, safe, and popular method of administering enteral feeding. Jejunostomies should be used only in patients with severe gastroesophageal reflux, in whom the procedure may provide additional protection against aspiration pneumonia.

Hiccups

Hiccups are intermittent, involuntary, spasmodic contractions of the diaphragm and accessory muscles of respiration that lead to abrupt ending of inspiration by airway closure at the glottal level. Transient hiccups are a common phenomenon often associated with overindulgence of food or drink, and they can be dealt with effectively by a variety of home nostrums and traditional remedies. Hiccups become a medical problem when they are prolonged and unresponsive to the usual approaches. Prolonged hiccups lasting for weeks or months are seen more commonly in men and can lead to insomnia, inanition with weight loss, and occasionally suicide. [332]

Particularly if the hiccups continue while the patient is sleeping, an organic cause should be sought. The potential causes of protracted hiccups are extensive and include foreign bodies in the ear canal, cervical tumors or adenopathy, central nervous system disease, metabolic disease (diabetes, uremia, hyponatremia), alcoholism, and chest (tumors or inflammation in the mediastinum, pericardium, pleural space, or diaphragm) disease. Gastrointestinal diseases associated with protracted hiccups include gastroesophageal reflux, gastric obstruction with distention, and stomach or esophageal tumors. Many of these problems can be defined with a careful history and physical examination, plain radiograph films of the chest or abdomen, and routine blood work. Further diagnostic studies may require CT of the chest, abdomen, and central nervous system, endoscopy, and otolaryngology and neurology consultations. For many patients, a specific causal etiology may not be found. [333]

In a practical sense, the most immediate problem confronting the clinician is how to abort the protracted hiccups. Assuming that the usual home remedies (e.g., breath holding, drinking water) have been unsuccessful, local stimulation of the pharynx with a nasogastric tube might be tried. Continued hiccups would lead to sequential trials of medications, none of which has been evaluated in randomized trials. Baclofen, a centrally acting antispasticity agent, has been effective when administered orally, 5 to 60 mg/d. [334] The dopaminergic antagonists (chlorpromazine, metoclopramide, haloperidol), amitriptyline, carbamazepine, diphenylhydantoin, quinidine, and nifedipine all have successfully stopped protracted hiccups. [335]

Migraine

Migraine is a periodic headache syndrome that usually begins early in life. Well-defined visual, sensory, or motor dysfunction may precede or accompany the headache. Gastrointestinal manifestations are almost universal and include nausea, vomiting, crampy abdominal pain, and diarrhea. The nausea and vomiting may impede the use of oral medications during an attack. A commonly employed antimigraine medication, sumatriptan, a selective 5-hydroxytryptamine-1 receptor agonist, has been associated with the development of ischemic colitis. [336]

Migraine equivalents such as cyclic vomiting [337] and abdominal migraine [338] are encountered, particularly in childhood. The diagnostic criteria include recurrent stereotypic attacks of either intractable vomiting or upper abdominal pain, no abdominal symptoms between attacks, a family history of migraine, and response to specific migraine therapy. These symptoms are only occasionally accompanied by headache or prodrome. Nortriptyline has been used with some efficacy in adults to prevent attacks of vomiting. The differential diagnosis of paroxysmal, repetitive abdominal pain includes the much less commonly encountered abdominal epilepsy, which is diagnosed by demonstration of spike and wave activity on the electroencephalogram.

Multiple Sclerosis

Multiple sclerosis (MS) is a focal demyelinating disorder of the central nervous system. Although oropharyngeal dysphagia occurs, in population-based studies, constipation and fecal incontinence are the most serious and disabling problems for patients with MS. Constipation is a problem for more than two thirds of MS patients, and about 25% have fecal incontinence weekly. [339] Causes of constipation are multiple, including difficulty in transferring to commode, increased segmenting contractions that lead to prolonged transit time, [340] and diminished gastrocolic response to a meal. Abnormalities of both anal sphincter function and diminished perception of rectal distention contribute to the incontinence. [341] The clinical use of improving outcomes of testing such as defecography or anal rectal manometry is unproved.

For patients with MS, careful attention to bowel function can markedly improve quality of life. Having an occupational therapist evaluate the home environment to improve access to commode, judicious use of fiber in the early stages of disease, and a strict bowel regimen that uses digital stimulation or glycerin suppositories and enemas to avoid impaction are all useful. Stimulant laxatives may increase bowel spasm and cause unpredictable bowel explosions that always are associated with incontinence and further lack of control.

Muscular Dystrophies

Muscular dystrophies are inherited myopathies featuring progressive weakness and muscle wasting. Although generally thought of as involving only the skeletal muscle, several forms have been associated with motor disturbances of the gastrointestinal system. Ptosis and dysphagia are the principal manifestations of oculopharyngeal muscular dystrophy. Radiographic abnormalities reflecting the global degeneration of skeletal muscle include altered clearance of barium from the pharynx, delayed initiation of swallowing, aspiration, and nasopharyngeal regurgitation. [342] More recent esophageal manometric studies also suggest abnormalities of the body of the esophagus and lower esophageal sphincter. [343] The external anal sphincter is also nonfunctional.

Duchenne muscular dystrophy is an X-linked recessive disorder that usually presents with initial proximal skeletal muscle weakness by the age of 5 years, progressing to incapacitation and death by the 3rd decade of life. Gastrointestinal symptomatology includes nausea, vomiting, abdominal distention, and constipation. Acute gastric dilation [344] and intestinal pseudoobstruction have been reported. [345] Gastric hypomotility occurs frequently in advanced disease. [346]

Myotonic Dystrophy

Myotonic dystrophy is an autosomal dominant, slowly progressive condition, with symptoms presenting in the 3rd decade of life. The distinctive features are delayed relaxation of muscle after initial contraction, muscle wasting of a characteristic pattern, frontal baldness in men, testicular atrophy, dysarthria, and cataracts. Studies have found abnormal muscle function throughout the gastrointestinal tract. Common symptoms are abdominal pain, dysphagia, emesis, chronic or episodic diarrhea, coughing while eating, and fecal incontinence. One fourth of patients with myotonic

dystrophy consider their gastrointestinal symptoms the most disabling consequence of the disease. [346]

Weak or myotonic contractions of the tongue and pharynx can result in oropharyngeal dysphagia and aspiration. Weakness of the upper esophageal sphincter and low-amplitude esophageal peristaltic contractions are frequent motor disturbances but may have little correlation with symptoms. [346] Delayed gastric emptying, prolonged intestinal transit, and abnormal anal sphincter function also may develop. [347], [348] Although rarely of clinical significance liver tests such as the alkaline phosphatase and transaminases may be mildly elevated. [349]

Parkinson Disease

Parkinsonism is characterized by progressive rigidity, tremor at rest, bradykinesia, and diminished postural reflexes. Autonomic dysfunction is common. Although 10% to 15% of cases occur in the 3rd and 4th decades of life, the disease increases exponentially in older adults. Over 3% of those over the age of 65 have Parkinson disease. Asians and African Americans are less likely to develop the disease than Caucasians. Regularly observed pathological changes include degeneration of pigmented brainstem nuclei, which contain distinctive eosinophilic intracytoplasmic inclusions termed Lewy bodies. Dementia is common and loss of sympathetic ganglia and parasympathetic neurons in the enteric nervous system has been documented. [350]

Gastrointestinal dysfunction is common and clinically important in patients with Parkinson disease. Dysphagia, bloating, nausea, constipation, and defecatory dysfunction are common symptoms. Over 50% of patients have swallowing disorders. For many, defined pharyngeal swallowing dysfunction is documented on swallowing studies and is similar to that seen after stroke or with amyotrophic lateral sclerosis. Although a variety of esophageal manometric abnormalities have been noted, they are not distinctly different from age-matched controls. [351] Gastric-emptying is disordered in many patients, and is associated with abnormal myoelectric activity. [352] The gastroparesis not only leads to disabling symptoms that may lead to malnutrition, it also may be responsible for some of the motor fluctuations seen with levodopa therapy. The drug therapy that appears to be most effective in reducing these symptoms, domperidone, [353] is not available in the United States.

Constipation characterized by colonic inertia is associated with depletion of dopaminergic neurons in the muscularis externa, [354] decreased colonic motility, and alteration of puborectalis and anal sphincter function. [351] Constipation is aggravated by the anticholinergic effects of anti-parkinsonian medications. The use of stimulant laxatives is common. Pelvic floor dyssynergia is frequently documented, and straining to defecate complicates the constipation. [355] A daily bowel regimen with the use of glycerin suppositories can be helpful.

Spinal Cord Disorders

Acute spinal cord injury is commonly associated with ileus, and patients are at increased risk of gastrointestinal bleeding. [356] Nasogastric suction and prophylaxis with continued acid suppression or sucralfate are warranted. After surviving the acute injury, constipation and fecal incontinence are almost universal and are a major source of disability and depression. [357] Over time laxative dependence, dilated colon, and increasing time to generate a movement occupies a great deal of the patient's day. Rectal sensation, voluntary control of defecation, and normal anal sphincter function are lost. [358] Abnormal colon compliance and motor activity are also present. [359] A carefully designed bowel program that includes laxatives, manual distention of the rectum to stimulate the intact defecation reflex, and careful attention to assistance in transfer to commode or low toilet can be helpful. A few patients may be aided by anterior sacral root stimulators. [360] High spinal cord lesions rarely can impair gastric and small bowel motility, which predisposes to gastric distention, esophageal reflux, and adynamic ileus. [361]

Other Neuromuscular Diseases

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disorder characterized by progressive loss of motor neurons, muscle atrophy, and weakness. Dysphagia ultimately will be present in all patients and is due to discoordination of the entire pharyngeal and upper esophageal swallowing mechanisms. Rapid nutritional disintegration is common, increasing the potential for respirator dependence. Studies demonstrate that placement of a percutaneous endoscopic gastrostomy (PEG) is safe, rapidly improves nutrition, and seems to improve quality of life in ALS patients. [362], [363] Delayed gastric emptying has been reported, and if present might necessitate the use of jejunal feeding.

Residual swallowing problems are common in patients who have had a stroke. The consequences are impaired nutritional intake, decreased quality of life, and a risk of aspiration pneumonia. Pharyngeal motor dysfunction and a delay in swallowing initiation are common after acute stroke, whereas secondary oropharyngeal sensory dysfunction is uncommonly seen on video swallowing studies. Vocal cord mobility is reduced, with resulting reduction in airway protection. Swallowing therapy may help maintain oral intake in some cases. [364] Commonly, a choice must be made with dysphagic stroke patients as to whether to provide nutrition via nasogastric feeding or percutaneous gastrostomy. One study compared these two methods of nutritional delivery and found that the endoscopic gastrostomy group had a lower 6-week mortality (13% vs. 57%) and a greater weight gain (77% vs. 12%) than the nasogastric feeding group. [365] Quality of life was not measured.

Myasthenia gravis is an autoimmune disorder of the neuromuscular junction that is a treatable cause of oropharyngeal dysphagia. [366] Some patients have coexisting immunodeficiency states and may have intestinal villus atrophy and increased susceptibility to enteric infections. [367] Intestinal pseudoobstruction that has occurred in patients with myasthenia gravis and thymoma has resolved with treatment of the myasthenia, suggesting that the gastrointestinal dysfunction may be a paraneoplastic syndrome associated with thymoma. [368]

Stiff-man syndrome consists of symmetrical, progressive stiffness and painful spasm of axial musculature. Dysphagia may develop, possibly related to muscle spasm of the cricopharyngeus and upper esophagus. [369] Whether epilepsy and abnormal brain discharges can cause intestinal symptoms (e.g., nausea, vomiting, pain) without overt seizures developing is controversial. [324]

NUTRITIONAL DISTURBANCES

Malnutrition

Malnutrition results from famine, poverty, poor dietary habits, and chronic disease. Kwashiorkor identifies the protein-deficient patient with an adequate intake of calories, exemplified in developed countries by the catabolic patient after trauma, infection, or burn. Typically such patients are characterized by a persistent edematous state. Marasmus syndromes are related causally to a deficiency in total caloric intake (i.e., the starved patient). [370] Diarrhea and infection are common manifestations of the terminal malnutrition. Malnutrition causes both humoral and cellular immunodeficiency, which renders the mucosa susceptible to bacterial overgrowth and infection by various pathogens, such as parasites, toxigenic bacteria, and viruses. Atrophy of the intestinal mucosa and pancreas contributes substantially to development of the diarrheal state. Hepatomegaly may develop in conjunction with fatty liver and pancreatic enzyme secretion may be reduced by over 80%. [371] In Western countries, chronic alcoholism and chronic liver disease are common causes of malnutrition. [372]

The indications for the delivery of nutrients by the enteral and parenteral route as well as the efficacy of nutritional supplementation in malnourished, hospitalized patients are unproved. [373] Recent weight loss of more than 10% of body weight, the inability to eat for 5 to 7 days in an undernourished patient or for 10 to 14 days in a well-nourished patient, and a hypercatabolic state (e.g., burn) are generally proposed criteria for initiation of nutritional supplementation, [263] especially in critically ill patients. Both parenteral and enteral formulations can provide all essential nutrients, but the enteral route is preferred whenever the gastrointestinal tract is functional. [374]

Refeeding of extremely malnourished patients should be done gradually to permit mucosal and metabolic adaptation and to avoid exacerbation of diarrhea. Many patients will need pancreatic enzyme supplementation. Too rapid refeeding with high-calorie solutions that are rich in carbohydrates can lead to death by precipitating severe hypophosphatemia, hypokalemia, and hypomagnesemia and by intensifying other metabolic disturbances. [375]

Obesity

Almost 50% of adult Americans weigh more than 10% above ideal body weight, and obesity-related conditions are estimated to contribute to more than 300,000 deaths annually. Detailed evaluation of this topic can be found in Chapter 21.

ORGAN TRANSPLANTATION AND COMPLICATIONS

Bone Marrow Transplantation

As a consequence of the induction regimen (lethal doses of radiation therapy and chemotherapy), impairment of the immune system, and graft-versus-host disease (GVHD), gastrointestinal complications are common after bone marrow transplantation. [376] It is usual for mucositis to ensue, resulting in oropharyngeal pain, nausea, vomiting, abdominal pain, diarrhea, and gastrointestinal

bleeding. These symptoms usually appear within a few days of induction and resolve after 3 to 4 weeks. Overt gastrointestinal bleeding is uncommon (7.4%) in such patients when sucralfate or histamine H2 antagonists are given prophylactically. Endoscopy usually does not define an isolated lesion and carries a 19% risk of inducing clinically relevant bacteremia. [377] Antibiotic prophylaxis should be given, and the risk and benefit of endoscopy should be considered before initiating the procedure.

A suppressed immune system predisposes the marrow transplant recipient to life-threatening infections. Bacterial and fungal infections are more common during the initial 30 days, whereas viral and parasitic infections are observed more often after day 30. [378] Oropharyngeal and esophageal thrush occur frequently. Cytomegalovirus (CMV) and herpesvirus infections are common and may involve any portion of the gastrointestinal tract. Acute diarrhea most commonly is caused by GVHD, but *C difficile* infection can cause severe, prolonged diarrhea. [379] Diagnosis depends on appropriate stool studies.

Graft-Versus-Host Disease Acute GVHD (see Chapter 129) often complicates allogeneic bone marrow transplantation and may be either acute (onset <100 days posttransplant) or chronic (onset >100 days posttransplant). In GVHD, donor cytotoxic T-lymphocytes destroy host cells in a variety of organs, including the skin, liver, and gut. [380] The earliest sign of acute GVHD is often the onset of a severe watery, secretory diarrhea. Anorexia, nausea, vomiting, jaundice, gastrointestinal bleeding, and abdominal pain may also be present. Some 30% to 50% of allogeneic bone marrow recipients develop acute GVHD, and of these 10% to 20% have either severe hemorrhage or perforation. [381] Although less common, chronic GVHD also may demonstrate gastrointestinal symptoms. The diagnosis is best made by endoscopy with biopsy, a relatively safe and simple procedure (Fig. 128-11). Tissue typically demonstrates apoptosis and gland destruction, sparse inflammatory infiltrate, and granular eosinophilic debris in dilated glands. The granular debris may be the most specific feature but is not seen commonly. [382] The use of oral beclomethasone dipropionate and prednisone are more effective than prednisone alone in treating intestinal GVHD. [383]

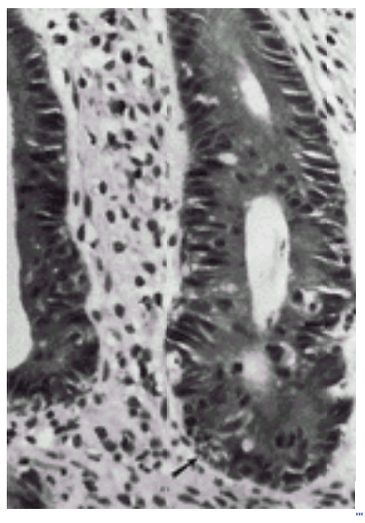

FIGURE 128-11. Rectal biopsy specimen shows crypt cell degeneration, which is the characteristic lesion of graft-versus-host disease. (Hematoxylin and eosin stain; original magnification ×100.)

Hepatic Venoocclusive Disease Liver damage secondary to cytoreductive therapy is common after bone marrow transplantation. The most prominent site is the terminal hepatic venule. Venoocclusive disease manifests by hyperbilirubinemia, hepatomegaly or right upper quadrant pain, and sudden weight gain within 20 days of transplantation without other cause. Pretransplant aminotransferase elevations, high-dose cytoreductive therapy, and persistent fever are independent risk factors. The incidence of venoocclusive disease after allogeneic bone marrow transplantation prepared with busulfan and cyclophosphamide was reduced by 60% in patients receiving ursodeoxycholic acid prophylaxis. [384] There is no clearly defined therapy for venoocclusive disease, which, when severe, is associated with multiorgan failure and death. [385]

Heart Transplantation

More than half of patients undergoing cardiac transplantation develop acute gastrointestinal problems. [386] The most common severe complications include upper gastrointestinal bleeding, pancreatitis, cholecystitis, and bowel perforation. [387] An increased risk for pancreaticobiliary disease persists for 1 year after the operation. [388] Although there is no evidence of an increased risk of colorectal cancer or adenomatous polyps in patients posttransplant, the chronic immunosuppression dictates a vigilant approach to colorectal cancer screening.

Liver Transplantation

The direct hepatobiliary consequences of liver transplantation are not unexpected and relate to performance of the transplanted liver and the patency of the created vascular and bilioenteric anastomoses. [389] The latter problems are commonly amenable to radiologic or endoscopic interventions. [390] Postoperatively, most infections are bacterial and relate to the surgery, ventilation, and intravenous lines. [391] CMV infection is common, any organ in the gastrointestinal tract can be infected, but infection may not be associated with clinical disease. Esophagitis with dysphagia, gastritis with delayed gastric emptying, [392] and colitis resulting from CMV have been recognized. Because effective therapies (e.g., ganciclovir) for CMV are available, an aggressive endoscopic diagnostic approach with multiple biopsies is warranted. Studies are being undertaken to determine whether risk-group–specific prophylactic therapy is useful. [393]

Gastrointestinal bleeding occurs in almost 10% of patients after liver transplantation, and endoscopy will reveal a source in most patients. Gastroduodenal ulcers are the most common cause, followed by enteritis, persisting portal hypertension, and bleeds at the Roux-en-Y anastomosis. [394] Acute pancreatitis is not a rare event after liver transplantation and is associated with a high mortality. [395] A strong correlation exists between the development of pancreatitis and the presence of hepatitis B, extensive surgical dissection around the pancreas, and the number of liver grafts received by the same patient. [396]

Lung Transplantation

The risks of lung transplantation are similar to those noted after other solid organ transplants; however, several reports have described a high frequency of postoperative colonic perforation. [397, 398] Because mortality is related directly to the duration of delay in diagnosis after symptoms are noted and symptoms may be blunted secondary to immunosuppression, careful evaluation for abdominal distention with plain films of the abdomen may help to guide clinical decisions. Because of the extensive mediastinal dissection required during heart-lung transplants, vagal injury can occur, leading to dysphagia and gastric stasis. Fortunately, there are few important clinical sequelae of the nerve injury. [399] Fatal hyperammonemia has been reported to occur uncommonly after lung transplantation, and is associated with hepatic glutamine synthetase deficiency. [400]

Renal Transplantation

More than 16% of patients who undergo renal transplantation develop gastrointestinal complications. [401] Whereas peptic ulcer disease with hemorrhage or perforation were common when high doses of prednisone were used, they are much less common in the cyclosporine era. More effective medical therapies exist for ulcers, making surgical intervention less common. [402] Intestinal ischemia, diverticulitis with perforation, CMV-induced colitis, intestinal tuberculosis, and intra-abdominal abscesses are increasingly common. [403] Infection with hepatitis C and B are common in dialysis patients who develop chronic renal failure. After transplantation, the immune suppression may accelerate the course of chronic hepatitis (particularly hepatitis B) and fulminant hepatitis may occur. [404]

PREGNANCY

Pregnancy is accompanied by a variety of physiological changes, many of which have been attributed to the effects of progesterone or a-human chorionic gonadotropin on gastrointestinal motility and displacement of the viscera by the gravid uterus. Common gastrointestinal symptoms of pregnancy include altered appetite, pica, ptyalism, gingivitis, vomiting, dyspepsia, heartburn, constipation, and hemorrhoids. Management of symptoms with pharmaceuticals is complicated by a paucity of clinical studies in humans demonstrating safety for the fetus. These issues are discussed in detail in Chapter 52.

