In general, net transepithelial transport requires the participation of at least two transport proteins to mediate ion uptake across one plasma membrane domain and exit of ions across the plasma membrane domain at the opposite pole of the epithelial cell. By definition, active transepithelial transport also requires involvement of a primary active transporter to provide the energy for net absorption or secretion of the ion. When the pump also serves as an uptake or exit step for the ion in question, only two transport

proteins are required. Net transepithelial electrolyte transport across the epithelium can be either electrogenic or electroneutral. However, transepithelial transport mechanisms can be electrogenic only when both the apical and basolateral membranes mediate electrogenic ion fluxes as part of the mechanism, or when transcellular fluxes drive electrogenic paracellular fluxes. For instance, the electrogen+,K +-ATPase is involved in both electroneutral and electrogenic N+ absorption, depending on the accessory Na + transport events.

The voltage clamp and Ussing chamber are used in combination to define the presence of active electrolyte transport between the lumenal and serosal surfaces of a tissu*Ussing chambe*r permits mounting of intestinal tissue (or a cultured cell monolayer) between two compartments to measure transport between the lumenal and serosal reservoirs. If tissue in an Ussing chamb*voltage clamped* eliminating the driving force for transepithelial ion movement (i.e., transepithelial voltage is clamped to zero), the magnitude of the current required to offset the potential difference (term*short circuit current* or I_{sc}) will reflect active, net electrogenic ion transport. In the same configuration, measurement of net transepithelial ion fluxes with isotopes can be used to detect transport of specific ions that is either electrogenic or electroneutral.

Classically, absorptive and secretory functions of the intestine are considered independent, and absorptive function may remain intact during periods when the secretory function is excessively stimulated. This is a clinically important concept because some antidiarrheal strategies (e.g., oral rehydration solutions) rely on stimulating absorption in the presence of abundant secretion. However, more recent evidence suggests that there are functional, and potentially molecular, linkages between the absorptive and secretory mechanisms. As discussed previously, more recent data have challenged the long-held dogma that villus cells are purely absorptive and crypt cells are purely secretory, and they have confirmed the presence of at least a subset of cells that mediate both absorption and secretion (at least in the colon).[223] Further, evidence that expression of the CFTR C- channel affects activity of the epithelial N+ channel provides an explanation for the observation that patients with cystic fibrosis have increased electrogenic Na+ absorption.[203] Thus, regulation of Cl- secretion and Na+ absorption can be intertwined, and cells that express machinery for both secretory and absorptive functions may have a significant role + absorption.

Electrolyte Absorptive Mechanisms

The small intestine performs electroneutral NaCl absorption and N+-coupled nutrient absorption, and it is responsible for most of the absorption of nutrients and water by the intestine as a whole+ absorptive mechanisms in the colon vary considerably as a function of both species and segment; however, in most species including human, the large intestine absorbs+ avidly through both an electrogenic mechanism involving apical N+ channels and an electroneutral NaCl absorptive mechanism similar to that in the small intestine.[4, 63, 224, 225] The colon also is responsible for SCFA absorption and some + absorption, and it is essential for conservation of fluid and electrolyte[4, 226]

Electroneutral NaCl Absorption A significant fraction of the Na+ and Cl- absorbed by the intestinal tract is electroneutral and is mutually dependent on the alternate ion (i.e., electroneutr+ absorption requires the presence of C- and vice versa).[227] Postprandially, after the absorption of nutrients has been completed, or in the fasting state, electroneutral NaCl absorption is the major route f+ absorption in the small intestine[158] This NaCl absorptive mechanism is also the principal route for N+ absorption in the proximal colon, with less prominence in the distal colc[4] The relative importance of electroneutral versus electrogenic N+ absorption in the colon also varies as a function of mineralocorticoid statu[4] To explain these coupled fluxes, two models of NaCl uptake in the apical membrane have been proposed: an electroneutral+/Cl - cotransporter[228] and the combined action of Na+/H + and Cl-/HCO_3 - exchangers. In either model, it is generally agreed that the I+,K +-ATPase in the basolateral membrane serves as the exit step for N+. Figure 14-4 outlines the dual exchanger model, which is the most widely accepted model for human NaCl absorption at this time. Abundant information supports the existence of electroneutral NaCl absorption composed of a Na+/H + exchange working in parallel with a C-/HCO_3 - exchange pathway[229, 230] Both Na +/H + exchange and C-/HCO_3 - exchange are present in vesicles prepared from the apical membranes of rabbit ileal villus c[139] In this model (see Fig. 14-4), coupling of the paired exchangers occurs through changes in intracellular pH. For example, the + gradient drives Na+ uptake and H+ efflux by Na+/H + exchange, which alkalinizes the cytoplasm and increases the activity of the Cl -/HCO_3 - exchanger. The action of carbonic anhydrase produces HCO_3^-, which then leaves the cell in exchange for uptake of lumenal -. The net reaction is Na+ and Cl- uptake in exchange for H+ and HCO_3 - efflux. Once in the cell, Na+ is pumped out by Na +,K +-ATPase, and Cl- follows by way of an electroneutral transport protein that has yet to be identified, but it is likely to be+/Cl - cotransporter.[180]

Electrogenic Na+ Absorption In humans, electrogenic, amiloride-sensitive N+ absorption accounts for about 50% of the N+ reabsorbed in the distal colon. There is a decreasing gradient of activity through the transverse colon and only minimal levels in the proximal colon.[224, 225] Aldosterone, a mineralocorticoid well known for its N+-retaining and K+-wasting effects on the distal nephron, also exerts profound effects on the distal colon. Induction of secondary hyperaldosteronism by the feeding of a low-sodium diet or administration of exogenous aldosterone converts the rat distal colon from electroneutral, NaCl absorption to amiloride-sensitive, electroge+ absorption.[231, 232 and 233] A similar induction of electrogenic Na+ absorption occurs in certain other species. Figure 14-5 shows the proposed mechanism of electrogenic N+ absorption by the surface epithelium of the distal colon. Lumenal N+ enters colonocytes by a Na+ channel in the apical membrane and exits by the basolateral I+,K +-ATPase. In the process of driving transepithelial Na+ absorption, Na+,K +-ATPase also catalyzes K+ uptake and creates a charge imbalance, and both effects must be compensated to sustain + absorption. The compensatory ion flux is probably achieved by the electrogenic efflux of K+ through K + channels. Whether apical or basolateral I+ channels perform this function remains controversial. It is likely that apical+ conductance is predominantly involved in + secretion, a crypt cell function that is not linked to N+ absorption[128, 234, 235] The simplest model suggests that basolateral I+ channels provide the compensatory flux and recycle + across the basolateral membrane. Finally, paracellular flux of - is driven by Na+ movement to restore electroneutrality between lumenal and serosal compartments.

Solute-Coupled Na+ Absorption The absorption of many nutrients, and also of bile acids (in the terminal ileum), is mediated by+-coupled cotransporters in the small intestine. The combined action of these transporters contributes significantly to+ and water absorption.[236] A common cellular mechanism (Fig. 14-6) is believed to mediate all solute-coupled N+ absorption that occurs in villus cells. Lumenal N+ enters through apical Na+-coupled cotransport and exits through the basolateral N+,K +-ATPase. The Na+-solute cotransporter uses the energy of the electrochemical gradient for I+ to drive intracellular accumulation of the cotransported solute above its equilibrium value. When two+ ions are coupled to the uptake of a single solute molecule (e.g., Na +/glucose cotransporter), the intracellular accumulation of solute can be nearly 100-fo[237, 238] Efflux of the solute down its steep concentration gradient across the basolateral membrane is then efficiently mediated by facilitated diffusive carriers, which are passive. For example, the GLUT2 passive glucose transporter performs this function for glucose absorpt[239] Electrogenic Na+ absorption stimulates absorption of a compensatory - anion by the paracellular route, and recycling of + through basolateral K+ channels ensures cellular electroneutrality.

SCFA Absorption and SCFA-Stimulated Na+ Absorption SCFAs are produced in the colon by bacterial catabolism of unabsorbed carbohydrate and protein. The combined concentration of the predominant lumenal SCFAs (acetate, propionate, and butyrate) is 100 to 150 mM, so they are the major anions and osmolytes in the colonic lum[226] Absorbed SCFAs account for 7% to 10% of ingested calories, and they serve as an important energy source for colonic epithelial c[240] SCFAs also stimulate electroneutral Na+ absorption, up to fivefold in humans[241] SCFAs stimulate Na+ absorption by activation of apical N+/H + exchange in colonocytes that leads to the subsequent exit of I+ through the basolateral Na+,K +-ATPase. Evidence suggests that lumenal SCFA uptake causes intracellular acidification and lumenal alkalinization, which are both known activators c+/H + exchangers.[242, 243] The mechanisms of SCFA uptake that lead to the change in pH are controversial, but it appears that both nonionic diffusion (uptake of the protonated form of these weak acids without intervention of a transport protein) and carrier-mediated transport by anion transporters (e.g., $SCFA_3$ - exchange, MCT1) both play a role[244, 245, 246 and 247] The ability of SCFA-induced acidification to stimulate apical, but not basolateral, N+/H + exchangers of colonocytes has been perplexing. The regulation of extracellular pH in microenvironments directly adjacent to colonocyte membranes may partially expl[248, 249] Physiological SCFA gradients cause alkalinization of the lumenal surface and acidification of the basolateral surf[242] which preferentially activates apical but not basolateral N+/H + exchange.[243] There are several candidate mechanisms for SCFA efflux across the basolateral membrane including nonionic diffusion, SCFA anion transport by SCFA/HCO_3 - exchange, and SCFA/H+ cotransport by MCT1.[124, 250]

K + Absorption In human metabolic balance studies, about 85% of ingested + is absorbed in the small intestine, with passive absorption driven by prevailing electrochemical gradients being sufficient to explain this u[62] In contrast, active electroneutral K + absorption occurs in the distal colon[99, 251] and it is believed to mediate absorption of 5% to 7% of + ingested daily,[62] leaving 3% to 5% to be lost in fecal water. The absolute magnitude of colonic+ fluxes are underestimated by these values because colonic K + secretion also occurs. No single model of colonic I+ absorption predominates. An apical I+,K +-ATPase promotes uptake of I+ from the lumen.[100, 101] Because evidence suggests that not all apical I+ uptake is coupled to proton efflux, there may be other modes of I+ entry as well.[252] K + likely leaves the cell by the I+/Cl - cotransporter KCC1, shown to be expressed in the intestin[253] Because not all K+ absorption is Cl- dependent, there is likely to be a second (or alternative) route for basolateral K+ efflux that is not as tightly coupled to C- anions.[4] The Cl --dependent portion of K+ absorption probably uses apical C-/HCO_3 - exchange to neutralize protons extruded by the +,K +-ATPase, providing a source of intracellular C- to drive the basolateral K+/Cl - cotransporter. Evidence also has shown that SCFA uptake by the guinea pig distal colon requires activity of tI+,K +-ATPase; therefore, an alternative model may exist in which+ absorption regulates SCFA fluxes and vice vers[108]

Genetic Defects in Electrolyte Absorptive Processes

Defects in NaCl absorption. Congenital chloride diarrhea produces profound C--rich, acidic diarrhea commencing at birth, resulting in systemic hypochloremic, hypokalemic acidosis with volume depletion. First described in 1[254, 255] the disease has been described in more than 60 children. The histology of the intestinal mucosa is found to be normal on routine examination. Intubation studies have revealed that the transport defect is limited to the ileum ar[256] Na + absorption against a chemical gradient remains intact and is accompanied by I+ secretion.[257, 258] The gene that causes congenital chloride diarrhea*CLD*) has been cloned.[172] Although the disease can be accounted for by a defective -/HCO_3 - exchanger, the defect may be more subtle than a total lack of anion exchange. Indeed, increases in lumenal HCO_3 - concentrations increase C- secretion in these patients, suggesting that residual C-/HCO_3 - exchange may still occur[256, 257] It is unclear whether this is the result of an alternative anion exchange protein in the apical membrane, or whether it is residual CLD function. Congenital sodium diarrhea is an even rarer disorder. This disease produces a sodium-rich, alkaline stool and results in systemic acidosis. Intubation studies have revealed that the usual inverse relation between N+ and H + fluxes does not hold, suggesting a defect in N+/H + exchange.[259] This defect has been confirmed in studies demonstrating a clear lack of proton-driven + uptake in jejunal vesicles[260] Field and Semrad[1] reported that the distribution of NHE3 mRNA does not correspond to the site of the transport defect in congenital sodium diarrhea, tentatively suggesting that anoth+/H + exchanger isoform may be affected. However, a genetic study failed to find an association with mutations of NHE1, NHE2, NHE3, or NHE5[261] demonstrating that the defect is associated with a yet uncloned NHE isoform or with an essential regulator of a known apical NHE.

Defects in electrogenic Na+ absorption. Liddle syndrome is an autosomal dominant disorder leading to salt-sensitive hypertension. It has been shown to be caused by mutations in the amiloride-sensit+ channel that is present in both distal colonic and renal epithelia.[262] The disorder leads to increased expression and activity of N+ channels because of truncation or frameshift mutations in the cytoplasmic C-terminal tail of a or ? subunits of the chan[193, 194] Curiously, no disorders of intestinal electrolyte absorption have been reported in Liddle syndrome despite severe defects in renal function, suggesting that down-regulation of alternati+ absorptive processes in the colon may compensate for any increased electrogenic absorption; however, this hypothesis remains untested. At least a subset of type 1 pseudohypoaldosteronism (the autosomal recessive version) is also caused by mutations in the epithe+ channel. In contrast to the gain-of-function mutants seen in Liddle syndrome, the mutations in type 1 pseudohypoaldosteronism diminish channel function and cause salt wasting. Intestinal malfunctions have been noted in this disease, including elevat+ levels in the stoo[263] and a lack of colonic responsiveness to mineralocorticoid[264] The disorder can be caused by frameshift, premature termination, and missense mutations in the a, ß, or ? subunits of the chan[265, 266] Cystic fibrosis leads to an increase in electrogenic N+ absorption, although cystic fibrosis is primarily a defect in C- secretory function caused by malfunction of a C- channel (CFTR). However, the expression of normal CFTR protein is thought to limit I+ channel activity, and the lack of CFTR (or presence of mutant CFTR) therefore removes an inhibitory influence on the amiloride-sensitive Na+ channel.[203] An activated CFTR Cl- channel is required to mediate the inhibitory regulatio[202, 203, 267]

Defects in nutrient-coupled Na+ uptake. Glucose-galactose malabsorption is a rare, autosomal recessive disorder in which +-coupled uptake of glucose and galactose is defective. Food ingestion leads to osmotic diarrhea, which can be treated by eliminating glucose and galactose from the diet. Children who have this disorder can maintain normal+ balance without glucose or galactose in their diets, illustrating the reserve capacity of the distal small intestine and colon for water ar+ absorption. Screening of 33 patients identified multiple mutations in SGLT1. These mutations caused transport defects resulting from impaired trafficking of SGLT1 to the plasma membrane and/or defects in glucose transport ki[120, 268]

Electrolyte Secretory Mechanisms

Secretory mechanisms throughout the gastrointestinal tract center around the - anion. HCl is the major secretory product of the stomach. In other intestinal segments, the predominant secreted ion is eith- or HCO_3 -.[269, 270] However, HCO_3 - secretion may be related to, or require, active C- secretion.[271, 272]

Electrogenic Cl- Secretion Electrogenic Cl- secretion is found in all segments of the gastrointestinal tract from the duodenum to the distal colon, presumably reflecting the common need for a mechanism to maintain hydration of the lumenal c Figure 14-7 introduces the model of C- secretion. Uptake of C- across the basolateral membrane is through the electroneutral N+/K +/2Cl - cotransporter.[127] A key function of the Na+/K +/2Cl - cotransporter is to use the energy of the N+ gradient to accumulate Cl - intracellularly above its electrochemical equilibrium. Under these conditions, - will exit the cell across the apical membrane when - channels are opened. Na+,K +-ATPase provides energy for this overall mechanism and recycles N+ across the basolateral membrane. K+ channels in the basolateral membrane allow for + recycling, maintain cellular electroneutrality by compensating for - efflux, and keep the cell hyperpolarized (i.e., negative intracellular voltage compared to outside the cell) s- Cl efflux across the apical membrane can be sustaine[273] It is believed that Na+ follows passively by paracellular flux through tight junctions to maintain electroneutrality between lumenal and serosal compartments. The product of the cystic fibrosis gene, CFTR,

encodes one Cl^- channel in the apical membrane, but other channels also may be important.

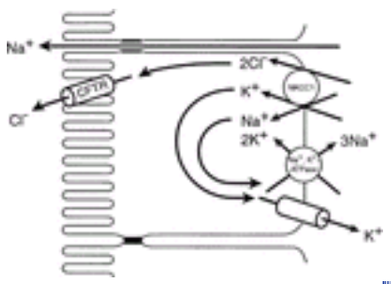

FIGURE 14-7. Cl^- secretion in the small intestine and colon. Cl^- enters cells at the basolateral membrane through $Na^+/K^+/2Cl^-$ cotransport and leaves cells at the apical membrane through Cl^- channels. Details of the model are described in the text.

HCO_3^- Secretion HCO_3^- secreted by the duodenal epithelium contributes to the mucus-HCO_3^- layer that overlies duodenal epithelial cells and thus may be an important protective factor that defends against duodenal ulcer.[270] Although the duodenum secretes large amounts of HCO_3^-, luminal HCO_3^- concentrations in the upper small intestine are relatively low because of neutralization by gastric acid. HCO_3^- secretion also takes place in ileum and colon, but its physiological role in these sites is less clear.[269] One suggestion is that apical Cl^-/HCO_3^- exchange in the colon acts to conserve Cl^- at the expense of HCO_3^- secretion. Conversely, because congenital chloride diarrhea causes systemic alkalosis, the lower gastrointestinal tract may play a significant role in acid-base homeostasis. More than one mechanism likely exists for duodenal HCO_3^- secretion. In the two models depicted in Figure 14-8, a common source of secreted HCO_3^- anion is carbonic anhydrase, which hydrates CO_2 to produce intracellular HCO_3^- and a proton. The proton is eliminated by basolateral Na^+/H^+ exchange, and Na^+ is recycled across the basolateral membrane by Na^+,K^+-ATPase. The models diverge in describing how HCO_3^- exits across the apical membrane. In an electroneutral mechanism, HCO_3^- is exchanged for intraluminal Cl^-.[271] An electrogenic mechanism has also been proposed, involving HCO_3^- secretion through apical channels.[274] It has been shown that the CFTR Cl^- channel can conduct HCO_3^-, making it a logical candidate for such a HCO_3^- secretory channel.[198] Convincing evidence from both patients with cystic fibrosis and CFTR knock-out mice suggests that CFTR plays an essential role in HCO_3^- secretion, both by conducting HCO_3^- and by regulating Cl^-/HCO_3^- exchange.[275], [276] and [277]

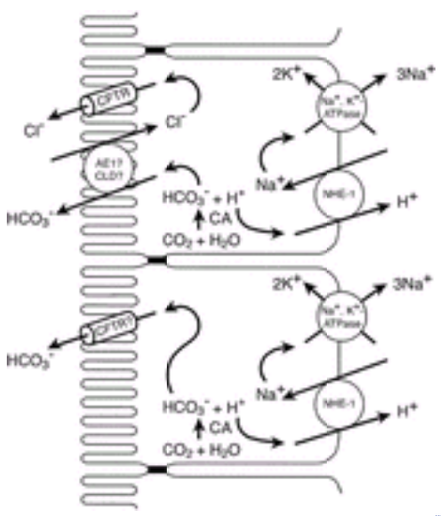

FIGURE 14-8. HCO_3^- secretion in the duodenum. The two models depicted differ in the mechanism for HCO_3^- exit at the apical membrane. As described in the text, both mechanisms may be important in mammalian duodenum. In both models, H^+ is produced by carbonic anhydrase (*CA*), which requires compensatory efflux of a proton by Na^+/H^+ exchange.

HCO_3^- secretion in colon is stimulated by SCFA,[226], [278] and it may occur by a mechanism that differs from those previously described. SCFA uptake is known to cause alkalinization of the colonic lumen, most likely because of nonionic uptake of protonated SCFA by tissues, which removes acid equivalents from the lumen.[242], [244] The resulting transepithelial pH gradient causes a vectorial titration of other weak acids (e.g., CO_2) across the epithelium and results in lumenal accumulation of the basic form (e.g., HCO_3^-). In support of this model, transepithelial CO_2/HCO_3^- gradients have been shown to drive lumenal pH changes consistent with transepithelial nonionic diffusion of CO_2.[244] The relative importance of this nonionic diffusion model versus one using apical Cl^-/HCO_3^- exchange has not been assessed.

K^+ Secretion All portions of the mammalian colon can perform active K^+ secretion.[4] K^+ secretion is enhanced by a low-sodium diet, which leads to increased plasma levels of aldosterone, and by acute K^+ loading.[128], [279], [280] K^+ secretion also can be stimulated by cAMP-dependent secretagogues and seems to occur concurrently with Cl^- secretion.[235] However, despite this evidence for acute regulatory mechanisms, the physiological role of active K^+ secretion remains unknown. The model of active K^+ secretion (Fig. 14-9) closely parallels that of Cl^- secretion. Because inhibitors of the $Na^+/K^+/2Cl^-$ cotransporter block K^+ secretion, at least in some tissues (e.g., rat and guinea pig colon), the $Na^+/K^+/2Cl^-$ cotransporter may be an important route for basolateral K^+ uptake.[129] K^+ secretion ultimately is dependent on the Na^+,K^+-ATPase pump to establish driving gradients, and in some tissues (e.g., rabbit proximal colon), the ATPase may supply the secreted K^+ instead of the $Na^+/K^+/2Cl^-$ cotransporter.[281] In contrast to Cl^- secretion, active K^+ secretion is sensitive to inhibition by K^+ channel blockers applied lumenally (e.g., barium and TEA).[282] The entire process is electrogenic, producing a current opposite to that produced by Cl^- secretion or Na^+ absorption. Although K^+ secretion is believed to be a function of colonic crypts, the interrelationship with Cl^- secretory cells at the same site is largely unexplored.[235]

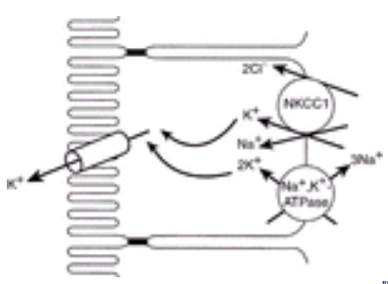

FIGURE 14-9. K^+ secretion in the colon. K^+ uptake at the basolateral membrane is mediated by either K^+,K^+-ATPase or $Na^+/K^+/2Cl^-$ cotransport, depending on the species and the intestinal segment. K^+ efflux at the apical membrane is through K^+ channels. Details of the model are described in the text.