Liver Disease

Although liver function is normal in pregnancy, palmar erythema and spider nevi are often observed, perhaps as a result of elevated steroid hormones. Serum alkaline phosphatase and leucine amino peptidase levels are increased, attributable to placental production. Other liver enzyme levels are normal. Jaundice is infrequent, but when it occurs it is most often the result of intrahepatic cholestasis of pregnancy (ICP). [405] Cholestasis presents in the 2nd or 3rd trimester as severe generalized pruritus that worsens at night. Marked increases in alkaline phosphatase and serum bile acids with normal ?-glutamyl transferase (?GT) are characteristic. A subgroup with raised ?GT is associated with heterozygous MDR3 mutations. [406] In Chile, ICP has been associated with a decrease in blood selenium level, suggesting environmental causes. [407] There is an increased risk of stillbirths and premature births. Ursodiol can help control the pruritus, but its effect on the outcome of pregnancy is uncertain. [408] Prophylactic vitamin K should be administered parenterally to avoid postpartum bleeding. [405]

The HELLP syndrome is a variant of severe preeclampsia characterized by hemolysis, elevated liver enzymes, and low platelets. Its features suggest a thrombotic microangiopathic process, and it must be distinguished from acute fatty liver of pregnancy, HUS, and TTP. [409] HELLP and acute fatty liver have been associated with the presence of long-chain 3-hydroxyl CoA dehydrogenase deficiency in the infants of these mothers. [410] Marked elevations of transaminases are unusual and may suggest complicating hepatic vein thrombosis or fulminant liver failure, or spontaneous intrahepatic hemorrhage and hepatic rupture with an increased mortality. [411] Despite studies suggesting high fetal and maternal mortality with the HELLP syndrome, [409], [412] other studies have noted greatly improved outcomes when interdisciplinary teams (that included a hepatologist) have managed the patients aggressively with expeditious delivery. [413], [414]

Acute fatty liver of pregnancy resembles Reye syndrome and usually occurs in young primigravida or multiparous women in the 3rd trimester. Vomiting, right upper quadrant pain, and a viral-like syndrome are common early in the course of disease. Jaundice, encephalopathy, and acute renal failure then supervene. As opposed to the HELLP syndrome hypofibrinogenemia, hypoglycemia, and hypoprothrombinemia are common. [414] Microvesicular fat accumulated in the central zone is seen on liver biopsy, but the diagnosis is based on clinical presentation and biopsy is rarely needed. When acute fatty liver is present, the pregnancy should be terminated promptly. Maternal and fetal mortality has been reduced to less than 5%, and survivors have no long-term liver disease. [413], [414]

Conception and viable pregnancy in patients with chronic liver disease is uncommon and fraught with complications. Patients with established portal hypertension have an increased risk of variceal hemorrhage during the third trimester of pregnancy with increase in both fetal and maternal mortality. Prophylactic variceal ligation with ablation of varices or transvenous intrahepatic portal shunt should be considered. [415]

PSYCHOLOGICAL DISORDERS

Anxiety and Stress

Anxiety and stress can alter gastrointestinal function and produce a broad range of gastrointestinal symptoms in otherwise healthy persons. It is not surprising, then, that patients with underlying gastrointestinal illness (e.g., inflammatory bowel disease, gastroesophageal reflux) might notice a worsening of their symptoms at those times; but this does not mean that stress is the cause of the disease. In some patients, however, emotional factors may be the cause of or may contribute to the symptoms of globus syndrome, esophageal spasm, nutcracker esophagus, nonulcer dyspepsia, and irritable bowel syndrome. [416] The close epidemiologic association between sexual and physical abuse as a child and the development of severe and refractory functional gastrointestinal illness as an adult is clear. [417] The mechanisms for the association are complex and probably relate to both psychological (somatization, reinforcement of abnormal illness behavior) and physiological (enhanced visceral sensitivity) factors. In addition, sexual abuse is a common feature of many psychiatric diagnoses (e.g., somatization disorders, depression) associated with functional bowel disorders. [418] Thus, the uniqueness of sexual abuse as an associated finding has not been established. One study has found striking hyperactivity of the hypothalamic-pituitary axis and autonomic nervous system is such patients when compared to age-matched controls. This supports the hypothesis that abnormal secretion of central nervous system corticotropin-releasing factor may mediate the association between early life stress and anxiety disorders in adults. [419]

The finding that altered emotional states increase the frequency of swallowing, and thus aerophagia, may provide insight into the common association of abdominal bloating with stressful life events. [420] Common diseases of unknown origin such as fibromyalgia or chronic fatigue syndrome are commonly associated with functional gastrointestinal complaints, such as nausea, abdominal pain, and disturbed bowel function, as well as defined gastrointestinal illnesses such as irritable bowel syndrome and hepatitis C. [421], [422] and [423] Low-dose tricyclic antidepressants can be quite helpful. The skillful and caring clinician always takes the patient's emotional state into account in the management of any patient with gastrointestinal illness.

Eating Disorders

Anorexia Nervosa Anorexia nervosa is a potentially fatal eating disorder characterized by severe voluntary weight loss, altered body image, and morbid fear of obesity that primarily affects adolescent girls. [424] Anorexia nervosa may carry a mortality of up to 9%. Gastrointestinal complaints are seen in more than half of patients, but multiple systems are involved secondary to the starvation. Delayed gastric emptying that contributes to a feeling of bloating and early satiety is common, but it usually resolves with a return to normal body weight. [425] Serum levels of trace metals such as zinc and copper are commonly depressed, and hypophosphatemia may supervene during refeeding. In severe cases, parenteral feeding may be needed. Details of evaluation and management are found in Chapter 35.

Bulimia Bulimia is a distinct syndrome characterized by cyclic binge eating, followed by self-induced vomiting, fasting, laxative abuse, or excessive exercising to promote weight loss. [424] As opposed to anorexia, severe weight loss and multisystem involvement are rare. Common gastrointestinal symptoms include bloating, flatulence, constipation, abdominal pain, borborygmi, and nausea. Binge eating causes acute gastric dilation, which can result in gastric rupture. Vomiting is associated with dental enamel erosion, parotitis, esophagitis, Mallory-Weiss tears, and esophageal rupture. [426] Although pancreatitis may occur, hyperamylasemia in patients with bulimia most often is caused by increased salivary-type amylase. Treatment is directed at the underlying psychiatric diagnosis.

Rumination Although frequently reported in children, rumination is uncommon in adults who are not developmentally disabled. It is characterized by daily effortless regurgitation of undigested food and may be associated with prominent weight loss. Screening for other eating disorders is important. Delays in diagnosis and the concomitant overuse of diagnostic tests are common. Esophageal and upper gastrointestinal studies are normal. There is no clearly effective medical therapy other than reassurance and psychiatric consultation. [427]

Münchhausen Syndrome

Münchhausen syndrome is the repeated seeking of medical care for factitious and purposefully self-generated illness. In contrast to hysteria, the symptoms are subject to "conscious" control. Patients have feigned many gastrointestinal diseases, including abdominal emergencies, hematemesis, hematochezia, and inflammatory bowel diseases. [428] Satisfactory treatment of this syndrome is rare.

PULMONARY DISORDERS

a_1-Antitrypsin Deficiency

a_1-Antitrypsin (aAT) deficiency is an autosomal recessive inherited condition that is the most common genetic cause of liver disease in children. It is also associated with chronic obstructive pulmonary disease, chronic liver disease, and hepatocellular cancer in adults. The ZZ phenotype has been associated most frequently with severe disease. [429] Adult patients can be screened effectively by serum aAT levels. Those with an aAT level below 80 mg/mL should undergo aAT phenotyping. [430] Liver disease tends to manifest late in life and is associated with inclusion bodies containing entangled polymers of mutant Z aAT within hepatocytes in the periportal areas on liver biopsy, a finding unrelated to the severity of the liver disease. [431] Liver transplantation is an effective form of therapy for patients with severe liver disease. [429]

Asthma/Chronic Cough

Asthma is a common cause of disability and death that is characterized by varying degrees of bronchial constriction. GERD is present in three fourths of asthmatic patients [432] and may be worsened by the use of asthma medications (theophylline, ß-adrenergic agonists) that lower esophageal sphincter pressure, but GERD also may substantially complicate the course of the lung disease. Worsened wheezing is thought to result from the aspiration of gastric contents, although reflex bronchial constriction also has been suggested as a mechanism. [433] Pyrosis as well as other symptoms of GERD, asthma onset in middle age, and the absence of coincident allergy or eosinophilia are clues to a possible association with GERD. When GERD-induced asthma is suspected, 24-hour ambulatory pH monitoring can confirm severe reflux. [434] Therapy of GERD in this setting usually requires prolonged potent acid inhibition with proton pump inhibitors. [435] Because of uncertainties in

demonstrating a causal relationship between asthma and GERD, antireflux surgery should be considered carefully. [436]

Chronic idiopathic cough is commonly associated with GERD. [437] Even in the absence of heartburn, acid may trigger nocturnal cough or laryngospasm. Laryngospasm may be mistaken for asthma unless appropriate pulmonary function tests are employed. Evaluation and management are the same as for asthma.

Consequences of Mechanical Ventilation and Respiratory Failure

Respiratory failure and mechanical ventilation may be complicated by gastrointestinal bleeding from erosive gastritis and ulcer disease. Associated coagulopathy further increases the risk of overt hemorrhage. It is important to emphasize the infrequency of this complication when it is monitored prospectively in large populations. [438] This said, giving antacids, H2 antagonists, and barrier-enhancing drugs prophylactically to critically ill patients reduces the incidence of stress ulcerations [439] and should be provided to ventilated patients. It has been suggested, however, that raising the gastric pH might permit colonization of the stomach by pathogenic bacteria, which, in turn, may predispose to nosocomial pneumonia. This is controversial, and careful attention to a general preventive strategy is likely to be more helpful than arbitrarily switching to sucralfate. [440] Administering sucralfate alone through a nasogastric tube may expose the patient to an increased risk of erosive esophagitis associated with a nasogastric tube because gastric pH remains low. [441]

Acute exacerbation of chronic respiratory failure is a common cause of ischemic hepatitis. In contrast to the severe hypertransaminitis seen after circulatory arrest, where severe hypotension is the proximate cause, in patients with acute respiratory compromise superimposed on chronic respiratory failure, the cardiac index is increased. The cause of the hepatic damage is a combination of severe arterial hypoxemia and elevated central venous pressure. [442] This has also been noted in a patient with severe obstructive sleep apnea. [443]

Cystic Fibrosis

Cystic fibrosis (CF) is the most common inherited disease of Caucasians in North America, with an incidence of about 1 per 2000. Mutations in the *CF* transmembrane conductance regulator gene [444] at the long arm of chromosome 7 lead to an underlying defect in mucosal cAMP ion and water transport. A net shift in fluid from the lumen results in viscous secretions and duct obstruction in the respiratory tract, salivary glands, pancreas, intestinal lumen, and biliary tree. [445]

The presence of viscous secretions in the intestinal lumen has important clinical consequences. Affected infants may present with meconium ileus, intussusception, distal intestinal obstruction syndrome (DIOS), intestinal atresia, volvulus, and perforation. [445] Chronic constipation is common and may lead to rectal prolapse. Mineral oil or acetylcysteine may be effective. [446] Recurrent use of gastrointestinal lavage with Golytely also may be helpful in reducing the symptoms of bloating and distention that characterize DIOS. [447]

Symptomatic gastroesophageal reflux is common in children who have CF. Contributing factors are decreased saliva production, gastrointestinal hypomotility, chronic cough, and the need for postural drainage of pulmonary secretions. [448] Standard antireflux therapy is usually effective. As more patients survive to adulthood, complications of GERD, such as stricture and Barrett esophagus, [449] will be seen with greater frequency.

Essentially all patients have severe nutritional impairment caused by pancreatic insufficiency and manifested by steatorrhea and malabsorption of nonfat nutrients. Protein-calorie malnutrition is aggravated by the catabolic state induced by chronic respiratory tract infections but also may contribute to worsening lung disease. Improvement of exercise tolerance and pulmonary function can result from enteral/parenteral nutritional support, pancreatic enzyme replacement, and fat-soluble vitamin supplementation. [450], [451] The use of large doses of high-potency pancreatic enzymes has caused a fibrosing colitis manifested by bloody diarrhea associated with diffuse narrowing of the colon with rectal sparing. [452] As survival to adulthood becomes more common, new problems are recognized. Symptomatic osteomalacia is a common sequela of chronic steatorrhea, 25-hydroxy vitamin D levels should be monitored, and supplemental calcium and vitamin D should be provided. [453] A greater than expected incidence of malignancies of the digestive tract has been found. [454] Thus persistent or unexplained gastrointestinal symptoms should be investigated carefully.

Focal biliary cirrhosis is common and asymptomatic, but about 10% of children with CF develop confluent biliary cirrhosis and progressive portal hypertension. [455] If variceal bleeding occurs, banding or portosystemic shunting would be the therapeutic modalities of choice. Ursodiol improves liver function tests, but it is unclear whether fibrosis is retarded. Improvements in surgical techniques have allowed end-stage cirrhotics with CF to undergo liver or combined liver and lung transplantation successfully. [455]

RENAL DISORDERS

Chronic Renal Failure

Chronic renal failure is associated with a number of gastrointestinal disturbances. Dysgeusia, a metallic taste in the mouth, and fetor uremia are often noted by uremic patients. Parotitis and sicca syndrome occur commonly in uremic patients, further limiting compliance with fluid restriction and impairing nutrition.

Renal failure commonly is associated with anorexia, nausea, vomiting, and epigastric pain. Endoscopy should be done to exclude ulcer or gastritis. Because uremia is associated with gastric emptying abnormalities, [456] however, symptoms may be alleviated by using agents such as metoclopramide. Gastrointestinal bleeding has multiple possible causes, [457] but in contrast to patients with normal renal function, arteriovenous malformations are particularly prevalent. Estrogen therapy may be helpful. [458] Peptic ulcer disease, gastritis, esophagitis, and duodenitis may be managed with H2 antagonists or antacids, with lower doses needed to prevent drug accumulation and magnesium antacids avoided to prevent hypermagnesemia. The diagnosis of *Helicobacter pylori* is difficult in uremics and relies on histological methods rather than the breath test. [459] Duodenal pseudomelanosis is an idiopathic condition in which pigmentation develops in the proximal duodenal mucosa (Fig. 128-12; see also Color Fig. 128-12). This syndrome has no known symptoms attributable to it.

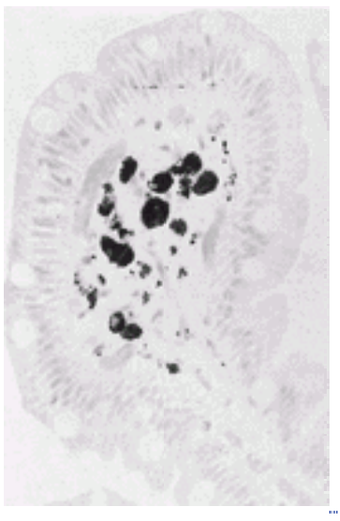

FIGURE 128-12. (See Color Fig. 128-12.) Duodenal biopsy specimen from a patient with pseudomelanosis duodeni shows the deposition of pigment within lamina propria macrophages.

Uremic patients may develop abdominal pain, constipation, pseudoobstruction, and intussusception. Important factors in the development of constipation include oral fluid restriction and the use of antacids that contain aluminum hydroxide. Diarrhea secondary to a variety of causes is common. Fecal impaction must be excluded. Although conditions such as bacterial overgrowth and pseudomembranous colitis must be considered, the cause of many cases remains idiopathic. The incidence of pancreatitis in chronic renal failure is unknown. [456] Elevation of serum amylase is common but should not be attributed necessarily to impaired renal clearance, especially if the level exceeds twice the upper limit of normal. [460]

Uremic patients can develop hepatic friction rubs without other manifestations of liver disease. Elevated alkaline phosphatase in such patients can be of intestinal origin and may not be indicative of

bone disease or cholestasis. Chronic hepatitis from hepatitis B and C is common, and may complicate the ability to provide effective dialysis and kidney transplantation. [461] Treatment with lamivudine for hepatitis B and interferon/ribavirin for hepatitis C can be undertaken with caution in such patients.

Hemodialysis

Inability to gain weight and diarrhea may be manifestations of inadequate dialysis. A few patients on long-term hemodialysis can develop severe obstipation, colonic pseudoobstruction, and spontaneous perforation of the colon. [462] Serum lipase levels can increase significantly after heparin administration and thus have reduced specificity for the diagnosis of pancreatitis in this setting. [463] Idiopathic refractory exudative ascites occurs in a few patients, is difficult to treat medically, and resolves with kidney transplantation. [464]

Peritoneal Dialysis Patients undergoing continuous ambulatory peritoneal dialysis are commonly subject to an easily treatable form of bacterial peritonitis. Differentiating this condition from peritonitis associated with important intra-abdominal pathology (bowel perforation, ischemic bowel, appendicitis) can be difficult because polymicrobial infections can occur without important gastrointestinal pathology, [465] and pneumoperitoneum is common after dialysis. Pneumoperitoneum not associated with perforated viscus was found in 4% of one series, and may take weeks to resolve. [466]

Polycystic Kidney Disease

Polycystic kidney disease (PKD) is an autosomal dominant disorder whose abnormal genes (PKD1, PKD2) have been localized to chromosome 16. PKD accounts for about 10% of the chronic dialysis population. [467] Hepatic cysts are an important manifestation of PKD. The frequency of coincident hepatic cysts increases with age, and the large cysts are more common in women who have had multiple pregnancies. [468] Despite large cysts, hepatic parenchymal volume is preserved, as is liver function. [469] Hepatic cysts can become infected, large cysts can obstruct the biliary tree, and early intervention with both antibiotics and percutaneous drainage is needed. [470] An association with congenital hepatic fibrosis has been reported. [471]

SUBSTANCE ABUSE

Alcohol

Alcohol consumption can enhance LES pressure, reduce the frequency of esophageal peristaltic contractions, and delay esophageal emptying. High-amplitude peristaltic contractions also have been noted (nutcracker esophagus). [472] These alterations in function may result in chest pain and esophagitis. Chronic alcohol ingestion increases the risk of esophageal cancer.

Alcohol produces acute and chronic gastritis by disruption of the gastric mucosal barrier. Binge drinking can result in gastric erosions and severe hemorrhage. Chronic use, however, seems to protect against development of serious mucosal injury. Epidemiologic studies suggest that the concomitant use of alcohol and NSAIDs [473] or alcohol and warfarin [474] potentiated the risks of severe GI bleeding or perforation from the use of either alone.

Alcoholism may result in diarrhea and malabsorption. Alcohol enhances small intestinal transit, decreases brush border enzyme activity, and impairs absorption of nutrients. Acute exposure of the small bowel to alcohol causes altered mucosal and microvascular permeability. [475] Chronic pancreatitis, the spectrum of chronic alcoholic liver disease, protein-calorie malnutrition, and vitamin deficiencies are contributing factors (Chapter 95).

Amphetamines

The social use of ecstasy (3,4-methylenedioxymethamphetamine, MDMA) and amphetamines has become widespread in the United States. They induce euphoria, intensify emotions, and have become a staple of the “rave” culture. In excess the use of these drugs causes anxiety, hallucinations, chest pain, palpitations, coma, subarachnoid hemorrhage, and death. [476] A panarteritis that is similar to polyarteritis nodosum (but negative for antineutrophil cytoplasmic antibody, or ANCA), with associated mesenteric ischemia, is reported. [477] As with cocaine hepatotoxicity is common, caused by both immune-mediated mechanisms and hyperthermic liver injury, and therapy for severe cases is largely supportive. [478]

Cocaine

The use of cocaine and related metabolites is widespread. Anorexia and diarrhea are common. Cocaine use can result in gastric ulcerations with perforation, [479] retroperitoneal fibrosis, and intestinal ischemia with infarction. [480] Severe liver injury is almost always associated with rhabdomyolysis and hyperthermia. The zone of hepatic necrosis will vary depending on other drugs being used. [481] The practice of smuggling cocaine in condoms concealed in the digestive system can result in intestinal obstruction and death.

Narcotics

Narcotic administration for abuse or for pain relief frequently results in physical dependency, with resulting physical symptoms on withdrawal. Gastrointestinal symptoms of withdrawal include anorexia, nausea, vomiting, and abdominal pain. These symptoms may be difficult to distinguish from structural gastrointestinal disorders. Narcotics slow colonic peristalsis and thus frequently induce constipation that can be a long-standing problem. [482] Clonidine therapy may ameliorate the symptoms of narcotic bowel syndrome.

Parenteral administration of illicit drugs can result in chronic viral hepatitis, cirrhosis, and hepatic abscess. Injected contaminants such as talc can cause hepatic granulomas.

VASCULITIDES

Behçet Disease

Behçet disease is a systemic illness of unknown etiology characterized by necrotizing vasculitis and most commonly described in people of Middle Eastern and Japanese extraction. Common manifestations include orogenital ulcerations, eye inflammation, skin lesions, arthritis, and migratory thrombophlebitis. Gastrointestinal tract involvement is uncommon. [483] A curious and virtually pathognomonic sign is the development of pustules at the site of needle punctures.

Oral lesions resemble aphthous ulcers and may be single or multiple. Esophageal ulcerations are common, but infrequently cause symptoms. [484] The most frequent extra-oral sites of gastrointestinal involvement are segmental inflammation and ulceration of the ileocecal region and colon, resembling Crohn’s disease. Intestinal bleeding or perforation may result. Therapy is similar to that of Crohn’s disease, with immunomodulating medications often ameliorating the disease. Resection of severely diseased segments of the gut may be required, but postoperative recurrence is common. [485]

Other than symptomatic Budd-Chiari syndrome, involvement of the liver and spleen are rare. Typically, such patients have cavernous transformation of the portal vein, associated with portal vein, inferior venal caval, and hepatic venous thrombosis. Definable coagulopathies have not been defined as the cause of the thrombosis, suggesting the primary importance of vasculitis. Once established the presence of Budd-Chiari in the patient with Behçet disease indicates a poor prognosis. [486], [487]

Churg-Strauss Syndrome

Churg-Strauss syndrome is a systemic vasculitis characterized by the presence of asthma, hypereosinophilia, and necrosis with extravascular eosinophil granulomas. Common symptoms other than asthma are weight loss, fever, myalgias, arthralgias, and vasculitic skin lesions. Small to medium-size vessels are involved, and ANCAs are commonly detected. Corticosteroids alone or in combination with cyclophosphamide will usually induce clinical remission, but recurrence is common. [488], [489]

Gastrointestinal manifestations are common, and when present are associated with a bad prognosis. [488] They include nausea, vomiting, abdominal pain, gastrointestinal hemorrhage, perforation, and cholecystitis, are related to mesenteric vasculitis, and are similar to those found in polyarteritis nodosa. Mesenteric ischemia with ulceration and perforation is reported. On occasion a case may be diagnosed with endoscopic biopsy. [490]

Cryoglobulinemia

Cryoglobulinemic vasculitis is caused by the localization immune complexes of mixed cryoglobulins in the walls of venules, capillaries, and arterioles, which incites acute inflammation. Mixed cryoglobulins, rheumatoid factor, and low levels of C_4 are typically found in the serum. The most frequent clinical manifestations are purpura, arthralgias, and nephritis (the main cause of morbidity). Cryoglobulinemia occurs in a variety of clinical settings, such as lymphoproliferative disorders, infections, and autoimmune diseases, or as an idiopathic process. However, cryoglobulinemic vasculitis is always associated with chronic hepatitis C. [488]

Gastrointestinal illness, such as recurrent episodes of crampy abdominal pain, enterocolitis, and, rarely, small or large bowel ischemia have been reported. It is likely that effective treatment of the hepatitis C infection with interferon-ribavirin will abolish the vasculitis. [491]

Giant Cell Arteritis

Giant cell arteritis is a granulomatous disease that usually involves large-sized arteries, including the aorta and the temporal arteries. The disease usually occurs in older adults and is associated with the clinical syndrome of polymyalgia rheumatica. Disseminated fibrinoid necrosis of smaller vessels can result in visceral ischemia, abdominal pain, nausea, anorexia, weight loss, bleeding, and perforation. Disturbances of liver function are common and have been attributed to hepatic artery involvement [492] and hepatitis associated with fibrin-ring granulomas. [493]

Henoch-Schönlein Purpura

Henoch-Schönlein purpura is a vasculitis syndrome with a peak age of onset in childhood, characterized by systemic deposition of immunoglobulin A (IgA)-dominant immune complexes in small vessels. The classic triad of symptoms includes a palpable purpuric rash, abdominal cramping, and hematuria typically begins after an upper respiratory infection. [488] ANCA is negative. Most children have a self-limited disease without chronic sequelae. Any part of the gastrointestinal tract may be affected. Gastrointestinal symptoms include abdominal pain, vomiting, diarrhea, intestinal obstruction, or intussusception and can precede the onset of the characteristic purpuric rash. [494] The bowel may be edematous and show evidence of submucosal or subserosal hemorrhage. Radiographic findings include thickening of small bowel folds (Fig. 128-13), colonic wall edema, and intussusception. Whether corticosteroids actually improve outcomes is controversial. [495]

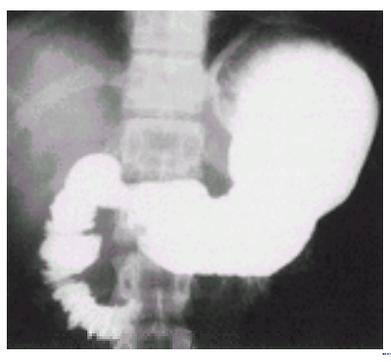

FIGURE 128-13. Henoch-Schönlein purpura. Thickened folds in the second part of the duodenum.

Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is a systemic necrotizing vasculitis that affects small and medium-size arteries of nearly every organ system, giving rise to a wide spectrum of clinical findings. Recently individualized from PAN, microscopic polyangiitis is an ANCA-positive systemic vasculitis of small-size vessels smaller than arteries characterized by rapidly progressive glomerulonephritis and pulmonary involvement that is usually absent in PAN. The absence of necrotizing granulomatous inflammation separates this entity from Wegener granulomatosis and Churg-Strauss syndrome. The gastrointestinal manifestations of the two disorders is similar. [488]

Many cases of PAN are associated with hepatitis B infection. [496] Fever, weight loss, arthralgias, subcutaneous nodules, hypertension, and peripheral neuropathy are common. Gastrointestinal complaints are present in about one third of patients, usually secondary to visceral ischemia. PAN is the most common cause of localized vasculitis of the gastrointestinal tract. [497] The most common clinical manifestations are epigastric pain, nausea, anorexia, mucosal ulceration, intestinal bleeding, and diarrhea. [498] Appendicitis, cholecystitis, pancreatitis, [499] cataclysmic intra-abdominal hemorrhage, bowel obstruction, and liver infarction have been reported. Typical aneurysmal dilation of small and medium-sized arteries on arteriogram (Fig. 128-14) may provide a diagnosis. Corticosteroid and cyclophosphamide therapy have improved the overall survival of these patients dramatically. [500]

FIGURE 128-14. Polyarteritis nodosa. Typical aneurysmal dilation of small and medium-size arteries.

Wegener Granulomatosis

Wegener granulomatosis is an ANCA-positive, small vessel vasculitis characterized by granulomatous inflammation involving the respiratory tract and necrotizing vasculitis of small to medium-size vessels. Glomerulonephritis is common. Manifestations of upper airway disease are sinus pain and purulent drainage, nasal mucosal ulceration, and otitis media. Tracheal inflammation causes stridor and may lead to dangerous airway compromise. Chest x-ray commonly shows nodular radiographic densities, and unlike Churg-Strauss syndrome there is no asthma. [488]

Odynophagia secondary to esophageal vasculitis manifesting as punched out ulcers in the esophagus has been reported. [501] Granulomatous inflammation of the stomach may be mistaken for Crohn's disease. [502] The associated vasculitis may result uncommonly in intestinal or colonic ischemia, bleeding, and perforation. [503]

CHAPTER 129

Fergus Shanahan

GASTROINTESTINAL MANIFESTATIONS OF IMMUNOLOGIC DISORDERS

IMMUNODEFICIENCY DISEASES AND THE GUT

The gut epithelium represents the largest surface area where the host interacts with the environment, separating the lumen from the internal milieu. This structure is vulnerable to access by infectious material. Strategic mucosal defense requires a precisely regulated mucosal immune system supported by a variety of nonimmunologic protective factors, such as gastric acidity, digestive enzymes, peristalsis, mucus secretion, epithelial cell regeneration, and the mutually competitive interactions of the gut flora. [1], [2]

The importance of effective mucosal defense is underscored by the frequency of mucosal infections. Mucosal infections are a major cause of mortality in children under 5 years of age; *Helicobacter pylori* is the most common infection in humans; and diarrheal infectious disease alone accounts for up to 5 million deaths among children worldwide annually. A wide spectrum of opportunistic infections occurs in patients with immune deficiencies. Patients with milder, more selective forms of immune deficiency (e.g., immunoglobulin A [IgA] deficiency), however, are frequently free of infectious complications. The nonimmunologic mucosal defenses as well as the functional reserve of the immune system, probably account for the resistance of these patients to infection. In addition immune deficiencies may predispose to autoimmunity and opportunistic cancers.

CLASSIFICATION OF IMMUNODEFICIENCY DISORDERS

Immune deficiency disorders are categorized into primary and secondary groups. The primary immune deficiencies may be congenital or acquired and result from intrinsic defects in the cellular components of the immune system or their secretory products. In many cases the specific metabolic defect or alteration in gene regulation results in aberrant signal transduction within lymphocytes. [3] Approximately 100 inherited immunodeficiency disorders have been identified; [4] those of particular gastroenterologic importance are discussed in this chapter. For convenience, this heterogeneous group of conditions will be discussed under the following headings: Predominantly B-Cell (Antibody) Defects, Predominantly T-Lymphocyte Defects, Combined B- and T-Lymphocyte Defects, Phagocytic Cell Defects, and Complement Deficiency.

Secondary immunodeficiencies are far more common than the primary disorders. Causes include protein-calorie malnutrition, protein-losing enteropathy, cancer, immune senescence with aging, and the increasingly recognized iatrogenic immunodeficiencies associated with organ transplantation and immunosuppressive agents. The most important secondary immunodeficiency disorder is acquired immunodeficiency syndrome (AIDS), which is discussed separately in Chapter 124.

Predominantly B-Lymphocyte (Antibody) Defects

X-Linked (Congenital or Bruton) Hypogammaglobulinemia This is the prototypic syndrome of a pure B-cell or humoral immunodeficiency. [2] It occurs in males, although rarely in females. The genetic defect results from mutations in the cytoplasmic signal transduction molecule, Bruton tyrosine kinase (Btk), although why the *Btk* gene defect results in arrest of B-cell development is unresolved. [5] The basis for genetic, clinical, and immunologic heterogeneity observed in this condition is unclear; additional genetic and environmental factors may determine the clinical phenotype. Serum levels of all immunoglobulins are less than 100 mg/dL, and there is an inability to make functional serum antibodies. An intrinsic B-cell defect with a maturation block in pre–B-cell to B-cell differentiation is present. [5] The pre–B cells fail to express functional immunoglobulin M (IgM) on the cell surface because of an inability to rearrange immunoglobulin light-chain genes. Pre–B cells are present in bone marrow in normal numbers, but circulating B cells are absent and peripheral lymphoid tissue is hypoplastic with rare or absent plasma cells. The thymus and T-cell function are normal. Patients usually present with recurrent pyogenic infection during infancy (after disappearance of maternal immunoglobulin G [IgG]) or in early childhood. The respiratory and gastrointestinal tracts are the most frequent sites of infection. [6], [7] and [8] Gastrointestinal infections occur in 30% of patients. [6] These are usually infectious diarrheal episodes commonly caused by *Campylobacter* species. Giardiasis can cause severe mucosal damage and steatorrhea in these patients, but it is responsive to therapy and is surprisingly uncommon. Perirectal abscess formation and small-bowel bacterial overgrowth also may occur. In asymptomatic patients, rectal biopsy characteristically reveals an absence of plasma cells and a mild lamina propria neutrophil infiltrate with early crypt abscess formation. [8] This may lead to an erroneous diagnosis of chronic colitis. Although cellular immunity is normal, these patients are susceptible to certain virus infections, notably hepatitis and enteroviral infections including chronic meningoencephalitis and poliomyelitis. [5] There is an increased risk of malignancy, particularly lymphomas and leukemias. Treatment consists of parenteral immunoglobulin replacement. [9]

Selective Immunoglobulin A (IgA) Deficiency Selective IgA deficiency is the most common primary immune deficiency with a variable prevalence in different ethnic groups, reported as high as 1 per 500 population in the Western world (range 1/500–1/3000). [10], [11] Its occurrence is usually sporadic, but familial cases have been reported. Most patients lack both serum and secretory IgA1 and IgA2. The basic defect is not known, and there may be etiologic heterogeneity as well as clinical heterogeneity. Occasionally IgA deficiency may be transient, and a large number of drugs including phenytoin, penicillamine, and sulfasalazine have been linked with reversible deficiency. [10] Although IgA deficiency is associated with a wide range of conditions, [10], [11] and [12] mainly recurrent infections of mucosal tissues and autoimmune disorders (Table 129-1), the majority of IgA-deficient individuals are asymptomatic and are free of a complicating disease. The associations with celiac disease and pernicious anemia may be due in part to a common linkage of IgA and such diseases with HLA-B8/DR3. In one case, IgA deficiency with malabsorption and villous atrophy was associated with an IgG antibody to intestinal epithelial cells and a favorable response to cyclophosphamide. [13]

Gastrointestinal manifestations and associations:
None (usually)
Infections, especially giardiasis (may not be any more common than in general population)
Gluten-sensitive enteropathy (IgA prevalence in celiac disease is 1:50)
Pernicious anemia
Vitamin B_{12} deficiency secondary to bacterial overgrowth
Intrinsic factor deficiency
Nodular lymphoid hyperplasia
Food allergy (increased serum antibodies to food antigens but clinical disease apparently rare)
Crohn's disease (IgA deficiency prevalence reported to be 1:73)
Disaccharidase deficiencies (unproven association)
Extraintestinal manifestations and associations of IgA deficiency:
Non–organ-specific autoimmune disorders (e.g., collagen vascular diseases)
Atopy
Malignancy (lymphomas, carcinoma reported but extent of risk is unclear and probably low)
Risk of anaphylaxis if given IgA-containing solutions, including blood

TABLE 129-1 Disorders That May Occur in Association With Immunoglobulin A (IgA) Deficiency

When infections occur in IgA deficiency, they are usually recurrent bacterial and viral sinopulmonary disorders; the gastrointestinal tract is seldom involved. Giardiasis occurs in IgA-deficient subjects, but unlike pan-hypogammaglobulinemia, its frequency is probably the same as in the general population. When persistent or recurrent infections occur, it suggests associated immunologic defects, such as deficiencies of IgG subclasses, particularly IgG2 and IgG4, which have been found in some patients with IgA deficiency. [10] Jejunal biopsy is usually morphologically normal in selective IgA deficiency, with an absence or paucity of IgA-producing cells and an increase in IgM-secreting cells. This may be an important compensatory response because, like IgA, IgM can bind to a secretory component. Most patients with IgA deficiency require no treatment. Replacement with serum IgA is futile because only locally produced IgA is transported into the lumen. Parenteral administration of IgA-containing blood products may be contraindicated because of the risk of anaphylactic reactions due to anti-IgA antibodies. Whether patients should be screened routinely for IgA antibodies is unclear, as the titer of antibody is not well correlated with risk of anaphylaxis to blood products. Prophylactic IgG therapy for IgA deficiency is either hazardous or ineffective, although some clinicians have reported a beneficial effect. [14] Patients with recurring infections should be screened for IgG subclass deficiency, but can usually be managed with prophylactic or periodic antibiotics without requiring immunoglobulin replacement. [10]

Secretory Component Deficiency Secretory component (SC) is a glycoprotein receptor on the basolateral surface of the mucosal epithelial cell that is essential for the transepithelial delivery of IgA and IgM from the lamina propria to the lumen. Deficiency of SC is very rare, and affects not only lumenal IgA levels but also any compensatory effects of IgM. In isolated case reports, it has been associated with intestinal candidiasis and diarrhea. [15], [16] Administration of IgA-rich bovine colostrum may result in symptomatic improvement. [15]

Common Variable Hypogammaglobulinemia ("Acquired" or Late-Onset Hypogammaglobulinemia) Common variable hypogammaglobulinemia is second to selective IgA deficiency as the most common primary immunodeficiency in adults and is the most common symptomatic primary immunodeficiency. Its variable phenotype and immunologic heterogeneity have hindered identification of the underlying defect(s). It comprises a group of disorders in which there is defective terminal differentiation of B-lymphocytes in the majority of patients. [10], [17] An intrinsic defect within B cells has not been demonstrated yet, and the fundamental defect(s) might reside within T cells or an anomaly of T- and B-cell communication, but not from excessive T-cell suppressor activity. Most cases are sporadic, but the condition can be familial. Clinically, common variable hypogammaglobulinemia may be similar to X-linked (Bruton) agammaglobulinemia, but differences include the later age of onset, less severe infections, the fact that the lymphoid tissue (tonsils, lymph nodes, and spleen) may be normal or enlarged, and the association with autoimmune and granulomatous disease in some patients. [17], [18] The chronic granulomatous disorder resembles the noncaseating lesions of sarcoidosis but is distinct from chronic granulomatous disease associated with defects in neutrophil function (vide infra). Patients present usually in the second or third decade with either recurrent respiratory tract infections (most commonly pneumococci, staphylococci, and *Haemophilus influenzae*) or diarrhea and steatorrhea [10], [17], [18], [19] and [20] (Table 129-2). Up to 60% of patients have chronic recurrent diarrhea; two thirds of these have malabsorption. Enteroviral infection of the central nervous system is rare. Giardiasis is a particularly common cause of symptoms in common variable hypogammaglobulinemia, but unlike in normal individuals, it may be persistent and lead to extensive mucosal damage with steatorrhea and malabsorption. [21] It is usually reversible with appropriate anti- *Giardia* therapy. Other parasitic infections, such as cryptosporidiosis and strongyloidiasis, occur less commonly. Patients with common variable hypogammaglobulinemia are susceptible to bacterial enteric pathogens including *Shigella, Salmonella,* and *Campylobacter* species (*C jejuni* and *C fetus*), which occasionally may mimic ulcerative colitis. Bacterial overgrowth with anaerobes has been described. [18]

Gastrointestinal:
Giardia lamblia infection
Small bowel bacterial overgrowth
Viral gastroenteritis (e.g., rotavirus)
Infectious diarrheas (Campylobacter, Salmonella, Shigella)
Secondary disaccharidase deficiency
Pernicious anemia, atrophic gastritis, gastric carcinoma
Gluten-sensitive sprue
Sprue refractory to gluten-free diet
Nodular lymphoid hyperplasia
Extraintestinal:
Increased incidence of generalized lymphomas
Increased incidence of autoimmune diseases
Recurrent respiratory tract infections
Chronic granulomatous disorder

TABLE 129-2 Disorders That May Occur in Association With Common Variable Hypogammaglobulinemia

In some patients, sprue-like changes may be found on intestinal biopsy, and giardiasis should always be ruled out. True gluten-sensitive enteropathy has not been well documented in common variable hypogammaglobulinemia. Jejunal biopsy generally shows a paucity of plasma cells in the lamina propria, unlike sprue. When the mucosa is flat, an enteropathy refractory to a gluten-free diet is likely. Other intestinal inflammatory disorders that have been reported in common variable hypogammaglobulinemia include Crohn's disease and idiopathic ulcerative jejunitis. [7], [9], [20] In one third of patients with common variable hypogammaglobulinemia, atrophic gastritis and pernicious anemia develop, with a markedly increased risk of gastric cancer. [7], [18] Differences from classic pernicious anemia include the absence of mucosal plasma cells, lack of autoantibodies, involvement of the entire gastric mucosa, and normal rather than elevated serum gastrin levels. Defective gastrin release in response to bombesin or food has been reported as a highly specific means of distinguishing common variable hypogammaglobulinemia from other forms of hypogammaglobulinemia. [22] Chronic liver disease has occurred in 10% to 15% of patients with common variable hypogammaglobulinemia [7], [20] due to hepatitis C or another non-A, non-B hepatitis virus acquired from prior plasma infusion; it has not been a problem with the use of the licensed intravenous immunoglobulin preparations. [20] Cholelithiasis is a frequent feature of common variable hypogammaglobulinemia. [19] Other potential causes of hepatobiliary disease include autoimmune hepatitis, sclerosing cholangitis, and biliary cryptosporidiosis. Nodular lymphoid hyperplasia is frequently found in common variable hypogammaglobulinemia, but it does not occur in X-linked hypogammaglobulinemia and is rare in selective IgA deficiency. The lymphoid nodules usually involve the small intestine but may affect the colon, rectum, and stomach. The nodules consist of large lymphoid follicles with germinal centers within the lamina propria. Plasma cells are either absent or markedly diminished. The lymphoid hyperplasia is thought to reflect B cells unable to undergo full differentiation to immunoglobulin-screening plasma cells. [23] Localized forms of nodular lymphoid hyperplasia may occur in apparently immunocompetent individuals, particularly in the large bowel. In children and adolescents, a self-limited lymphoid hyperplasia in the terminal ileum is a frequent radiologic finding. Although there is an increased incidence of lymphomas in common variable hypogammaglobulinemia, [24] intestinal nodular lymphoid hyperplasia per se does not appear to be premalignant. Almost all patients with common variable hypogammaglobulinemia require parenteral immunoglobulin replacement therapy.

Miscellaneous B-Cell Defects A variety of other syndromes associated with immunoglobulin abnormalities have been reviewed. [3], [4] Gastrointestinal manifestations may occur but are seldom a dominant component of the clinical picture.

Predominantly T-Lymphocyte Defects

Congenital Thymic Hypoplasia (DiGeorge Syndrome) DiGeorge syndrome, the most common contiguous-gene deletion syndrome in humans, is associated with defective formation of the third and fourth pharyngeal pouches during embryogenesis. It is characterized by absent T-lymphocyte function, hypoparathyroidism, and cardiovascular abnormalities, particularly of the aortic arch. The syndrome is due to deletions in the short arm of chromosome 22, and several studies have implicated the transcription factor TBX1 as a key candidate gene, although other genes have a contributory role. [25] Presentation is usually with neonatal tetany or seizures. There may be unusual facies. Other structures developing at the same stage of embryogenesis also may be affected; for example, esophageal atresia may occur. Other gastrointestinal manifestations include candidiasis, chronic diarrhea, and partial villous atrophy with malabsorption. [7]

Chronic Mucocutaneous Candidiasis Chronic mucocutaneous candidiasis (CMCC) represents a spectrum of clinical syndromes in which there is an increased susceptibility to chronic *Candida* infections of the mucosa, skin, and nails. [26], [27] and [28] Most patients become infected with other organisms in addition to *Candida* species. There is variability in mode of inheritance (autosomal recessive and sporadic), age of onset (early or late), and frequency of association with autoimmune disorders such as pernicious anemia and endocrinopathies, including Addison disease, diabetes mellitus, hypothyroidism, and hypoparathyroidism. The latter subset

of patients comprise the autoimmune polyglandular syndrome type 1 (APS1) or autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), a recessive disorder due to mutations in the *AIRE* (autoimmune regulator) gene.[29] Most patients develop infections before the age of 5 years, but some may have the onset of *Candida* infections in adulthood. *Candida* infection most commonly involves the oropharyngeal mucosa, but involvement of the esophagus also may occur and may be present in the absence of oral lesions. Esophageal strictures, nutritional deficits, and the endocrinopathies account for most of the morbidity and mortality associated with the disease. More commonly the skin lesion is a sharply demarcated scaly erythematous macular rash; less commonly it may be granulomatous. Nails of the hands and toes are frequently involved. The *Candida* infection is usually superficial, involving the epidermis, but does not penetrate the dermis or become systemic. A variety of defects in T-cell function have been described. Autoantibodies may precede the development of endocrinopathies. The development of endocrine abnormalities is often insidious, and it is important to evaluate patients regularly for endocrine function. CMCC does not respond well to topical antifungal therapy; systemic agents are usually required. Immunologic reconstitution with therapeutic benefit has been achieved with transfer factor alone or in combination with fetal thymus transplantation.

Miscellaneous T-Cell Defects The molecular basis of several primary disorders of T-lymphocytes has been recognized.[3,30] These rare immunodeficiencies have revealed that although one phenotype may be the result of several gene mutations, a single gene mutation may lead to multiple phenotypes because of the interaction of environmental factors and modifier genes. In many cases, the defects reside in the signaling or transduction pathways for T-lymphocyte activation. Intractable diarrhea caused by diffuse inflammatory enteropathy similar to that seen in genetically engineered mice lacking cytokines such as interleukin-2 (IL-2) and IL-10 is common in disorders associated with T-cell dysfunction.

Combined B- and T-Lymphocyte Defects

Severe Combined Immunodeficiency Syndromes Severe combined immunodeficiency (SCID) is the most severe form of primary immunodeficiency and represents a syndrome caused by several distinct genetic defects, characterized by profound deficiency of T- and B-lymphocyte function and sometimes natural killer (NK) cells.[3,31] At least seven different forms of SCID in humans are now recognized, and the responsible genetic defect has been identified in some of these.[3] The most common form of SCID (60% of cases) is X-linked.[3] It is caused by defective cytokine signaling due to a mutation of the common cytokine receptor ?-chain (?c), a component of the receptors for IL-2, IL-4, IL-7, IL-9, and IL-15. The remainder of SCID cases are autosomal recessive, most of them due to deficiencies of purine-degradation enzymes, such as adenosine deaminase (ADA) and nucleoside phosphorylase. Mutations in the gene for Janus kinase 3 (*Jak3*) which transduces the receptor signal from the common ?c, also cause autosomal recessive SCID, as do mutations in the gene encoding the a-chain of the IL-7 receptor. Another variant of SCID is reticular dysgenesis, in which there is a coexisting deficiency of granulocytes. Clinically, the syndrome presents in early infancy with severe life-threatening infections, chronic diarrhea, malabsorption, and failure to thrive. Graft-versus-host disease (GVHD) due to transplacentally acquired maternal lymphocytes may occur during the neonatal period. There is increased susceptibility to viral infections, including cytomegalovirus, and chronic rotavirus infection may account for the intractable diarrhea in some patients. Jejunal biopsy reveals absent plasma cells, and in some cases there is partial villous atrophy with numerous periodic acid-Schiff–positive macrophages in the lamina propria. A high incidence of gastroesophageal reflux has been reported in association with SCID.[32] Without a bone marrow graft, the clinical course is rapidly fatal. In cases of ADA deficiency, enzyme replacement with irradiated erythrocytes or enzyme conjugated to polyethylene glycol is possible. Results with gene therapy have been encouraging, despite suboptimal initial results in ADA deficiency.[33,34]

Wiskott-Aldrich Syndrome Wiskott-Aldrich syndrome is an X-linked recessive condition characterized by eczema, thrombocytopenia, recurrent infections, progressive defect in T-cell function, and a poor antibody response to polysaccharide antigens. Atopy with elevated immunoglobulin E (IgE) levels is common. The underlying defective gene encodes the Wiskott-Aldrich syndrome protein, a member of a family of proteins responsible for signal transduction from the cell membrane to the actin cytoskeleton in hemopoietic cells.[35] Gastrointestinal manifestations include hemorrhage, chronic diarrhea, malabsorption, and nonspecific colitis. Without treatment, patients die from hemorrhage or the development of Epstein Barr virus–induced lymphoma. Stem cell transplantation is the only curative therapy for Wiskott-Aldrich syndrome.