Genetic Defects in Electrolyte Secretory Mechanisms

Defects in Cl^- secretion. Cystic fibrosis is an autosomal recessive disease that causes defective epithelial transport in numerous organs.[283] It is the most common genetic disease of ion transport, with one of every 20 whites being a heterozygote carrier and harboring a mutant *CFTR* allele. There are more than 800 naturally occurring missense, frameshift, and truncation mutations in *CFTR* that cause defective Cl^- secretion by either diminishing the amount of CFTR protein in the membrane (i.e., defective trafficking or synthesis) or decreasing appropriate Cl^- channel opening (i.e., defective ATP gating, cAMP activation, or ion conductance).[284] Mutations occur in all portions of the CFTR molecule, but with the highest frequency occurs in the first nucleotide-binding domain, which controls channel gating. The most common mutation, found in 70% of all mutant *CFTR* alleles, is a triplet deletion that removes a phenylalanine (?F508) and results primarily in defective trafficking of CFTR to the plasma membrane. Intestinal obstruction and meconium ileus associated with cystic fibrosis in newborns appear to result from the inability to maintain appropriate viscosity of lumenal contents. Intestine from patients with cystic fibrosis fails to exhibit normal secretory responses.[205], [285] It has been suggested that one reason for the prevalence of the disease is a heterozygote advantage of being partially protected from the severe, life-threatening consequences of infectious secretory diarrhea, although others have disputed this hypothesis.[286], [287] Another finding in this regard is that the ability of *Salmonella* to invade intestinal epithelial cells is significantly impaired in cells carrying one mutant allele of *CFTR*, which might confer some resistance to typhoid fever.[288]

Other Disorders of Water and Electrolyte Transport

Although genetic diseases associated with specific alterations in transport proteins have provided unique insights into the underlying molecular physiology of electrolyte transport, it should be recognized that the most common diseases of fluid and electrolyte absorption are not related to transporter mutations. This section briefly describes other disorders of intestinal fluid and electrolyte transport, some of which are far more common than the diseases discussed earlier.

Infectious Diarrhea Diarrhea caused by infectious agents is sometimes only an inconvenience in the developed world, but it is a major killer in nonindustrialized nations, responsible for about 5 million deaths per year worldwide. Many infectious diarrheas result from infections with microorganisms capable of producing classical enterotoxins. Cholera is the prototype; a multimer toxin binds to receptors on the apical surface of intestinal epithelial cells and thereby simulates a sustained increase in intracellular cAMP, which, in turn, inhibits electroneutral NaCl absorption and evokes profound Cl^- secretion. Other bacterial toxins may subvert other cellular signaling mechanisms or activate subepithelial cell types to evoke secretion (see the section "Regulation of Electrolyte Transport"). Information is also emerging regarding the mechanisms by which nontoxigenic pathogens, such as invasive bacteria, evoke diarrhea. Such organisms may evoke a program of gene expression in intestinal epithelial cells that predisposes them to display increased secretory responses to endogenous agonists, as well as diminished barrier function.[289]

Microvillus Inclusion Disease This is a rare hereditary disease that commences in the first few days of life with the appearance of severe diarrhea. The histological appearance of the intestinal epithelium is abnormal, characterized by inclusions of brush border membranes as vesicular structures within the cytoplasm of villus cells and a corresponding absence of apical microvilli. It has been suggested that cytoplasmic transport of Golgi-derived vesicles destined to fuse with the apical membrane may be defective in microvillus inclusion disease.[290], [291] Endoscopic biopsies from patients with this disorder showed markedly reduced levels of several apical transport proteins, with those transporters instead residing diffusely in the apical cytoplasm. Levels of basolateral transporters, in contrast, were normal. This led to the hypothesis that the disease results from a genetic defect specifically affecting a late stage of apical membrane trafficking.[292]

Disaccharide Intolerance This term encompasses genetic variability in the ability to conduct brush border digestion of carbohydrates, such as reduced levels of lactase in adulthood, or sucrase-isomaltase deficiency. Such conditions cause osmotic diarrhea

resulting from a reduced rate of brush border hydrolysis of specific disaccharides; only monosaccharides, not disaccharides, can be absorbed by villus enterocytes. The undigested disaccharides remain in the lumen, in contrast to specific peptidase deficiencies, which do not usually result in fluid and electrolyte transport abnormalities because the intestinal epithelium can absorb both free amino acids and small oligopeptides.

Celiac Disease This genetic disorder is characterized by a sensitivity to gluten: a water-insoluble protein found in certain cereal grains, notably w[293] The disease results in diarrhea and nonspecific nutrient malabsorption, which can be rapidly reversed by elimination of offending substances from the diet. Celiac disease causes characteristic and striking morphologic changes in the small intestine, including loss of villi, damage to remaining epithelial cells, and crypt hyperplasia. The underlying cause of the disease is unknown but may include defective digestion of gluten or an inappropriate immune response to normal or improperly processed gluten molecules. The accompanying diarrhea may have both osmotic and secretory components, with the latter mediated, in part, by inflammatory mediators released by activated immune cells in the lamina propria.

Inflammatory Bowel Diseases Patients with inflammatory bowel diseases often present with diarrheal disease, although constipation also is common. It is widely believed that the disorders of fluid and electrolyte absorption in patients with inflammatory bowel disease result from elevated levels of cytokines and other mediators in the inflamed bowel, although disruption of genes involved in maintaining an epithelial barrier also may play a role. Evidence for altered barrier function as a predisposing factor in inflammatory bowel disease has been derived from studies of mice lacking the multidrug resistance protein [294] This protein, expressed in the epithelium, may be responsible for effluxing toxic substances inappropriately absorbed from the gut lumen, and it may also regulate the expression and function of other transport proteins, such as CFT[295] Likewise, disruption of electrolyte absorption, including Na^+ nutrient cotransport, electrogenic Na^+ absorption, and electroneutral NaCl absorption, have also been reported in animal models of intestinal inflammatio[296], [297] and [298]

REGULATION OF ELECTROLYTE TRANSPORT

With molecular information regarding the transport proteins that constitute specific transport mechanisms in the small and large intestines as a foundation, one can study the pathways that regulate these transport mechanisms. Ultimately, all regulatory mechanisms are targeted to the specific protein components of the transport mechanisms, by modulating their activity, abundance, or localization within the epithelial cell.

Appreciation of the more proximal portions of the regulatory cascades has increased. In general, proximal mechanisms responsible for regulating electrolyte transport can be divided into two classes. The first consists of mechanisms operative within the epithelial cells themselves. The second class of regulatory mechanisms is intercellular and includes the release of hormones and neurotransmitters from endocrine cells and enteric nerves, the influence of mediators released by cells of the intestinal immune system, and the role of mesenchymal elements such as fibroblasts.

The kinetics of regulatory processes also should be considered. Intestinal water and electrolyte transport is subject to both acute and chronic regulation. Acute regulation accommodates rapid changes in the lumenal or neurohumoral environment of the epithelium, such as that required in response to the ingestion of a meal. This acute level of regulation usually is provided for by signal transduction events that alter the chemical nature or location of transporter proteins. In general, transport rate is increased by making individual transport molecules work more rapidly or by inserting more transport molecules into the plasma membr[199] The former type of regulation usually occurs on a rapid time scale, in a matter of seconds to minutes. Membrane insertion of transport molecules also can occur on the same time scale if it is mediated by trafficking of transporter-laden vesicles to fuse with the plasma membrane; it may take several hours if translation of new proteins is required. Rapid vesicle trafficking (and interaction with cytoskeletal proteins) is now known to be important for the regulation of certain electrolyte transport proteins. Second messenger–induced phosphorylation of the transport molecule or associated regulatory molecules, with or without transporter insertion, often mediates the rapid regulatory effects[299] Conversely, more protracted changes in whole-body electrolyte status, food intake, or development are balanced by long-term effects on transport regulation that are mediated at a genomic level and are often, although not invariably, the result of alterations in the expression levels of specific transport proteins. A schematic depiction of the various levels at which transport can be regulated is pro Figure 14-10.

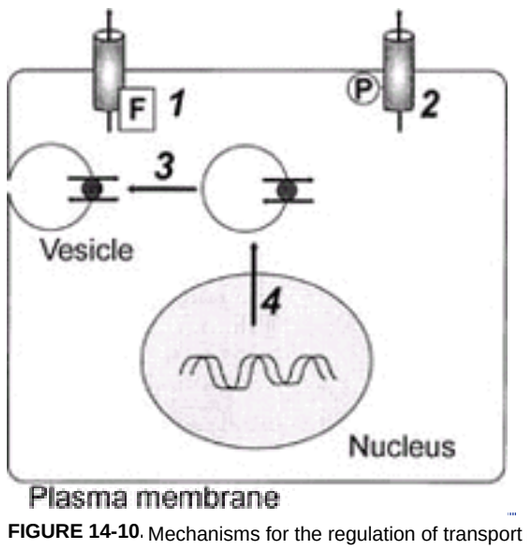

FIGURE 14-10 Mechanisms for the regulation of transport protein function at the level of the epithelium. Four levels of regulation are currently recogni*arabic numerals*). *Mechanism 1* involves direct interactions of regulatory factors*F*) with transport proteins. An example of this mechanism is the interaction of Ca^{2+} with the Ca^{2+}-activated K^+ channel. *Mechanism 2* involves covalent modification of transport proteins, most often mediated by kinase-dependent phosphorylation events. An example of this mechanism is the opening of the cystic fibrosis transmembrane conductance regulatc*CFTR*) Cl^- channel in response to phosphorylation by protein kinase *Mechanism 3* involves changes in the insertion of preformed transport proteins from vesicular pools into the plasma membrane or a change in their rate of retrieval from the plasma membrane. This mechanism appears to involve cytoskeletal cooperation. An example is the increased numbe$Na^+/K^+/2Cl^-$ (*NKCC1*) cotransporters in the basolateral membrane of secretory epithelial cells after an increase in cAM*Mechanism 4* involves changes in the synthesis of specific transport proteins at the level of gene transcription or translation. An example is the increase in epithelNa^+ channel (*ENaC*) expression in response to mineralocorticoids. For further details, see text.

Intracellular Regulatory Mechanisms

This section focuses on a stepwise analysis of the mechanisms intrinsic to the epithelium that ultimately mediate changes in transport function. The intestinal epithelium has evolved a complex network of pathways that regulate its function in a largely autonomous fashion, once an initial signal is received. In addition, signaling cascades intrinsic to the epithelium may modulate its responsiveness to subsequent stimulation.

Receptor Binding The initial step in the activation of the intracellular regulatory mechanisms that control ion transport is the binding of various hormones and neurotransmitters to membrane receptors on epithelial cells. Generally, endogenous regulatory peptides and neurotransmitters bind to and activate receptors on the basolateral aspect of epithelial c[300] whereas bacterial toxins act on the apical membran[301] There are, however, well-recognized exceptions to this polarization. For example, receptors for the endogenous agonists adenosine and bradykinin are found on both sides of the epitheli[44], [302] and this may reflect the finding that these agonists (or their precursors) are the products of inflammatory cells capable of traversing the epithelium and releasing mediators into the lumenal compartmen[303] Similarly, receptors for guanylin, the endogenous ligand for the receptor that binds the heat-stable enterotox*Escherichia co* (ST_a), are located in the apical membrane, implying that this endogenous peptide is secreted specifically into the lumen to produce its biologic effects. Conversely, epidermal growth factor (EGF), normally present in the lumen, has basolaterally localized receptors. It has been suggested that EGF functions as a “lumenal surveillance peptide” in that it regulates epithelial function only in the setting of mucosal damage, where it can gain access to the basolateral aspect of the epithe[304] Some hormones influence epithelial cell function by interacting with intracellular receptors, initiating nuclear signaling events that lead to changes in gene expression. Epithelial cell receptors thus receive signals from either sensor cells (i.e., endocrine cells, neurons, or immune cells) or microorganisms and initiate an appropriate biologic response. For microbial toxins, the secretory response that is initiated may be a primitive defense mechanism designed to wash away the offending microorgan[66] Many substances have been identified that directly affect the Cl^- secretory function of intestinal epithelial cells and, accordingly, are thought to bind to epithelial receptors. The effects of such agents, and the second messenger mechanisms that they initiate, are summariz Table 14-2. The agonists listed in Table 14-2 are limited to those thought to be of physiological relevance. It is of interest that many of the agonists listed are capable of simultaneously inhibiting electroneutral NaCl absorption (although not, importanNa^+/nutrient absorption). Conversely, other substances, such as peptide growth factors, inhibitCl^- secretion yet up-regulate NaCl absorption. This reciprocity in the regulation of Cl^- secretion versus NaCl absorption ensures that the transport functions of different epithelial cells normally do not work at cross-purposes. Further, the independence of the nutrient-coupled processes allows ongoing secretion even during the digestion of a meal and provides for the efficacy of oral rehydration.

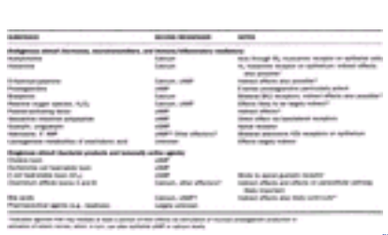

TABLE 14-2 Endogenous and Exogenous Regulators of Intestinal Chloride Secretion

Signal transduction pathways, previously thought to couple receptor occupancy to downstream effectors, can no longer be thought of as linear cascades. A more complete understanding of these pathways includes the concepts of receptor cross talk and branching of signaling mechanisms. Some of the effects of various agonists on intestinal transport may actually be the result of promiscuous coupling to alternate signal transduction pathways. Similarly, the spatial segregation of receptors and effectors in epithelial cells influences the precise mechanisms underlying transport regulation, which can result in signaling asymmetry, whereby the binding of an agonist to the basolateral membrane results in the assembly of signaling components at the apical membrane. [305] Certain protein kinases, including one isoform of the cAMP-dependent protein kinase, protein kinase A, may be selectively anchored in specific subcellular domains. The anchoring of protein kinase A is mediated by a family of proteins known as AKAPs (A-kinase anchoring proteins)[306]

Epithelial Signal Transduction Pathways Once hormones or toxins bind to epithelial cells, they initiate a cascade of events that ultimately results in the regulation of ion transport proteins. Important constituents of this cascade are the small molecules that act within the cell as second messengers. Altered levels of these second messengers control the level of activity of various protein kinases and other effectors and thereby regulate, directly or indirectly, the activity and/or abundance in the membrane of the various transport proteins that constitute the transport mechanisms. The classic second messengers recognized for their involvement in transport regulation are cAMP, cGMP, and free cytosCa^{2+}. More recent studies have identified many novel additional messengers that amplify, antagonize, or modify the effects of these classic messengers within the epithelium.

Cyclic nucleotides. cAMP and cGMP have long been recognized to play important roles in the control of intestinal epithelial ion trans[307], [308] An increase in the level of cAMP or cGMP within the epithelium stimulates Cl^- secretion and inhibits the neutral NaCl absorptive mechanism. cAMP, at least, may also play a role in stimulating the Na^+-glucose absorptive pathway[309] and duodenal HCO_3^- secretion.[274] Several key endogenous hormonal regulators of ion transport, including prostaglandins and vasoactive intestinal polypeptide (VIP), act through an increase in cAMP productio[310], [311] and [312] Exogenous substances may also activate the cAMP pathway. A well-known example is cholera toxin, which causes irreversible activation of G_s^{α} protein by

ADP-ribosylation, leading to prolonged adenylate cyclase activation and elevation of cAMP.[313] Similarly, the apical receptor for the *E coli* heat-stable enterotoxin (ST_a) is a membrane-bound guanylyl cyclase.[314, 315] The binding of toxin to this receptor thereby increases intracellular cGMP concentrations, stimulating Cl^- secretion and inhibiting NaCl absorption.[316, 317] The existence of a receptor for ST_a implied the existence of an endogenous ligand for this system.[318] Such a ligand was subsequently identified and named *guanylin*.[318] Guanylin is produced by intestinal epithelial cells and goblet cells.[319] It may play an important role in normal intestinal water and electrolyte homeostasis, although the details of this role have yet to be fully elucidated.[320] The guanylin family of peptides may also link the salt homeostatic mechanisms of the intestine and kidney.

Intracellular Ca^{2+}. The other primary second messenger system known to regulate intestinal ion transport involves increased levels of free cytosolic Ca^{2+}.[307] Increases in this messenger stimulate both Cl^- and HCO_3^- secretion while inhibiting electroneutral NaCl absorption. The starting point for this mechanism is the receptor-mediated activation of phospholipase C, which cleaves membrane phosphatidylinositols to yield a Ca^{2+}-mobilizing messenger, inositol 1,4,5-trisphosphate (IP_3), and a messenger capable of activating certain isoforms of protein kinase C, diacylglycerol.[321] IP_3 is the messenger responsible for stimulating the release of Ca^{2+} from intracellular stores.[322] Release of Ca^{2+} from stores also triggers the influx of Ca^{2+} from the extracellular milieu.[322] The actions of hormones and neurotransmitters that mediate their effects through cytoplasmic Ca^{2+} are more complicated than the direct pathways described for the cyclic nucleotides. There is a relatively poor correlation between the magnitude and duration of increases in Ca^{2+} and the resulting ion transport responses that result.[323] Whereas Ca^{2+} alone appears to be sufficient to activate epithelial Cl^- secretion, the end effects of this messenger also can be modified by other substances within the cell.[324] For example, other products of phospholipid turnover, including diacylglycerol, inositol 3,4,5,6-tetrakisphosphate (IP_4), or 3-phosphorylated inositol phospholipids produced by the enzyme PI3-K, may be involved in modulating Ca^{2+}-dependent ion transport responses.[325, 326] These auxiliary messengers have been shown to have reciprocal effects on secretory and absorptive processes, for example, inhibiting Ca^{2+}-dependent Cl^- secretion while stimulating electroneutral NaCl absorption.[325, 327]

Downstream targets of epithelial signaling pathways. The downstream effects of cyclic nucleotides and Ca^{2+} within epithelial cells are mediated largely through the actions of specific protein kinases and phosphatases. These downstream effectors alter the conformation of transport proteins or other intermediaries and thereby alter transporter activity. The mechanisms whereby these enzymes alter ion transport have been best defined for protein kinase A. This enzyme phosphorylates CFTR, resulting in channel opening.[328, 329] The efficiency of this process likely is enhanced by clustering of protein kinase A and CFTR in a signaling complex, with the participation of scaffolding proteins including AKAP.[330] Likewise, various kinases, including protein kinase A, alter the activity of Na^+/H^+ exchanger isoforms.[331, 332] For NHE3, the apparent epithelial isoform involved in small intestine NaCl absorption, the reported effect of protein kinase A is to inhibit transporter activity. This phosphorylation requires a cofactor, one of two closely related accessory proteins termed E3KARP (NHE3 kinase regulatory protein) or NHERF (NHE regulatory factor).[333, 334] Further, as discussed for CFTR, scaffolding interactions are critical in ensuring proper NHE3 regulation by protein kinase A.[335] Moreover, as alluded to earlier, an intracellular signaling pathway that enhances Cl^- secretion also causes a concomitant inhibition of NaCl absorption. Similarly, guanylin and ST_a appear to activate Cl^- secretion and to inhibit NaCl absorption through the type II cGMP-dependent protein kinase that is expressed in the intestinal epithelium.[336] The downstream basis of these cGMP-dependent effects is not entirely clear, however, because this kinase neither phosphorylates nor activates CFTR.[329] Moreover, in some segments of the intestine, the effects of cGMP may be mediated by cross-reactivity with protein kinase A.[336] The protein kinases or other effectors responsible for mediating the secretory effects of Ca^{2+} are less well understood. Increases in Ca^{2+} within the epithelial cytosol can activate the Ca^{2+}-calmodulin–dependent (CaM) kinase directly and also act in concert with diacylglycerol to translocate protein kinase C to the plasma membrane and induce its action.[321, 337] A family of Cl^- channels activated by Ca^{2+} and CaM kinase II has also been cloned.[338] It seems possible that such channels may also contribute to Cl^- secretion in response to Ca^{2+}-mobilizing agonists in the intestine, because they are expressed in native intestine and intestinal epithelial cell lines, and a related channel has been cloned from porcine intestine.[339] The relative importance of these channels, as opposed to CFTR, in setting the overall level of secretion has yet to be elucidated, although a channel with similar properties may account for residual Cl^- secretion in the intestine of some patients with cystic fibrosis or in murine models of the disease.[340, 341] Protein kinase C may mediate both decreased epithelial absorption and increased secretion, although its effect on the latter process is controversial.[342] In fact, although protein kinase C activation is capable of inducing active Cl^- secretion in some systems, a more prominent effect of this enzyme appears to be its ability to reduce secretory responses induced by both cAMP and Ca^{2+}-mobilizing agonists.[343, 344] This may result, in part, from the involvement of at least some protein kinase C isoforms in regulating vesicular trafficking of basolateral transport proteins.[345] Some effects of Ca^{2+} within the epithelium are undoubtedly mediated by a direct effect of the cation itself on basolateral, Ca^{2+}-activated K^+ channels.[346] For the Cl^- secretory process, K^+ channel opening increases the driving force for Cl^- exit across the apical membrane.[346] In fact, molecular characterization of a candidate K^+ channel involved in intestinal Cl^- secretion, hIK1, has revealed that the channel is activated by either calcium or protein kinase A in an ATP-dependent fashion, but not by CaM kinase or protein kinase C.[347] Other transport proteins also may be modified as a result of kinase cascades. For example, the basolateral NKCC1 cotransporter involved in Cl^- secretion is phosphorylated by protein kinase A and is thereby activated; this activation is balanced, in turn, by phosphatase action.[348] Furthermore, the intracellular Cl^- concentration also seems to regulate cotransporter activity by impeding its phosphorylation when Cl^- concentrations are high.[348] Thus, intracellular Cl^- self-regulates the rate of anion entry into the cell. Overall, these mechanisms balance Cl^- exit and entry in the actively secreting epithelial cell. Transport regulation also can be mediated by second messenger cascades that alter transport protein localization rather than activity (Fig. 14-10). Several transport mechanisms are regulated in an agonist-sensitive fashion by changing the rate of transport protein insertion into, or retrieval from, the plasma membrane. This is a common mechanism whereby enhanced transport can be accomplished rapidly, having been described for NKCC1,[349] NHE3,[131, 350] SGLT1,[332] Na^+ channels,[351] and Na^+,K^+-ATPase.[352] Transport protein insertion may be stimulated by known signaling pathways, such as by cAMP for NKCC cotransport[353] or PI3-K for NHE3 and Na^+,K^+-ATPase.[325, 354] Similarly, acute effects of the mineralocorticoid aldosterone may partly reflect the insertion of additional Na^+ channels and/or active Na^+,K^+-ATPase pumps into the appropriate membrane of the epithelial cell.[351] As noted previously, transporter abundance also can be reduced by retrieval from the plasma membrane, downstream of protein kinase C activation.[345] The resulting alterations in the abundance of the various transport proteins in the membrane can be considered a complementary mechanism for regulation to those previously described that alter determinants of transport protein activity (e.g., open probability, substrate affinity, or turnover number). A final mechanism whereby epithelial signaling cascades can alter transport activity is brought into play for chronic regulation. Certain hormones, particularly steroids, alter transport activity by transcriptional regulation; the entire pool of transporters within the cell is increased with an accompanying increase in transport capacity. Chronic regulation is an adaptive response to long-term changes in whole-body status, such as occur during fasting and malnutrition, or if salt intake is modified substantially.[355] This mechanism has been best established for the regulation of colonic Na^+ transport by aldosterone.[356] This hormone stimulates the expression of both epithelial Na^+ channels (ENaC) and the Na^+,K^+-ATPase, thereby increasing electrogenic Na^+ absorption.[356, 357] Similar mechanisms almost certainly alter the expression of other transport proteins in the intestine, but they remain relatively underexplored. Note, however, that not all effects of steroid or other hormones on transport regulation are mediated at the genomic level. For example, estradiol rapidly down-regulates Cl^- secretion in the female rat colon without altering Na^+ absorption.[358] One setting in which transcriptional regulation of transporters has a clearly established role, however, is during development.[359] The fluid and electrolyte transport capabilities of the gut are not fully developed at birth in most mammalian species. Development of the intestine is characterized by the appearance and modification of specific transport proteins and changes in the regulation of these pathways. The newborn intestine has elevated levels of ion absorption, in particular Na^+-dependent glucose absorption in the small intestine and amiloride-sensitive Na^+ absorption in the colon.[360] In preterm human infants, the appearance of colonic Na^+ absorption precedes that in the kidney, suggesting that the colon may be a major site for Na^+ conservation in young infants.[361] A subsequent decline in amiloride-sensitive Na^+ absorption correlates with a sharp decline in circulating levels of mineralocorticoids.[362] In contrast, the Cl^-/HCO_3^- exchanger is absent in the colon of preterm infants and only slowly develops during the first year of life.[363] Low levels of Cl^-/HCO_3^- exchange may account for the susceptibility of infants to Cl^- depletion. In the rat colon, Na^+,K^+-ATPase activity is elevated at birth and declines to adult levels during the first few days of life.[364] Conversely, the amount of Na^+,K^+-ATPase mRNA is low at birth and increases with age.[94] Cyclic nucleotide-dependent Cl^- secretion also is fully functional in newborn and infant intestine. Interestingly, the number of guanylin/ST_a receptors is high in infants and declines rapidly with increasing age.[365] Some scientists have speculated that the ability of guanylin to stimulate Cl^- secretion through CFTR may be involved in the clearance of meconium from the newborn intestine,[366] which could account for the finding of meconium ileus in babies with cystic fibrosis.[367] Conversely, bile acids, which normally elicit a Cl^- secretory response in adult colon, do not stimulate Cl^- secretion in newborns.[368, 369] There also is a developmental delay in the appearance of active ileal reabsorptive mechanisms for bile acids.[370] Thus, the concomitant absence of a Cl^- secretory response to these agonists in the colon has obvious beneficial consequences. In fact, newborn intestine may have a more general maturational delay in all receptor-mediated Ca^{2+}-dependent secretion,[369] secondary to reduced phospholipase C activity.[371]