Ataxia Telangiectasia Ataxia telangiectasia is an autosomal recessive, multisystem disorder. There are defective DNA repair mechanisms, cell cycle abnormalities, frequent chromosomal abnormalities, increased sensitivity to ionizing radiation, and predisposition to cancer. The gene responsible for this syndrome (*ATM*) encodes a product similar to phosphatidylinositol-3-kinases, which are involved in signal transduction and cell-cycle control.[36] The most prominent clinical features are progressive cerebellar ataxia, oculocutaneous telangiectasia, chronic recurrent sinopulmonary infections, and a high incidence of malignancy. The immune deficiency is variable and affects both cellular and humoral elements. IgA deficiency occurs in over 50% of patients and may be associated with IgG2 subclass deficiency. Malignancies are the most common cause of death. They usually are lymphoreticular, but adenocarcinomas also occur. Other gastrointestinal complications are not common in ataxia telangiectasia. Mild abnormalities of liver function may occur, and levels of a-fetoprotein are elevated.

Phagocytic Cell Defects: Chronic Granulomatous Disease

Intrinsic defects in neutrophils, monocytes, and macrophages include several disorders of cell locomotion, chemotaxis, killing, and metabolism. Numerically, the most important of these and the most frequently encountered in gastroenterology is chronic granulomatous disease.

Chronic granulomatous disease represents a group of disorders of phagocytic cell oxidative metabolism. There are several variants of the basic defect in oxidase function, and more than one mode of genetic transmission is involved.[37,38] In its classic form, inheritance is X-linked and is caused by mutations in the gene coding for the ß-subunit of cytochrome ß558, which is the catalytic redox entity of nicotinamide adenine dinucleotide phosphate (NADPH) and responsible for generating superoxide in phagocytes. More rarely, chronic granulomatous disease may be transmitted in an autosomal recessive or dominant pattern caused by mutations in the a-subunit of cytochrome ß558 or in cytosolic proteins required for activation of NADPH.

The respiratory burst associated with stimulation of phagocytes is lacking. This results in defective microbicidal activity because of the failure to generate toxic oxygen metabolites such as hydrogen peroxide. There is a markedly increased susceptibility to pyogenic and fungal infections, including staphylococci, *Serratia marcescens, Salmonella,* gram-negative enterococci, and *Candida* and *Aspergillus* species. There is particular susceptibility to infections with catalase-positive organisms. In contrast, catalase-negative organisms such as pneumococci, streptococci, and lactobacilli are not major pathogens in chronic granulomatous disease because they do not destroy their endogenous hydrogen peroxide and thereby contribute to their own demise.[37]

The condition classically presents during infancy, although variants of the disease may present later. Every organ is vulnerable to infection, and the associated granulomas occur throughout the body. Their formation is not well understood. They consist of plasma cells, lymphocytes, macrophages, and occasional multinucleated giant cells without organisms. A second type of granuloma occurs in which hyphal elements of fungi are found in giant cells. Pigmented, lipid-bearing tissue histiocytes also are found.[39]

Hepatic and gastrointestinal disorders are a prominent feature of chronic granulomatous disease. Hepatomegaly is very common, with liver abscess formation in more than 30% of patients. *Staphylococcus aureus* is the most common organism in the abscesses, which often require surgery and may be recurrent.

Gastrointestinal presentations of chronic granulomatous disease may mimic Crohn’s disease, and commonly include chronic gingivitis and stomatitis, perianal abscesses with fistulae, *Salmonella* gastroenteritis, diarrhea, and malabsorption.[37,39] The characteristic granulomas and pigmented histiocytes may be found in patients with no gastrointestinal symptoms. In some patients the granulomatous reaction leads to stricture formation, most commonly in the gastric antrum. Although surgical treatment may be required, resolution of strictures following antibiotic therapy is well known, and aggressive antimicrobial therapy is the treatment of first choice.[37,40]

Complement Deficiency: Hereditary Angioedema (C1 Esterase Inhibitor Deficiency and Nondeficiency Syndromes)

Deficiency states involving individual complement proteins are rare. In general, they are associated with a high incidence of infectious and autoimmune disorders.[41] Deficiency of C1 esterase inhibitor is the most common complement deficiency state and the major one in which gastrointestinal symptoms are a prominent feature. Defective C5a inhibitor protein in serosal fluid in patients with familial Mediterranean fever also occurs.[42]

Hereditary angioedema is characterized by recurrent, self-limited attacks of circumscribed nonpitting, subepithelial edema in the skin and mucous membranes.[43] The skin lesions are painless, and, unlike urticaria, pruritus is absent. The onset of symptoms is variable, although most patients have their first episode in childhood. A positive family history is common. Attacks may develop over hours and may last from hours to several days, often precipitated by minor local trauma, dental extractions, infections, and surgery. There is frequently initial awareness of a tingling sensation in the affected area, and a faint macular or serpiginous erythema may precede the swelling. The most serious manifestation is laryngeal edema, which may lead to fatal airway obstruction. Gastrointestinal involvement is common and includes colicky abdominal pain, vomiting, and watery diarrhea. Significant intestinal fluid loss can occur, leading to hypotension and shock. Fever and leukocytosis are notably absent. The abdomen may be tender but not rigid. Bowel sounds may be increased. Barium studies during an attack may show the “stacked coin”

appearance of mucosal edema. The lesions consist primarily of circumscribed edema without inflammatory cellular infiltrates. The edematous segment of bowel can cause intussusception. When gastrointestinal symptoms precede other manifestations, or occur in isolation, the diagnosis is often delayed, and many of these patients have been subjected to unnecessary abdominal surgery. [44]

Hereditary angioedema is transmitted in an autosomal dominant manner. [45] In approximately 85% of patients, the levels of C1 esterase inhibitor (C1-INH) are low due to heterozygosity for a non-expressed C1 inhibitor allele. In a minority of patients, levels of the inhibitor protein are normal but it is functionally defective due to heterozygosity for a nonfunctional C1 inhibitor allele. A third, estrogen-dependent, inherited form of angioedema has been described with no defect in C1-INH. [46], [47] and [48] This is transmitted in an autosomal dominant manner but may be X-linked in some cases. Episodes of angioedema are indistinguishable from those associated with other forms of the disease, but occur only during pregnancy or with the use of exogenous estrogens. Acquired forms of angioedema due to increased catabolism of C1-INH are clinically similar to the hereditary disorders occurring particularly in patients with lymphoproliferative disorders and collagen vascular diseases. [49] Drugs such as angiotensin-converting enzyme inhibitors may also cause angioedema.

The pathogenesis of angioedema is not fully understood, but the increased vascular permeability may be mediated by kinins. C1-INH prevents autoactivation of C1 and inhibits activated Hageman factor and kallikrein. The diagnosis, in most cases, is confirmed by quantitative and qualitative analysis of C1-INH. In addition, levels of C4 are secondarily reduced between attacks and nearly absent during attacks. Infusion of C1-INH concentrate is safe and effective treatment for severe attacks of hereditary angioedema. [50], [51] For prophylaxis, attenuated androgenic steroids, such as danazol and stanozolol, are effective. These drugs restore levels of C1-INH and C4, but may have other effects because patients often respond to low doses that do not raise levels of C1-INH and C4. The dose used should be tailored mainly to clinical rather than biochemical response.

Immunodeficiency Secondary to Gastrointestinal Disease: Protein-Losing Enteropathy and Intestinal Lymphangiectasia

Immunodeficiency due to protein loss may be a component of any severe inflammatory condition in the gastrointestinal tract; examples include protein-losing gastroenteropathy (PLGE) (e.g., Ménétrier disease) and extensive Crohn's disease. [52] However, the more severe cases of gastrointestinal protein loss occur in the setting of primary lymphangiectasia or secondary lymphatic obstruction [53] (see Chapter 81).

Other Secondary Immunodeficiencies of Gastroenterologic Importance

Protein-calorie malnutrition leads to significant depression of cell-mediated immune function. This may occur in association with malignancy, particularly lymphoreticular tumors. Iatrogenic immunosuppression is an increasingly common cause of secondary immunodeficiency (e.g., the occurrence of reversible IgA deficiency with drugs such as sulfasalazine, penicillamine, and phenytoin or in patients undergoing organ transplantation) (see Chapter 51). The increased susceptibility to *Candida* and other infections with corticosteroids is well known, but it is also important to be aware that corticosteroids are the most common cause of superinfection with *Strongyloides stercoralis.* [54]

Within developed countries, older adults are increasingly at risk of immunodeficiency. Systemic immune deficiency has been associated with increasing age, and infectious diseases are an important cause of morbidity and mortality in older patients. Studies of age-related changes in immune function have yielded conflicting results, however, and there is a lack of conclusive information on mucosal immune senescence in humans. The significance of age-related alterations in immune function is uncertain; reduced mucosal resistance and risk of bacterial overgrowth in older adults are probably multifactorial. Nonimmunologic risk factors include motility disturbances, achlorhydria, co-morbidity, polypharmacy, and antibiotic use with altered enteric flora. [55]

Neutropenic Enterocolitis Neutropenic enterocolitis is commonly a complication of chemotherapy for hematologic malignancy but may occur in patients with neutropenia of any cause. [56], [57] and [58] It is increasingly recognized, probably because of greater use of potent chemotherapy, occurring in 6% of patients treated for leukemia. [57] Neutropenic colitis is also called necrotizing enterocolitis, ileocecal syndrome and typhlitis (from the Greek *typhlos* meaning "blind sac" or cecum). It usually begins 7 to 10 days after chemotherapy, and affects primarily the ileocecal region with clinical manifestations ranging from abdominal discomfort, vomiting, distension, diarrhea, and tenderness to local or generalized peritonitis after perforation. Secondary sepsis due to bacterial translocation is common. Diagnosis requires a high index of suspicion—many cases are diagnosed postmortem. Bowel wall thickening may be evident on plain radiography and on ultrasonography or computerized tomography. Barium studies are generally avoided because of the risk of perforation. Management includes fluid and electrolyte replacement, broad-spectrum antibiotic coverage, and restoration of neutrophil count if possible. Depending on the severity, surgery may be required. [56], [58]

FOOD ALLERGY (HYPERSENSITIVITY)

Increasing public perception of potential adverse reactions to foods and food additives requires that physicians have a clear understanding of the true significance of food allergies. Although immunologic hypersensitivity to food stuffs was demonstrated almost 70 years ago, the issue of food allergy has been controversial. [59], [60] Much confusion has been created by the failure to use appropriate terminology distinguishing food allergy from other forms of adverse food reaction and to use an unbiased approach to the investigation of potential adverse reactions to foods. The development of scientifically sound experimental approaches has advanced our understanding of the pathogenesis of food allergy and improved diagnostic management of the problem. [61], [62] Reviews by the American Academy of Allergy and National Institutes of Health [63] and the American Gastroenterological Association [64], [65] have clarified and standardized terminology regarding adverse reactions of foods.

Classification and Prevalence

The terms *food allergy* and *food hypersensitivity* may be used interchangeably but should be reserved for those reactions that have been shown to be mediated by the immune system (Table 129-3). *Food intolerance* is a term that should be used to describe nonimmunologically mediated adverse reactions to food or food additives that may closely mimic acute allergic reactions. Reactions to food additives, such as sulfites, salicylates, and tartrazine, may be more common and as important as allergy to natural food components (see Table 129-3). Some foods may produce adverse reactions by multiple mechanisms in different individuals, including allergic reactions to milk proteins or, rarely, to contaminant antibiotics, or they may result from lactose intolerance or fat intolerance.

Immunologically mediated:
Early: Immunoglobulin E–mediated
Delayed: Late-phase reactions, immune (complex-mediated or cell-mediated immunity (e.g., celiac disease, most cases of cow's milk allergy)
Nonimmunologically mediated:
Idiosyncratic
Gastrointestinal (e.g., lactase deficiency)
Systemic (e.g., glucose 6-phosphate-dehydrogenase deficiency)
Pharmacological (e.g., caffeine, tyramine, serotonin, alcohol, histamine)
Toxic (e.g., aflatoxins, botulism, mushroom toxins)
Infectious (e.g., salmonellosis)
Other contaminants and additives
Antibiotics, pesticides
Dyes (e.g., tartrazine)
Flavorings and preservatives (e.g., monosodium glutamate [Chinese restaurant syndrome], sulfites, benzoate, nitrites, and nitrates)
Gastrointestinal disorders (e.g., peptic ulcer, cholelithiasis)
Psychological (e.g., phobias, avoidance, faddism)

*This list is intended to be representative and is not comprehensive.

TABLE 129-3 Differential Diagnosis of Adverse Reactions to Foods*

The spectrum of nonimmunologically mediated food intolerance is wide (see Table 129-3) and includes food avoidance, which may arise for various reasons, including faddism, anorexia nervosa, or even dysgeusia. Common causes of dysgeusia include medications (mostly halogen salts), menopause, and depression.

Community surveys indicate that at least 20% of adults believe that they have an adverse reaction to some food. When tested objectively, using blinded food challenges, the majority of complaints cannot be reproduced; estimates closer to 1% are more realistic. [66], [67] and [68] Most adverse reactions to food are probably not

immunologically mediated. The prevalence of true food allergy is more common in atopic individuals and in children, but declines with age. Estimates of the frequency of food allergies in children are about 5%, although cow's milk allergy may be more common. [65] In adults, food allergy is a well-documented entity, [66] but is uncommon. True food allergy is a most unlikely diagnosis in adults presenting with new onset of gastrointestinal symptoms in the absence of a strong atopic background or without a history of food allergy since childhood.

Immune Response to Dietary Antigens

Small amounts of antigenic macromolecules normally penetrate the gastrointestinal mucosal barrier and reach the systemic circulation, occurring more in early life and in conditions causing disruption of the mucosal defenses. Uptake of antigenic material and presentation to the mucosal immune system may occur by three main routes. [2] First, the specialized microfold or M cells that overlie lymphoid follicles are adapted to sampling lumenal antigens and delivering them to dendritic cells for presentation to T cells. [70] Second, the surface enterocytes lining the intestine are also capable of presenting antigens, and can selectively stimulate suppressor T cells in vitro. [71], [72] Although the significance of enterocyte-mediated uptake and processing of antigens in vivo is unclear, preferential stimulation of suppressor cells could be an important mechanism preventing hypersensitivity to dietary antigens. Finally, antigen sampling occurs across the epithelium by dendritic cells, which are capable of extending to the lumen without disrupting epithelial tight junctions. [73]

When dietary antigen engages the immune system, there may be a local secretory IgA antibody response, but a systemic immune response seldom occurs. Most commonly, a state of immunologic tolerance develops. Oral tolerance (sometimes termed the Sulberger-Chase phenomenon) is a state of specific immunologic unresponsiveness that occurs following oral ingestion of antigen, and significantly regulates immune responses to dietary antigens. [2], [74] Immune responses that are most easily suppressed or tolerated by feeding proteins are IgE-mediated and delayed-type hypersensitivity responses. Not surprisingly, these are the major immunologic reactions mediating food allergy. Stated differently, food allergy or hypersensitivity represents a breakdown in oral tolerance. Mechanisms responsible for the induction and maintenance of oral tolerance appear to involve activation of regulatory T cells. The molecular mediators include suppressive cytokines, particularly transforming growth factor-ß. [75] Moreover, the liver appears to down-regulate systemic immune responses to dietary antigens, [59] and the enteric flora have an obligatory role in the establishment of immune tolerance. [76]

Susceptibility to food allergy is genetically influenced but environmental determinants also play a role. All forms of allergy, including food allergies, are more common in developed countries, linked with improved sanitation and changes in the pattern of exposure to childhood infections. Some enteric infections may have a protective effect against food allergy, [76] although the relationship is complex since enteric infections may also act as an adjuvant for responses to ingested antigens. [77]

Pathogenesis of Food Allergy

The majority of food hypersensitivity reactions are caused by a relatively small number of foods, [64], [65] especially milk, eggs, nuts, fish, shellfish, soybeans, and wheat. For several of these foods, the specific allergen has been isolated or cloned. [78] Many food allergens are heat- and acid-stable, are resistant to proteolysis, and have a relatively low molecular weight. Their immunogenicity may be retained with food processing and digestion, and they have the appropriate size for bridging IgE on the surface of mast cells.

Since food-labeling regulations vary in different countries, allergens may be hidden in processed foods. [79] With the development of transgenic foods, it is also important to be aware that food allergens may be transferred by genetic manipulation. [80]

Food-allergic or hypersensitivity reactions are either immediate (IgE-mediated, type I hypersensitivity) or delayed (late-phase IgE-mediated, immune complex–mediated, and cell-mediated). Immediate or IgE-mediated hypersensitivity reactions account for the majority of immunologically mediated adverse reactions to foods. Delayed-type hypersensitivity is involved in the pathogenesis of gluten-sensitive enteropathy (see Chapter 76).

The wheal and flare reaction that occurs in some individuals after intradermal injection of a food allergen is due to the presence of food-specific IgE antibodies on the surface of cutaneous mast cells; adjacent IgE molecules are cross-linked by the allergen and trigger degranulation of the mast cell. This phenomenon could be passively transferred by a factor now known to be IgE. [81] When normal subjects were injected with serum from fish-sensitive patients, they developed wheal and flare reactions at the injection site upon ingestion of fish, showing that such antigens can reach and trigger mast cells at extragastrointestinal sites.

The central role of mast cell degranulation (Fig. 129-1) in the pathogenesis of food allergy is supported by the increased plasma levels of histamine in patients with cutaneous, gastrointestinal, and respiratory symptoms elicited by double-blind, placebo-controlled food challenge but not in patients with negative food challenges. [61], [62] Peripheral blood mononuclear cells from some patients with food allergy may spontaneously produce an IgE-dependent histamine-releasing factor that is associated with high spontaneous release of histamine in vitro from the patient's basophils and mast cells. [82] Studies in mast cell-deficient murine models of food hypersensitivity confirmed the central role of mast cells and their functional interaction with nerves and epithelial cells. [83] Eosinophils may partially mediate the late phase of food allergic reactions within the gut mucosa in experimental animals [84], [85] and may contribute to allergy-related dysmotility syndromes. [65] Interleukin-5 and the eosinophil chemokine ecotaxin are the primary mediators of eosinophil recruitment to the mucosa. [84], [85] and [86]

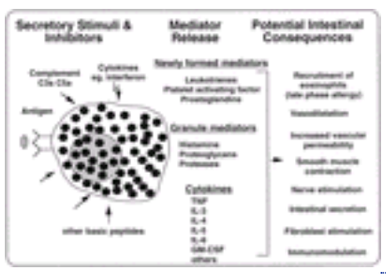

FIGURE 129-1. Mast cell mediators and potential consequences of their release. Mediator release is triggered when adjacent IgE antibodies on the surface of the mast cell are bridged by binding to an allergen. Mast cell secretion may also be stimulated by a variety of other endogenous and exogenous factors, including activated complement components (C3a and C5a), neuropeptides, bee venom, polymyxin, ionomycin, and opiates.

Clinical Features of Food Allergy

Symptoms usually occur within minutes of ingestion but may be delayed several hours. Systemic anaphylaxis is the most serious manifestation of food hypersensitivity and may be the first presentation. Co-factors such as aspirin ingestion or exercise may have a profound effect on the clinical expression of food hypersensitivity. Postprandial, exercise-induced systemic anaphylaxis has been well documented. More common, a variety of less severe and usually transient symptoms may be experienced. The organs primarily affected are the skin (eczema, urticaria), the respiratory tract (rhinitis, asthma), and the gut. [65], [87]

Gastrointestinal symptoms are nonspecific and range from edema and pruritus of the lips, buccal mucosa, and pharyngeal mucosa to vomiting, cramping, distension, and diarrhea, depending on the level of the gut primarily affected. Symptoms primarily involving the buccal or lingual mucosa (oral allergy syndrome) are particularly common and may not be associated with other gastrointestinal manifestations. Chronic diarrhea and malabsorption may arise as a result of non–IgE-mediated delayed hypersensitivity reactions, such as in food-protein enteropathies and celiac disease (see Chapter 76). Cows' milk hypersensitivity in infants may cause occult bleeding or frank colitis. [65], [88] Food allergy is not responsible for most cases of irritable bowel syndrome but should be considered in the small subset of patients with a strong history of atopy. [89] The importance of taking a careful history is confirmed by studies showing that symptoms can discriminate irritable bowel from food allergy. [90] There is no convincing evidence for food allergy in the pathogenesis of inflammatory bowel disease. Links between food allergy and other syndromes including esophageal reflux and dysmotility appear important in children and have been reviewed elsewhere. [65]

Evaluation of the Patient With Suspected Food Allergy

Only a small number of adult patients referred with a supposed food allergy have a reproducible, immunologically mediated adverse reaction to food. [67], [91] A careful and objective assessment is important not only to detect preventable disease in such patients but also to offset inappropriate and potentially harmful dietary restriction in others. Although the differential diagnosis of food-related symptoms is broad (see Table 129-3), a detailed history and physical examination will often indicate the correct diagnostic category. The most definitive criteria for the diagnosis of food allergy are:

- ingestion of the implicated food reproducibly induces the patient's symptoms evidence that an immunologic mechanism is involved.