Interactions among second messengers. Hormones that affect intestinal ion transport through different second messengers may have synergistic effects when they are supplied in combination.[372] The physiological implication of this observation is that greater effects on ion transport can be achieved for a given hormone level. The pathophysiological implication is that the combinations of mediators that are commonly encountered in the setting of intestinal inflammation can cause profound secretory diarrhea. The underlying basis of these synergistic interactions among messengers has been studied extensively. For Cl^- secretion, the synergism appears, in part, to depend on the transport proteins activated by a given messenger. Thus, Cl^- secretion induced by cAMP is regulated primarily by the opening of apical CFTR Cl^- channels, whereas Ca^{2+} appears to act predominantly by opening basolateral K^+ channels. When both second messengers are elevated simultaneously, the rate-limiting step for each type of secretion is effectively removed. This may be an oversimplification, however, given emerging evidence for Ca^{2+}-activated Cl^- channels in the intestine.[373] Moreover, synergism also may result from interactions at the level of second messenger generation. cAMP has been shown to modify Ca^{2+} mobilization responses within cultured epithelial cells.[374] Some agonists of secretory processes may also stimulate the secondary production of additional messengers that inhibit or antagonize the effects of the initial messenger.[327] Some of these agents may serve only to induce negative signals within the epithelial cell, without being agonists of secretion themselves. An example is the peptide growth factor, EGF, which inhibits epithelial Cl^- secretion evoked by Ca^{2+}-dependent agonists without acting as a secretagogue itself.[375] Conversely, EGF acts to stimulate both NaCl and glucose-coupled Na^+ absorption.[376, 377] All these processes involve common signaling pathways in which PI3-K plays a central role.[304] Other neurohumoral agents may interfere with the initial production of second messengers. Somatostatin, acting through an SS_1 receptor, inhibits agonist-stimulated accumulation of cAMP in colonic epithelial cells, presumably through the activation of a linked inhibitory G protein (G_i).[378] This effect may underlie, at least in part, the clinical efficacy of somatostatin analogs in cases of severe secretory diarrhea.[379]

Intercellular Regulatory Mechanisms

In addition to the regulatory mechanisms intrinsic to the epithelium itself, transport function is regulated by a plethora of other influences that arise as a consequence of intercellular interactions. The mediators of such effects include those released by endocrine cells, nerve endings, and resident and infiltrating immune and inflammatory cell types (see Fig. 14-3).

Endocrine and Paracrine Regulation Both endocrine (i.e., blood-borne hormones from distant sites) and paracrine (i.e., local) factors are of critical importance in the regulation of epithelial transport. Endocrine cells located within the epithelium sense the nature and composition of lumenal contents and can also mediate responses to extraintestinal signals, such as those from neural inputs. The hormones released by these cells act on epithelial receptors to alter ion transport. Table 14-2 presents a partial listing of some of the neurohumoral agents that have been identified as potential physiological regulators of intestinal ion transport and their presumed mechanism of action. The topic of gastrointestinal hormones is covered in Chapter 4.

Neural Regulation Another key regulatory mechanism for intestinal ion transport is that provided by the enteric nervous system.[380] Various ion transport responses are modified in the absence of neuronal transmission, and electrolyte transport likewise can be stimulated by directly activating resident nerves using electrical stimulation. Neurotransmitters released by enteric nerve endings can bind directly to enterocytes, as described for acetylcholine,[381] and can affect their function in much the same way that has been described for endocrine and paracrine hormones. Enteric neurotransmitters identified as being able to alter intestinal ion transport are included in Table 14-2. Neurotransmitters also may indirectly affect ion transport through their ability to release secondary hormones and mediators. In addition, the enteric nervous system responds to mediators released from endocrine or immune cells,[382] or to lumenal secretagogues, such as bacterial toxins and bile acids.[380] Neural regulation, particularly through cholinergic pathways, appears to be important in maintaining the basal ion transport tone of the intestine. The enteric nervous system probably is also critical for the integration of intestinal electrolyte transport with motility.[383] Activation of the enteric nervous system has various consequences, depending on the intestinal segment examined. In the duodenum, nerve stimulation evokes HCO_3^- secretory responses.[384] In the jejunum, ileum, and distal colon, the most prominent effect is a stimulation of electrogenic Cl^- secretion.[380] In contrast, electrical field stimulation of guinea pig proximal colon inhibits electroneutral Na^+ and Cl^- absorption.[385] Neural regulation of transport function also is likely to be important in coordinating net fluid transport with the passage of contents through the intestine. Thus, stroking of the mucosa, which may model the physical passage of a food bolus during peristalsis, evokes the secretion of both fluid and mucus.[386] This reflex may be a local one, likely involving acetylcholine and 5-hydroxytryptamine,[56, 387] that serves to lubricate the mucosa and protect it from mechanical damage. Neural regulation of epithelial function, in part mediated by central input, also has been implicated in pathophysiological settings. Rats subjected to acute systemic stress show significant increases in baseline secretion and permeability in their intestinal tissues when they are examined in vivo and in vitro.[388] Likewise, the enteric nervous system clearly plays a role in mediating at least a portion of the Cl^- secretory response to specific enteric pathogens such as cholera, *Clostridium difficile*, and rotavirus.[389, 390] and [391]

Immune Regulation Knowledge about the ways in which cells and mediators of the intestinal immune system can affect ion transport has expanded rapidly.[66] This knowledge enhances understanding of the dysfunction of intestinal ion transport that accompanies intestinal inflammatory disorders. Immune cell types also may play a broader role in the control of intestinal fluid and electrolyte homeostasis under noninflammatory conditions than previously thought. For example, mice that are genetically deficient in tissue mast cells not only display defective ion transport responses to antigen challenge, but also have reduced responsiveness to the Cl^- secretory effects of electrical field stimulation and bile acids.[392, 393] In cooperation with the enteric nervous system, mast cells also may mediate Cl^- secretory responses to certain bacterial enterotoxins, most notably the toxins produced by *C difficile*.[390, 394]

Mast cells. Mast cells are the primary effector cells involved in allergic reactions, including those to foods, and they also have been implicated in the pathogenesis of inflammatory bowel disease.[395] In a variety of animal models, immunologic (IgE-dependent) activation of resident mast cells leads to a stimulation of Cl^- secretion.[66] These responses reflect the combined effects of the various mediators that are released from mast cells on activation; the relative contribution of various substances is species dependent. Treatment of human small and large intestine tissue segments with anti-IgE has been reported to produce Cl^- secretory responses that involve histamine, 5-hydroxytryptamine, and functional enteric neurons.[396, 397] The functional association of mast cells and nerves in controlling ion transport is mirrored by a morphologic association; mast cells and nerves are in close proximity in the intestinal mucosa.[398] Mast cell mediators capable of inducing Cl^- secretion include histamine, adenosine, platelet-activating factor,

cysteinyl leukotrienes, and prostaglandin D_2.[399] Mast cells also may be important indirect regulators of ion transport by virtue of their ability to influence other inflammatory or mesenchymal cell types. The mast cell produces various cytokines and other chemotactic factors that attract inflammatory cells.[400] These latter cells, in turn, can alter ion transport. Substances capable of recruiting neutrophils and other inflammatory cells also can be released by the epithelium itself in response to challenge with inflammatory cytokines or in response to bacterial invasion.[401,402]

Neutrophils. Neutrophils accumulate at inflammatory foci in response to peptide and lipid chemotactic factors. The bacterial chemotactic peptide f-met-leu-phe has been used experimentally to activate resident neutrophils. In colonic and ileal tissues from rats, rabbits, and humans, f-met-leu-phe induces a Cl^- secretory response that is attenuated by cyclooxygenase inhibitors and is at least partially dependent on enteric ne[397,403,404] Several mediators released from activated neutrophils may contribute to secretory responses, including neutrophil-derived oxidant[405] as well as 5'AMP. This latter mediator is interesting in that it exhibits only apical activ[303] reflecting a requirement for an apically localized 5' ectonucleotidase that cleaves the 5'AMP to its final active mediator, adenosine. 5'AMP may be an important stimulus of intestinal Cl^- secretion after neutrophil migration into the intestinal lumen, as occurs in a crypt absce[406]

Other immune effector cells. Other inflammatory cells have not been examined as extensively as the mast cell or neutrophil for their ability to regulate epithelial ion transport functions. It seems likely, however, that such cells, including eosinophils, lymphocytes, and monocyte/macrophages, also participate in the control of electrolyte transport because they all can synthesize potent mediators that have either direct or indirect effects on the epi[66] Such cells also may cooperate to influence the transport and barrier properties of the epithelium. For example, activation of T cells with consequent synthesis of interferon-? in the presence of monocytes induces the latter cell type to synthesize TNF-a. This cytokine and other soluble mediators produced by the monocyte, in turn, can selectively down-regulate secretory responses of intestinal epithelial cells to a variety of agonists, as well as diminish their barrier prop[407] In fact, many studies reveal that the overall effect of ongoing inflammation is to down-regulate overall transport function of the intestine, including Na^+ or NaCl absorption[408] and to render the epithelium more permeable. These effects, in sum, predispose to diarrhea. Paneth cells form part of the innate immune system. These cells, localized at the base of intestinal crypts, synthesize a variety of antimicrobial products, including a family of peptides known *cryptdins*. Research suggests that certain of these latter molecules, which are cationic, may be capable of forming anion channels in the apical membrane of colonocytes.[409] Because these peptides are secreted into the crypt lumen by activated Paneth ce[53] their electrophysiological effects also may represent another mode of immune-epithelial interactions that modulate transport.

Role of mesenchymal cells. Immune cells also may interact with the structural elements of the mucosa to control epithelial function. Thus, the myofibroblast sheath underlying the epithelium is thought to act as a regulatory site, whereby signals from elements in the lamina propria, including immune cells, can be amplified, suppressed, translated, or spatially restrict[410] An example of such indirect regulation through myofibroblasts is demonstrated by the coculture of epithelial cells with myofibroblasts that up-regulates the secretory responses of the epithelial cells to both mast cell and neutrophil produ[410] This effect may be attributable, at least in part, to the ability of myofibroblasts to synthesize prostaglandin E_2. In turn, the capacity of the myofibroblast layer to synthesize this mediator may be selectively enhanced in the setting of local inflammation, through the induction of cyclooxygena[76]-2.

Interactions between Intercellular Regulatory Mechanisms The epithelium can respond to signals from a variety of regulatory systems, including those supplied by the endocrine, neurocrine, and immune systems, and there is substantial interplay among the mediators produced. As noted previously, mediators that exert their effects on ion transport through different intracellular signaling mechanisms can display synergistic interactions when supplied to the epithelium in combination. Further, because neural input provides a basal tone to the epithelial cells, they can respond more readily to increased levels of other hormones or inflammatory mediators. Evidence of the importance of this neurally defined tone is provided by the observation that the secretory responses of intestinal tissues to a wide variety of substances are reduced by neurotransmission blocking agents such as tetrodotoxin or atro[411] Thus, even for hormones and immune mediators known to affect the epithelium directly, the degree of neural input appears to be of paramount importance in setting the cellular sensitivity of the syste[412] The topic of intestinal neuroimmunophysiologc[66] has aroused interest because of the intimate spatial relations between the enteric nervous system and the immune elements of the intestine. These spatial relationships appear to have functional correlates. Ion transport responses stimulated by electrical field stimulation can be reduced by antagonists of inflammatory mediators; conversely, the stimulation of immune cells such as mast cells has measurable effects on enteric nerves and consequent indirect effects on ion transpc[66] Another indirect means whereby immune and inflammatory mediators have been shown to influence ion transport function is by the chronic regulation of epithelial responsiveness. Tissues from sensitized animals are more responsive to the Cl^- secretory effects of histamine and substance P[413] Long-term exposure to mast cell products similarly has been shown to enhance the responsiveness of cultured colonic epithelial cells to the Cl^- secretagogues carbachol, VIP, and ST_a without altering their basal electrical properties or their responsiveness to prostaglandins or adenos[414] Although the underlying mechanisms of these effects are not known, their existence suggests that the epithelium may be primed to display secretory responses in the setting of intestinal inflammation or infection. Similarly, sensitization primes the epithelium for rapid antigen transfer from the lumen by the expression of the low-affinity IgE receptor CD23, [415] further amplifying abnormal transport responses in the setting of gastrointestinal allergi[415] Certain other factors indirectly influence fluid and electrolyte transport by intestinal epithelial cells. These include acid-base homeosi[416] gastric and intestinal motility,[383] lumenal flow rates,[417] intestinal permeability[416] oncotic pressure of the blood, arterial pressure, venous pressure, plasma volume, lumenal pressi[418] and physical and psychological stress[419] Some of these factors may have important clinical implications. Retardation of the flow of intestinal contents achieved by the coordinated contraction of gastrointestinal smooth muscle allows more contact time for absorption and thereby may decrease stool[379] Antidiarrheal drugs, particularly the synthetic opiates, act mainly through their effects on gut motilit[379] although neuronal, hormonal, and immunologic influences also are involved. Intestinal permeability increases in diseases that cause mucosal injury, such as inflammatory bowel disease and celiac disease.[420] In theory, an increase in intestinal permeability may allow oncotic and hydrostatic pressure gradients to exert greater effects on electrolyte transport. Increased permeability also may allow macromolecules, normally excluded by the epithelium, to diffuse across the intestinal mucosa more readily. This nonspecific increase in macromolecular permeability should be contrasted with the specific CD23-mediated increase in transcytotic antigen transfer alluded to in the previous pa[415] Nevertheless, both mechanisms may amplify immune responses to transferred macromolecules and may thereby further enhance immune regulation of epithelial fun[66] on.

CONCLUSIONS

The ability of the intestine to control the fluidity of intestinal contents is clearly of key importance for many digestive functions. Both absorption and secretion of electrolytes, as well as other solutes, regulate this fluidity. Over the last few years, an explosion of molecular information regarding the precise structure and function of the transport proteins involved in these transport mechanisms has provided unprecedented insights into the basis of transport and its regulation. Moreover, the identification of various genetic disorders in which epithelial transport function is compromised has provided a deeper understanding of molecular physiology and pathophysiology. The classic disease of intestinal transport is secretory diarrhea; however, it also is apparent that many other disease states can result when transport function is either compromised or overexpressed. In the long-term, the molecular insights described in this chapter will form the basis for advances in the treatment of patients with such conditions.

Acknowledgments

Studies from our laboratories have been supported by grants DK42457 and DK54940 (MHM), and DK53480, DK35108 (Unit 5) and DK28305 (KEB) from the National Institutes of Health and by grants from the Crohn's & Colitis Foundation of America (KEB and SJK). We are grateful to numerous investigators who shared research findings with us before publication and also to Glenda Wheeler for assistance with manuscript preparation.

CHAPTER 15

Chung Owyang and John A. Williams

PANCREATIC SECRETION

The pancreas is an organ with exocrine and endocrine functions. The secretions of the exocrine pancreas, including digestive enzymes and bicarbonate, affect the digestion and absorption of nutrients. The endocrine pancreas releases hormones that regulate metabolism and the disposition of the breakdown products of food within the body. The combined exocrine and endocrine functions make the pancreas one of the most important and complex organs involved in the assimilation of food.

In humans and other mammals, the exocrine pancreas consists of clusters of acini that form lobules separated by loose connective tissue. Eighty percent or more of the pancreas consists of acini. Each acinus is a sphere composed of 20 to 50 pyramidal cells arranged with their broad bases around the circumference and their apices pointed toward a central lumen. Each acinus is drained by a ductule; the most proximal cells of the ductules, which extend into the lumen of the acinus, are called *centroacinar cells*. The ductules drain through a series of ducts of increasing caliber until the main ducts are reached.

Distributed within the pancreas are the islets of Langerhans, containing the cells of the endocrine pancreas. Morphologic studies have revealed cell-to-cell contact between the exocrine and endocrine tissue and direct connections between the capillaries of the islets and the acini. [1], [2] These morphologic arrangements may reflect the regulatory influences of the islet hormones on the function of the exocrine pancreas and vice versa. Of the pancreatic hormones, glucagon, somatostatin, and pancreatic polypeptide (PP) inhibit pancreatic exocrine secretion. [3], [4] and [5] Insulin potentiates the stimulatory effect of cholecystokinin (CCK) on pancreatic exocrine secretion. [6] In addition, exocrine pancreatic secretion can influence pancreatic hormone release.

Over the last decade, basic science research has significantly advanced the understanding of the control of pancreatic secretion. Several new observations have caused the paradigm shift from hormonal-neural control of pancreatic secretion to neurohormonal control with significant control system plasticity. The most significant findings include the following: (1) the cloning of the CCK receptor with the subsequent recognition that the CCK-A receptor is virtually absent from the human pancreas [7], [8]; (2) the discovery that CCK acts on CCK-A receptors on vagal afferent fibers to mediate pancreatic secretion [9], [10]; (3) the observations that most inhibitory mediators of pancreatic exocrine secretion target the dorsal vagal complex, [11], [12] and [13] suggesting a central site of coordination of pancreatic secretion; and (4) the discovery of several protease-sensitive CCK-releasing factors [14], [15] in the proximal intestine that participate in the feedback regulation of pancreatic enzyme secretion. This chapter highlights the details of these discoveries.

FORMATION AND COMPOSITION OF PANCREATIC JUICE

The human pancreas daily secretes about 1 L of juice, consisting mostly of water, electrolytes, and digestive enzymes. The morphologic appearance of the different cells of the exocrine pancreas and the results of micropuncture studies suggest that the acinar cells secrete digestive enzymes and that the ductal cells are mainly responsible for an electrolyte secretion that is rich in bicarbonate. [16] This thesis is further supported by animal experiments in which administration of a toxin or a special diet selectively destroyed acinar or duct cells. Administration of alloxan, which destroys ductal but not acinar cells, results in diminished secretion of fluid and bicarbonate. [17] Ethionine administration damages acinar cells with a concomitant reduction in enzyme secretion, but the secretion of fluid and electrolytes is relatively unaffected. [17]

Water and Electrolytes

Pancreatic electrolytes are secreted in a clear, alkaline fluid that is isosmotic with extracellular fluid. Evidence suggests that water enters the juice passively along osmotic gradients established by the active secretion of electrolytes or other solutes. The major cations in the pancreatic juice are Na^{+} and K^{+}; both are secreted at concentrations similar to their plasma concentrations. The concentrations of both cations are constant and independent of secretory rates (Fig. 15-1). The major anions in the pancreatic juice are HCO_3^{-} and Cl^{-}, the concentrations of which depend on flow rates. As the flow rate increases, the HCO_3^{-} concentration rises asymptotically, approaching a plateau value in humans of about 150 mEq/L at about 30% to 50% of the maximal secretory rate. Because the Cl^{-} concentration falls reciprocally with the increasing secretory rate, the sum of the two anions remains constant and approximately equal to the sum of Na^{+} and K^{+} at all secretory rates. In humans and other animal species, the pancreatic juices also contain Ca^{2+} (1–2 mEq/L) and traces of Mg^{2+}, Zn^{2+}, HPO_4^{2-}, and SO_4^{2-}.

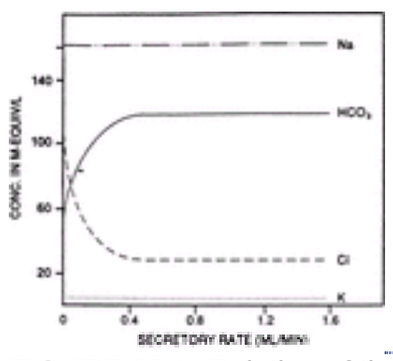

FIGURE 15-1. Relation of the secretory rate to the electrolyte composition of pancreatic juice.

The application of micropuncture and electrophysiological measurements and the use of fluorescent probes and ultrastructural analysis in the study of pancreatic duct cell function have provided important information on the mechanism of ductal electrolyte secretion. Several comprehensive reviews on this topic have been published. [18], [19] Micropuncture studies in rats, cats, and rabbits show that secreted HCO_3^- originates from the intralobular ducts and small interlobular ducts. In the large ducts, some of the HCO_3^- may be exchanged with Cl^- (Fig. 15-2). Evidence supporting a ductal origin of HCO_3^- in humans comes from studies demonstrating that the biochemical lesion of cystic fibrosis is a defect in cyclic AMP (cAMP)–regulated membrane Cl^- conductance in epithelial cells. [20], [21] In the pancreas, this is associated with defective secretion of HCO_3^-. [22] Immunofluorescence studies show that the cystic fibrosis transmembrane conductance regulator (CFTR) is localized to the apical domain of centroacinar cells and intralobular duct cells. [23] CFTR is identical to the small conductance (4 pS) Cl^- channels in the apical plasma membrane of rat pancreatic duct cells, which are regulated by cAMP. [24]

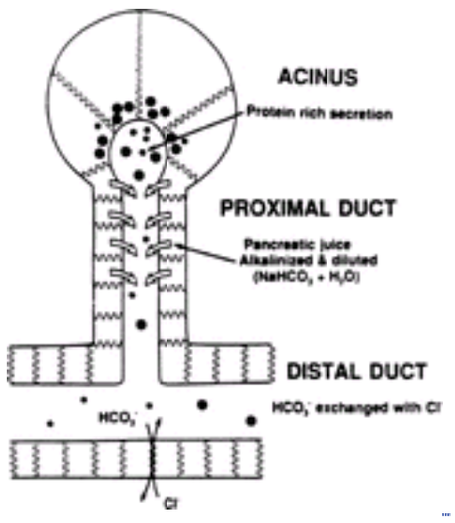

FIGURE 15-2. Ductal origin of secretin-dependent pancreatic HCO_3^- secretion. *Open arrows* indicate secretion of $NaHCO_3$ and water from the proximal duct cells. Some of the secreted HCO_3^- is exchanged with Cl^- in the distal ducts (*curved, solid arrows*). (From ref. [18].)

Electrophysiological studies have shown that by increasing Cl^- exit into the lumen, the CFTR Cl^- channels facilitate the function of a Cl^-/HCO_3^- exchange protein present in the apical membrane. The net result is a recycling of Cl^- and secretion of HCO_3^-. [19], [25] The CFTR channel has some permeability to HCO_3^-, but it is not believed to be a major pathway for HCO_3^- exit into the lumen. An additional function of CFTR is to depolarize the duct cell, with depolarization resulting in basolateral membrane transport (see later discussion).

The mechanism at the basolateral membrane of the duct cell is less well understood. Originally, HCO_3^- was thought to be derived in duct cells from CO_2 under the influence of carbonic anhydrase, which is present in the duct epithelium. [26] Although H^+ extrusion often is shown to be mediated by a Na^+/H^+ exchanger in the basolateral membrane, this protein is now known to play a role in basal cell pH regulation and to account for no more than 1% to 2% of stimulated H^+ extrusion (i.e., equivalent to HCO_3^- uptake). [27] Moreover, both experimental evidence and mathematical models have indicated that some form of energy input is necessary to obtain secretion of 150 mM HCO_3^-. The rat, unfortunately, is a poor model because it secretes HCO_3^- at only 70 to 90 mM. Two competing theories have emerged to account for higher HCO_3^- secretion rates in other species. Based on study primarily of pig pancreas, Veel and colleagues [27] have presented evidence for a primary active proton efflux mediated by a vacuolar H^+-ATPase. The ATPase at rest is located in a tubulovesicular compartment and inserted into the basolateral plasma membrane by exocytosis in response to stimulation by secretion. [28] The action of the ATPase to extrude H^+ allows HCO_3^- to accumulate in the cell and to exit by the apical mechanism previously described. Colchicine, a microtubule-depolymerizing drug, was shown to block secretion-stimulated insertion of tubulovesicles into the basolateral plasma membranes and to inhibit secretin-invoked HCO_3^- secretion by 60%. [29]

The other mechanism has emerged from work on isolated pancreatic ducts from guinea pig, which are capable of secreting 150 mM HCO_3^-. Secretion was blocked by omitting Na^+ from the bath, but not by inhibiting Na^+/H^+ exchange or vacuolar H^+-ATPase activity. [19] Based on an analysis of intracellular pH and Na^+ influx, Ishiguro and colleagues [30], [31] concluded that Na^+-HCO_3^- cotransport accounted for 75% of secretion-stimulated bicarbonate secretion. In their model, the energy of the Na^+ gradient maintained by Na^+, K^+-ATPase present on the basolateral plasma membrane [32] serves to drive HCO_3^- into the cell. This model also agrees with earlier data from the study of perfused cat pancreas showing that fluid secretion increases as a function of perfusate HCO_3^-. [26]

Some details of the nature of the protein mediating Na^+-HCO_3^- transport have emerged. A Na^+-HCO_3^- cotransporter (NBC) was originally cloned from amphibian kidney, and subsequently, a family of at least four NBCs has been molecularly characterized. The NBC1 form has alternatively spliced variants, termed *p* and *k* for *pancreatic* and *kidney*, that differ at the amino terminal as a result of alternate mRNA splicing. [33] pNBC1 has been localized to the basolateral membrane of pancreatic duct cells by immunohistochemistry. [34] The human pNBC1 analog codes for a 1079–amino acid protein, and when expressed in *Xenopus* oocytes, it induces $NaHCO_3$ uptake. [33] Although the stoichiometry of Na^+ and HCO_3^- varies in different cells, it appears to be 1 Na^+ to 2 HCO_3^- in pancreatic duct cells. [35] Because the transporter is electrogenic, it is influenced by the Na^+ gradient, the HCO_3^- gradient, and the membrane potential. In healthy duct cells, transporter-mediated HCO_3^- uptake is enhanced by depolarization induced by Cl^- exit through CFTR. [36] Thus, in this model, secretin, by activating CFTR, increases HCO_3^- uptake via the pNBC exchanger. The transcellular secretion of anions sets up a lumenal electronegative potential, enabling cations such as Na^+ and K^+ to reach the pancreatic juice by moving passively through the paracellular pathway driven by the electrical gradient that increases in response to a stimulation. [37] A cellular model depicting these events in a pancreatic duct cell is shown in Figure 15-3.

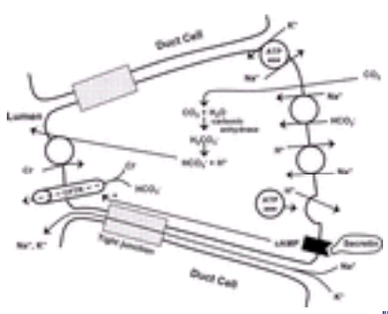

FIGURE 15-3. Cellular model of pancreatic ductal ion transport events that bring about the primary secretion of pancreatic juice. HCO_3^- enters the cell by means of the Na^+-HCO_3^+ cotransporter on the basolateral membrane or by diffusion of CO_2 that becomes hydrated to carbonic acid under the influence of carbonic anhydrase. Transport of H^+ out of the cell by the Na^+/H^+ exchanger or the vascular H^+-ATPase contributes to the provision of intracellular HCO_3^-. Other important

components at the basolateral membrane are the secretin receptor, which activates the production of cAMP, a Na^+, K^+-ATPase that maintains the low level of intracellular Na^+, and a K^+ channel (not shown) that allows K^+ to exit from the cell. The apical membrane contains the cystic fibrosis transmembrane conductance regulator (CFTR) Cl^- selective anion channel and a Cl^-/HCO_3^- exchanger, which together bring about secretion of HCO_3^- and a net lumenal negative potential. The transcellular electrical gradient between blood and lumenal fluid drives the secretion of Na^+ and K^+. The activation of the CFTR Cl^- channel also depolarizes the ductal cell and thereby links events at the apical membrane to the activation of Na^+-HCO_3^- cotransport at the basolateral membrane.

Enzymes

Depending on the species, the enzyme component of pancreatic juice is mixed in various proportions with the aqueous component. Human pancreatic juice contains a concentration of 0.7% to 10% protein. Most proteins are enzymes and proenzymes; the remainder are plasma proteins, trypsin inhibitors, and mucoproteins. The four major enzyme groups are amylolytic, lipolytic, proteolytic, and nucleolytic. The proteolytic enzymes, which include trypsinogen, chymotrypsinogen, procarboxypeptidase, and proelastase, account for most enzymes in the juice and are secreted as inactive proenzymes. After entering the intestinal lumen, trypsinogen is converted by enterokinase, an enzyme secreted by the duodenal mucosa, to the biologically active trypsin. Trypsin autocatalytically activates trypsinogen and converts chymotrypsinogen and other proteolytic enzymes into their active forms.

Pancreatic juice also contains a low concentration of trypsin inhibitor, a polypeptide that, at pH of 3 to 7, combines with and inactivates trypsin in a 1:1 ratio. Trypsin inhibitor also partially inhibits chymotrypsin. Trypsin inhibitor in the pancreas is thought to protect the organ against autodigestion by small amounts of active trypsin within the pancreas. Because it is present in minute quantities, the proteolytic activity of fully activated pancreatic juice in the intestinal lumen is not inhibited. Unlike the proteolytic enzymes, amylase, lipase, and ribonuclease are secreted by the acinar cells in their active forms. Pancreatic juice also contains a 10-kd peptide, called *colipase*, that is essential for optimal lipolysis. [38] It facilitates lipase action by binding with bile salt–lipid surfaces to increase the interaction of lipase with triglyceride. [39] In the presence of bile salts, colipase lowers the optimal pH of lipase from 8.5 to 6.5, the usual pH in the proximal intestine.

Pancreatic enzymes are synthesized within acinar cells and packaged into zymogen granules. [40], [41] The entire process, from synthesis to the point at which the enzymes are ready to be secreted into the lumen, requires about 50 minutes. Total enzyme synthesis is estimated at 20 mg/g of dry tissue per hour or 10 million enzyme molecules per acinar cell per minute. [16] Studies in rats demonstrated that CCK plays an important role in the regulation of gene expression of pancreatic enzymes. [42] Intraduodenal infusion of soybean trypsin inhibitor raises plasma CCK and increases trypsinogen I and chymotrypsinogen ß mRNA levels fivefold after 48 hours. In contrast, soybean trypsin inhibitor infusion has no effect on amylase mRNA levels. Similar effects on pancreatic enzyme mRNA levels are observed after intravenous infusion of CCK to plasma levels comparable to those obtained with soybean trypsin inhibitor. In addition to their effects on gene regulation, CCK and other hormones may exert posttranscriptional control to regulate the synthesis of specific digestive enzymes as mRNA is translated by ribosomes. [43]

Research has begun to reveal the mechanisms by which hormones, especially CCK and insulin, regulate protein synthesis at a translational level and account for the stimulation of pancreatic digestive enzyme synthesis with each meal. CCK and insulin can stimulate acinar protein synthesis in vitro without changes in mRNA. [44] These actions appear primarily at the initiation step in translation and involve the rate-limiting initiation factor eIF4E. Acinar secretagogues and insulin, through a series of steps most likely involving phosphatidylinositol 3-kinase (PI_3-K) and the mammalian target of rapamycin (mTOR), lead to the phosphorylation of the binding protein for eIF4E, and thereby the release of eIF4E, which becomes incorporated into a complex that binds the mRNA 5' cap. [45], [46] Through a separate pathway, CCK also activates the phosphorylation of eIF4E, which increases its affinity for the mRNA cap. In addition, mTOR activates ribosomal S6 kinase (p70 S6K), thereby phosphorylating S6, which increases the translation of messages with terminal polypyrimidine tracts. [47] The importance of the mTOR pathway is shown by the fact that rapamycin can block the stimulation of acinar protein synthesis in vitro. [45]

According to the classical model of Palade, amino acids are actively transported into the acinar cells, and protein synthesis occurs in the ribosomes. The newly synthesized proteins eventually find their way to the rough endoplasmic reticulum. [48] Translation of RNAs for all classes of proteins begins on polysomes, which are free in the cytosol. Pancreatic enzymes and a variety of other exportable proteins are synthesized with an amino acid terminal peptide extension called the *signal peptide*, which recognizes the endoplasmic membrane and allows the attachment of the polysome to the membrane. [48], [49] Translation is temporarily halted when the signal peptide emerges from the ribosomal subunit and interacts with the signal recognition particle, which is associated with the large ribosomal subunit. The protein-RNA complexes find their way to the endoplasmic reticulum membrane, where they interact with a membrane protein known as the *docking protein*. [48] Interaction between the signal recognition particle and the docking protein permits the completion of translocation, after which the ribosomal subunits, signal recognition particle, and RNA dissociate from the endoplasmic reticulum while the protein crosses the endoplasmic reticulum membrane into the cisternae.

The need for the signal recognition particle and docking protein complex to form on the endoplasmic reticulum before the translation of RNAs containing a signal peptide codon can be completed has important physiological implications. This process ensures that potentially noxious proteins, such as proteinases, cannot gain access to the cytosolic compartment. It also provides an initial mechanism for sorting proteins not destined for export from those that must be processed by the endoplasmic reticulum–Golgi pathway and packaged for later secretion. [50] Inside the cisternae of the endoplasmic reticulum, pancreatic secretory proteins undergo conformational changes, assuming tertiary and, in some cases, quaternary structure. These structural changes may account for the irreversible segregation of proteins within the rough endoplasmic reticulum.

The transfer of pancreatic enzyme proteins from the endoplasmic reticulum to the Golgi complex occurs within 20 to 30 minutes of synthesis. [51] Their transfer is mediated by vesicles arising from pinched-off transitional elements of the rough endoplasmic reticulum, which act as transport containers for the secretory proteins. [51] Further modification and concentration occur in the Golgi complex and may result partially from the interaction of the predominantly basic secretory proteins with polyanionic substances formed in the Golgi complex. [52] It is also facilitated by the relatively acidic pH within the Golgi complex. After their formation in the Golgi complex, secretory granules move to the apical portions of the acinar cell by a mechanism involving microtubules, where they remain until an appropriate neurohormonal stimulus triggers exocytosis.

Pancreatic enzymes from a single cell probably are secreted in a fixed ratio that is independent of the nature of the stimulus and of the rate of secretion but determined at the time of synthesis. This phenomenon may be explained by the model proposed by Scheele and Palade, [53] which states that secretory proteins are mixed together in the zymogen granule and discharged in parallel. Under certain experimental conditions, there may be nonparallel secretion of pancreatic enzymes. In humans, increasing doses of CCK infusion result in pancreatic secretion characterized by a greater response of lipase than chymotrypsin concentrations, both of which are greater than the amylase concentration. [54] Similar nonparallel secretion has been reported by Dagorn and colleagues in rats and humans. [55], [56]

Several possible explanations for nonparallel secretion have been proposed: different rates of enzyme synthesis in response to different degrees of stimulation; the existence of a soluble cytoplasmic pool of enzyme proteins that are in equilibrium with those contained in zymogen granules; and different enzymic contents within populations of acinar cells. Morphologic studies show considerable differences in cell sizes in periinsular or teleinsular acinar cells. [57] This, coupled with the observation that the enzyme content and the ratio of amylase to chymotrypsin varies widely among granules taken from the same animal, supports the latter hypothesis and suggests that nonparallel secretion is the result of exocytosis from heterogeneous cells within the pancreas. [58], [59]

Although much controversy exists regarding short-term deviations from parallel secretion, there is little doubt that long-term adaptation of enzymes to diet occurs in animals. Adaptation occurs in rats fed diets containing a preponderance of carbohydrate, protein, or fat, as indicated by increased pancreatic content, mRNA, and rates of synthesis and secretion of the appropriate class of hydrolytic enzymes by the pancreas. [60] Moreover, the dietary effects are thought to be mediated by specific hormones. Insulin mediates the increased amylase synthesis, and CCK released by protein increases the synthesis of proteases. Although such adaptive changes are unreported in humans, preferential secretion of lipase occurs in the chronic renal failure associated with hypercholecystokininemia, consistent with the adaptive change observed in rats after chronic CCK administration. [61]

STIMULATION OF PANCREATIC SECRETION

Mediation of postprandial pancreatic secretion has been ascribed mainly to the hormones secretin and CCK and to vagovagal reflexes that activate cholinergic postganglionic neurons in the pancreas. Considerable knowledge has been gained about these classical regulatory mechanisms, but the picture has become

increasingly complicated by evidence suggesting that other regulatory peptide hormones and neurotransmitters are also involved.

Hormonal Mechanisms

Secretin Secretin is synthesized by S-type enteroendocrine cells of the small intestine and released during a meal. Mutoh and colleagues [62] identified BETA2/neuroD, a transcription factor expressed in the intestinal mucosa cells of mice that also express secretin. This may be the first transcription factor identified that specifically activates cell type–specific expression of an intestinal hormone gene. Secretin is the most potent and efficacious stimulant of pancreatic fluid and HCO_3^- secretion in humans and all other species tested. Duodenal pH is the major regulator of secretin release. The threshold value for secretin release and stimulation of pancreatic HCO_3^- secretion is pH 4.5. [63], [64] Below this pH, pancreatic HCO_3^- output is related to the total amount of titratable acid presented to the duodenum. The increase in postprandial secretin levels in humans amounts to only a few picomolar increments because of the buffering of an appreciable amount of acid produced in the stomach by food and the neutralization of the remaining acid entering the duodenum by pancreaticobiliary secretion. [65] The pH of gastric chyme in the first portion of the duodenum is in the range of 4 to 5.0. [66] However, dilute HCl infused into duodenum at a rate of 2 to 4 mmol/hour can increase plasma secretin significantly in humans and dogs. [65], [67], [68] H^+ bound to solid food particles may be a potent stimulus of pancreatic HCO_3^- secretion. [69] The H^+ slowly diffusing from the particles stimulates pancreatic HCO_3^- secretion by triggering H^+ receptors located in the more distal small intestine. The mechanism by which HCl stimulates the release of secretin is unclear. Studies of rats indicate that H^+ releases a secretin-releasing factor into the upper intestinal lumen to stimulate the release of secretin. [70] This factor has a molecular weight of more than 5000 and is heat stable and trypsin sensitive. The secretin-releasing peptide(s) has not yet been completely characterized, but investigators have reported that purified porcine pancreatic phospholipase A_2 (PLA_2) stimulates secretin release from rat intestinal S cells. [71] Furthermore, PLA_2-like immunoreactivity has been demonstrated in the intestinal mucosa and released into the lumen during duodenal acidification. [72] Pretreatment with a specific anti-PLA_2 antiserum abolished the secretin-releasing bioactivity of the intestinal acid perfusate, suggesting that intestinal PLA_2 is a secretin-releasing peptide. Nonacid factors may play a role in the postprandial release of secretin. Among the major components of a mixed meal, fatty acids such as oleic acid and other digestive products of fat can increase plasma secretin levels and pancreatic HCO_3^- secretion. [73], [74] Bile in the upper small intestine can also stimulate secretin release. [75] However, the physiological importance of these nonacid factors in the release of secretin is questionable, because postprandial plasma secretin does not increase in subjects who are achlorhydric or in healthy subjects in whom meal-induced acid secretion is neutralized with $NaHCO_3$. The pancreas appears to be sensitive to the small amounts of secretin released into the circulation after a meal. Secretin given in a dose that mimics postprandial plasma secretin levels can stimulate pancreatic secretion of water and HCO_3^-. [76], [77] Administration of secretin antiserum to conscious dogs greatly reduces the pancreatic HCO_3^- response to a meal. [78] The site(s) by which secretin acts to stimulate pancreatic secretion is not fully understood. In vitro animal models clearly demonstrate that secretin stimulates HCO_3^- secretion in isolated ducts or duct fragments. [30], [31] With the use of a radiolabeled ligand ^{125}I-secretin and autoradiography, a secretin-binding site was demonstrated on pancreatic acini and duct cells. [79] No binding was evident on pancreatic islets or vascular structures. This supports but does not necessarily prove that secretin acts directly on the pancreas to stimulate pancreatic secretion. On the other hand, in vivo studies indicate that secretin may act on vagal afferent fibers to stimulate pancreatic secretion. [80] When secretin is given with CCK or with simultaneous vagal stimulation, the full postprandial HCO_3^- response is observed, suggesting that the synergistic effects of secretin with CCK or acetylcholine probably account for most of the postprandial HCO_3^- secretion. [77], [81], [82] In the isolated perfused rat pancreas, with the use of electrical field stimulation, it was shown that intrapancreatic cholinergic neurons potentiated the pancreatic exocrine secretion stimulated by intraarterial infusion of secretin, suggesting that cholinergic innervation and secretin may act synergistically to control pancreatic secretion. [83]