A general diagnostic guideline is shown in Figure 129-2. [64] In practice the diagnostic approach should be individualized, and the rigor with which one attempts to prove the diagnosis will be influenced by several factors, such as the age of the patient, the nature and nutritional importance of the food implicated, the likely reliability of the patient's history and compliance with challenge test protocols, and the severity of the symptoms. For example, patients who are thought to be allergic to several major food groups require an accurate confirmation of the diagnosis because of the inconvenience and potential danger of malnutrition with prolonged, complicated restriction diets. In contrast, patients with only episodic symptoms triggered by uncommonly encountered or nonessential foods should be instructed to avoid such foods and do not require rigorous food challenges. For reliable patients with a clear history of objectively verifiable symptoms and signs, an open challenge may suffice. The patient with vague or subjective complaints, self-diagnosed as an adverse reaction to food, poses the greatest difficulty. In adults, particularly the nonatopic individual, the likelihood of such symptoms being due to food allergy is small. Prolonged investigative evaluation beyond simple screening tests may not be appropriate or desirable for these patients. [91]

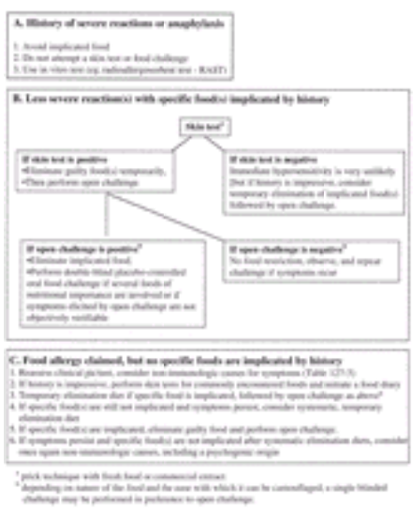

FIGURE 129-2. General guidelines for the investigation of adult patients with suspected food allergy.

Food challenges and skin testing with food antigens can trigger potentially serious and even fatal anaphylaxis in a small percentage of patients. Such diagnostic tests should be performed only by experienced physicians and only in a facility equipped to address serious allergic reactions.

Skin Tests and In Vitro Assays In vitro tests for cellular immunity to food antigens and assays for food antigen-antibody complexes are still under investigation and not recommended for routine diagnostic use. For practical purposes, the demonstration that an adverse reaction to food is immunologically mediated involves the demonstration of IgE antibodies specific for the implicated food allergen. Direct skin testing with the prick technique with food extract and control solution is a simple and sensitive method of detecting specific mast cell–bound IgE antibodies. [65], [69] If properly performed, a negative skin test indicates that immediate hypersensitivity to the food tested is highly unlikely. However, a positive test (wheal >3 mm in diameter larger than that of the control wheal) merely indicates the presence of sensitizing antibodies and not necessarily the presence of clinical food hypersensitivity, which can be confirmed conclusively only by food challenge (see Fig. 129-2). Skin testing should not be attempted if the clinical history indicates there is a substantial risk of anaphylaxis; an in vitro assay for the presence of allergen-specific IgE in the serum should be used. Assays for IgE antibodies to several of the known food allergens include the commercially available radioallergosorbent test and enzyme-linked immunosorbent assay (ELISA) kits. Less commonly used is the basophil histamine release assay, which is performed mainly in research laboratories. There is no place for the nonvalidated, so-called cytotoxicity food allergy test, which is still widely advertised in the lay press. [64], [65]

Elimination Diets Systematic elimination of different foods and the use of a food/symptom diary may help identify foods to which a patient might be allergic. Resolution of symptoms and recurrence with reintroduction of selected foods is consistent with a diagnosis of food hypersensitivity. If multiple or several major food groups are implicated, confirmation should be obtained by controlled food challenge. The design of the diet, particularly the degree of food restriction, will depend on the patient's history and the number of potential food allergens thought to be involved. Detailed discussion and examples of different elimination diets are available. [63], [65] Ideally, the design of the diet should involve an experienced dietitian. Reintroduction of the implicated food(s) should be supervised by a physician; anaphylaxis was reported in 5% of patients with atopic dermatitis during food challenge following elimination trials. [92] The most restrictive elimination diet is an elemental diet. Elemental diets are unpleasant to take, but on a short-term basis they may be diagnostically useful in patients claiming to have allergies to multiple foods, or where the possibility of food allergy is a major concern but no specific food has been implicated by the clinical history. Persistence of symptoms on such a diet excludes food allergy from the differential diagnosis. If symptoms resolve on an elemental diet, various foods may be reintroduced in a systematic fashion.

Food Challenge A double-blind, placebo-controlled oral food challenge is the most reliable and unbiased method for determining if symptoms are related to a specific food. However, like direct skin testing, oral food challenge is contraindicated in patients with a history of food-related anaphylaxis. Dehydrated foods are most convenient for diagnostic challenges because they can easily be disguised in a variety of vehicles or gelatin capsules, and are commercially available. Detailed guidelines for the performance of food challenges have been published. [93], [94] Because the double-blind, placebo-controlled food challenge is time consuming and expensive, "single-blinded" or "open" challenges are convenient initial tests in selected cases to rule out food allergy or to help identify those who require a double-blind challenge (see Fig. 129-2). Direct challenge of the intestinal mucosa with food antigen extracts using colonoscopy has been used to identify patients with intestinal allergy. Mucosal wheal and flare reactions are recorded semiquantitatively and tissue biopsy specimens are examined for mast cell and eosinophil activation. As with skin testing, positive and negative controls are required and similar safety considerations must be applied. The most suitable gastrointestinal site for the challenge has not been determined and may vary in different individuals and depend on the nature of the allergen. [95]

Treatment and Prevention of Food Allergy

The majority of patients can be reassured they will outgrow their food allergy. Peanut allergy, the most common cause of severe food allergy in adults, may be an exception, although it is outgrown in approximately 20% of cases. [96] The only acceptable treatment of food allergy is avoidance of the offending food. Patient education is the best means of ensuring dietary compliance. Expert instruction and supervision by an experienced dietitian reduce the likelihood of inadvertent ingestion of allergens. Drug therapy with antihistamines and corticosteroids has only a secondary role in the management of symptoms due to inadvertent ingestion of food allergens. [97] Parenteral immunotherapy (hyposensitization) with food extracts has been disappointing and has no role at present. There is some evidence to suggest that breast-feeding until infants are 6 months old may have a protective effect against the development of food allergy. The potential prophylactic role of altering the enteric microflora with probiotics has become an area of investigation. [98]

EOSINOPHILIC GASTROENTERITIS

Pathophysiology

Eosinophilic gastroenteritis is probably not a single entity but rather a heterogeneous collection of disorders of varied causes with similar clinicopathologic features. [65], [99], [100] Allergic phenomena, particularly food hypersensitivity, have been proposed to account for eosinophilic gastroenteritis but the evidence for this is limited in

many patients. Although food hypersensitivity (usually to milk) may be found in children with eosinophilic gastroenteritis, the response to dietary elimination is often disappointing. Some patients have no atopic symptoms, and fewer than half of all patients with eosinophilic gastroenteritis have a positive family history of allergy. Studies of experimental models of allergic intestinal disorders have demonstrated the role of the eosinophil chemokine, ecotaxin, and of eosinophils in mediating intestinal injury including neuronal damage. [84], [85] Other cytokines including IL-3, granulocyte-macrophage colony-stimulating factor, and IL-5 promote persistence of the eosinophil infiltration within the gut. [86], [101], [102]

Clinical Manifestations

The clinical manifestations of eosinophilic gastroenteritis depend on the gastrointestinal site primarily affected and the layer of bowel wall predominantly involved. [65], [99] The stomach and intestine are most commonly involved, but the disease may affect any part of the gastrointestinal tract as well as the pancreatic and biliary tree. When the predominant involvement is mucosal, the condition behaves like other forms of inflammatory bowel disease, with diarrhea, cramping, postprandial nausea, vomiting, and periumbilical pain. If the eosinophilic infiltration is extensive, there may be malabsorption, weight loss, protein-losing enteropathy, blood loss, and anemia. In preadolescents, growth retardation may occur. A low level of peripheral eosinophilia occurs in most cases. Stools may be positive for occult blood, although frank hematochezia is rare. Charcot-Leyden crystals secondary to lumenal extrusion of eosinophils may be seen. Detection of these distinctive hexagonal bipyramidal crystals may be easier with fluorescence microscopy than conventional light microscopy. Although characteristic of eosinophilic involvement in inflammation, they may also be derived from basophils and are not specific for allergic reactions, being found in parasitic and other causes of inflammation including idiopathic inflammatory bowel disease. Quantification of mediators such as eosinophil cationic protein and eosinophil protein X within stool samples promises to be an alternative diagnostic strategy. [103] Definitive diagnosis of mucosal eosinophilic gastroenteritis is made by barium roentgenography and gastric and small bowel biopsy. A diffuse mucosal pattern with nodules or intralumenal masses and a sawtooth mucosal pattern may be noted in the small bowel. A widening of small bowel segments may be seen secondary to mesenteric nodal involvement. Gastric lesions may have a cobblestone appearance in the antrum and thickening of mucosal folds. Small bowel biopsies may be diagnostic, showing a diffuse infiltration of the mucosa with eosinophils. However, because eosinophilic gastroenteritis may present as a patchy intestinal disease, multiple biopsies at different levels of the gastrointestinal tract should be performed.

When eosinophilic gastroenteritis predominantly involves the muscularis layer of the intestine, the clinical presentation consists of intestinal obstruction with nausea, vomiting, pain, and abdominal distention. Barium studies of the upper gastrointestinal tract will usually demonstrate irregular narrowing of the distal antrum or small bowel. Endoscopic mucosal biopsy may not be helpful. Occasionally, isolated infiltration of esophageal muscle may be seen with symptoms and manometry evaluations suggestive of achalasia. Rarely, the eosinophilic infiltration is predominantly serosal and may be associated with eosinophilic ascites or pleural effusions.

Some cases of gastroesophageal reflux, particularly in children, may represent a localized form of eosinophilic infiltration—eosinophilic esophagitis. [65] This suggests that food allergy or other hypersensitivity phenomena should be considered in the management of children with reflux. Whether there is a similar process in adults is less clear and probably uncommon.

Differential Diagnosis

Diseases associated with peripheral eosinophilia in addition to mucosal eosinophilic infiltrates may mimic idiopathic mucosal eosinophilic gastroenteritis. The most frequently encountered is the hypereosinophilic syndrome, characterized by diffuse gastrointestinal involvement, frequent peripheral eosinophilia, and eosinophils in several other organs. Periarteritis nodosa may be associated with a peripheral eosinophilia, and abdominal pain and nodular masses in the stomach and small bowel may be seen on radiography. This condition may be distinguished from eosinophilic gastroenteritis by the systemic nature of the inflammatory process and by the eosinophilic infiltrate localized to the perivascular region. The nodular polypoid mucosal findings on radiograph in periarteritis nodosa are secondary to ischemia and inflammation rather than eosinophilic infiltration. Intestinal parasitism (hookworm, *Ascaris, Strongyloides, Toxocara, Trichuris, Capillaria,* and *Trichinella* species) causes peripheral eosinophilia and gastrointestinal symptoms, including diarrhea and abdominal pain. The diagnosis is usually suggested by the clinical history and confirmed by stool analysis and examination of a duodenal aspirate. Protozoal infections such as amebiasis and giardiasis are not associated with eosinophilia. Finally, intramural collections of mature eosinophils, most commonly in the stomach, are often seen in eosinophilic granuloma. These patients present with symptoms of gastric obstruction. The isolated nature of the granuloma may help distinguish this disorder.

The second major category of diseases that may mimic eosinophilic gastroenteritis clinically and radiologically includes inflammatory and infiltrative disorders, such as gastrointestinal lymphoma, scirrhous carcinoma of the stomach, and Crohn's disease. These conditions may be associated with a mild increase in eosinophils histologically.

Treatment

There is no specific treatment for eosinophilic gastroenteritis. An attempt to identify a specific environmental or food allergen may be considered if there is a convincing history of symptoms triggered by food and if there is a strong background of atopy. In most adult patients, a specific food will not be implicated, and prolonged investigation with elimination diets is not appropriate. If necessary, a trial of an elemental diet can quickly eliminate a role for food hypersensitivity. Oral corticosteroids, 20 to 40 mg prednisone/d are effective in most patients. A short course of 7 to 10 days usually produces clinical remission, although repeat courses may be required. Some patients may require more prolonged treatment. The long-term prognosis for patients with eosinophilic gastroenteritis is generally favorable, and the disease course is one of waxing and waning severity. Occasionally, the use of total parenteral nutrition is required to manage patients with severe disease and symptoms that are refractory to steroids. Segmental resection of the intestine is not curative.

GASTROINTESTINAL COMPLICATIONS OF ORGAN TRANSPLANTATION

Gastrointestinal complications are common in patients undergoing transplantation, particularly bone marrow transplantation. Complications include toxicity of induction protocols (radiation or chemotherapy) prior to bone marrow grafting; acute and chronic GVHD; and opportunistic infections due to immunodeficiency associated with both the induction procedure and graft-versus-host reactions. [104], [105] and [106] Some of the clinical and diagnostic characteristics that help distinguish these entities in the setting of bone marrow transplantation are shown in Table 129-4.

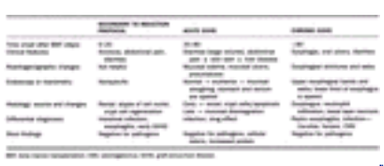

TABLE 129-4 Gastrointestinal Complications of Bone Marrow Transplantation

Intestinal Disease Secondary to Induction Protocols

Induction protocols are varied and include multiple agents (both chemotherapeutic agents and high-dose radiation), which are capable of injuring rapidly dividing cell populations and producing intestinal cell death (see Table 127-4). Enterocyte death occurs immediately during the induction and requires up to 3 weeks before there is mucosal regeneration. Both the small and large intestine are damaged during this process, although the small intestinal epithelium is more susceptible to this form of cell death. [107] Anorexia, cramping, and abdominal pain, with watery diarrhea, may develop. During healing, there is atypia of cell nuclei and regeneration of crypt cells, but the surface epithelium is normal. [108] This histopathological picture is important in helping distinguish this entity from acute GVHD or secondary viral infections. The time of onset following bone marrow transplantation is a helpful clue, and rectal biopsy with negative stool cultures are the most important diagnostic tests (see Table 129-4). Treatment consists of supportive measures and parenteral nutrition.

Graft-Versus-Host Disease

GVHD is most frequently seen in the setting of bone marrow transplantation but may occur with other transplants. Acute GVHD is characterized by epithelial cell death mainly in the gastrointestinal tract, liver, and skin, whereas chronic GVHD is characterized by fibrosis and atrophy of these and other organs. [109] GVHD is a multistep process in which the induction phase involves primarily CD4 T-lymphocytes transferred with the donor graft which recognize disparities with the recipient's major histocompatibility complex (MHC) antigens as foreign. Different subsets of memory T cells expressing distinct adhesion olecules home separately to the gut and skin. [110] Activation of these alloreactive donor T cells within the tissues is followed by clonal expansion (expansion phase). This is followed by cytokine and chemokine release ("cytokine storm") which leads to recruitment of additional inflammatory cells (effector phase). [111] The immunopathology is consistent with T-cell–mediated tissue injury, [112], [113] with predominance of tumor necrosis factor-a (TNF-a) and other T_H1 cytokines. [114], [115]

Acute GVHD A moderate to severe degree of acute GVHD develops in 30% to 50% of patients with sustained bone marrow engraftment. Acute GVHD may be staged on the basis of skin (dermatitis), gut (mucositis, enteritis), and liver damage. [104], [105] The onset or continuance of profuse, watery diarrhea 3 weeks following bone marrow transplantation is indicative of intestinal acute GVHD. The severity of the intestinal condition generally parallels that of the skin and liver involvement, although profound gastrointestinal symptoms can occur without any gross skin or liver changes. Altered mucosal barrier function due to conditioning protocols is associated with increased translocation of bacterial lipopolysaccharide (LPS) and the responsiveness of donor cells to LPS appears to predict the severity of acute GVHD. [116] The clinical picture, when severe, includes anorexia, vomiting, buccal mucositis, abdominal pain, intestinal bleeding, protein loss, and secondary infection (see Table 129-4). High-volume diarrhea may occur, and the amount of fluid generated is an index of extent and severity of disease activity. Extensive disease may be associated with up to 10 L of diarrheal fluid loss per day. The large stool volume may lead to distention and pain. Distention of the bowel may be exacerbated by opiate analgesics, which should be used with caution. Because the symptoms of GVHD are not specific, vigilance is required for other complications, particularly infections. The most common cause of gastrointestinal bleeding in these patients is esophagitis and gastric erosions. However, when a discrete ulcer develops, cytomegalovirus infection is an important consideration. Medical treatment of such lesions is often unsatisfactory, and if bleeding is persistent, surgical resection may be required. Features that distinguish acute GVHD from the enteritis associated with the induction protocol include an erythematous, maculopapular skin rash over the palms, soles, and trunk, as well as liver test abnormalities, including hyperbilirubinemia. The diagnosis of acute GVHD may be made with confidence approximately 3 weeks following bone marrow transplantation if there is evidence of a functioning graft and if there is watery diarrhea accompanied by a diffuse skin rash and jaundice (see Table 129-4). The patient who presents with gastrointestinal symptoms but without jaundice or skin rash represents a much more difficult diagnostic challenge. Other diagnostic considerations include an opportunistic intestinal infection and the residual effects of the chemoradiotherapy conditioning lasting beyond the usual 3-week period. A combination of stool examinations, barium radiographic studies, endoscopy, and histopathology may be helpful (see Table 129-4). The stool usually contains large amounts of cellular debris and red and white blood cells. Protein loss in the stool may be sufficiently severe to lead to profound hypoalbuminemia. The absence of pathogens in the stool is important but does not necessarily rule out an infection of the gastrointestinal tract. Barium roentgenography may be helpful in the differential diagnosis and in establishing extent of disease. Widespread changes may occur, including mucosal and submucosal edema, pneumatosis cystoides intestinalis, and mucosal ulcerations. These radiologic findings may also be consistent with other conditions, such as cytomegalovirus enteritis and the effects of acute radiation. The acute radiologic features may return to normal, or in some cases they may progress to a chronic segmental, ribbonlike appearance, usually in the small intestine. Endoscopic appearances may be normal or may show patchy erythema or extensive mucosal sloughing. These lesions are most prominent in the ileum, cecum, and ascending colon, with relative sparing of the gastric and rectal mucosa. Histological changes seen in biopsy samples from advanced or severe lesions may not be as diagnostically useful as those from early lesions. Therefore, endoscopic biopsy samples should be taken from intact mucosa as well as from areas involved with gross inflammation. The earliest change seen on light microscopy is apoptosis of individual cells in the intestinal crypts (Fig. 129-3). This is diagnostic, if obtained from normal-appearing mucosa at least 20 days following transplantation. [117] Inflammatory cells or microorganisms are not present in the adjacent mucosa. Later, the histopathology can progress to a total denudation of the mucosa; the apoptosis lesion is no longer evident, and changes are not specific.

FIGURE 129-3. FIGURE Rectal biopsy specimen taken after bone marrow transplantation from a patient with acute graft-versus-host disease shows apoptotic bodies (*arrows*). This necrosis of individual cells within the crypt is the first change seen on light microscopy and is characteristic of acute graft-versus-host disease if found after day 20, when damage from chemoradiation therapy has resolved.

Management of intestinal acute GVHD consists of nutritional support, maintenance of fluid and electrolyte balance, steroid and immunosuppressive treatment, and vigilance for secondary infectious complications. Common opportunistic pathogens include astrovirus, *Clostridium difficile,* and adenovirus. [118] For patients with severe high-volume diarrhea, subcutaneous administration of octreotide may provide relief. To improve long-term survival, doses ranging up to 2 mg/kg of prednisone, for up to 1 to 2 weeks, may be used. Cyclosporine may be used in combination with specific anti–T-cell monoclonal antibodies and inhibition of TNF-a is promising. [114] A subset of patients with intestinal GVHD do not progress to severe multisystem disease and can be managed more conservatively with less toxic drug strategies, including topically active steroids, thereby minimizing the risk of opportunistic infections. [106], [119] Prevention of GVHD can be achieved by prior removal of mature donor T-lymphocytes from the bone marrow graft. Unfortunately, this is associated with reduced graft survival. To circumvent this, several new experimental strategies for bone marrow transplantation and prevention of GVHD are under investigation. [120], [121] and [122]

Chronic GVHD Chronic GVHD is a multisystem disorder that occurs 80 to 400 days after allogeneic transplantation (see Table 129-4). The majority of patients have had prior acute GVHD. However, approximately one fourth of the patients with chronic GVHD have had no clinical indications of any prior acute graft-versus-host illness. The skin, liver, and gastrointestinal tract are predominantly involved. The clinical features resemble those of sicca syndrome and systemic sclerosis. Gastrointestinal involvement occurs particularly in the oral mucosa (mucositis), esophagus, and small intestine. Esophageal symptoms of dysphagia with weight loss are common presenting gastrointestinal manifestations. [123], [124] Patients with skin involvement (hyperpigmentation and scleroderma-like changes) frequently, but not always, have esophageal involvement. Dysphagia with chronic esophageal reflux can lead to chronic lung disease. Small bowel involvement with chronic GVHD is characterized either by a patchy fibrosis of the lamina propria and submucosa, or by bacterial overgrowth as a result of stasis and dysmotility. This latter abnormality responds to oral broad-spectrum antibiotics. As with other immunosuppressed conditions, opportunistic gastrointestinal infections are a constant threat posttransplantation and must always be considered in the differential diagnosis. The combination of radiology, esophagoscopy with biopsy, and manometry may be required to distinguish between esophageal involvement with chronic GVHD and reflux peptic disease of the esophagus. Endoscopic lesions of chronic GVHD can range from generalized desquamation of the upper and midesophagus to weblike fibrous bands. [123] Manometry with pH monitoring shows a nonspecific motor abnormality and a decreased ability to clear acid from the esophagus. In contrast to peptic esophagitis, the distal esophagus is usually spared in chronic GVHD. [124] Histological changes within the esophagus include infiltration with neutrophils and lymphocytes with necrosis of individual cells of the basal mucosa, similar to the changes found in the skin and oral mucosa. Submucosal fibrosis may be found, but there are no muscle or neural abnormalities. In contrast to acute GVHD, the treatment of chronic GVHD is frequently satisfactory. Early diagnosis and drug therapy have prevented much of the disability associated with this condition. Prednisone alone or in combination with azathioprine has been effective. Aggressive antireflux therapy is important for reducing the symptoms associated with esophageal involvement. However, fibrosis tends to be progressive, and esophageal dilation may be required for treatment of webs and strictures.