Cholecystokinin CCK is the other gut hormone that plays an important role in pancreatic secretion. It is released by hydrolytic products of digestion such as amino acids and fatty acids. In dogs, proteins do not stimulate pancreatic secretion, but crude enzyme digests of protein that contain peptides and amino acids are effective stimulants of pancreatic enzyme secretion, presumably by means of CCK release. [84], [85] Undigested fat is ineffective, but products of lipolysis such as fatty acids are the most potent stimulants of CCK release. [86] Factors that influence CCK response to fatty acids include their chain length, degree of saturation, concentration, and total load. [87] The mechanism by which nutrients stimulate the release of CCK is not clear. In species such as the rat, in which feedback inhibition of pancreatic enzyme secretion occurs, CCK release may be mediated by a trypsin-sensitive CCK-releasing peptide. [88] Peptone in the duodenum stimulates serotonin release from the intestinal enterochromaffin cells. The serotonin released into the submucosa activates the sensory substance P neurons. Signals would then be transmitted to cholinergic interneurons and to epithelial CCK-releasing peptide–containing cells via cholinergic secretomotor neurons. [88] In this manner, CCK release may be controlled by the level of active intralumenal proteases. [89], [90] and [91] Proteins, the major food stimulants of CCK secretion in the rat, may bind or inhibit intralumenal endopeptidases, which would otherwise inactivate the CCK-releasing peptide. [92] Research indicates that ethanol-stimulated CCK release is also mediated by a CCK-releasing peptide. [93] In dogs, the mechanism of CCK release may be nutrient dependent. [94] CCK release in response to sodium oleate but not tryptophan or HCl is atropine sensitive. [94] It is conceivable that the release of CCK by sodium oleate may be mediated by a CCK-releasing peptide, the release of which is mediated by cholinergic input, and tryptophan or HCl may stimulate CCK cells directly. [92] Under fasting conditions, the plasma CCK levels are low, averaging about 1 pmol/L in humans. [95], [96] and [97] After the ingestion of a protein- and fat-rich meal, the concentration increases to 6 to 8 pmol/L within 10 to 30 minutes, followed by a gradual decline to basal levels during the ensuing 3 hours. [96], [97] Several molecular forms of CCK appear to be released into the circulation postprandially, including CCK-58, CCK-33, CCK-22, CCK-12, and CCK-8. [98] Their relative contribution to the CCK activity of plasma in basal and stimulated states remains to be determined. CCK plays an important role in the stimulation of pancreatic enzyme secretion during the postprandial state. Infusion of physiological doses of CCK produces the same levels of pancreatic enzyme secretion as during the postprandial state. [99] Furthermore, administration of lorglumide or MK-329, both of which are potent CCK antagonists, produces a 50% to 60% inhibition of meal-stimulated pancreatic secretion in dogs. [100] These antagonists have similar effects on meal-stimulated pancreatic secretion in humans. [101] CCK can stimulate fluid and HCO_3^- secretion to some extent. [102] The effect on HCO_3^- secretion is weak but physiologically relevant, because CCK potentiates the action of secretin on the pancreas. [103] In intact dogs and humans, CCK-stimulated pancreatic enzyme secretion is not potentiated by secretin. [81], [99], [104] The mechanisms by which CCK acts to stimulate pancreatic enzyme secretion remain controversial. In vitro studies using dispersed pancreatic acini demonstrate that CCK-stimulated amylase release is insensitive to atropine or tetrodotoxin, indicating a direct action on pancreatic acini. [105] The effects of cholinergic agonists and CCK in isolated preparations of pancreatic acini are additive, suggesting that CCK may stimulate enzyme secretion by a cholinergically independent mechanism. [106] However, in vivo studies of humans and dogs have demonstrated that pancreatic secretion stimulated by CCK can be blocked by atropine, implying the involvement of cholinergic pathways. [107], [108] and [109] Furthermore, enzyme output in response to low doses of CCK is reduced in patients after vagotomy compared with healthy controls. [110] It appears that CCK can act through atropine-sensitive and -insensitive pathways to stimulate pancreatic exocrine secretion. Human studies have demonstrated that infusions of CCK-8 to produce plasma CCK levels similar to those observed after ingestion of a standard mixed meal stimulate pancreatic enzyme output predominantly in an atropine-sensitive manner. [107] Furthermore, studies in rats indicate that physiological doses of CCK act through stimulation of vagal afferent pathways originating from the duodenal mucosa (Fig. 15-4). [111] CCK receptors in the rat vagus nerve have been detected with the use of in vitro receptor autoradiography. [112] Like those in the pancreatic acini, vagal CCK receptors exist in both high- and low-affinity states. [9], [10], [113] Under physiological conditions, CCK appears to act through high-affinity vagal CCK-A receptors to mediate pancreatic enzyme secretion. [10] In contrast, the effect of CCK on satiety is mediated by low-affinity vagal CCK-A receptors. These findings suggest that different affinity states of the vagal CCK receptors mediate different digestive functions. Therefore, under physiological conditions, CCK stimulates postprandial pancreatic enzyme secretion through cholinergic pathways rather than through direct action on the pancreatic acinar cell. The muscarinic receptor on the pancreatic acini that mediates these responses appears to be an M_3 muscarinic receptor sensitive to 4-diphenylacetoxy- *N*-methylpiperadine-methiodide. [114]

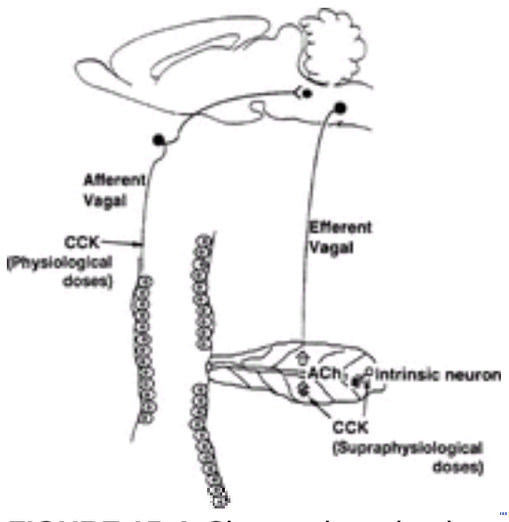

FIGURE 15-4. Sites and mechanisms of action of cholecystokinin (CCK) to stimulate pancreatic enzyme secretion. Doses of CCK-8 that produce physiological plasma CCK levels act through stimulation of the vagal afferent pathway originating from the gastroduodenal mucosa. In contrast, doses that produce supraphysiological plasma CCK levels act on intrapancreatic neurons and, to a lesser extent, on pancreatic acini. (From ref. [111].)

The molecular cloning of the CCK receptor gene and the subsequent recognition that its expression is virtually absent in the human pancreas [7], [8] further supports the possibility that CCK may be acting at an extrapancreatic site. A study indicated that human acini did not respond to CCK agonists, although they responded to a muscarinic agonist. [8] In contrast, the cells responded to CCK agonists after adenovirus-mediated gene transfer of CCK-A receptors. [8] Quantitative reverse transcriptase–polymerase chain reaction (PCR) demonstrated that the message levels of CCK-A receptors were about 30-fold lower than those of CCK-B receptors, which were about 10-fold lower than those of M_3 muscarinic receptors. In situ hybridization did not detect CCK-A receptor mRNAs in adult human pancreas. These observations indicate that human pancreatic acinar cells do not respond to CCK receptor agonists and show that this is caused by an insufficient level of receptor expression.

Serotonin Intestinal serotonin (5-hydroxytryptamine [5-HT]) appears to play an important role in the mediation of postprandial pancreatic secretion. [115], [116] 5-HT is found in abundance in intestinal enterochromaffin (EC) cells, where it is stored in subcellular granules and released by exocytosis when the EC cells are stimulated. EC cells have a morphology consistent with a “sensory” paracrine role. [117] 5-HT is released in response to a wide variety of stimuli, [118] including acidification of the duodenal lumen, [119] instillation of hypertonic glucose, sucrose, and maltose solutions, [115], [120] vagal stimulation, [121] and mechanical stimulation. [122] Studies have shown that 5-HT may increase the discharge of vagal afferent fibers from the stomach and proximal intestine in ferrets [123], [124] and stimulate vagal nodose ganglia activity in rats. This sequence in turn stimulates pancreatic secretion via the vagovagal reflex through a cholinergic pathway. [115] Studies in rats have indicated that administration of the CCK-A receptor antagonist inhibited 54% of postprandial pancreatic protein secretion. The combination of the CCK-A receptor antagonist and a 5-HT_3 antagonist almost completely abolished exocrine pancreatic secretion, [114] suggesting that non–CCK-dependent pancreatic stimulants account for about 50% of postprandial pancreatic secretion and that 5-HT plays a critical role in mediating non–CCK-dependent pancreatic secretion. Similarly, pancreatic HCO_3^- secretion and secretin release in response to duodenal acidification in rats were inhibited by the 5-HT_3 antagonist ondansetron and the 5-HT_2 antagonist ketanserin. [125] In addition, pancreatic fluid and HCO_3^- secretion stimulated by exogenous secretin was also inhibited by these 5-HT antagonists. Thus, 5-HT appears to regulate acid-stimulated exocrine pancreatic secretion through modulation of both the release and action of secretin via two 5-HT receptor subtypes. Under certain experimental conditions, activation of the 5-HT pathway may inhibit pancreatic exocrine secretion. It has been reported that in isolated guinea pig pancreatic ducts, 5-HT inhibited basal and secretin- or acetylcholine-stimulated fluid secretion. This effect was antagonized by a 5-HT_3 agonist, indicating the involvement of a direct 5-HT_3 inhibitory pathway. [126] On the other hand, administration of a 5-HT_3 antagonist, azasetron, in rats stimulated pancreatic secretion of fluid and protein. [127] This effect was abolished by atropine but not by vagotomy, suggesting the involvement of a vagus-independent cholinergic pathway. Researchers recently identified the presence of 5-HT–containing cells in guinea pig pancreatic ducts and 5-HT_3 receptors on their basolateral cell membranes. [126] The elevation of intraductal pressure reduced secretin-stimulated fluid secretion, an effect that was attenuated by a 5-HT antagonist. These authors proposed a distention-stimulated negative feedback on fluid secretion by pancreatic duct cells.

Other Hormones and Stimulatory Factors

Insulin plays a significant role in modulating exocrine pancreatic secretion. [6] Studies have demonstrated that insulin potentiates the secretory response to secretin plus CCK [128] and that ouabain, an inhibitor of Na^+, K^+-ATPase activity, abolishes this stimulatory action of insulin. Insulin potentiates the stimulatory action of secretin on Na^+, K^+-ATPase activity, without affecting the binding of secretin to pancreatic acini. Physiologically, this action of insulin is important because immunoneutralization experiments in conscious rats show that pancreatic secretion of water, HCO_3^-, and protein stimulated by a meal or by a combined intravenous administration of physiological doses of secretin and CCK-8 is markedly reduced when the circulating insulin is neutralized with a rabbit anti-insulin antibody. [129] Similar observations have been made in studies of an isolated perfused rat pancreas preparation. These studies indicate that insulin is needed locally for the action of secretin and CCK on the exocrine pancreas. A clinical confirmation of this hypothesis is that pancreatic enzyme secretion is frequently reduced in human diabetics who have no overt pancreatic disease. [130]

In view of the structural similarity between CCK and gastrin (see Chapter 4), it is not surprising to find that gastrin stimulates pancreatic enzyme secretion. In the dog, gastrin is about one-third as effective as CCK on a molar basis in stimulating the pancreas. Irrigation of a canine antral pouch with peptone and liver extracts at neutral pH stimulates pancreatic protein secretion, but irrigation with acidified solutions does not. [131] The stimulatory effects of the protein solution may be caused by the release of gastrin, and the inhibitory effects of acidification may be the result of the suppression of gastrin release. The evidence, however, is indirect; it is unlikely that the postprandial increase in plasma gastrin is sufficient to significantly stimulate pancreatic secretion.

Bombesin (i.e., gastrin-releasing peptide in mammals), a polypeptide isolated from the skin of frogs and the human alimentary tract, stimulates pancreatic secretions that contain small amounts of HCO_3^- and high concentrations of enzymes in humans. [132], [133] Bombesin can act directly on the pancreas by means of specific receptors identified on pancreatic acinar cells. [134] It has been suggested that bombesin exerts its stimulating effect on the exocrine pancreas indirectly by promoting the release of CCK from the small intestinal mucosa. [135] In other systems, bombesin has been reported to exert its effect by way of a cholinergic pathway. [136] Bombesin stimulates amylase release from rat pancreatic lobules through the release of acetylcholine from intralobular nerves. [137] In contrast, in vivo studies indicate that the action of bombesin in rats is probably direct, however, because the combined administration of atropine and the CCK antagonist proglumide does not affect pancreatic protein output stimulated by bombesin. [138] Similarly, the stimulatory action of bombesin on pancreatic secretion in humans is not affected by the CCK receptor antagonist loxiglumide. [139] The physiological importance of bombesin in pancreatic secretion is brought into question by studies demonstrating that bombesin receptor antagonists do not influence postprandial enzyme secretion in intact rats. [140]

The tridecapeptide neurotensin has been shown to stimulate pancreatic secretion in humans and dogs. [141], [142] In rats, the mechanism of stimulation appears to be neurally mediated, involving capsaicin-sensitive sensory fibers and cholinergic vagal efferent pathways. [143] Neurotensin is released by intestinal fatty acids, raising the interesting possibility that neurotensin may play a significant role in mediating pancreatic secretion stimulated by fat. [142] However, exogenous infusion of neurotensin in doses that stimulate pancreatic secretion results in plasma levels much higher than those that occur after a normal meal. [141], [142] Neurotensin stimulates HCO_3^- secretion but decreases enzyme secretion stimulated by secretin and cerulein, a CCK analog, in humans. [141] These observations do not support a role for neurotensin as a regulator of meal-stimulated pancreatic secretion.

Nitric oxide (NO), a ubiquitous substance that is present in the neurons and vascular endothelium of the pancreas, [144] also appears to play a significant role in regulating pancreatic secretion. In rats, inhibition of NO production with N^G-nitro-L-arginine-methyl ester (L-NAME) reduced basal amylase secretion by 60%. [145] The NO synthase inhibitor also inhibited pancreatic enzyme secretion in response to a meal, duodenal infusion of acid, or intravenous infusion of physiological doses of secretin or CCK in anesthetized and conscious rats. [146] In humans, graded doses of the NO synthase inhibitor N^G-monomethyl-L-arginine dose-dependently reduced pancreatic enzyme secretion stimulated by secretin and cerulein. [147] Because the NO synthase inhibitor did not inhibit amylase release or changes in intracellular Ca

$^{2+}$ concentration in rat pancreatic acini stimulated by carbachol and CCK-8, [148] it is likely that the effect of NO on exocrine pancreatic secretion is indirect. NO synthase is abundant in intrapancreatic nerves [149] and ducts, the enteric nervous system, and the vagus nerve. [150] The source of NO that mediates the action of CCK and secretin on pancreatic secretion is not yet clear.

Administration of L-NAME reduces CCK-stimulated pancreatic microvascular blood flow and at the same time decreases pancreatic fluid and protein output in cats. [151] This observation may have clinical importance, because inadequate blood flow has been associated with clinical pancreatitis. It has been reported that administration of a NO synthase inhibitor in rats with edematous pancreatitis causes a decrease in pancreatic blood flow and exacerbates cerulein-induced pancreatitis. [152] Conversely, treatment with the NO donor L-arginine before and after cerulein injection increases pancreatic blood flow and reduces the severity of cerulein/water immersion–induced hemorrhagic pancreatitis. These observations suggest that NO may have a protective role against the development of pancreatitis, possibly because it increases pancreatic blood perfusion.

Neural Mechanisms

Parasympathetic Nervous System The pancreas is innervated by parasympathetic and sympathetic nerve fibers. The parasympathetic fibers pass to the pancreas directly through the vagus nerves and indirectly through the celiac ganglion, the splanchnic nerves, and perhaps the intramural plexus of the duodenum. The functional effect of vagal stimulation of the pancreas varies greatly with the species and with the experimental conditions. [153] In the rat, both CCK and non–CCK-mediated lumenal stimuli evoke pancreatic enzyme secretion via stimulation of a vagal afferent pathway originating from the duodenal mucosa. [116], [154] Acute vagotomy or administration of atropine completely abolishes pancreatic secretion stimulated by these agents. [116], [154] In the dog and rabbit, vagal stimulation has a small stimulatory effect on enzyme output, but the increase is smaller in magnitude than with CCK stimulation. This response persists after removal of the stomach and intestine, indicating a direct stimulatory effect on the pancreas. In cats, stimulation of the vagus results in some increase in the secretion rate that does not depend on hormones. The secretion of enzymes is blocked by atropine, but atropine has no effect on HCO_3^- secretion. In pigs, vagal stimulation results in copious secretion of pancreatic juice rich in enzymes and HCO_3^-, even after extirpation of the stomach and intestine. In humans, the vagus appears to play an important role in the mediation of pancreatic secretion. Insulin-induced hypoglycemia, which is presumed to stimulate the vagus, augments secretin-stimulated pancreatic protein output. [155] Vagotomy reduces the HCO_3^- secretory response to exogenous hormones. Maximal enzyme secretion is not significantly affected, but the sensitivity of the pancreas to submaximal doses of CCK is decreased. [110] Vagotomy reduces pancreatic enzyme responses to intestinal stimulants and food. [110], [156] It seems that the cholinergic stimulation primarily modulates the action of gut peptides on pancreatic secretion but has no physiologically relevant effect on the release of CCK or secretin. [157] There are volume receptors and osmoreceptors in the human duodenum. Stimulation of these receptors by distention or administration of a hyperosmolar solution elicits a pancreatic enzyme response mediated by cholinergic neurons. [158], [159] Increased firing rates in peripheral afferent vagal neurons and in central sites have been recorded after gastric distention and intestinal perfusion with amino acids and HCl. [160], [161] and [162] The neurotransmitters involved in central vagal transmission and regulation of pancreatic secretion remain to be identified. Microinjection of the thyrotropin-releasing hormone analog in the dorsal vagal complex of rats stimulates pancreatic juice flow and enzyme output in a dose-dependent manner. [163] Vagotomy and atropine eliminate this stimulatory effect, indicating that thyrotropin-releasing hormone modulates pancreatic exocrine secretion through the dorsal vagal complex. Intrapancreatic postganglionic cholinergic neurons regulate enzyme and HCO_3^- secretion. These neurons are activated by central input during the cephalic phase and by vagovagal reflexes initiated by gastric- and intestinal-phase stimulation. Acetylcholine released by the intrapancreatic neurons may act directly on acinar cells or potentiate the action of secretin on HCO_3^- secretion from duct cells. The interaction of acetylcholine and CCK is additive. The enteropancreatic reflex also may play a role in mediating postprandial enzyme secretion. [159] This is especially important after chronic vagotomy. [164]

Sympathetic Nervous System Adrenergic innervation of the pancreas occurs mainly through the splanchnic nerves. In the pancreas, most of the fibers are distributed to the blood vessels, and a few pass to the acini or ducts. [103] Signals of the splanchnic nerves usually inhibit exocrine and endocrine pancreatic secretion; stimulation of the nerves usually decreases the response to pancreatic stimulants, but splanchnicectomy increases it. [103], [165] The pancreatic inhibitory effect of splanchnic nerve stimulation appears to be synchronous with and dependent on intense vasoconstriction that is caused by stimulation of the ß-adrenergic receptors on blood vessels. In isolated guinea pig pancreatic acini, norepinephrine alone has no effect on the response to submaximal concentrations of CCK-8. [166] Epinephrine produces a modest stimulation of enzyme output in mouse and rat pancreas in vitro, and the stimulatory effect is inhibited by ß-adrenergic receptor antagonists. [167] No clear pattern emerges from the many studies of the regulation of exocrine pancreatic secretion by the sympathetic nervous system. The major role of the adrenergic mechanism appears to be the inhibition of fluid and HCO_3^- secretion, which is mediated partially by vasoconstriction.

Enteropancreatic Neural Reflex Functional and anatomic enteropancreatic neural connections have been shown by antegrade and retrograde tracer studies; neurons in ganglia of the myenteric plexuses of the stomach and duodenum project to the pancreas. [168] Activation of the myenteric neurons in the duodenum can influence the exocrine and endocrine pancreatic function in the rat. These enteropancreatic neural pathways have cholinergic and serotoninergic components. [168], [169] The cholinergic nerves from the duodenum stimulate intrapancreatic neurons by way of nicotinic synapses. Abundant enteropancreatic serotonergic axons may inhibit pancreatic secretion through presynaptic receptors 5-HT_{1P} on cholinergic nerves. [169] Further studies are needed to define the physiological role of the serotonergic enteropancreatic neural pathways.

Peptidergic Nervous System Immunocytochemical studies have revealed several peptides in nerve cell bodies or fibers in the pancreas. Among these, nerve fibers and cell bodies containing vasoactive intestinal polypeptide (VIP) are the most abundant. [170] The VIP fibers appear to surround the cell bodies of intrapancreatic ganglia and innervate duct cells. In pigs, VIP is the neurotransmitter that mediates much of the HCO_3^- secretory response to electrical stimulation of the vagus nerve. [171] Vagal stimulation after administration of atropine increases the pancreatic venous outflow of VIP and pancreatic HCO_3^- secretion; somatostatin blocks both effects. [171] The time courses for increased venous efflux of VIP and for increased HCO_3^- secretion after vagal stimulation are similar, and a specific VIP antiserum reduces the HCO_3^- response to vagal stimulation. [170] The importance of intrapancreatic neuronal VIP as a regulator of pancreatic secretion may be species specific. VIP is a weak partial agonist in humans. [172] In some species, VIP may also induce pancreatic vasodilation and increase blood flow in response to the activation of the exocrine pancreas. The neuropeptide galanin, which has been found in intrapancreatic nerve endings surrounding the endocrine and within the exocrine pancreas, appears to have a modulatory effect on exocrine pancreatic secretion. Depending on the experimental models used, galanin may stimulate or inhibit pancreatic secretion. With the use of an isolated perfused rat pancreas, it has been shown that porcine galanin in concentrations of 1 and 10 nmol/L significantly enhances CCK-stimulated amylase secretion and stimulates insulin release. [173] However, at higher concentrations (1–100 nmol/L), galanin inhibits insulin secretion and has no effect on CCK-stimulated amylase secretion. Because insulin potentiates CCK-stimulated enzyme secretion, low concentrations of galanin probably act through the release of insulin to stimulate pancreatic secretion. In contrast, galanin appears to be a potent inhibitor of the pancreatic exocrine secretion stimulated by either bombesin, secretin, or CCK in intact animals. [174] Galanin completely inhibits 2-deoxy-D-glucose–stimulated amylase secretion in anesthetized rats and significantly inhibits veratridine-stimulated release of acetylcholine in rat pancreatic lobules. [175] Thus, in intact animals, galanin appears to inhibit pancreatic secretion by inhibiting cholinergic transmission. Other peptidergic neurotransmitters identified in the pancreas include the carboxyl-terminal tetrapeptide of gastrin or CCK, [165], [176] gastrin-releasing peptide, [177] substance P, [165], [176] peptide histidine isoleucine, [178] neurotensin, [179] neuropeptide Y, [178], [180] enkephalin, [165], [176] and calcitonin gene–related peptide (CGRP). [181] Pharmacological studies have found that CCK, gastrin, substance P, gastrin-releasing peptide, peptide histidine isoleucine, neurotensin, and CGRP stimulate and that enkephalin and neuropeptide Y inhibit exocrine pancreatic secretion. The physiological relevance of their mediation of pancreatic secretion is unknown.

Intrapancreatic Nerves

Pancreatic ganglia share many of the characteristics of the enteric neurons and receive input from the parasympathetic, sympathetic, and enteric nervous systems. The vast majority of pancreatic neurons (86%) are choline acetyltransferase (ChAT) positive. [182] All ChAT-positive pancreatic neurons possess neuropeptide Y immunoreactivity, and most also express NO synthase. [182] Most pancreatic neurons innervate the acini. Intrapancreatic neurons receive fast and slow excitatory postsynaptic potentials (EPSPs); 5-HT appears to inhibit the slow EPSPs through a 5-HT_{1P} receptor in some neurons. 5-HT and 5-HT_{1P} agonists are known to inhibit amylase secretion. Furthermore, intravenous injections of 5-HT_3 receptor antagonists, such as azasetron and granisetron, increase pancreatic protein output in conscious rats. [127] Blockade of this effect by atropine, but not truncal vagotomy, [127] is consistent with a site of action on intrapancreatic ganglia and nerves.

INTRACELLULAR CONTROL OF PANCREATIC SECRETION

Receptors

Most of the hormones and neurotransmitters that stimulate pancreatic secretion do so by directly regulating acinar and duct cells, but some may regulate indirectly by their actions on nerves or blood vessels. To determine the regulatory pathway, it is important to identify the physiological effects on isolated acinar and duct cells and to localize the high-affinity receptors for each regulator to its target cell. Because of the great preponderance of acinar cells in the pancreas, several preparations of isolated cells or pancreatic acini have been established. By using amylase secretion as the criterion for functional response, studies of the effects of agonists and antagonists on secretion have identified the presence of specific receptors on acinar cells. The receptors have been confirmed by binding studies with radiolabeled analogs and antagonists. [183], [184] Electron microscopic autoradiography and confocal fluorescence microscopy have localized binding to the basolateral membrane domain, although bound ligand may be internalized subsequently by an energy-dependent process. [185], [186] Preparations of isolated duct segments or cultured monolayers of duct cells also have been developed. [30], [187]

Through such studies, acinar cells from a variety of species, including humans, have been shown to bear receptors for CCK, bombesin, acetylcholine, VIP, and secretin. CCK interacts with both CCK-A receptors, which are highly specific for CCK and CCK-B, or gastrin receptors, which respond to both CCK and gastrin. Much is known about CCK-A and M_3 muscarinic receptors and their signaling, because of their presence on rodent acinar cells; however, the human pancreas contains few CCK-A or CCK-B receptors, and little is known about their function on acinar cells. CCK receptors on afferent nerves appear to have properties similar to those on acinar cells. Less is known about duct cell receptors because of the relatively small number of these cells in the pancreas and the greater difficulty in studying their physiological functions (e.g., ion transport). Duct cells bear receptors for secretin, ATP, CCK, and acetylcholine and may have receptors for VIP.

Receptors for major pancreatic secretagogues belong to the receptor family characterized structurally by seven hydrophobic transmembrane domains and functionally by their interaction with guanine nucleotide–binding proteins (i.e., G proteins). [188] The M_3 muscarinic receptor, the bombesin receptor, and the CCK-A and CCK-B receptors have been cloned and found to possess similar structures. The cloned secretin receptor, although possessing seven transmembrane regions, is somewhat different in its amino acid sequence. [189]

Structure-function studies with site-directed mutagenesis and chimeric receptors have established some general principles of function for the G protein–coupled receptor family. [188], [190] The transmembrane segments may form a pocket for the binding of small molecules, such as acetylcholine, and the extracellular amino-terminal end and loops may be important in the interaction with peptide molecules. The third cytoplasmic loop, projecting between the fifth and sixth transmembrane domains, is thought to interact with the appropriate G protein, and the serine and threonine residues in the cytoplasmic carboxyl-terminal tail may be involved with regulatory mechanisms such as desensitization and down-regulation by way of phosphorylation. The function of glycosylation on externally directed sites at the amino terminus is not yet well established, but these sites may play a role in ligand binding or in the intracellular processing of new receptors and their insertion into the plasma membrane. A number of techniques are now being applied to elucidate the details of ligand-receptor interaction.

Transmembrane Signaling

Although all membrane receptors are integral proteins spanning the lipid bilayer, the pancreatic secretagogue receptors convey information by interaction with G proteins. G proteins are heterotrimeric proteins with unique a subunits and a smaller number of shared ß? subunits. [191] Acinar cells possess a_s and a_i subunits, which stimulate and inhibit adenylate cyclase, respectively. These subunits can be ADP-ribosylated by cholera toxin and pertussis toxin, which permanently activate or inhibit adenylate cyclase, respectively. Acinar cells also possess a_q and a_{11} subunits that activate phospholipase C. [192] The full complement of a and ß? subunits expressed in acinar and duct cells and their functions still need to be fully explored.

The a subunit possesses the guanine nucleotide–binding site, which, in the resting state, is occupied by GDP. After the receptor binds its ligand, it interacts with the G protein to catalyze the exchange of GTP for GDP. The GTP-a subunit dissociates from the ß? complex and activates its effector (i.e., phospholipase C, adenylate cyclase). The system is amplified because the lifetime of the GTP–a subunit complex is much longer than that of the hormone-receptor complex. Eventually, GTP is cleaved to GDP by an intrinsic GTPase activity, and the a subunit reassociates with the ß? subunit. It is because of this cycle that secretagogues stimulate GTPase activity in pancreatic membranes and that nonhydrolyzable analogs of GTP, such as GTP?S, activate adenylate cyclase or phospholipase C in pancreatic membranes or permeabilized acinar cells. [193]

The final component in transmembrane signaling is the membrane effector that generates the intracellular messenger. The two major effector enzymes in acinar cell membranes are the polyphosphoinositide-specific phospholipase C, which cleaves phosphatidylinositol 4,5-bisphosphate, producing inositol 1,4,5-trisphosphate (IP_3) and 1,2-diacylglycerol (DAG), and adenylate cyclase, which converts ATP to cAMP. [194] Multiple forms of phospholipase C have been purified, cloned, and shown to be expressed in a variety of tissues. [195] The $ß_1$ and $ß_3$ forms are differentially activated in rat acini by CCK, carbachol, and bombesin. [196] Adenylate cyclase has also been cloned, and its primary structure is consistent with its role as an integral membrane protein with multiple membrane-spanning domains, although its catalytic site is clearly intracellular. [197] Multiple isoforms of adenylate cyclase exist, some of which are also regulated by G-protein ß? subunits, Ca^{2+}, and protein kinases. Adenylate cyclase is clearly the major effector enzyme in duct cells, but there is some evidence for the participation of a phospholipase C. Other membrane effectors in the pancreas may include phosphatidylcholine-specific phospholipases C [198] and D, [199] PLA_2, Na^+/H^+ ion exchanger, and various ion channels. However, these may be regulated by intracellular messengers rather than directly by G proteins.

Intracellular Messengers

The major intracellular messengers involved in the regulation of pancreatic secretion are IP_3, Ca^{2+}, DAG, and cAMP. [194], [200] The first three are predominant in the acinar cell and increase after the activation of phosphoinositide-specific phospholipase C by CCK and acetylcholine, whereas cAMP is the predominant messenger in duct cells, where it is produced in response to secretin.

Phosphatidylinositol and its polyphosphate derivatives—phosphatidylinositol 4-phosphate (PIP) and phosphatidylinositol 4,5-bisphosphate (PIP_2)—constitute about 10% of membrane phospholipids. PIP_2 serves as a precursor for IP_3. When acinar cells are stimulated with acetylcholine or CCK, there is a rapid fall in prelabeled PIP_2 and PIP, an increase in DAG, and a delayed rise in phosphatidic acid. This indicates the primary breakdown of polyphosphoinositides, with production of DAG, which is subsequently converted to phosphatidic acid by DAG kinase. When the production of the water-soluble inositol phosphatases is assessed after labeling with ^{3}H-inositol, the IP_3, IP_2, IP_1, and inositol products are all increased. Because IP_3 can be produced only by hydrolysis of PIP_2, this is presumed to be the primary event, with further synthesis of PIP and PIP_2 from phosphatidylinositol by the action of a phosphatidylinositol kinase.

Although production of IP_3 was initially measured by prelabeling with ^{3}H-inositol, it is possible to measure the actual mass of cellular IP_3 by a competitive binding assay. Such measurements show a rapid increase within 5 seconds in rat acini stimulated with CCK, carbachol, or bombesin (Fig. 15-5). This 10- to 30-fold increase rapidly declines after 30 to 60 seconds to a smaller, sustained plateau. Coincident with this rapid peak of IP_3 is a rapid increase in DAG of similar magnitude (Fig. 15-6), which is thought to arise simultaneously from the hydrolysis of PIP_2. The later, larger increase in DAG may result from the hydrolysis of phosphatidylinositol or phosphatidylcholine by distinct phospholipases. [198], [199] These results mean that IP_3 and DAG can act as separate signals and are not necessarily in lockstep. Phosphorylation of 1,4,5-IP_3 produces 1,3,4,5-IP_4, which can be dephosphorylated to yield 1,3,4-IP_3. Whether a biologic role exists for these other inositol phosphates and for additional degradation products, such as IP_2 and IP_1, has not been established.

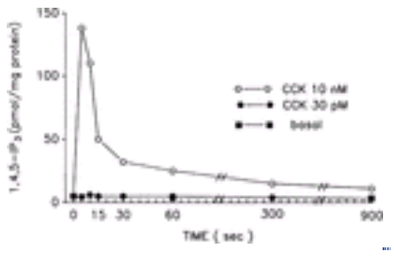

FIGURE 15-5. Time course of inositol 1,4,5-trisphosphate (*1,4,5-IP* $_3$) increase induced by cholecystokinin (*CCK*) in rat pancreatic acini. (From ref. [198].)

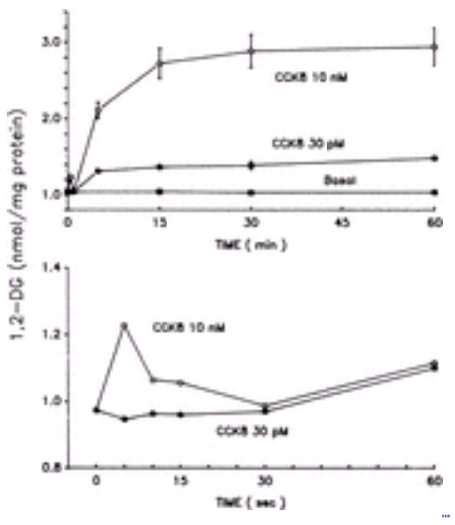

FIGURE 15-6. Time course of 1,2-diacylglycerol (*DG*) increase induced by cholecystokinin (*CCK*) in rat pancreatic acini. (From ref. [198].)

The established function of IP $_3$ is to bind to a receptor on an intracellular Ca $^{2+}$ storage site and release Ca $^{2+}$ into the cytoplasm. The IP $_3$ receptors are large, 260-kd molecules that form tetramers, which function as ligand-gated ion channels. Three forms of IP $_3$ receptors (types I, II, and III) are known, and all exist in acinar cells. [201] The sensitivity of these receptors to IP $_3$ can also be regulated by phosphorylation of the IP $_3$ receptor channel, by G-protein ß? subunits, Ca $^{2+}$, and thiol-reacting reagents. Modulation of IP $_3$ sensitivity may explain how certain agonists can release Ca $^{2+}$ without a measurable increase in IP $_3$ levels. IP $_3$ receptors undergo down-regulation in response to prolonged stimulation. Another homologous gated intracellular Ca $^{2+}$ channel, the ryanodine receptor, exists in muscle and other cells and mediates Ca $^{2+}$-induced release. The existence of ryanodine receptors in acinar cells has recently been verified.

The morphologic identity of the Ca $^{2+}$-sequestering and -releasing organelle in the pancreas is not clear. Probably multiple membrane-bound compartments all related to the endoplasmic reticulum have the ability to take up and release Ca $^{2+}$. Some investigators have suggested the existence of multiple populations of vesicles with different Ca $^{2+}$ transport or release characteristics. [202] Immunocytochemistry is being used to localize IP $_3$ receptors in intact cells. [203], [204] All three IP $_3$ types are present primarily in the apical pole of the cell just under the lumenal membrane and partially overlapping the submembranous network of actin filaments. Several types exist in the nuclear membrane but in fewer numbers.

Much of the knowledge about secretagogue-induced changes in the intracellular Ca $^{2+}$ concentration ([Ca $^{2+}$] $_i$) in acinar cells has been obtained by using fluorescent Ca $^{2+}$ probes such as fura-2. These studies have been carried out on suspensions of cells or acini and on individual cells by microspectrofluorometry [205] and digital imaging. [198], [206] Such studies have shown that high concentrations of CCK, bombesin, and cholinergic analogs cause a rapid five- to tenfold increase of [Ca $^{2+}$] $_i$, which declines over 2 to 5 minutes to a level slightly above the basal level (Fig. 15-7). This initial large increase is essentially independent of extracellular Ca $^{2+}$, but the small, sustained plateau increase in [Ca $^{2+}$] $_i$ absolutely depends on extracellular Ca $^{2+}$. The initial increase shows a similar time course and dependence on secretagogue concentrations, as does the rapid increase in IP $_3$, and is presumed to depend on IP $_3$-stimulated release of intracellular Ca $^{2+}$. Much of this released Ca $^{2+}$ is extruded from the cell, as shown by earlier studies documenting an increased efflux of prelabeled ^{45}Ca $^{2+}$ and a fall in total acinar Ca $^{2+}$. [200], [207] All three of the major phospholipase C–activating secretagogues (i.e., CCK, acetylcholine, bombesin) access the same intracellular pool of Ca $^{2+}$, and after maximal stimulation by one agonist, the addition of another has no additional effect. After removal of the agonist, the IP $_3$-releasable intracellular pool refills over 2 to 10 minutes as Ca $^{2+}$ is taken up from the medium and resequestered.

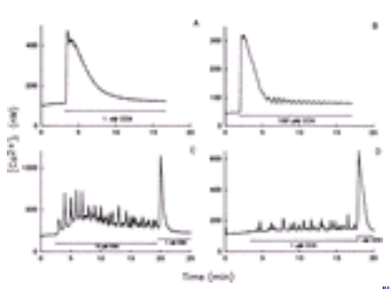

FIGURE 15-7. Increase in intracellular calcium ion concentration (*[Ca* $^{2+}$*]* $_i$) in individual rat acinar cells in response to various concentrations of cholecystokinin (*CCK*). (From ref. [205].)

The sustained increase in [Ca $^{2+}$] $_i$ and the refilling of the intracellular Ca $^{2+}$ pool involve activation of a poorly understood Ca $^{2+}$ entry mechanism. Studies measuring ^{45}Ca $^{2+}$ uptake and the influx of Mn $^{2+}$, which quenches the intracellular fluorescence of fura-2, indicate that the phospholipase C–coupled secretagogues increase Ca $^{2+}$ influx two- to fourfold. [207] The influx mechanism is blocked by La $^{3+}$ but is not voltage-dependent or sensitive to organic Ca $^{2+}$ channel blockers. Patch clamp studies have not yet clearly defined a constituent channel. It is better defined as an entry mechanism. The mechanisms controlling Ca $^{2+}$ influx are sensitive to the state of the intracellular Ca $^{2+}$ stores, as most directly shown by using inhibitors of the microsomal Ca $^{2+}$-ATPase such as thapsigargin, which releases intracellular Ca $^{2+}$ and activates the Ca $^{2+}$ influx mechanism, bypassing the receptor and the generation of inositol phosphates. Evidence also exists for tyrosine phosphorylation in gating Ca $^{2+}$ influx. That a sustained increase in [Ca $^{2+}$] $_i$ is important for sustained amylase release is demonstrated by the fact that La $^{3+}$ inhibits the sustained component of amylase release, similar to removal of Ca $^{2+}$ from the medium. [208]

Recordings of the [Ca $^{2+}$] $_i$ from individual cells of rat and mouse acini have revealed that low physiological concentration of CCK, acetylcholine, and bombesin induce a different pattern of Ca $^{2+}$ increase characterized by oscillations in [Ca $^{2+}$] $_i$ increases. [205], [206], [209] Superimposed on any steady increase are phasic increases in [Ca $^{2+}$] of up to 500 nmol/L (see Fig. 15-7). These oscillations, which occur one to four times per minute, are relatively independent of extracellular Ca $^{2+}$ and involve the release and reuptake from the intracellular Ca $^{2+}$ stores. That [Ca $^{2+}$] oscillations can drive secretion is shown by the fact that the CCK analog JMV-180 induces Ca

$^{2+}$ oscillations and can stimulate maximal amylase release. [210]

Confocal digital imaging of Ca^{2+} in acinar cells has shown that the $[Ca^{2+}]_i$ increase is initiated in the apical pole of the cell and then spreads basally. [211] The response to lower agonist concentrations is a series of local increases in Ca^{2+} in the apical pole of the cell. [212] Improved imaging techniques have shown that local Ca^{2+} spikes are the result of pacemaker hot spots of Ca^{2+} release that entrain the surrounding region. [213] Interestingly, in the same cell, different agonists (i.e., carbachol, CCK, and bombesin) initiate $[Ca^{2+}]$ increases in distinct apical areas, indicating compartmentalization of signaling. [214], [215] Further complicating the process, protein kinase A phosphorylation of IP_3 receptors can modulate the pattern of Ca^{2+} increase. [216] Besides the apical-to-basal spread of Ca^{2+} in intact acini, Ca^{2+} waves appear to spread from cell to cell around an acinus. Gap junction coupling remains open as these Ca^{2+} waves spread but closes in response to supermaximal stimulation. [217] This cell-to-cell spread [217] increases the cellular sensitivity, allowing acinar activation to be triggered by the most sensitive cell.

Intracellular Messenger–Induced Secretion The evidence to support the importance of Ca^{2+}, DAG, and cAMP as intracellular mediators regulating pancreatic secretion is based on the ability of artificial changes in the level of each messenger to influence secretion. [183], [200] In the case of Ca^{2+}, the discovery that certain antibiotics, such as A23187 and ionomycin, functioned as Ca^{2+} ionophores and could be used to increase Ca^{2+} influx and trigger secretion provided one of the cornerstones of evidence for the importance of Ca^{2+} in this process. The Ca^{2+}-ATPase inhibitor thapsigargin also increases $[Ca^{2+}]_i$ and can be used to define the contribution of Ca^{2+} in stimulating secretion. [218] The discovery that certain phorbol esters could activate protein kinase C in a manner similar to DAG led to extensive studies of the activation of this pathway. [219] Ca^{2+} ionophores and phorbol esters stimulate acinar cell secretion, and their effects are additive or potentiating. In the case of cAMP, derivatives such as dibutyryl-cAMP or Br-cAMP that are lipophilic or phosphodiesterase resistant have been used to activate the pathway normally initiated by secretin or VIP. In most species, cAMP derivatives used alone have minimal effects on acinar cell secretion but potentiate the effects of agents working by means of Ca^{2+} and DAG.

Mechanism of Action of Intracellular Messengers The intracellular messengers active in pancreatic acinar cells have been identified and characterized, but much less is known about the mechanisms by which they act to induce granule exocytosis, fluid secretion, protein synthesis, and gene expression. Although other mechanisms may exist, all the intracellular messengers activate protein kinases and phosphatases and thereby regulate the state of protein phosphorylation. Considerable data suggest that changes in the phosphorylation of regulatory proteins mediate the acini or hormones and neurotransmitters in a variety of tissues. In support of this postulate, more than 25 phosphoproteins (not all identified) that are regulated by pancreatic secretagogues have been visualized by two-dimensional gel electrophoresis in pancreatic acini. [220], [221] Some are uniquely regulated by Ca^{2+}, phorbol esters, or cAMP, and others are regulated by multiple second messengers. When a Ca^{2+} ionophore and a phorbol ester are combined, they reproduce all the phosphorylation changes induced by secretagogues. Several Ca^{2+}-activated kinases have been identified in pancreatic acinar cells, including Ca^{2+}/calmodulin-activated type II and type III kinase and myosin light chain kinase. [194], [200] Although some kinases are highly substrate specific, calmodulin-activated type II kinase is a multifunctional kinase that acts on several proteins. Its activation by CCK is supported by its temporary conversion to a Ca^{2+}-independent form. [222] Protein kinase C, originally described as a Ca^{2+}-, phospholipid-, and DAG-dependent kinase, [219] is also present in acinar cells. Multiple isoforms are present, including a, d, e, and ?, which include both classical and atypical forms. [223] In addition to Ca^{2+}- and cAMP-activated kinases, acinar cells contain the major classes of serine/threonine phosphatases (i.e., PP1, PP2A, and PP2B). [224], [225] Although some of these are constitutively active and are involved in reversing phosphorylation induced by kinases, PP2B, or calcineurin, is specifically activated by Ca^{2+} through calmodulin. This phosphatase, which is activated by pancreatic secretagogues, is blocked by the immunosuppressant cyclosporine, which also partially inhibits secretagogue-activated amylase secretion. [225] A specific substrate protein of 24 kd, CRHSP-24, also exists in acini, but its function is unclear. [226] The role of intracellular messengers and effectors in pancreatic enzyme secretion is summarized in Figure 15-8. Stimulation of secretion normally involves synergistic interactions among intracellular messengers. In the case of acetylcholine and CCK, this includes interactions between Ca^{2+}- and DAG-activated pathways. Agents such as VIP and secretin, which increase cAMP, add a further interaction at the post–intracellular messenger level. Proteins localized on the granule and lumenal plasma membrane and several soluble and cytoskeletal proteins may be involved in exocytosis. In pancreatic duct cells, the same intracellular messengers and kinases may regulate ion pumps, carriers, and channels involved in fluid and electrolyte secretion.

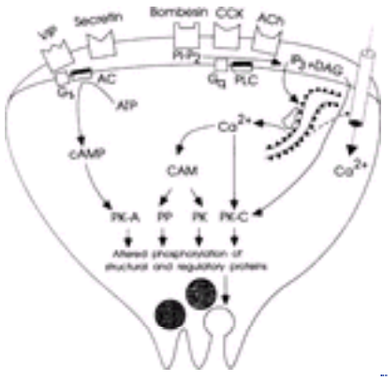

FIGURE 15-8. Stimulus-secretion coupling of pancreatic acinar cell protein secretion. In one intracellular pathway, receptors for vasoactive intestinal polypeptide (*VIP*) and secretin couple through a G protein (G_S) to activate adenylate cyclase (*AC*), and the cAMP produced activates protein kinase A (*PK-A*). In the other and quantitatively more important pathway, receptors for bombesin, cholecystokinin (*CCK*), and acetylcholine (*ACh*) couple through G proteins of the Gq family (*Gq*) to activate phospholipase C (*PLC*). This enzyme hydrolyzes phosphatidylinositol 4,5-bisphosphate (*PI-P2*) to produce inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (*DAG*). IP_3 releases Ca^{2+} from intracellular stores in the endoplasmic reticulum, activating Ca^{2+} influx across the plasma membrane. Ca^{2+}, by binding to calmodulin (*CAM*), activates several protein kinases (*PK*) and one protein phosphatase (*PP*). Diacylglycerol with Ca^{2+} activates several species of protein kinase C (*PK-C*). This battery of protein kinases and phosphatases, by altering phosphorylation of diverse proteins, brings about the secretion of digestive enzymes and other cellular effects on growth and metabolism.