The Liver in GVHD

In acute GVHD, liver involvement is manifested by cholestasis and mild hepatocellular necrosis. Hepatic failure is uncommon. [104] Although liver abnormalities may be the presenting feature of acute GVHD, skin and intestinal GVHD are usually evident by the time jaundice occurs, and diagnosis is relatively clear when these multisystem manifestations arise at least 3 weeks following bone marrow transplantation. Within the first 2 to 3 weeks after transplantation, venoocclusive disease

secondary to chemoradiotherapy may be a more important diagnostic consideration, whereas throughout the posttransplant period, GVHD must be distinguished from, or may coexist with, several other causes of hepatotoxicity. These include parenteral nutrition, viral infections, drug-induced liver damage (such as immunosuppressants, antibiotics, and antifungals), hypotension, and sepsis.

Biochemical abnormalities due to liver complications of GVHD include a marked elevation in serum alkaline phosphatase followed by hyperbilirubinemia, but serum transaminases are elevated to a lesser extent. Liver biopsy is hazardous because of the risk of bleeding due to thrombocytopenia in bone marrow transplant patients, but may be helpful particularly where additional causes of liver disease are suspected. Histological changes of GVHD within the first week after the onset of biochemical abnormalities are nonspecific and consist of a mild lobular hepatitis with variable eosinophilic necrosis of hepatocytes and necrosis of biliary epithelium. Subsequently, the changes become more characteristic with abnormal interlobular bile ducts followed by destruction of small bile ducts and proliferation of ductules. The histological picture may evolve into one of profound chronic cholestasis with portal inflammation and fibrosis. Progression to liver failure may occur but most patients with severe GVHD die of infection or other complications before this. At least half of the patients who survive severe acute GVHD develop chronic GVHD and most of these will have liver involvement. In contrast to the mixed hepatocellular-bile duct damage of acute GVHD, the liver damage in chronic GVHD is predominantly portal with dense plasmacytic infiltration, loss of small bile ducts, and cholestasis. [105]

SMALL BOWEL TRANSPLANTATION (See AlsoChapter 79)

Transplantation of the small bowel has become a realistic therapeutic strategy for patients with intestinal failure where continued parenteral nutrition is no longer a safe option. [125], [126], [127] and [128] These will usually be patients with complications of parenteral nutrition such as advanced liver disease or loss of venous access due to catheter sepsis or venous thrombosis. Intestinal failure in adults is generally due to short bowel syndrome following resection for conditions such as Crohn's disease or infarction associated with trauma or hypercoagulable states. In children, congenital disorders such as atresia or necrotizing enterocolitis are the most common indications for small bowel transplantation. Improvements in the success rate for intestinal transplantation have been due, in large part, to the introduction of potent immunomodulatory agents such as tacrolimus, [129] and 5-year survival rates for graft and patient have been reported in the range of 32% to 52% and 33% to 38%, respectively. [130] Unfortunately, graft survival is not equivalent to freedom from parenteral nutrition; results from the international intestinal transplant registry indicate full graft function has been achieved in only 78% of survivors, with partial or nonfunctioning grafts in 10% and the requirement for removal of the graft in the remainder. [131]

Contrary to what had been expected, GVHD has not been a major obstacle. [128], [129], [130], [131] and [132] However, the procedure still has relatively high mortality and morbidity because of rejection, sepsis, and posttransplant lymphoproliferative disorder. Rejection predisposes to sepsis because of loss of mucosal barrier function. This is compounded by potent immunosuppression with the risk of opportunistic infections, particularly cytomegalovirus enteritis, and a subsequent lymphoproliferative disorder that is probably related to Epstein-Barr virus infection. [129]

Distinguishing rejection from infections and other pathology may be difficult, particularly because the rejection process is often focal or patchy. Multiple endoscopic biopsies are required to monitor the progress of the graft. Crypt cell apoptosis characterizes acute rejection, whereas chronic rejection is associated with fibrosis, focal ulceration, and obliterative arteriopathy. [133] Recipient lymphocytes infiltrate the lamina propria of the graft and replace donor lymphoid cells within weeks to months. The rejection reaction is associated with local production of T_H1 cytokines including TNF-a and interferon-?, and targets mainly the crypt epithelium and local endothelium. [134] Neither the morphology nor the cytokine response is specific to the rejection process. Clinical details including preventive and therapeutic strategies for rejection have been reviewed. [130] Vigilance and careful attention to detail are required, and the degree of immunosuppression to prevent rejection must be balanced against risk of opportunistic infection. Gene therapy of the graft may in the future render it resistant to immune assault [135] and normal mechanisms of tolerance and immune privilege might be used to prevent graft rejection. [136]

With longer survival of intestinal grafts additional complications may be anticipated (e.g., recurrence of Crohn's disease in the intestinal graft). [137] This contrasts with reported resolution of Crohn's disease following bone marrow transplantation. [138] Thus, substitution of host immunity rather than the target organ is required, consistent with the concept that the fundamental defect in Crohn's disease does not reside exclusively within the target organ and probably reflects a dysregulated immune response to enteric flora.

CHAPTER 130

Mitchell S. Cappell

GASTROINTESTINAL VASCULAR MALFORMATIONS OR NEOPLASMS: ARTERIAL, VENOUS, ARTERIOVENOUS, AND CAPILLARY

The classification of gastrointestinal vascular lesions has been confusing due to variable classification schemes and inadequate consideration of anatomic and pathophysiologic principles. [1] Figure 130-1 presents a simple classification based on anatomic and pathophysiologic principles. Vascular lesions are divided into neoplastic lesions and nonneoplastic malformations, the latter including inflammatory (vasculitis) and structural malformations. Structural malformations are divided anatomically according to the most affected vascular component: arteriovenous, arterial, capillary, and venous. Only the entities highlighted in color in Figure 130-1 are discussed in this chapter.

FIGURE 130-1. Classification of vascular gastrointestinal lesions. Diagrammatic outline of a new classification of vascular gastrointestinal lesions according to pathophysiology and according to the most affected vascular structure, whether arterial, venous, arteriovenous, or capillary. Diseases highlighted blue are discussed in this chapter.

The nomenclature of these lesions has also been confusing owing to redundancy, application of erroneous pathophysiologic mechanisms, use of the same name for disparate diseases, and inconsistent application of names to disparate diseases. For example, the Dieulafoy lesion has been called an exulceratio simplex, cirsoid aneurysm, caliber persistent artery, and submucosal arterial malformation; the Dieulafoy lesion is not an aneurysm. [2] The term phlebectasia has been used to describe both small hemangiomas or isolated venous varicosities. [3] The most commonly used name is employed in this chapter, provided the name is pathophysiologically reasonable. The vascular lesions described herein are rare, except for angiodysplasia, the Dieulafoy lesion, and gastric antral vascular ectasia (GAVE). However, it is important to recognize even the rare vascular diseases because they are frequently misdiagnosed and mistreated. For example, until recently, most rectal hemangiomas were misdiagnosed and mistreated as internal hemorrhoids. [4]

DIEULAFOY LESION

Pathology and Pathophysiology

Although uncommon, the Dieulafoy lesion is important because it tends to bleed repeatedly and massively. Arteries normally progressively narrow in the arterial tree as successive branches approach the mucosa to terminate as submucosal end arteries. In the Dieulafoy lesion, the submucosal end artery is abnormally large; the alternative name of caliber-persistent artery is based on this abnormality. The lesion usually, but not always, occurs in the stomach, within 6 cm of the gastroesophageal junction and near the lesser curvature. The propensity for this location is explained by the absence of the usual submucosal arterial anastomotic gastric plexus in this region. [5] In three large clinical series, this lesion was in the proximal stomach in 75% of patients, the distal stomach in 13%, and the duodenum in 12%. [6], [7] It occurs rarely in the esophagus. [8]

The Dieulafoy artery is vulnerable to relatively minor mechanical trauma because it is large and superficial. Pulsations of the artery, peristaltic contractions, or passage of the food bolus may cause gastrointestinal bleeding. [9] Alternatively, the large artery might cause hypoperfusion, ischemia, and erosion of overlying mucosa by shunting of blood (steal phenomenon). Both theories are compatible with the pathological findings of a thrombus attached to a large superficial artery overlying a

small nonexcavated mucosal defect, with a normal vascular endothelium, without atherosclerosis, inflammation, or aneurysm. [2], [9], [10] Whether the lesion is congenital or acquired is unknown. [2], [11]

Epidemiology and Clinical Presentation, Upper Gastrointestinal Lesion

The incidence is about 1.5% among patients with upper gastrointestinal bleeding. [6], [12], [13] and [14] The male-to-female ratio is about 2:1, [7], [10], [14] and the mean age at diagnosis is 55 years, with a range of 1 to 95 years. [7], [10] The lesion is not associated with use of alcohol, nonsteroidal antiinflammatory drugs, or tobacco, nor with the presence of peptic ulcer disease or *Helicobacter pylori* infection. [7], [10], [15], [16]

Patients present with acute, usually severe, gastrointestinal bleeding, often associated with manifestations of hemodynamic compromise such as hypotension, orthostasis, tachycardia, and prerenal azotemia. The bleeding is rarely occult and usually presents as hematemesis, melena, or hematochezia; about 50% of patients manifest both hematemesis and melena. [10] Other gastrointestinal complaints, such as abdominal pain, are atypical, and their presence should suggest another diagnosis, such as peptic ulcer or esophagitis. [7]

Diagnosis, Upper Gastrointestinal Lesion

The lesion is usually diagnosed by endoscopy, which reveals a pigmented protuberance, representing the vessel stump, with minimal surrounding erosion nd no ulceration (Fig. 130-2; see also Color Fig. 130-2). The lesion is typically small; sometimes only a tiny necrotic spot is found in the proximal stomach. A pigmented protuberance within an ulcer represents a visible vessel in a peptic ulcer, not a Dieulafoy lesion. Stigmata of recent hemorrhage, such as frank bleeding or an adherent clot, commonly occur. The lesion should be suspected when a fresh densely adherent clot in the proximal stomach has a narrow point of attachment to a small mucosal defect. The lesion may be missed at endoscopy because of small size, concealment between gastric rugae or underneath blood in the gastric lake, or careless gastric retroflexion. [17] Indeed, in one series of 177 cases, the lesion was missed in 51% of the initial esophagogastroduodenoscopies (EGDs) and then detected in 33% of cases on repeat EGD. [10] Meticulous endoscopic technique—including careful examination during gastric retroflexion, aspiration of the gastric lake, and adequate gastric insufflation to efface the gastric rugae—should increase the sensitivity of endoscopy.

FIGURE 130-2. (See Color Fig. 130-2.) Endoscopic appearance of Dieulafoy lesion. Videophotograph shows a gastric cardial Dieulafoy lesion as a small, pigmented protuberance, which represents the vessel stump, with minimal surrounding erosion and no ulceration. (From: Lee JG, Leung JWC. Stigmata of recent hemorrhage in Dieulafoy's lesion. Gastrointest Endosc 2000;51:191.)

Angiography is indicated for ongoing upper gastrointestinal bleeding after a nondiagnostic EGD and was found to be diagnostic in 11 of 14 patients. [10] Angiography is suggestive of this lesion when extravasation of contrast is detected from a point source in the proximal stomach after a nondiagnostic EGD. Angiography may also demonstrate arterial tortuosity in the territory of the left gastric artery without other vascular abnormalities. [18] Angiographic findings of arteriovenous shunting and an early-filling or late-draining vein are consistent with angiodysplasia and not a Dieulafoy lesion. The Dieulafoy artery is too small in caliber to be recognized as enlarged by angiography and, besides, is often obscured by extravasated contrast.

Recent anecdotal reports suggest endoscopic ultrasound can confirm the diagnosis. In one series of eight patients, an abnormally large, 2- to 3-mm wide, tortuous gastric vessel penetrated through the muscularis propria and coursed through the submucosa for at least 2 cm [19], [20] (Fig. 130-3).

FIGURE 130-3. Videoendosonographic image of a Dieulafoy lesion. A relatively large gastric vessel courses outside the muscularis propria (left of figure, *solid arrow*), penetrates the muscularis propria (middle of figure), and runs tortuously through the submucosa (right of figure, *open arrow*). (From ref. [6].)

Therapy, Upper Gastrointestinal Lesion

Most patients require vigorous fluid resuscitation and transfusion of three or more units of packed erythrocytes to treat the severe bleeding. The lesion is not related to gastric acidity, and gastric acid suppression has no proven therapeutic role.

Endoscopic therapy for this point source of bleeding is particularly attractive, and fatal hemorrhage may occur without it. The most experience has accumulated with endoscopic injection therapy with epinephrine or polidocanol, [13] which has been shown to achieve hemostasis in 27 of 28 patients. [21] There may be a higher risk for gastric perforation from sclerotherapy for a Dieulafoy lesion than for a gastric ulcer [22] owing to a lack of inflammation and fibrosis around a Dieulafoy lesion. [6] Other endoscopic therapies include bipolar electrocoagulation, thermocoagulation, laser photocoagulation, endoscopic band ligation, and hemoclips. [23], [24] and [25] In three reviews, involving 79 to 111 patients, long-term hemostasis was achieved in about 85% of patients by various endoscopic therapies. [6], [10], [26] Savides and Jensen recommend endoscopic epinephrine injection to reduce lesion vascularity before electrocoagulation with a Gold probe. [27]

Surgery was the treatment of choice before the development of endoscopic therapy, but it is currently restricted to patients who fail endoscopic therapy. Surgical therapy has included electrocoagulation with vessel ligation, wedge resection, or proximal partial gastrectomy. Bleeding may recur after electrocoagulation or limited wedge resection because of the long span of the abnormal artery. [28] On the other hand, gastrectomy is theoretically unnecessary because the abnormal artery is usually restricted to the proximal stomach. [29] A wide wedge resection is a reasonable compromise between resecting too little and resecting too much. [7], [15]

Therapeutic angiography with selective left gastric artery embolization before surgery for ongoing bleeding is supported by anecdotal evidence, but the hemostasis may only be transitory. [30] Although this lesion used to have a grave prognosis, the mortality rate decreased to about 25% with the advent of endoscopic therapy in the 1980s [7] and has recently declined further. [26]

Lower Gastrointestinal Lesion

Dieulafoy lesion of the jejunum, ileum, colon, and rectum has been increasingly reported. In a recent review, this lesion occurred in 0.3% of about 3000 patients with gastrointestinal bleeding. [31] The lesion also tends to bleed suddenly and severely, [32], [33], [34] and [35] manifesting as bright red blood per rectum, rather than melena, with hemodynamic instability. [31]

Dieulafoy lesions of the jejunum, ileum, and colon are diagnosed preoperatively by endoscopy or angiography. [36] Lesions are more commonly detected in the colon and rectum than the jejunum and ileum, probably because of the more frequent use of colonoscopy than enteroscopy and the easier identification of lesions at colonoscopy because of a wider endoscopic field. The incidence of jejunal and ileal lesions may therefore be underestimated. [37] The colonoscopic diagnosis is often complicated by severe lesion hemorrhage, which increases the risk and decreases the yield of colonoscopy. [38] However, rectal lesions are readily diagnosed by sigmoidoscopy. [38], [39] The endoscopic appearance and histology of these lower gastrointestinal lesions are similar to those of gastric lesions. [37]

Surgery has been the traditional therapy for these lower gastrointestinal lesions, [38], [39] but colonoscopic hemostasis is being increasingly attempted, with the same modalities as are used for gastric lesions. Numerous small case studies suggest that endoscopic therapy should be initially performed for a bleeding colonic lesion and surgery reserved for refractory bleeding. [31], [39] The colonic Dieulafoy lesion is not a polyp and should not be removed by snare polypectomy because this can cause massive postpolypectomy hemorrhage. [40]

EHLERS-DANLOS SYNDROME

The Ehlers-Danlos syndrome is a rare heterogeneous group of about 10 genetic disorders of collagen metabolism that cause skin hyperextensibility, articular hypermobility, and tissue fragility. The syndrome is diagnosed by the characteristic clinical presentation, family pedigree analysis, and demonstration of genetic or biochemical defects. [41] Type IV is the most commonly associated with vascular lesions. [41], [42] Patients with type IV disease have thin transparent skin, wide thin (papyraceous) cutaneous scars overlying bony prominences, and cutaneous ecchymoses from spontaneous arterial rupture due to vascular and perivascular connective tissue friability. [43], [44] They have an increased risk of intramural intestinal hematomas, [43] colonic diverticular bleeding, [43], [45] gastrointestinal bleeding, [46], [47] and rarely intestinal perforation [43], [48] due to dissection or rupture of intestinal arteries. The syndrome does not predispose to peptic ulcer disease, but patients with this syndrome who have coincidental peptic ulcers often develop severe bleeding due to the weakness of perivascular supportive tissue. [41] Type IV disease is diagnosed by biochemical analysis of collagen. [46] Type IV disease carries a high mortality rate from repeated gastrointestinal bleeding. [47] Gastrointestinal surgery produces poor results owing to tissue fragility and a bleeding diathesis.

PSEUDOXANTHOMA ELASTICUM

Pseudoxanthoma elasticum is a rare genetic disorder of elastin synthesis characterized by yellowish xanthomatoid papules (pseudoxanthomas) on the skin, angioid streaks in the ocular fundi, and intermittent claudication and weak peripheral pulses due to vascular occlusion. [49] Gastrointestinal bleeding occurs frequently; a rate of 13% has been observed in 200 patients. [49] The hemorrhage typically commences in young adulthood. [49], [50] Most commonly, patients bleed from a characteristic lesion: numerous petechiae or erosions as well as yellowish xanthomatoid nodular lesions that resemble the cutaneous lesions are predominantly found in the gastric fundus. [51], [52], [53] and [54] Bleeding is attributed to elastin degeneration in small gastric arteries (Fig. 130-4) and is frequently severe and recurrent. [55] The bleeding arterioles do not vasoconstrict normally in response to hemorrhage owing to intimal calcification and elastin degeneration and are refractory to available pharmacological therapy. [52] The lesions also may not be amenable to endoscopic therapy because of their diffuseness. Gastrectomy is the primary therapy.

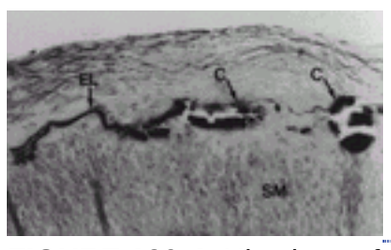

FIGURE 130-4. Histology of pseudoxanthoma elasticum. An elastin stain of a cross section of the proximal stomach from a patient with pseudoxanthoma elasticum, who underwent total gastrectomy for massive refractory gastric bleeding, reveals a submucosal gastric artery with focal intimal thickening, fragmentation of the elastin lamina (EL), and intramural calcifications (C). SM, smooth muscle; L, lumen. (From ref. [52].)

ANGIODYSPLASIA

Epidemiology

Angiodysplasia is an important cause of acute and chronic gastrointestinal bleeding, particularly from the lower gastrointestinal tract. About 1% of asymptomatic healthy subjects have colonic angiodysplasia, [56] whereas about 3% to 6% of lower gastrointestinal bleeders have angiodysplasia. [57], [58], [59] and [60] The frequency of asymptomatic upper gastrointestinal angiodysplasia in healthy subjects is unknown, but angiodysplasia accounts for about 2% to 5% of acute upper gastrointestinal bleeding. [61], [62] and [63] About 3% to 5% of gastrointestinal bleeding arises from the jejunum and ileum, [64] and angiodysplasia is the most common cause of bleeding in this location. [64], [65] and [66] The recognition of angiodysplasia has increased markedly because of greater use of endoscopy, causing the incidence to increase more than sixfold during the 1980s at one university hospital. [67] Angiodysplasia is increasingly recognized also in the jejunum and ileum with greater use of enteroscopy. [64], [65]

The incidence is unaffected by sex or race. [60], [67] Angiodysplasia is not familial but may be confused with hereditary hemorrhagic telangiectasia (HHT), which is familial. Patients with bleeding from colonic angiodysplasia are generally elderly, with an average age of about 70 years, [58], [61], [67], [68] and [69] but it occasionally occurs in infants, children, and young adults. [70]

Pathology

Colonic angiodysplasia occurs most commonly in the right colon, especially the cecum, [71] but up to 40% of colonic lesions occur distal to the hepatic flexure. [56], [72], [73] The predilection for the cecum is explained by the higher cecal mural tension owing to its larger lumenal diameter, according to the LaPlace law. [74] Upper gastrointestinal lesions occur most commonly in the stomach, sometimes in the duodenum, and rarely in the esophagus. [61], [67], [71], [75]

Angiodysplasias are often multiple [76] and tend to be clustered [69] (Fig. 130-5; see also Color Fig. 130-5). Despite clustering, 15% to 20% of patients with colonic angiodysplasia have upper gastrointestinal angiodysplasia, and vice versa. [69], [77]

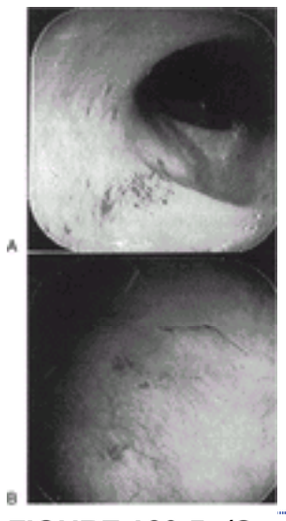

FIGURE 130-5. (See Color Fig. 130-5.) Endoscopic photo of cluster of angiodysplasia. **A:** Colonoscopic videophotography demonstrates two adjunct clusters of angiodysplasia in the descending colon in an elderly female with iron deficiency anemia; colonoscopy revealed no other angiodysplasia in the rest of the colon. **B:** Close-up views demonstrate the characteristic endoscopic appearance of angiodysplasia: an intensely red color, an intricate reticulonodular structure, and communication with prominent feeding or draining vessels. (From ref. [69].)

Unlike the lesions of HHT, which occur in all layers of the bowel wall, angiodysplasia occurs in the mucosa and submucosa. [64] Histologically, angiodysplasia consists of dilated, distorted, tortuous, and thin-walled vessels lined by endothelium with no or little smooth muscle and no inflammation, fibrosis, or atherosclerosis. [61], [68], [78] Initially, submucosal veins are dilated, but in older lesions, mucosal veins and capillaries and even arteries become dilated [74], [78] (Fig. 130-6). Congenital arteriovenous malformations, in contrast to angiodysplasia, typically have thick-walled arteries.

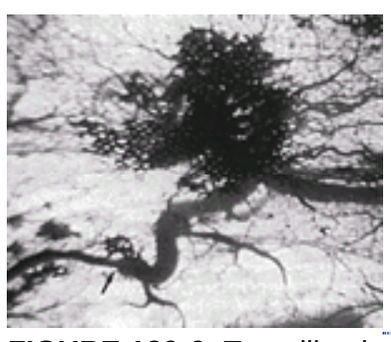

FIGURE 130-6. Transilluminated view of angiodysplasia. Photomicrograph through a dissecting microscope of a transilluminated, cleared colon after intravascular silicone injection reveals a mucosal ectatic vascular tangle surrounded by normal colonic crypts. The vascular tangle is drained by ectatic venules that lead to a large, distended, and tortuous underlying submucosal vein (*arrow*). (From Boley SJ, Brandt LJ, Mitsudo SM. Vascular lesions of the colon. Adv Intern Med 1984;29:301.)

Associations and Pathophysiology

Angiodysplasia is reported as the most common cause of upper gastrointestinal bleeding (19% to 32%) in patients with *chronic renal failure,* as compared with only about 3% to 5% in the general population. [79], [80], [81] and [82] Similarly, colonic angiodysplasia is a frequent cause of lower gastrointestinal bleeding in patients with chronic renal failure. [83]

The association with chronic renal failure is, however, somewhat controversial because several studies report no association. [84], [85] and [86] The reported discrepancies could arise from several sources. First, the risk of angiodysplasia appears to increase with the duration and severity of renal dysfunction, [79] and studies showing no association may include patients with a short duration and mild severity of renal insufficiency. Second, many studies that show a lack of an association were published in the early 1980s when angiodysplasia was an obscure diagnosis. Third, the presence of an association may be artifactual: coagulopathy associated with renal insufficiency may promote bleeding from and detection of otherwise clinically silent angiodysplasia. [79] Alternatively, a coagulopathy would promote erosions and ecchymoses during endoscopy that could be misinterpreted as angiodysplasia. In conclusion, angiodysplasia appears to be associated with chronic renal failure, but a prospective, controlled, investigator-blinded endoscopic study is needed to resolve the controversy.

The pathophysiology of this apparent association is speculative. Chronic, intermittent fluid overload in patients with renal failure may result in venous hypertension, microvascular venous dilation, and retrograde capillary dilation. [81] Renal failure patients might be older and have asymptomatic angiodysplasia, which could clinically manifest as a result of the bleeding diathesis associated with renal failure. [82] Hypertension and vascular disease, common in renal failure, could also augment bleeding from angiodysplasia. [61]

Several case reports have suggested that congenital or acquired *von Willebrand disease* may be associated with gastrointestinal bleeding from angiodysplasia. [87] Duray and associates reported two patients and reviewed eight other cases in the literature, [88] but Gostout and colleagues failed to find any cases of von Willebrand disease in a prospective study of 22 patients, published as an abstract. [89]

After an association between *aortic stenosis* and unexplained gastrointestinal bleeding was proposed in 1958, [90] several retrospective studies showed that up to 25% of patients with angiodysplasia had aortic stenosis. [71], [74], [76], [80], [91], [92] In many of these studies, aortic stenosis was diagnosed by clinical criteria without confirmation by echocardiography or cardiac catheterization. [93] An association was further strengthened by several case reports of cessation of bleeding from angiodysplasia after successful aortic valve replacement. [94], [95] and [96] In two recent prospective endoscopic studies of 29 to 40 patients with gastrointestinal angiodysplasia, none had aortic stenosis detected by two-dimensional Doppler echocardiography. [57], [97] Thus, an association is unproven. [98]

A number of case reports have noted an association between gastrointestinal angiodysplasia and *scleroderma* or the *CREST syndrome* (calicinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia). [99], [100], [101] and [102] Although this association has not been proven in a large controlled trial, the known occurrence of cutaneous telangiectasia in scleroderma renders an association with gastrointestinal telangiectasia both credible and likely. Several cases of angiodysplasia have been reported in association with *Turner syndrome* [103], [104] and *portal hypertension*. [105], [106] These associations, however, are unproven.

The pathogenesis of angiodysplasia is unknown and may vary according to the associated condition and the age of onset. [107] A popular theory is that angiodysplasia is a degenerative lesion of aging caused by chronic intermittent low-grade obstruction of veins, capillaries, and arterioles that supply the mucosa [74] (Fig. 130-7). A neurovascular (or hormonal) mechanism could contribute to angiodysplasia. [94] In response to low-grade local hypoperfusion, sympathetic nerves may stimulate intestinal vascular smooth muscle relaxation to increase flow and reverse the hypoxia. With chronicity, local vascular overload, dilation, and ectasia pathologically develop. [94] This theory could explain the disappearance of angiodysplasia with intravenous meperidine injection (a problem with endoscopic diagnosis) [108] or cold water colonic perfusion [97] and reappearance with naloxone administration. Increased expression of angiogenic factors [109] and deficient production of type IV collagen [110] have also been proposed as pathogenetic factors. Conceivably, the same genetic lesion that occurs in germ cells in HHT, as discussed later, may occur focally in somatic cells in sporadic angiodysplasia. This hypothesis, although speculative, is easily tested by molecular genetic analysis of tissue from isolated angiodysplasia.

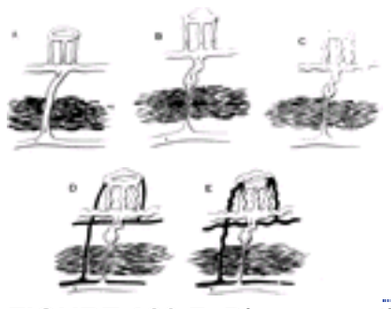

FIGURE 130-7. Diagrammatic illustration of a popular theory of angiodysplasia pathogenesis. **A:** Normally patent distal veins within the muscular layer of gut drain proximal mucosal vessels, including the capillary ring. **B:** These distal veins become partially obstructed due to muscular contractions or increased intralumenal pressure. **C:** Chronic repeated intermittent obstruction of these distal veins results in proximal venous dilation and tortuosity. **D:** With time, gut veins become progressively more dilated and tortuous, and the lesion propagates proximately. **E:** Ultimately, the capillary ring becomes dilated, the precapillary sphincter becomes incompetent, and a small arteriovenous communication occurs through the ectasia. (From ref. [74].)

Clinical Presentation

Bleeding from angiodysplasia is usually low grade and recurrent, and always painless. About 10% to 15% of patients present with acute severe hemorrhage. [91] The bleeding pattern may depend on the lesion stage, with more advanced lesions causing more frequent and more severe bleeding. [68] The clinical presentation depends on the bleeding site, chronicity, and severity. Acute upper gastrointestinal bleeding most commonly manifests as melena, and occasionally as hematemesis [67]; acute jejunal and ileal bleeding as melena [64]; and acute lower gastrointestinal bleeding as hematochezia, and rarely as melena. [61], [67]

Chronic bleeding presents with fecal occult blood or iron deficiency anemia. Patients bleeding from angiodysplasia tend to have a longer history of gastrointestinal bleeding than other patients owing to greater difficulty in diagnosis. [63], [111] Patients sometimes present with prior gastrointestinal bleeding without an endoscopic diagnosis, although this phenomenon is occurring less frequently with increasing endoscopic lesion recognition. [67], [107]

Physical examination is unrevealing except for signs of gastrointestinal blood loss. Although, in the past, angiodysplasia was associated with severe gastrointestinal bleeding, [71] angiodysplasia is increasingly associated with mild bleeding, probably owing to earlier identification and recognition of milder cases. [67]

Diagnosis

Endoscopy is the diagnostic procedure of choice. [72], [111] In a study of 80 patients, colonoscopy had a sensitivity of 81% when compared with angiography and pathologic examination of the resected colon. [112] Angiodysplasia may be missed behind folds, at sharp turns, or when covered by stool. True angiodysplasia can be carelessly dismissed as endoscopic erosions or fresh blood. [75] Angiodysplasia may be inconspicuous in a patient with hypotension or severe anemia and may become obscured after meperidine administration for endoscopy. [108] Although endoscopy should generally be performed after correction of anemia or hypotension with fluid resuscitation or blood transfusion, this principle is particularly important when angiodysplasia is suspected. When colonic angiodysplasia is suspected, complete colonoscopy with careful cecal examination is important. Although endoscopy is generally superior to barium studies in the evaluation of any cause of chronic gastrointestinal bleeding, this is particularly true when angiodysplasia is suspected because angiodysplasia is mucosal and macular and not visualized with barium contrast, and barium studies preclude subsequent angiography. [113]

Endoscopy is a fairly specific test provided strict diagnostic criteria are applied. At endoscopy, angiodysplasia appears as a dense macular and reticular network of vessels (vascular tuft), which is typically 2- to 8-mm wide and is intensely red because of the high oxygen content in erythrocytes within vessels supplied by arteries without intervening capillaries (Fig. 130-5 and Fig. 130-8; see also Color Fig. 130-5 and Color Fig. 130-8). Sometimes a prominent feeding artery or draining vein is observed. [57], [112], [114] Some endoscopists note a pale (anemic) mucosal halo surrounding angiodysplasia due to shunting of blood (vascular steal) from surrounding tissue by the low-resistance angiodysplastic shunt. [92]

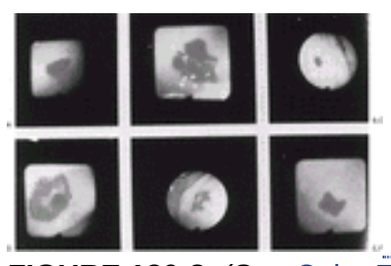

FIGURE 130-8. (See Color Fig. 130-8.) Spectrum of endoscopic appearance of upper gastrointestinal angiodysplasia. The characteristic endoscopic findings of angiodysplasia are intense erythema, well-demarcated margin, irregular stellate (fern-like) margin, fine internal reticular (fern-like) structure, and macular mucosal location. Lesions range from 2 × 3 mm to 5 × 7 mm in size. All angiodysplasia are from the stomach, except for **A,** which is from the duodenum. (From ref. [80].)

It is important to assess at endoscopy whether observed angiodysplasia is the source of blood loss. In two large studies of patients with angiodysplasia, 30% to 44% had other significant gastrointestinal lesions, such as colonic polyps, colon cancer, inflammatory bowel disease, or peptic ulcer disease. [59], [114] Bleeding is attributed to angiodysplasia when it is actively bleeding or has an overlying clot. Otherwise, the diagnosis is made only by exclusion of other causes.

The hot biopsy technique is preferred to reduce the risk of bleeding from endoscopic biopsy, but endoscopic biopsy is generally not recommended because of the low diagnostic yield and the increased risk of provoking hemorrhage. [61], [76] Pathological examination of an endoscopic biopsy supports the endoscopic diagnosis in only about 40% of cases because endoscopic biopsies are superficial, and the most consistent and characteristic histological abnormalities are submucosal.

The angiographic hallmarks of angiodysplasia are (1) a vascular tuft or tangle resulting from the local mass of irregular vessels, best visualized in the arterial phase; (2) an early and intensely filling vein resulting from a direct arteriovenous connection without intervening capillaries; and (3) persistent opacification beyond the normal venous phase (slowly emptying vein), possibly resulting from venous tortuosity [115] (Fig. 130-9). About 60% to 90% of patients have each of these angiographic signs. [73], [115] Angiodysplasia bleeds only intermittently, and extravasation of contrast material from angiodysplasia is detected in only about 10% of angiograms. [68] Angiography has the advantage of detecting lesions of the small intestine as well as colonic angiodysplasia and can be performed during severe hemorrhage when colonoscopy is ineffective. [61] Small intestinal angiodysplasia can, however, be missed at angiography owing to misidentification as normal vascular arcades. [116] Recently, helical computed tomographic angiography has been proposed as a minimally invasive technique to image colonic angiodysplasia. [117]

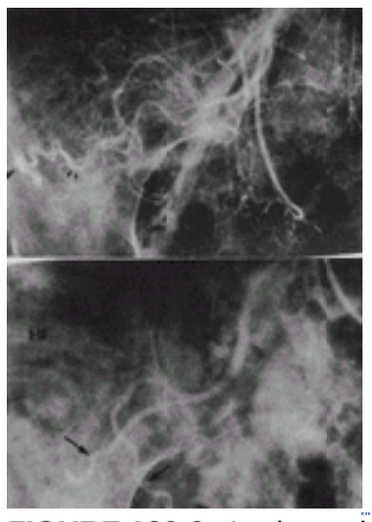

FIGURE 130-9. Angiographic findings in angiodysplasia. **Top:** Arterial phase shows a vascular tuft (*large arrow*) and two early filling veins (*small arrows*) that have filled with contrast before other veins. **Bottom:** Late phase reveals two densely opacified, dilated, and tortuous cecal veins (*arrow*) that still retain contrast after other veins have cleared. (From ref. [115].)

Angiodysplasia is seldom detected at laparotomy by visual inspection or by manual palpation of the serosal surface of gut because of its small size and mucosal location. [61] Richardson and colleagues [73] correctly identified angiodysplasia in only one of 39 laparotomies. hus, preoperative diagnosis by endoscopy or angiography is critical to avoid blind bowel resection for gastrointestinal bleeding. Intraoperative enteroscopy can help localize angiodysplasia to minimize the extent of small bowel resection. [118]

Differential Diagnosis

At endoscopy, angiodysplasia can be differentiated from other red lesions, such as gastritis, Barrett esophagus, inflammatory bowel disease, tumor, phosphosoda enema-induced lesions, and other vascular lesions. Phlebectasia and hemangiomas are blue or wine-colored submucosal vascular masses that collapse with endoscopic air insufflation. Kaposi sarcoma presents as a violaceous submucosal nodule or mass. A Dieulafoy lesion is typically elevated with one visible vessel. GAVE is distinguished from angiodysplasia by a characteristic antral location and a characteristic arrangement of red lesions on longitudinal ridges. Portal gastropathy is distinguished from angiodysplasia by a distinctive pale reticular border surrounding polygonal intensely erythematous patches located in the proximal stomach.

The endoscopic appearance of gastrointestinal telangiectasias of HHT may be identical to that of angiodysplasia, except that the lesions of HHT tend to be greater in number, occur in all bowel wall layers, and occur in all bowel segments. Patients with HHT may also have cutaneous telangiectasia, a positive family history, and a history of epistaxis. The diagnosis of scleroderma, CREST, or renal failure in association with angiodysplasia is based on the clinical manifestations of these conditions. The endoscopic findings in radiation colitis, aside from telangiectasia, include fibrosis, exudation, erosions, and mucosal friability, findings not compatible with angiodysplasia. [119]

Red mucosal lesions at endoscopy resembling angiodysplasia can be created iatrogenically by nasogastric aspiration or by endoscopic abrasion or suction. Lesions from nasogastric aspiration are round, colinear, equidistant, and relatively uniform in size, owing to the geometric arrangement of the nasogastric tube apertures, and are at the same stage of lesion evolution because of their simultaneous creation. [120] Lesions of endoscopic trauma are not seen initially during endoscopic intubation, but typically identified during endoscopic extubation. As compared with endoscopic trauma lesions, angiodysplasia has a finely reticular (fernlike) internal structure owing to a vascular tuft, an irregular (stellate) border as opposed to a round border with trauma, an abrupt lesion margin as opposed to an indistinct margin with trauma, and lesions lying flush (coplanar) with mucosa (see Fig. 130-5 and Fig. 130-8; see also Color Fig. 130-5 and Color Fig. 130-8). Thus, angiodysplasia is best diagnosed by detailed mucosal examination during endoscopic insertion with minimal use of suction. [91] The angiographic findings of angiodysplasia are occasionally mimicked by tumor or inflammatory bowel disease, [61] but these other conditions are differentiated by endoscopy.

Therapy

Endoscopic Therapy At EGD and colonoscopy, isolated, actively bleeding angiodysplasia is treated by endoscopic thermocoagulation, electrocoagulation, or photocoagulation. When bleeding, angiodysplasias are sometimes first injected with alcohol or epinephrine to slow the bleeding. These endoscopic therapies are relatively safe and highly successful at achieving short-term hemostasis when performed by an experienced endoscopist. Gostout and colleagues [77] reported cessation of bleeding in 72 of 83 patients (87%) after laser photocoagulation during a mean follow-up period of 12 months. These therapies are also relatively effective long term: among 47 patients receiving laser photocoagulation, 61% had no significant gastrointestinal bleeding during 54 months of follow-up. [121] Enteroscopic therapy may be similarly effective for accessible small intestinal angiodysplasias provided the technical expertise is available. [122] The major complication of therapy is gastrointestinal perforation which occurs in about 4% of cases. [77], [121] The highest risk for perforation is in the thin-walled cecum, the most common location of angiodysplasia. Laser therapy has the advantage of not requiring probe contact with the lesion, whereas the other endoscopic therapies entail a risk for probe adherence to the lesion after application. Laser therapy, however, has the important disadvantage of greater depth of tissue destruction and a possibly higher perforation rate. [107] This appears to be less of a problem with argon as compared with Nd:YAG lasers. [107] Most endoscopists prefer thermocoagulation or electrocoagulation over photocoagulation because of lower equipment costs and simpler technique. Recently, endoscopic band ligation has also been reported to be effective. [123]

Angiographic Therapy At angiography, active bleeding may be arrested by intra-arterial vasopressin infusion or by transcatheter embolization. This may obviate the need for surgery or may slow bleeding enough to permit elective rather than emergent surgical resection. Vasopressin infusion has an initial success rate of about 50% to 90%, with about a 33% chance of rebleeding. [124], [125] Although embolization used to produce a high rate of intestinal infarction, the frequency of this complication has recently decreased markedly as a result of improved catheter design and application of distal embolization. Two recent studies reported a high rate of hemostasis with embolization without complications. [126], [127] Angiography offers an alternative nonoperative therapy for jejunal or ileal angiodysplasia when enteroscopy is unavailable.

Surgical Therapy Surgery is reserved for severe bleeding from well-characterized and localized lesions that are refractory to endoscopic or angiographic therapy. Endoscopy of both the upper and lower gastrointestinal tract should be performed preoperatively to exclude distant synchronous angiodysplasia or other lesions. [69] Right hemicolectomy is indicated for refractory bleeding from cecal angiodysplasia. [91] Even if angiodysplasia were identified exclusively in the cecum, the entire right colon should be resected to ensure that no angiodysplasia is left behind. In right-sided angiodysplasia, none of the left colon should be removed even if colonic diverticulosis is present to avoid the increased morbidity and mortality of subtotal colectomy. [91] This resection strategy yields a significant but manageable long-term risk of postoperative rebleeding. In one study, 6 of 16 patients (37%) rebled after right hemicolectomy during an average follow-up of 3.6 years [71]; in another study, 4 of 17 patients (24%) rebled. [111] Early rebleeding, which accounts for half or more of the cases, is usually due to unappreciated lesions in the remaining colon and is usually successfully treated by subtotal colectomy. [91]

Medical Therapy After reports of their use to control epistaxis from intranasal telangiectasia in HHT, estrogen and progesterone have been used to control chronic recurrent gastrointestinal bleeding from angiodysplasia. These hormones are believed to promote vascular integrity. [128] In seven patients bleeding from angiodysplasia associated with renal failure, blood transfusion requirements decreased from 1.2 units/month to 0.21 units/month after instituting hormonal therapy. [129] In a study of four patients with angiodysplasia and six with telangiectasia from HHT, estrogen and progesterone decreased transfusion requirements from 10.9 to 1.1 units during a 6-month period. [130] However, in a study of 64 patients with small bowel angiodysplasia, no difference was noted in the rate of bleeding cessation or in the number of units transfused between patients treated with estrogen and progesterone versus untreated controls. [128] Hormonal therapy is currently reserved for patients with chronic bleeding from numerous or widespread angiodysplasias and from angiodysplasias in the jejunum or ileum that are relatively inaccessible to endoscopic therapy and in patients who either fail or cannot tolerate endoscopic or surgical therapy. [128], [131] Hormonal therapy can cause feminization in male patients. [132] Other side effects include vaginal bleeding, fluid retention, thromboembolism, and congestive heart failure. [133]

Natural History

In a retrospective comparison of angiodysplasia and other causes of gastrointestinal bleeding, patients with angiodysplasia had a milder hospital course with fewer transfusions of packed erythrocytes, shorter hospitalizations, and lower mortality rates. [67] Yet, patients occasionally have severe acute bleeding from angiodysplasia requiring surgery. Among 31 patients with angiodysplasia presenting with bleeding or anemia treated conservatively by blood transfusions alone, 26% rebled within 1 year and 46% within 3 years. [114] Thus, endoscopic therapy for angiodysplasia should be performed for gastrointestinal bleeding, even when the bleeding manifests as fecal occult blood or mild chronic anemia, because of the significant risk of rebleeding. In patients with numerous lesions, the endoscopist should concentrate on the largest and most accessible lesions, especially on those with endoscopic stigmata of recent hemorrhage.

Many angiodysplasias are asymptomatic and incidentally found at endoscopy, as, for example, during screening for colon cancer. Elderly patients with no history of bleeding frequently have small angiodysplasias detected in resected colonic specimens removed for unrelated colonic disease. [74] In a review of 41 patients with upper gastrointestinal angiodysplasias, 21 (51%) were incidental endoscopic findings. [92] Management guidelines for asymptomatic angiodysplasia should depend on their risk of subsequent bleeding. In two series of 9 or 15 subjects with asymptomatic angiodysplasia, none experienced gastrointestinal bleeding during a mean follow-up of 2 to 3 years. [56], [114] These findings suggest a conservative approach for asymptomatic angiodysplasia. [61], [134]

HEREDITARY HEMORRHAGIC TELANGIECTASIA

The term telangiectasia denotes vascular ectasia, which is part of a systemic disease or syndrome, in contradistinction to angiodysplasia, which is nonsyndromic. [3] Gastrointestinal telangiectasia, which appears nearly identical to angiodysplasia, is associated with HHT, scleroderma, CREST syndrome, and possibly Turner syndrome. CREST and Turner syndrome were aforementioned with angiodysplasia.