Zymogen Granules and Exocytosis The terminal steps in secretion involve fusion of the zymogen granules with the lumenal membrane of the acinar cell. This fusion event shares basic mechanisms with other membrane fusion events from yeast to neurons. Two types of proteins, SNARE proteins and small G proteins of the Rab family, appear to play prominent roles. In the SNARE paradigm, transport vesicles destined to fuse with another membrane possess a set of proteins, termed *v-SNAREs*, that interact with t-SNAREs—that is, proteins on the target membrane—and with soluble attachment factors. [227] Synaptobrevins/VAMPs, which act as v-SNAREs on synaptic vesicles, are present on zymogen granules, with both VAMP2 and cellulobrevin present. [228] t-SNAREs on the plasma membrane of neurons include SNAP-25 and syntaxin. Multiple isoforms of syntaxin in acini have been identified. Syntaxin 2 is present on the apical plasma membrane, [229] but other syntaxins are also present on zymogen granules. The interaction of VAMPs and syntaxins in acini remains poorly understood. The additional importance of cytosolic proteins was shown by the observation that permeabilizing acini with a-toxin, which produces small pores that prevent protein leakage, prevented the rundown of secretion seen with streptolysin-O permeabilization that induces large pores. Moreover, cytosol from brain or lacrimal glands restores secretion in streptolysin-O–permeabilized acini. One of the responsible proteins is CRHSP-28, a Ca^{2+}-regulated phosphoprotein that associates with zymogen granules through a 70-kd protein. [230] Whether Ca^{2+} in acini directly regulates a SNARE or cytosolic protein or indirectly through activating a kinase or phosphatase is unknown. An experimental approach that should prove useful in this work is monitoring secretion by following the capacitance of patch-clamped acinar cells. Low concentrations of acetylcholine, which are known to induce $[Ca^{2+}]$ oscillations in the apical pole of the cell, also induced an increase in membrane capacitance without an increase in membrane conductance. [231] Work on Rab species in the pancreas has focused on Rab3, because Rab3A is present on synaptic vesicles and an immunoreactive Rab3 species has been identified in pancreas. Studies using PCR amplification and immunocytochemistry with specific antibody have identified conclusively the presence of Rab3D on zymogen granules [232], [233] as well as on granules in salivary and lacrimal glands, and on chief cells of the stomach. Overexpression of Rab3D in acinar cells of transgenic mice enhances a component of amylase secretion, [234] indicating that Rab3D may be rate-limiting for secretion. Another cellular component believed to be involved in exocytosis is the cytoskeleton. It may serve as a barrier, preventing premature secretion, and it may be involved in the movement of zymogen granules to the cell surface. The former role may be mediated by an actin network under the plasma membrane. Evidence of this role for actin is the observation that introducing the monomeric actin-binding protein ß-thymosin into permeabilized acini to shift the monomer-polymer equilibrium induces secretion in a Ca^{2+}-independent manner. [235] Moreover, high concentrations of CCK and ß-thymosin, the actin monomer–binding protein, decreased polymerized actin at the apical membrane. In contrast, phalloidin, which binds and stabilizes polymerized actin, inhibited secretion by the permeabilized cells.

Intracellular Pathways Leading to Growth and Gene Regulation Pancreatic secretagogues, particularly CCK, have long been known to induce pancreatic hypertrophy, hyperplasia, and gene expression. Initially, it was assumed that the same intracellular mediators that regulate secretion might mediate these effects. It is

now clear, however, that nonsecretagogues, such as insulin and epidermal growth factor, can also regulate nonsecretory pancreatic functions and that classical secretagogues, such as CCK, activate novel signaling pathways, many of which involve tyrosine phosphorylation. There are also cases in which a nonsecretagogue input, such as the extracellular ligation of integrins, leads to both tyrosyl phosphorylation and an increase in intracellular Ca^{2+}. [236] Because of the increasing evidence that cytokines can affect the pancreas, at least in pancreatitis, it seems likely that cytokine receptors also activate intracellular signaling. G protein–coupled receptors can activate tyrosine kinase signaling pathways in a variety of cells. [237] Most growth factor receptors include an intracellular tyrosine kinase domain, and autophosphorylation of the receptor on tyrosines leads to docking of signaling molecules such as phosphoinositol 3-kinase, phospholipase C-?, and adapter molecules such as Grb-2 and Shc. G protein–coupled receptors do not possess tyrosine kinase activity, nor are they tyrosyl phosphorylated. However, CCK is known to increase tyrosyl phosphorylation of multiple acinar proteins [238] and to activate the mitogen-activated protein kinase (MAPK) cascade involving Ras-Raf-MEK-ERKs. [239], [240] The kinase $p90^{rsk}$, which is downstream of ERKs and acts to phosphorylate nuclear transcription factors and cytoplasmic targets, also is activated by CCK. [241] The early events by which secretagogues may activate Ras and the MAPK cascade leading to ERKs have been studied. In rat acini, CCK, carbachol, and bombesin, as well as epidermal growth factor, increased the tyrosyl phosphorylation of Shc, [242] leading to the binding of Grb2 and SOS. Because SOS is a guanine nucleotide exchange factor for Ras, this could mediate an activation of Ras in response to CCK. Shc phosphorylation induced by CCK was shown to be largely protein kinase C–dependent, whereas that due to epidermal growth factor was fully protein kinase C–independent. [242] In pancreas-derived AR42J cells, which possess primarily CCK-B receptors, gastrin has also been shown to increase tyrosyl phosphorylation of Shc. [243] In AR42J cells, gastrin also induced the tyrosyl phosphorylation of the docking protein, insulin receptor substrate 1 (IRS-1). [244] Because Grb-2 also binds to IRS-1, this is a potential alternative means of activating the MAPK cascade. IRS-1 has not been identified in normal acinar cells, although it is overexpressed in some pancreatic cancer cells. The major unanswered question, however, is the identity of the tyrosine kinase that phosphorylates Shc and IRS-1 and how it is activated. Interest has centered on cytoplasmic tyrosine kinases of the Src family, and published data would suggest that protein kinase C activates Src. Two other MAPK cascades, called *stress-activated protein kinase (SAPK)* and *p38 MAPK,* lead to activation of Jun kinase. Both of these pathways exist in acinar cells and can be activated by CCK as well as other extracellular signals. [245], [246] Activation of SAPK is an early event in secretagogue-induced pancreatitis, although it is not clear whether it is a cause or effect. [247] A known effect of p38 MAPK is to activate MAPKAP kinase-2, which phosphorylates Hsp27 and thereby regulates actin polymerization. [246], [248] Both SAPK and p38 are activated by dual phosphorylation on tyrosine and threonine residues by upstream dual function kinases related to MEKs. [249] These are activated by a serine/threonine kinase analogous to Raf that is farther upstream. However, the three MAPK cascades can be activated independently. Evidence exists for two other signaling pathways in pancreatic acini. [194] The first is the activation of focal adhesion kinase, or $p125^{FAK}$, and its downstream target, paxillin. Both of these molecules are associated with the cytoskeleton and, in other cells, are activated by growth factors and integrins. CCK has been shown to increase the tyrosine phosphorylation of $p125^{FAK}$ and paxillin in rat acini. [250] This effect is probably mediated by the small G protein Rho. The second is the pathway through phosphatidylinositol 3-kinase (PI3-K) to $p70^{S6K}$, the kinase that phosphorylates ribosomal protein S6. CCK, carbachol, and bombesin activate $p70^{S6K}$ in rat acini by a pathway that can be blocked by PI3-K inhibitors such as wortmannin, and by rapamycin, which binds intracellularly to the immunophillin FKBP-12. [47] Because $p70^{S6K}$ also mediates the initiation of protein translation, this pathway probably underlies, at least in part, the stimulation of protein synthesis in acinar cells by pancreatic secretagogues discussed earlier. Identification of intracellular regulation by both conventional and novel pathways is a rapidly developing field, and further progress is expected.

INHIBITION OF PANCREATIC SECRETION

The regulation of pancreatic secretion depends on a balance between inhibitory and stimulatory influences on the gland, which are exerted through hormones and the autonomic nervous system. Although much has been written about pancreatic stimulation, less is known about the inhibitory influences on the pancreas.

Inhibitory Phase of Pancreatic Secretion

In humans, hyperglycemia induced by intravenous infusion of glucose inhibits the pancreatic secretory response to a test meal. [251] Similarly, intravenous infusion of amino acids inhibits the human pancreatic enzyme response to intestinal amino acid perfusion. [252] Although the mechanisms responsible for these observations are unknown, the secondary release of inhibitory hormones is postulated. Pancreatic glucagon exhibits characteristics consistent with such an inhibitory hormone. In most of the studies, glucagon inhibits pancreatic secretion stimulated by secretin and CCK, alone or in combination, or by ingestion of a test meal in dogs, cats, rats, and humans. [3], [253], [254] and [255] The inhibitory effect is characterized by reduction of the volume of flow and of HCO_3^- and enzyme secretion.

Pancreatic glucagon is secreted concomitantly with the hyperaminoacidemia observed after the intestinal perfusion of amino acids or a high-protein meal. [208] This postprandial level of glucagon may be sufficient to inhibit secretin- or CCK-stimulated pancreatic secretion.

Another pancreatic hormone, somatostatin, may also play a role in the inhibition of pancreatic secretion. Somatostatin-containing cells are also present in the upper gastrointestinal tract and the central nervous system. Somatostatin is processed to multiple molecular sizes and interacts with a variety of receptors on acinar cells, dorsal root ganglia, and islets of Langerhans, and on nerves of the peripheral and central nervous systems. One mechanism to provide a degree of specificity could be the release of different forms of somatostatin. For example, glucagon-like peptide 1, oleic acid, and gastrin-releasing peptide stimulate the secretion of both somatostatin-28 and somatostatin-14, but secretin induces a preferential release of somatostatin-14. [256] In humans, pharmacological doses of somatostatin cause marked inhibition of CCK-stimulated pancreatic enzyme secretion and modest inhibition of secretin-stimulated HCO_3^- secretion. [4], [257] Studies in rats demonstrate that somatostatin inhibits 2-deoxy-D-glucose– and CCK-evoked pancreatic enzyme secretion through a vagal pathway. [11] Somatostatin does not act on peripheral vagal afferent or efferent pathways or directly on pancreatic acini; it exerts its inhibitory action at a central vagal site. [11] Studies of the perfused canine pancreas have demonstrated that somatostatin is released from the pancreas during perfusion with high concentrations of amino acids or glucose. [258] This peptide may exert a paracrine inhibitory effect on the exocrine pancreas.

Six somatostatin receptor (SSTR) subtypes have been cloned from five genes; SSTR2 is expressed in an A and a B form by variant mRNA splicing. Inhibition of pancreatic secretion is mediated by SSTR2 receptor agonists (e.g., octreotide), whereas SSTR5 inhibits insulin release. In addition, SSTR2A has been localized to acinar cells, and to glucagon and PP immunoreactive islet cells. [259] Although somatostatin is one of the few peptides to inhibit pancreatic secretion in an isolated pancreas, the role of the acinar cell SSTR may be to modulate the nonparallel secretion of digestive enzymes [260] rather than to inhibit secretion. It is believed that somatostatin inhibits pancreatic exocrine secretion mainly through a central cholinergic mechanism. [11]

Intrajejunal perfusion of hypertonic glucose (50%) produces dose-related inhibition of secretin-stimulated pancreatic fluid and HCO_3^- secretion in humans. [261], [262] Similar inhibition occurs with intraintestinal hypertonic (9%) NaCl infusion in dogs. At least part of this inhibitory effect has been attributed to the release of enteric glucagon. [252] Infusion of oxyntomodulin, a 37–amino acid, glucagon-containing peptide isolated from porcine lower intestine, inhibits basal and cerulein-stimulated pancreatic secretion of HCO_3^- and enzymes. [263] This intestinal glucagon is ten times more potent than pancreatic glucagon.

Factors in the ileum and colon can inhibit pancreatic secretion. Hage and colleagues [264] demonstrated that infusion of oleic acid into the proximal colon of conscious dogs inhibits secretin-stimulated pancreatic secretion. Similar inhibitory effects have been observed in rats. [265] In the anesthetized cat, infusion of oleic acid or hypertonic glucose or saline into the colon or terminal ileum inhibits secretin- or CCK-stimulated secretory volume and HCO_3^- and enzyme output from the pancreas. [266]

In humans, nutrients (e.g., lipid) in the colon inhibit CCK-stimulated pancreatic enzyme and HCO_3^- output. [267] These late postprandial events may serve as physiological signals to reduce exocrine pancreatic secretion after digestion and the absorption of nutrients are complete. The inhibitory effect of nutrients in the distal gut on pancreatic secretion appears to be independent of the vagus and splanchnic nerves. [266] Cross-circulation studies in the rat have shown that a humoral factor mediates the inhibition of pancreatic enzyme secretion induced by colonic perfusion of oleic acid.

Harper and colleagues [268] used the term *pancreotone* to describe an inhibitory substance extracted from the colonic mucosa. The function of pancreotone is abolished when the extract is preincubated with trypsin, demonstrating it is a peptide. Peptide YY, a 36–amino acid peptide named for its amino- and carboxyl-terminal tyrosines, is abundantly present in the distal small intestine, colon, and rectum. [269] This peptide is released by fat and, to a lesser degree, protein in the distal gut or colon. The infusion of this peptide in dogs significantly inhibits basal and meal-stimulated pancreatic HCO_3^- and enzyme secretion. [270] Physiological experiments demonstrate that intraileal, but not intracolonic, carbohydrate increases plasma peptide YY levels and decreases amylase secretion in dogs. [271] These observations support the

hypothesis that peptide YY is at least a component of pancreotone in dogs. In humans, ileal perfusion of carbohydrate inhibits exocrine pancreatic secretion. Glucagon-like peptide 1 (GLP-1), another ileal hormone, but not peptide YY, is elevated in the circulation during ileal infusion of carbohydrate. GLP-1 does not appear to act directly on the pancreas to inhibit exocrine secretion. In anesthetized pigs [272] with cut splanchnic nerves, intravenous infusion of GLP-1 inhibited hypoglycemia-induced pancreatic HCO_3^- and protein secretion. These effects were not observed in vagally stimulated, isolated, and perfused porcine pancreas, [272] suggesting that GLP-1 acts via a central mechanism. Subsequent studies in rats indicated that the inhibitory action of GLP-1 depends on intact vagus nerves. [12] GLP-1 acted on the dorsal vagal complex to inhibit pancreatic enzyme secretion. [12] Similarly, oxyntomodulin, which is released after ileal administration of nutrients, also inhibits pancreatic secretion by a vagus-dependent central mechanism. [273] Because oxyntomodulin does not interact with the receptor for glucagon or truncated GLP-1, its effects appear to involve an oxyntomodulin-specific receptor. Although the mediator(s) of ileal carbohydrate-induced inhibition of exocrine pancreatic secretion has not been firmly identified, it appears that the action of these potential mediators is dependent on central neural pathways.

PP, a peptide closely related to peptide YY, is another hormone that may play an important role in regulating pancreatic exocrine secretion. PP is localized in the islets of Langerhans and between the acinar cells of the exocrine pancreas. [274] Its only apparent physiological actions are to inhibit pancreatic and biliary secretion. The secretion of PP is governed mainly by a cholinergic mechanism. [275] Postprandial release of PP is mediated by a long vagovagal reflex and short local cholinergic pathways. [275] Vagal cholinergic activity is the most powerful stimulant of PP release, and it is also key to most other stimulation of the PP cell. [275]

In humans and dogs, infusion of physiological concentrations of PP inhibits basal and stimulated pancreatic secretion. [5], [276] In vivo, PP appears to act preferentially by inhibiting vagal stimulation. [277] In vitro, PP inhibits pancreatic enzyme secretion by way of the presynaptic modulation of acetylcholine release. [278] Because its secretion is under cholinergic control and it acts by interfering with cholinergic transmission, PP is an ideal candidate to modulate pancreatic secretion stimulated by the cholinergic enteropancreatic reflex. After ingestion of a meal, the enteropancreatic reflex is activated to stimulate pancreatic enzyme secretion and PP release. PP inhibits cholinergic transmission and reduces pancreatic enzyme secretion. PP may play an important role in the feedback regulation of pancreatic enzyme secretion activated by the enteropancreatic reflex. The primary target of PP appears to be the central nervous system. [13] PP receptors have been identified in discrete locations in the hypothalamus, limbic system, brainstem, and other central locations with the use of receptor autoradiography. [279] In contrast, mRNA is almost undetectable, [280] suggesting that peripheral PP is modulating central neural function through sites with an incomplete blood-brain barrier. Microinjection of PP into the dorsal motor nucleus inhibits pancreatic secretion stimulated by CCK, suggesting that the dorsal motor nucleus of the vagus is a site for neural feedback inhibition of pancreatic exocrine secretion. [281]

Although the list of peptides known to inhibit exocrine pancreatic secretion has expanded, little is known about the mechanisms through which hormones or neurotransmitters inhibit pancreatic enzyme secretion. An important feature shared by these agents is the lack of direct inhibition of the pancreatic acinar cells. Many substances suppress pancreatic enzyme secretion in vivo but do not act directly on the acinar cell to suppress enzyme release. Based on animal studies, it appears that peptides such as PP, somatostatin, CGRP, enkephalin, and pancreastatin inhibit pancreatic enzyme secretion by modulating cholinergic transmission, and most, if not all, act through a central vagal site. [277], [278], [282], [283], [284] and [285] Intracerebroventricular administration of CGRP inhibitors stimulates (basal) pancreatic secretion in conscious rats, and this appears to be mediated by sympathetic nonadrenergic efferents through the a-adrenergic receptor. [286] In contrast, CGRP in the central nervous system inhibits pancreatic enzyme secretion stimulated by 2-deoxy-D-glucose and CCK by modulating vagal parasympathetic outflow. [287]

Feedback Regulation of Pancreatic Secretion

A series of observations suggests that the intralumenal action of pancreatic proteases plays an important role in regulating pancreatic enzyme secretion. [89], [288] The underlying concept of feedback regulation of the pancreas is based primarily on studies of rats that show that diversion of pancreatic juice from the duodenum stimulates CCK release and pancreatic enzyme secretion. [90] However, intraduodenal administration of trypsin or chymotrypsin inhibits the release of CCK and pancreatic enzymes. [90] This phenomenon is specific for activated proteases and is not observed with inactivated trypsin, amylase, lipase, or $NaHCO_3$. Subsequent studies demonstrated that intravenous infusion of proglumide, or L364,718, a specific CCK receptor antagonist, abolishes the increase in pancreatic exocrine secretion evoked by the diversion of bile-pancreatic juice. [90], [289] These observations indicate that feedback inhibition of pancreatic secretion by trypsin is mediated by inhibiting the release or action of CCK.

The increased plasma CCK levels and pancreatic secretion after diversion of pancreatic juice appear to be mediated by a trypsin-sensitive substance secreted by the proximal small intestine, which has been designated *CCK-releasing factor (CCK-RF)*. [92] When trypsin is present, this peptide is cleaved and inactivated. CCK-RF may act as a mediator of pancreatic enzyme secretion in response to dietary protein intake in rats. Dietary protein in the intestine competes for the trypsin that would otherwise inactivate CCK-RF. [91] The resulting increase of CCK-RF in the intestinal lumen enhances CCK release, stimulating pancreatic enzyme secretion. Although this appears to be the principal mechanism regulating CCK release in rats, it is not known whether the same mechanism operates in other species.

A number of CCK-releasing peptides have been identified, including one from porcine mucosa [14] and another from rat upper intestinal fluid. [15] Herzig and colleagues [14] isolated and purified a CCK-releasing peptide from porcine small bowel mucosal extracts. This trypsin-sensitive peptide, which is secreted intraduodenally, releases CCK and stimulates pancreatic secretion in rats (Fig. 15-9). Peptide sequencing and mass spectrometry have shown that this peptide is identical to the porcine diazepam-binding inhibitor. Diazepam-binding inhibitor–like immunoreactivity has been found in intestinal mucosal cells, [290] and this peptide is secreted into the lumen under neural regulation. [291] Peptone in the duodenum stimulates serotonin release, which activates the sensory substance P neurons in the submucous plexus. Signals are then transmitted to cholinergic interneurons and to epithelial CCK-releasing peptide–containing cells by way of cholinergic secretomotor neurons. [291] This enteric neural circuitry, which is responsible for the secretion of CCK-releasing peptide, may in turn play an important role in the postprandial release of CCK. Spannagel and colleagues [15] successfully purified another lumenal CCK-releasing peptide from the duodenal secretion of rats. Partially purified fractions increase the release of CCK and stimulate pancreatic secretion of fluid and protein. Amino acid sequencing and mass spectral analysis of this peptide reveal that it is composed of 70 to 75 amino acid residues and has a mass of 8136 kd. The monitor peptide [292] in rat pancreatic juice, which is secreted into the duodenal lumen, is another CCK-releasing peptide. The physiological significance of these releasing peptides is unknown.

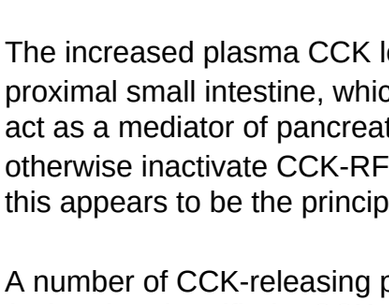

FIGURE 15-9. A schematic representation of the postulated mechanism by which cholecystokinin-RP (*CCK-RP*) stimulates the secretion of CCK postprandially. CCK-RP is secreted into the proximal small intestine and inactivated by trypsin. When food enters the duodenum postprandially, protein binds to trypsin and prevents the inactivation of CCK-RP. CCK-RP stimulates CCK cells in the duodenum to release CCK into the bloodstream. CCK, in turn, stimulates pancreatic enzyme secretion. (From ref. [14].)

Despite several attempts to demonstrate a protease-sensitive feedback mechanism in humans, the issue remained controversial because the technical limitations in removing or blocking intralumenal protease activity made studies of humans difficult. Using a different approach, researchers have reported that intestinal administration of trypsin or chymotrypsin in humans suppresses CCK release and partially blocks the pancreatic response to intestinal administration of amino acids or oral ingestion of a test meal. [97], [293] These results support the existence of feedback regulation of pancreatic enzyme secretion in humans.

Using an alternative approach, Dlugosz [294] and Hotz [295] and their colleagues observed that duodenal infusion of aprotinin, a trypsin inhibitor, had no effect on basal pancreatic enzyme secretion. Similar findings were reported with use of the trypsin inhibitor FOY-305. [296] Neither compound, however, strongly inhibits human

chymotrypsin. Liener and colleagues [297] demonstrated that Bowman-Birk soybean trypsin inhibitor, an inhibitor of chymotrypsin and elastase, markedly stimulates pancreatic enzyme secretion in humans. These observations suggest that the removal of trypsin and other proteases such as chymotrypsin and elastase would evoke pancreatic enzyme secretion in humans.

Studies of rats show that biliary secretion may also participate in the feedback regulation of CCK release. Secretion of bile into the proximal intestine inhibits CCK release and pancreatic secretion by protecting pancreatic proteases from autodigestion in the lumen. [298]

Postprandial pancreatic enzyme secretion is under hormonal and neural control. Distention of the duodenum or administration of hyperosmolar solutions into the duodenum elicits pancreatic enzyme secretion without raising plasma CCK levels. [159] This stimulatory effect is inhibited by atropine, suggesting that it is cholinergically mediated. In contrast to amino acid–stimulated pancreatic enzyme secretion, pancreatic responses to stimulation by volume or osmolality in the duodenum are not suppressed by trypsin. [159] This indicates that feedback regulation of pancreatic secretion by trypsin is stimulus specific and is mediated by inhibiting CCK release. The enteropancreatic reflex is unaffected by intralumenal proteases.