HHT, a disease with autosomal dominant transmission, produces a syndrome of multiple cutaneous telangiectasias, especially on the face, lips, tongue, oral mucosa, and hands, together with multiple mucosal telangiectasias, especially in the nose and gastrointestinal tract (see Chapter 49). The cutaneous lesions are usually a minor cosmetic problem, whereas the nasal and gastrointestinal lesions frequently bleed significantly and repeatedly. [135] This bleeding tendency is explained by the thin and fragile vascular wall that lacks an elastic lamina or muscle layer, vulnerability to trauma because of vessel superficiality, and perhaps intralesional venous hypertension due to arterial shunting of blood. The syndrome is caused by at least two different genetic mutations that impair blood vessel growth and repair, resulting in irregular, tortuous blood spaces lined by a thin single layer of endothelial cells. [136]

The disease prevalence is about 10 per 100,000 population. [137] Both sexes are affected equally. [138], [139] More than 80% of patients experience epistaxis, spontaneously or after minimal trauma, which typically begins during the teenage years. [137] About 25% of patients with epistaxis require blood transfusions. [133]

About 25% of patients experience clinically significant gastrointestinal bleeding, which typically begins during middle age. [140], [141] Upper gastrointestinal bleeding is more common than lower gastrointestinal bleeding because upper gastrointestinal telangiectasias are more common. [141] Gastrointestinal bleeding typically manifests as melena and occasionally as hematemesis. The differential diagnosis of melena in these patients includes swallowed blood from epistaxis. The gastrointestinal bleeding is typically painless, chronic, episodic, and progressive. [139] Among 25 patients with gastrointestinal bleeding, one half required blood transfusions, and one fourth required transfusion of more than 6 units. [140]

About 15% of patients have pulmonary arteriovenous malformations or fistulae, which can cause hypoxemia or hemoptysis, [142] and about 10% have cerebrovascular malformations, which can cause a hemorrhagic stroke or brain abscess. [143] Symptomatic liver involvement is uncommon but important in that it can cause high-output heart failure, portal hypertension, biliary disease, or liver failure. [144], [145]

The diagnosis is straightforward in patients with the triad of telangiectasia, recurrent epistaxis, and a compatible family history. [146] The cutaneous telangiectasias, unlike spider nevi, only partly blanch by diascopy because of vessel tortuosity. The site and source of gastrointestinal bleeding is diagnosed by endoscopy. The endoscopic appearance of telangiectasia resembles that of nonsyndromic angiodysplasia and resembles the cutaneous telangiectasia occurring in this syndrome. Lesions tend to be widespread throughout the gastrointestinal tract. As for angiodysplasia, other causes of gastrointestinal bleeding should be excluded at endoscopy, [139], [141] barium contrast radiography should not be used for diagnosis, [139] and angiography may be useful to diagnose the extent of bowel telangiectasia. [147]

The therapy resembles that for nonsyndromic angiodysplasia, with endoscopic thermocoagulation, electrocoagulation, or photocoagulation, [77], [121] but treatment is complicated by lesion multiplicity, dissemination, and progression. Isolated actively bleeding telangiectasias are usually successfully treated, but patients often rebleed from other, untreated gastrointestinal telangiectasias and, therefore, require multiple endoscopic sessions. [148] Segmental bowel resection is reserved for active, severe, and well-localized bleeding refractory to medical or endoscopic therapy because of the tendency to rebleed subsequently from telangiectasias at other sites. [111], [114], [138] When available, angiographic embolization can obviate the need for surgery.

In theory, systemic or generalized therapy should be favored over local therapy because of the typically large number and widespread extent of the telangiectasias. A few studies have reported a markedly decreased incidence in chronic gastrointestinal bleeding after estrogen and progesterone therapy. [130], [149]

GASTRIC ANTRAL VASCULAR ECTASIA

Clinical Presentation

GAVE is uncommon, reported in only three cases among 10,000 consecutive endoscopies in 1984. [150] The reported incidence appears to have increased somewhat since then owing to greater lesion recognition. The mean age at presentation is 70 years (range, 50 to 90 years), [151], [152] and [153] with a female-to-male ratio of about 5:1. [150], [152], [153] and [154] Patients typically present with iron deficiency anemia from chronic occult gastrointestinal bleeding [150], [153], [155] but occasionally have melena from acute bleeding. [151], [152] Hematemesis is unusual. The occult bleeding and anemia may be longstanding because of delayed diagnosis. [152] The lesion is painless. Physical examination reveals pallor and fecal occult blood. [153]

Diagnosis

Endoscopy reveals multiple parallel prominent longitudinal folds that traverse the antrum and converge to the pyloric sphincter. The folds contain intensely erythematous linear streaks at their apices [150] (Fig. 130-10; see also Color Fig. 130-10). Occasionally, the streaks extend into the proximal stomach. [156], [157] The term *watermelon stomach* derives from the resemblance of these erythematous linear streaks to the stripes on a watermelon rind. Despite lesion vascularity, endoscopic biopsy appears safe in that it can cause slight but not severe bleeding. [150], [158] Histological analysis of endoscopic biopsy samples taken from the apices of the longitudinal folds reveals hypertrophied mucosa, dilated and tortuous mucosal capillaries that are often occluded by bland fibrin thrombi, and dilated and tortuous submucosal veins. [150], [158], [159] Computed tomography may reveal focal mural thickening of the gastric antrum. Double-contrast upper gastrointestinal series may reveal prominent, scalloped antral folds radiating to the pyloric sphincter. [160] Angiography may reveal mild antral hypervascularity. [161] All these radiologic procedures are seldom necessary because the endoscopic appearance and endoscopic biopsy findings are generally diagnostic.

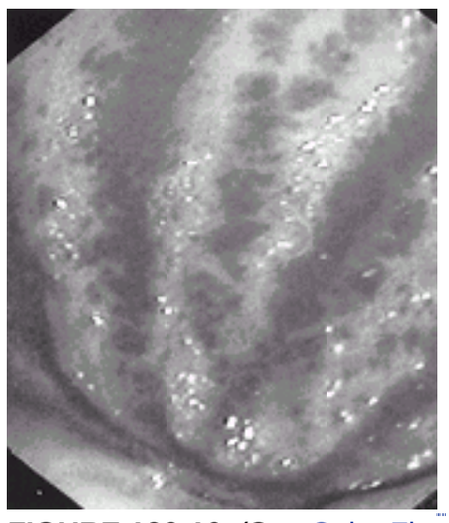

FIGURE 130-10. (See Color Fig. 130-10.) Videophotograph shows the characteristic endoscopic finding in gastric antral vascular ectasia (GAVE) of linear, intensely erythematous lesions at the apices of longitudinal antral folds radiating to the pylorus. The alternative lesion name of *watermelon stomach* derives from the resemblance of these erythematous linear streaks to the stripes on a watermelon rind. (From Clouse RE. Vascular ectasias, tumors, and malformations. In: Yamada T, Alpers DH, Laine L, Owyang C, Powell DW, eds. Atlas of gastroenterology. 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 1999:550.)

Etiology

The etiology is unknown. The disease is associated with gastric hypochlorhydria, [154] cirrhosis, [162], [163] bone marrow transplantation, [164] and scleroderma, [157], [165] but these associations do not appear to provide a clue to the etiology. A trophic etiology has been proposed [166] because of the finding of elevated blood or mucosal tissue concentration of gastrin, [167] prostaglandin E2, [168] and 5-hydroxytryptamine, [169] but these abnormalities have not been conclusively proven. [162]

Alternatively, the lesions may arise from repeated antral mucosal trauma from pyloric prolapse. [150] The lesions are generally restricted to the antrum, the only gastric region subject to peristaltic contractions, and generally occur on longitudinal folds, the antral area subjected to the most trauma during peristaltic contractions. [153] Affected antral mucosa appears to be abnormally mobile and loosely attached to the underlying muscularis propria, as would be expected if mucosa had been chronically pulled from the underlying muscularis propria. [150] The vascular ectasia resembles that seen in other traumatic gastrointestinal lesions, such as the solitary rectal ulcer syndrome or prolapsed hemorrhoids. [153], [170] Cirrhotic patients might develop the lesion as a result of antral dysmotility. [171]

Therapy

Patients require transfusion for acute gastrointestinal bleeding and iron replacement for chronic bleeding. The underlying lesions may be treated by medical, endoscopic, or surgical therapy. Estrogen and progesterone therapy has been successfully used in anecdotal reports. [172], [173] Even though antrectomy removes the lesion and cures the disease, [150], [154] endoscopic therapy is usually attempted first because it has lower morbidity and mortality. Antrectomy is reserved for patients with refractory bleeding. [174] Endoscopic lesion ablation requires multiple endoscopic sessions because of the extensiveness of the lesion. Laser therapy has been most commonly used because it requires fewer endoscopic sessions than other modalities, [152], [157], [174], [175] but the heater probe has also been successfully used. [153] From 87% to 100% of patients have stable hematocrits without transfusions for up to 2 years after endoscopic therapy. [152], [157], [176] Endoscopic complications, such as perforation, stenosis, ulceration, and hemorrhage, are infrequent. [151], [152] Transjugular intrahepatic portosystemic shunt does not stop bleeding from GAVE in cirrhotic patients. [177]

HEMANGIOMAS

Capillary and Cavernous Hemangiomas

Intestinal hemangiomas are rare, with an incidence of about 1 per 15,000 patients. [178] About one half of these hemangiomas are associated with cutaneous hemangiomas, most commonly in the blue rubber bleb nevus syndrome and rarely in Klippel-Trenaunay syndrome, as described later. [179] Intestinal hemangiomas are either capillary, cavernous, or mixed. Capillary hemangiomas consist of small (capillary-sized), thin-walled, closely packed vessels; cavernous hemangiomas consist of large, dilated, blood-filled, thin-walled vessels; and mixed hemangiomas contain both types of vascular lesions. [180], [181] Capillary hemangiomas tend to be small and well circumscribed, whereas cavernous hemangiomas are often large and poorly circumscribed. In both types of hemangiomas, vessels are lined by well-differentiated, flattened, and hyperplastic endothelial cells. Capillary hemangiomas tend to be located in the perianal skin, whereas cavernous hemangiomas tend to be located in the rectum and distal colon. [4], [182]

Intestinal cavernous hemangiomas are clinically more significant owing to their propensity to bleed because of their frequent large size and large blood volume. Thrombocytopenia due to platelet sequestration and consumption within large hemangiomas also predisposes to bleeding. [183], [184] Multiple lesions often occur within the gastrointestinal tract. [185]

Colonic cavernous lesions may be asymptomatic (10%) or may produce acute gastrointestinal bleeding that manifests clinically as hematochezia or melena (72%), [182], [186], [187] or chronic gastrointestinal bleeding that manifests clinically as iron deficiency anemia. [188], [189], [190] and [191] The bleeding is painless. [192] It is typically episodic, recurrent, and progressive. Bleeding usually begins in childhood or young adulthood but occasionally begins in old age. [193] Bleeding lesions are generally large and more likely to be cavernous than capillary hemangiomas. Gastrointestinal lesions occasionally intussuscept and cause gastrointestinal obstruction. [194], [195] Rectal hemangiomas may produce tenesmus and rectal urgency. [181], [196] Hemangiomas occasionally occur in other organs and manifest as hematuria, epistaxis, hemoptysis, or menorrhagia, according to their location. [190], [193], [197]

Abdominal radiographs demonstrate phleboliths from thrombosis and calcification within about 50% of hemangiomas [4], [198] (Fig 130-11A). Barium contrast studies typically reveal multiple polypoid filling defects in the stomach, small bowel, or colon but occasionally reveal an annular intestinal constriction [186], [197], [199], [200] and [201] (see Fig. 130-11B). Computed tomography may demonstrate a large, thickened mesentery containing large vacuoles next to an abnormal intestinal segment with a thickened wall. [4]

FIGURE 130-11. Radiographic appearances of intestinal hemangiomas. **A:** Abdominal radiograph of a 16-year-old white male patient with an extensive distal colonic cavernous hemangioma demonstrates a cluster of radiopaque phleboliths partly outlining the distal colonic wall. **B:** Barium enema demonstrates irregular narrowing in the rectosigmoid and “thumbprinting” in the sigmoid and descending colon caused by intramural hemangiomatous masses. Although the rectosigmoid narrowing resembles an apple-core lesion found in colon cancer, the radiographic findings of phleboliths and intramural masses point to the diagnosis of cavernous hemangioma. (From ref. [212].)

EGD and colonoscopy have high diagnostic sensitivity and specificity in patients with characteristic dermatologic syndromes (see later), but the lesion can be misdiagnosed at endoscopy in patients without the dermatologic syndromes. At endoscopy, intestinal hemangiomas appear as violet-blue, sessile, polypoid lesions. [189] (Fig. 130-12A, Fig. 130-12B; see also Color Fig. 130-12A, Color Fig. 130-12B). It is often difficult to determine at endoscopy which lesion bled because of lesion multiplicity and multifocality. [200] Endoscopic biopsy should be performed cautiously, and only if necessary, owing to the risk of profuse hemorrhage. [4] Pathological examination reveals typical findings of a capillary or cavernous hemangioma: numerous ectatic dilated blood-filled spaces lined by a thin layer of cuboidal endothelium and surrounded by scant fibrous stroma with occasional smooth muscle cells. [190] Lesions lack cellular atypia or dysplasia and do not undergo malignant transformation.

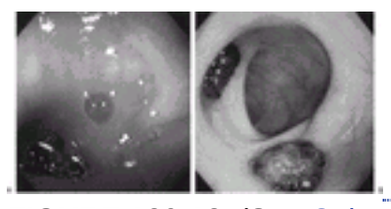

FIGURE 130-12. (See Color Fig. 130-12A, Color Fig. 130-12B.) Endoscopic appearance of colonic hemangiomas. **A:** Videophotograph of a 3-mm colonic capillary hemangioma adjacent to a mid-sigmoid diverticulum. **B:** Videophotograph from the colon shows the characteristic endoscopic appearance of a cavernous hemangioma as a bluish, round, smooth, and well-circumscribed sessile polypoid lesion. (**A,** Courtesy of T.G. Tietjen, M.D., Petoskey, Michigan; **B,** From ref. [206] .)

The differential diagnosis includes colon cancer, adenomatous polyps, hemorrhoids, and ulcerative colitis. [202] Colonic hemangiomas are distinguished from colonic polyps at endoscopy by their bluish color, typical submucosal location, compressibility, and poorly defined margins. [203] Rectal hemangiomas are distinguished from internal hemorrhoids by a nodular, as opposed to serpiginous, shape; submucosal versus superficial location; and extension beyond the anorectum. Colonic hemangiomas are differentiated from pseudopolyps of ulcerative colitis by the presence of a bluish color, submucosal location, and lesion compressibility and by the absence of mucosal granularity, of blunting of the vascular pattern, and of continuous involvement on colonoscopy. [179] The correct diagnosis is critical for proper management. Polypectomy may be inadvisable because of the risk for postpolypectomy hemorrhage from a cavernous hemangioma. Hemorrhoidectomy is ineffective therapy for bleeding from rectal hemangiomas. [202]

Patients typically require frequent blood transfusions for chronic gastrointestinal bleeding. Surgery for gastrointestinal bleeding is limited by the tendency for the lesions to be multiple and widespread and by the frequent evolution of new lesions. [204] Surgery is reserved for severe well-localized bleeding. [197] , [199] Recently, endoscopic hemostasis by coagulation, [187] , [205] band ligation, [206] or endoscopic polypectomy [204] , [206] has been reported without complications.

Blue Rubber Bleb Nevus Syndrome

The blue rubber bleb nevus syndrome, although rare, should be suspected when characteristic dermatologic lesions occur in conjunction with gastrointestinal bleeding (see Chapter 49). Patients present with multiple violet-blue, slightly raised, and elastic cutaneous hemangiomas resembling a rubber nipple [207] and ranging in size from 0.5 to 5 cm in diameter, together with multiple gastrointestinal hemangiomas, which are commonly located from the stomach through the rectum and rarely in the esophagus or oropharynx [188] , [194] , [199] (see Fig. 130-12A, Fig. 130-12B and Color Fig. 130-12A, Color Fig. 130-12B). The cutaneous lesion has a wrinkled surface and can be emptied of blood by manual pressure, leaving a wrinkled blue or white sac that slowly refills when the pressure is released. [189] , [193] Lesions usually begin in early childhood, and they tend to increase progressively in number and sometimes in size with age. [197] , [200] , [206] Most cases are sporadic, but several families have been reported with disease transmission in an autosomal dominant genetic pattern. [197] A candidate gene has been identified on chromosome 9. [208]

The clinical presentation, diagnosis, and therapy of the gastrointestinal lesions were aforementioned in the section “Capillary and Cavernous Hemangiomas.” Cutaneous lesions rarely require treatment because they rarely bleed and never become malignant. [199]

Intestinal Hemangiomas in Klippel-Trenaunay Syndrome

Klippel-Trenaunay syndrome is characterized by port-wine cutaneous hemangiomas, bony and soft tissue hypertrophy, superficial varicose veins, and abnormal—atretic, hypoplastic, or occluded—deep veins, usually affecting one lower extremity but occasionally affecting both lower extremities or one or both upper extremities [209] , [210] (Fig. 130-13). A family history of similar lesions is usually lacking. [209] In *Parkes-Weber syndrome,* patients additionally have arteriovenous fistulae.

FIGURE 130-13. Leg lesions in Klippel-Trenaunay syndrome. A 23-year-old man has the characteristic physical findings in one lower extremity of superficial varicose veins (see left calf), an increased girth (compare size of ankles and calves in the two legs), an increased length, and a port-wine cutaneous hemangioma (see left calf). (From ref. [209] .)

This syndrome is associated with extensive infiltrative cavernous hemangiomas of the distal colon [211] , [212] , [213] and [214] and, rarely, the small intestine. [215] Patients present with chronic intermittent hematochezia and chronic iron deficiency anemia in childhood or young adulthood. [212] , [216] Thrombocytopenia due to platelet sequestration and consumption may contribute to the bleeding, [213] as may mesenteric venous hypertension due to the congenital obstruction of lower extremity veins and consequent overload of the internal iliac veins. [214] The frequency of rectal bleeding associated with this syndrome is poorly characterized [212] but reported as 1% to 13%. [214] , [217] Diagnostic features found on plain abdominal radiographs, barium enema, colonoscopy, computed tomography, and selective inferior mesenteric angiography are essentially the same as those for multiple cavernous hemangiomas (see earlier). [211] , [212] , [215] Abdominoperineal resection of the colonic hemangioma is the definitive therapy. Endoscopic hemostasis may provide a nonsurgical alternative therapy in the future.

Disseminated Hemangiomatosis

Rarely, patients present with more than 50 intestinal hemangiomas, which range in size from 2 to 20 mm, as part of a syndrome of disseminated hemangiomatosis involving three or more organ systems. [218] Patients typically present at birth with numerous cutaneous hemangiomas. Untreated patients have about a 60% mortality rate during infancy from massive gastrointestinal bleeding, hemorrhagic stroke, or high-output cardiac failure due to arteriovenous shunting. [219], [220] Corticosteroids and interferon-a have been successfully used to promote lesion regression. [219], [220]

Phlebectasias

Intestinal phlebectasias are venous varicosities consisting of a markedly dilated tortuous vein, with a normal vascular wall and scant connective tissue stroma unassociated with portal hypertension. [221] Endothelial cells within the vessel appear normal. They are generally classified as multiple, small hemangiomas, but this classification is somewhat controversial. [181], [183] They occur primarily in elderly men. [222] Phlebectasias may also occur in the oral cavity, mostly at the base of the tongue, where they are called caviar spots (varices) or sublingual phlebectasia, and in the genitalia, where they are called Fordyce lesions or scrotal phlebectasia. [221] These cutaneous and oral findings are clues to the presence of intestinal lesions in elderly men with gastrointestinal bleeding.

Intestinal lesions are characteristically dark bluish-black, range from several millimeters to 10 mm in size, are soft and compressible, blanch with pressure, are multiple, and are located in the submucosa. [222] Although usually asymptomatic and an incidental finding, they occasionally produce chronic occult or acute gross intestinal bleeding. [221], [222] and [223] Because of their location, small intestinal phlebectasias must be diagnosed by enteroscopy. [223] Angiography can occasionally demonstrate the site of bleeding by contrast extravasation but does not diagnose the specific lesions. [221] Surgery is currently the only definitive therapy but is reserved for severe ongoing bleeding because of the multiplicity and extent of the small bowel lesions.

ANGIOSARCOMAS

Angiosarcomas are rare, highly vascular malignancies derived from endothelial cells, representing less than 1% of sarcomas. They may be divided into hemangiosarcomas and lymphangiosarcomas. [224] They commonly arise in the skin and subcutaneous tissue, and rarely in the gut. [178] Chronic lymphedema and prior local radiotherapy are risk factors for cutaneous angiosarcomas, [225] and exposure to thorium dioxide (Thorotrast) during angiography, arsenic in insecticides, or polyvinyl chloride in manufacturing plastics are risk factors for hepatic angiosarcomas. [226]

Grossly, lesions may appear as a hemorrhagic mass. Histologically, angiosarcomas contain numerous interconnecting vascular channels (vasoformative structures) that are irregular in size and shape and contain atypical cells with some mitotic activity or sheets of pleomorphic cells that display prominent mitotic activity. Poorly differentiated angiosarcomas are differentiated by immunohistochemistry from poorly differentiated adenocarcinomas by the presence of factor VIII–related antigen. [227]

Patients are generally elderly. [228], [229] Lesions have been reported in the esophagus, stomach, small intestine, colon, and rectum. [178], [228], [229] and [230] Symptoms are similar to those with cavernous hemangiomas. [229], [230] Endoscopy may demonstrate an ulcerated mass or tight asymmetric stricture. Surgical resection is the standard therapy. Angiosarcomas are often multifocal at diagnosis and typically biologically aggressive. [228], [229] The prognosis appears to be poor as a result of early metastasis. [225]

HEMANGIOPERICYTOMAS

Hemangiopericytomas are uncommon, richly vascular neoplasms composed of pericytes, the mesenchymal cells normally closely apposed to endothelial cells. The stomach is the most commonly involved gastrointestinal organ, [231], [232] but the small intestine, [233], [234] and [235] colon, [236], [237] rectum, [238] and even mesentery or retroperitoneum [239] can be involved. The neoplasm occurs primarily in adults. Symptoms include gastrointestinal bleeding, abdominal pain, constipation, abdominal distention, nausea and vomiting, [231], [236], [237] and occasionally intestinal intussusception. [233], [234], [235] and [236] Large tumors are rarely associated with hypoglycemia. [240]

Barium studies typically reveal a smoothly contoured polypoid lesion. [231], [232] Angiography demonstrates a richly vascular mass with a diffuse capillary blush. [240] Endoscopy may reveal a solitary, fairly well-circumscribed submucosal mass or polyp covered by normal or ulcerated mucosa. Pathological examination of endoscopic biopsy specimens reveals tightly packed spindle-shaped neoplastic pericytes surrounding intercommunicating vascular channels of variable caliber and shape. [236], [241]

Most tumors are benign and slow growing, and many are bulky. [231], [236], [240] Malignancy is characterized histologically by increased cellularity, prominent mitotic activity, hyperchromatism, cellular pleomorphism, and foci of necrosis or hemorrhage. [240], [242] Wide local surgical resection is the primary therapy. [242]

HEMANGIOENDOTHELIOMAS

Hemangioendotheliomas are rare, borderline malignancies with a histological appearance between benign hemangiomas and malignant angiosarcomas. Hemangioendotheliomas display more cellularity and mitotic activity than hemangiomas but less mitotic activity and cellular atypia than angiosarcomas. In epithelioid hemangioendothelioma, the most important subtype, neoplastic endothelial cells focally line small extracellular vascular spaces or contain small intracellular spaces or vacuoles. [243] The tumor often arises from a vein, and like angiosarcoma, immunohistochemistry shows the presence of factor VIII–related antigen. Hemangioendotheliomas are sometimes locally invasive but rarely metastasize.