The existence of a feedback regulation of pancreatic enzyme secretion in humans may have important clinical implications. It is conceivable that in patients with chronic pancreatitis, decreased pancreatic enzyme secretion may result in elevated plasma CCK levels, reflecting a failure in the feedback modulation of CCK release. This may cause hyperstimulation of the pancreas and produce pain. Effective enzyme replacement therapy may reduce pancreatic stimulation, decrease intraductal pressure, and diminish pain. Large doses of pancreatic extract have reduced pain in some patients with chronic pancreatitis (see Chapter 95). [299], [300] This exciting observation awaits confirmation.

PATTERNS OF SECRETION

Basal Secretion

Under basal conditions, pancreatic secretion occurs at very low rates, although a small amount of enzymes is always present in the pancreatic juice. Basal secretion rates of enzymes and HCO_3^- are about 10% and 2% of maximal levels, respectively. A pattern of cyclic change in basal pancreatic secretion has been demonstrated in dogs [301] and humans, [302] and this is characterized by brief increases in HCO_3^- and enzyme secretion, which recur every 60 to 120 minutes during the interdigestive period. These bursts of pancreatic secretory activity are temporarily associated with periods of increased motor activity in the stomach and proximal intestine known as *interdigestive migrating motor complexes (IMMCs)*. [301], [302]

Associated with the bursts of pancreatic secretion are brief increases in gastric acid and biliary secretion. [302] Plasma motilin and PP levels also fluctuate in phase with the IMMCs. [302], [303] The concentrations of pancreatic enzymes and bile acids during the transient surge of pancreaticobiliary secretion are similar to maximal postprandial outputs, although the concentrations diminish rapidly with the onset of type III duodenal motor activity. [302], [303] It has been postulated that the cyclic secretion of pancreatic and biliary juice may be important in the digestion of residual food particles or cellular debris in the gastrointestinal tract during the interdigestive period.

The mechanism of control of the cyclic patterns of pancreatic secretion is unclear. Bursts of increased acid secretion are unlikely to be the principal mediators for the cyclic changes in pancreatic secretion, because removal of gastric acid by aspiration or through a fistula does not affect the pattern of interdigestive pancreatic secretion. [302], [303] Infusion of motilin prematurely initiates cyclic pancreatic secretion and shortens the periodicity between peaks. [304] Administration of motilin antiserum abolishes the cyclic pattern of pancreatic secretion. [305] Cholinergic blockade with atropine also markedly decreases trypsin output and abolishes interdigestive motor activity. However, administration of phentolamine, an a-adrenergic blocker, increases basal trypsin output fourfold without disrupting the periodicity of pancreatic secretion. [306] These observations suggest that motilin and the autonomic nervous system are important in the initiation of the cyclic pancreatic secretion that occurs during fasting.

Prandial and Postprandial Secretion

After ingestion of a meal, the exocrine pancreas is stimulated to secrete enzymes and HCO_3^-. Total postprandial pancreatic output is about 60% to 70% of the output attained in response to maximal stimulation with intravenous infusion of CCK. [99] The stimulatory effect of a meal can be described by separating its components into cephalic, gastric, and intestinal phases (Table 15-1).

PHASE	PANCREATIC RESPONSE (%)	STIMULANTS	MEDIATORS
Cephalic	25	Sight, smell, taste, eating	Vagal innervation
Gastric	10	Distention	Vagal-cholinergic pathways
Intestinal	50–70	Amino acids	Cholecystokinin, secretin
		Fatty acids	Enteropancreatic reflexes
		Ca^{2+}, H^+	Other hormones (?)
		Distention	

TABLE 15-1 Three Phases of Postprandial Pancreatic Secretion

Cephalic Phase In humans and experimental animals, pancreatic secretion rich in enzymes is stimulated by the sight, smell, and taste of appetizing food. [307] This cephalic effect in dogs amounts to 25% of the enzyme response to an ordinary meal. In humans, the contribution of the cephalic phase to the postprandial pancreatic enzyme secretion appears to be larger and amounts to 50% of the maximal responses induced by exogenous secretin and CCK. [308] The pancreatic response to sham feeding lasts only for the duration of feeding. [308] The vagus nerve appears to be important in mediating the cephalic phase, as this phase can be completely abolished by vagotomy in rats. [309] Administration of an anticholinergic drug decreases or abolishes the pancreatic response to sham feeding in humans. [308] The efferent cholinergic fibers probably act directly on the pancreas because vagal stimulation causes pancreatic secretion in dogs even when the pancreas is perfused extracorporeally to eliminate any humoral effects of nerve stimulation. [310] Sham feeding increases gastric acid secretion, but because sham feeding induces a pancreatic response in patients who are achlorhydric, it is unlikely that gastric acid secretion contributes significantly to the cephalic phase of pancreatic enzyme secretion.

Gastric Phase In dogs and humans, gastric distention increases the rate of pancreatic enzyme secretion. [311], [312] Gastric distention to a volume of 250 to 400 mL with a balloon doubles the basal pancreatic protein output. [313] Although the actual contribution of the gastric phase to the total postprandial pancreatic secretion has not been determined in humans, the magnitude of the distention-induced pancreatic response in dogs is about 20% of the maximal CCK response over a range of distention from 300 to 1500 mL. [311] Vagotomy and atropine reduce or abolish the pancreatic response to gastric distention, suggesting that it is mediated mainly by vagal cholinergic pathways. [312], [313] The mechanoreceptors appear to be located in the body of the stomach because distention of antral pouches does not stimulate pancreatic secretion, whereas distention of the remaining stomach does. [313] The presence of food in the stomach also releases antral hormones such as gastrin or gastrin-releasing peptide, which can stimulate pancreatic secretion directly or indirectly. However, this possibility is considered unlikely because a transplanted portion of pancreas does not respond to gastric distention in dogs. [313] Moreover, distention of the intact stomach has only a slight effect on gastrin release in humans and dogs. [314], [315] The stomach facilitates digestion by fractionating solid food into small particles and by initiating digestion of dietary proteins and lipids by pepsin and gastric lipase, respectively. [316], [317] Gastric emptying is important in determining the rate of delivery of acid and nutrients into the duodenum, thereby determining the pattern and magnitude of the intestinal phase of pancreatic secretion. Abnormal postprandial pancreatic enzyme secretion is common after gastric surgery. [156]

Intestinal Phase The intestinal phase is the most important phase of postprandial pancreatic secretion. In humans and animals, the delivery of food into the small intestine stimulates pancreatic enzyme secretion to about 70% of the maximal level. [156] The major hormonal mediators of the intestinal phase of pancreatic secretion are secretin and CCK. Intestinal serotonin also appears to play an important role in the mediation of postprandial pancreatic secretion through the vagal cholinergic pathway. [115], [116] The intestinal mucosa has receptors for important vagal cholinergic reflexes that regulate pancreatic HCO_3^- and enzyme secretion. The proximal intestine plays an important role in the stimulation of pancreatic HCO_3^- secretion, primarily by the release of secretin. Although duodenal pH is the major regulator for the release of secretin, nonacid factors such as fatty acids and bile may also participate. The physiology of secretin was discussed in a previous section. Among the hydrolytic products of digestion, amino acids and fatty acids are potent stimulants of enzyme secretion but have only a weak effect on water and HCO_3^- secretion. Amino acid mixtures are more potent than fatty acids, and among the amino acids, only phenylalanine, valine, and methionine stimulate enzyme secretion in humans,

but in dogs, phenylalanine, leucine, tryptophan, oligopeptides, and casein are effective. [318] The pancreatic response to intestinal perfusion with amino acids above a concentration of 8 mmol/L depends on the total load administered. [319] This dependence on load rather than concentration is the result of exposure of longer segments of small intestine to amino acids at a concentration above a threshold value. In humans, the mechanisms responsible for the pancreatic response to amino acids are confined to the duodenum and jejunum; amino acid perfusion into the ileum elicits no response. Undigested fats are ineffective in stimulating pancreatic secretion, but fatty acids in micellar form are potent pancreatic stimulants when present in micellar form. [74] Monoglycerides, the other product of lipolysis, also stimulate pancreatic secretion. [74], [318] The chain length of fatty acids influences their potency in stimulating pancreatic secretion. In humans, the order of potency is C18 > C12 > C8. [320] Other factors that influence pancreatic response to fatty acids include the degree of saturation, the concentration and total load, and the concentration of bile salts relative to fatty acids. [317] In humans, intestinal perfusion of 10 mmol of monoolein per liter produces a pancreatic enzyme output greater than that stimulated by intestinal amino acids and almost equal to the maximal response to exogenous CCK. [321] The release of CCK and intestinal serotonin by nutrients and mechanical factors appears to play a major role in mediating the intestinal phase of pancreatic enzyme secretion. Plasma CCK levels increase after oral or intraduodenal administration of fat and protein or amino acids. [95], [96] and [97], [322] Administration of proglumide, a CCK receptor antagonist, partially inhibits pancreatic secretory responses to intestinally perfused amino acids and fat emulsions. In contrast, a wide variety of non–CCK-dependent stimuli, such as acid, carbohydrates, and mechanical factors, stimulate pancreatic secretion through intestinal serotonin. [115], [116] Serotonin, in turn, stimulates submucosal vagal afferent fibers to evoke pancreatic exocrine secretion through a vagal cholinergic pathway. Increased firing rates in peripheral afferent neurons and in central sites have been recorded during intestinal perfusion with amino acids. [161], [323] This finding, coupled with the observation that truncal vagotomy or administration of atropine markedly increases the latency of the pancreatic secretory response to intestinal nutrients but not to CCK, indicates the participation of vagovagal cholinergic reflexes. [324] Ca^{2+}, which is intimately involved in the action of CCK on pancreatic acinar cells, stimulates the pancreas. In humans, intraduodenal perfusion of Ca^{2+} solutions in concentrations similar to those found in the duodenum after ingestion of a meal stimulates pancreatic enzyme secretion and gallbladder contraction. Intraduodenal Ca^{2+} concentrations of 12 to 25 mmol/L induce pancreatic enzyme responses similar to the maximal enzyme output evoked by intravenous infusion of CCK. [325] Intestinal perfusion with $MgSO_4$, $MgCl_2$, and $ZnSO_4$ also stimulates pancreatic enzyme secretion by undetermined mechanisms. [326] The human duodenum contains receptors for volume and osmolality that mediate pancreatic enzyme secretion. Volume distention or hyperosmolar solutions in the duodenum elicit pancreatic enzyme secretion via intestinal serotonin without raising plasma CCK levels. [115], [159] This enzyme secretion is inhibited by atropine, suggesting mediation by cholinergic pathways. [159] The volumes of saline required to induce pancreatic secretion are as low as 1 to 5 mL/min, within the range observed in the duodenum postprandially. The degree of stimulation by volume receptor or osmoreceptor activation is 15% to 20% of the maximal enzyme response to CCK. [158] Therefore, both CCK- and non–CCK-dependent stimuli act in concert to mediate the intestinal phase of pancreatic secretion.

CHAPTER 16

Steven A. Weinman and Nyingi Kemmer

BILE SECRETION AND CHOLESTASIS

The formation and secretion of bile are among the most central and earliest recognized functions of the liver. [1], [2], [3], [4], [5], [6] and [7] In addition to its digestive function as the source of intraintestinal bile acids, [8] bile formation is necessary for numerous other functions of the liver. These include the obvious functions, such as elimination of toxins, heavy metals, and xenobiotics, [9], [10] and [11] and the less obvious, such as regulation of whole-body lipid homeostasis [12], [13] and prevention of liver toxicity from endogenously produced bile acids. [14] *Cholestasis* is a term that was initially defined in terms of morphologic criteria, [15] but it also refers to a syndrome of serum biochemical abnormalities in conjunction with distinct functional abnormalities. The unifying process of cholestasis is an abnormality of the composition and rate of bile formation. [16], [17]

This chapter describes the cellular and molecular processes responsible for bile formation and the mechanisms that result in cholestasis. Knowledge in this field has increased dramatically, and many excellent detailed review articles on this subject are available. [18], [19], [20], [21], [22], [23], [24], [25] and [26] Specific cholestatic states are discussed as examples of the mechanisms involved, but the focus of this chapter is on cellular processes, and the reader is referred to other chapters for specific discussions of diagnosis and management of cholestatic liver diseases such as drug-induced cholestasis, primary sclerosing cholangitis, primary biliary cirrhosis, and the approach to the jaundiced patient.

GENERAL ASPECTS OF BILE FORMATION

Bile is the secretory product of the liver and bile ducts. It flows through the biliary tract and empties into the duodenum. Bile secretion results from the transport activities of several different epithelia working in concert. It is initially produced by hepatocytes, and its volume and composition are subsequently altered as it passes through the bile ducts. [6], [27] Bile is a complex suspension that has an electrolyte composition similar to that of plasma, except for higher HCO_3^- concentration. In addition, bile contains significant concentrations of bile acids, phospholipids, cholesterol, proteins, amino acids, and peptides. [16] Heavy metals, particularly copper, are also excreted in bile, and biliary metal excretion is the major mechanism for their elimination.

Anatomy and Physiology of Bile Secretion and Enterohepatic Circulation

Hepatocytes are specialized epithelial cells with distinct basolateral and apical membrane domains. They are depicted schematically in Figure 16-1. The sinusoidal or basolateral membrane surrounds the majority of the cell, and the canalicular or apical membrane occupies a small area of the cell surface near the points of contact between adjacent cells. The canalicular membranes, from which numerous microvilli protrude, make up only about 15% of the total surface area. [28] Opposing canalicular membrane domains border an enclosed space called the *bile canaliculus* measuring about 1 to 2 µm. [6] At the point of contact of the two cell membranes is the tight junction, also known as the *zonula occludens.* Tight junctions constitute a permeability barrier that consists of several transmembrane proteins including members of the claudin family and occludin. These proteins form a seal between the membranes of adjacent cells. [29] Intracellular proteins such as ZO-1, ZO-2, and numerous others serve as anchors for the claudin molecules. [30], [31] and [32] These tight junctions are cation selective, and they form a barrier between the bile canaliculus and the sinusoidal space that prevents back-diffusion of the secreted organic anions. [33], [34]

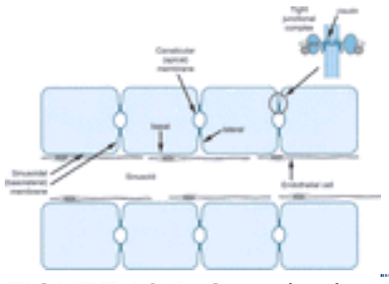

FIGURE 16-1. Organization of hepatocyte membrane domains. The relationship of canalicular and basolateral membrane domains is represented for the heptaocyte plates and sinusoidal space. The sinusoidal space and canalicular space are separated from each other by the tight junctional permeability barrier, which is composed of the extracellular loops of claudin molecules from adjacent cells.

Bile is produced as a result of the osmotic consequences of solute secretion. [35] The hepatocytes directly secrete solutes, primarily bile acids, into the canalicular space, and water follows passively driven by osmotic forces across the tight junctions and the cell membranes themselves. [16] The bile canaliculi encircle the hepatocytes in a beltlike fashion and form an interconnecting three-dimensional network. This network communicates with the canals of Hering, which form the transitions to the smallest bile ductules. The flow into the canalicular network thus results in net fluid flux into the biliary tree. Small bile ducts can secrete or absorb fluid and consequently modify the composition and amount of bile. [36], [37] and [38] They serve as tributaries of the larger ducts. During fasting, the sphincter of Oddi contracts and the gallbladder relaxes, causing bile to enter the gallbladder for storage, but postprandially, the gallbladder remains contracted and the sphincter of

Oddi relaxes, resulting in bile's bypassing the gallbladder and emptying directly into the duodenum.

In the duodenum and proximal ileum, some bile acids, particularly unconjugated bile acids, are passively absorbed, but conjugated bile acids are primarily absorbed in the terminal ileum. This absorption results from the apical Na^+-dependent bile acid transporter (ASBT), a Na^+-dependent transport protein located in the apical membrane of the ileal enterocytes. [39] Within the enterocytes, bile acids interact with a cytosolic bile acid binder, the ileal lipid-binding protein, [40], [41] and are transported to the basolateral membrane. From here they are secreted into the superior mesenteric vein by an Na^+-independent organic anion exchange system. [42] The identity of this ileal basolateral transporter appears to be a protein that results from alternative splicing of the same gene that produces the ASBT protein. [43] In this case, a truncated protein molecule localizes to the basolateral instead of the apical membrane and mediates Na^+-independent transport of bile acids from the cells into the portal circulation. [43] The bile salt bound to albumin is then transported into the portal venous blood, through the fenestrae between the sinusoidal endothelial cells, and passes into the space of Disse. It is efficiently extracted by specific transporters present in the basolateral membrane of the hepatocytes. [44] The uptake of bile salts occurs predominantly in periportal zone 1 hepatocytes. [45] Although 98% of bile salts are typically extracted from the portal blood during a single pass, the fractional extraction varies considerably according to the particular bile acid molecule. The general scheme for this enterohepatic circulation of bile acids is depicted in Figure 16-2.

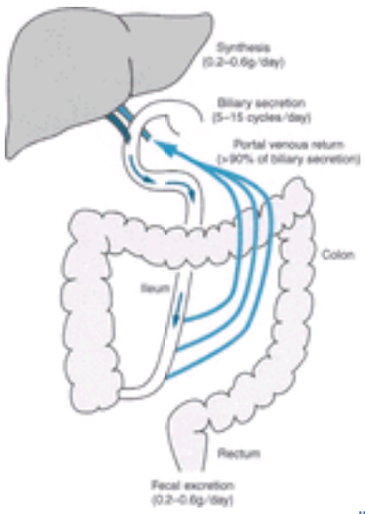

FIGURE 16-2. Schematic representation of the enterohepatic circulation. The routes of secretion and absorption of bile acids are indicated.

Multiple solutes are responsible for bile flow, but the primary ones are organic anions, and the most important of these are bile acids. Bile acids are amphipathic products of cholesterol metabolism that have several important functions. [46] They are natural detergent molecules that assist in solubilizing the lipid components of bile and are critical for solubilization, digestion, and absorption of lipids in the intestine. In addition, they serve as the primary vehicle for cholesterol elimination, [13] they can specifically trigger apoptosis, [47], [48] and they bind to transcription factors altering gene expression. [49], [50] and [51] Bile acids are synthesized de novo from cholesterol within the hepatocytes. They are also efficiently recycled through the enterohepatic circulation. Each day, up to 30 g of bile acid is secreted into bile, but only approximately 3 g is newly synthesized.

During the transit of bile through the bile ducts, its composition and volume are modified. [52] Some bile acids in the biliary tract are absorbed by the biliary epithelial cells and are returned into the portal circulation without entering the intestine. This process is known as *cholehepatic shunting* and serves to amplify the amount of fluid flow produced by a given net bile acid secretion. [53] Cholangiocytes take up unconjugated bile acids passively after protonation by H^+ derived from the activity of carbonic anhydrase present in the cholangiocytes. [53] In addition, conjugated bile acids can be taken up by the activity of a specific Na^+/bile acid cotransport protein, ASBT, which is present in the apical membrane of both cholangiocytes and ileal absorptive epithelial cells. [39], [54] Intracellular bile acids are then transferred to the basolateral membrane and are transported through the periductal capillary plexus into the sinusoids for uptake into the hepatocytes. Cholehepatic shunting plays an important role in bile formation, but it also is a mechanism of removal of potentially toxic bile acids during pathological states, such as bile duct obstruction. It has also been postulated to play a signaling role in which hepatic bile acid secretion can alter the function of the cholangiocytes themselves. [55]

Role of Bile Acids in Bile Flow

The concept that bile acids increase bile flow because they provide an osmotic driving force for filtration of water and electrolytes was first proposed by Sperber, [35] and it was subsequently confirmed by Brauer and colleagues, [56] who demonstrated that the administration of increasing loads of bile acids to rats led to an increase in bile flow. It was further demonstrated that the amount of bile acid in bile exhibited a linear correlation with the amount of bile flow. [1], [57] Although there were no circumstances in which bile acids were absent from bile, the linear relationship allowed an extrapolation back to a theoretical quantity of bile flow that would be predicted to occur in the complete absence of bile acids. This type of analysis has led to the concept that bile flow has two discrete components: bile acid–independent flow, which would occur entirely in the absence of bile acids, [58] and bile acid–dependent flow, which is a result of the osmotic coupling of water to bile acid transport. [59]

The concepts of bile acid–dependent flow and bile acid–independent flow are useful descriptions of the type of data obtained from perfused livers, assuming that the liver is a scientific "black box" with analysis restricted to measuring input and output only. Unfortunately, this concept suggested that there are two fundamentally different mechanisms at work in the liver, such as organic ion transport for bile acid–dependent flow and inorganic salt transport for bile acid–independent flow. [16] We now know that essentially all canalicular bile formation is the consequence of organic ion transport, and the fraction referred to as bile acid–independent flow results largely from the transport of other organic compounds such as glutathione and its conjugates, [60], [61] by mechanisms fundamentally the same as for bile acids.

Fortunately, since the early 1990s, dramatic advances have been made in the identification and characterization of the transport proteins responsible for hepatic transport and bile formation. We are now able to understand the mechanisms of bile formation on a molecular rather than a "black box" level. The concepts of bile acid–independent and bile acid–dependent flow have thus given way to a specific understanding of what is being transported and how. This new information has allowed an explanation of the transport specificity of the liver and the mechanisms of decreased bile flow in cholestasis. It has also successfully predicted the phenotype of genetic and acquired liver diseases. To understand the mechanisms of bile formation and cholestasis, therefore, it is critical to consider the identities and regulation of specific transport proteins at each of the critical steps of the process.

HEPATIC TRANSPORT MECHANISMS

Inorganic Ion Transport

Hepatocytes possess multiple transport proteins for inorganic ions. These primarily function to generate transmembrane ion gradients, to regulate intracellular pH and cell volume, and to create the electrical potential difference between the cell interior and the extracellular space. Although inorganic ion transport in hepatocytes generates the electrochemical gradients necessary for bile acid transport, it is not directly responsible for bile secretion. This differs from the situation in most fluid-transporting epithelia such as bile duct epithelial cells, in which inorganic ion transport is directly responsible for fluid secretion. The inorganic ion transport proteins in hepatocyte are indicated in Figure 16-3.

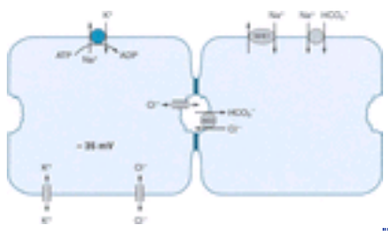

FIGURE 16-3. Inorganic ion transport pathways of the hepatocytes. Ionic gradients are maintained by Na^+,K^+-ATPase, which, in conjunction with K^+ and Cl^- channels, maintains the cell interior at an electrical potential of approximately -35 mV with respect to the sinusoid. Cl^- is distributed across the membrane passively in accordance with electrochemical equilibrium, and there is normally no net driving force for Cl^- secretion. The Na^+/H^+ exchange protein, NHE-1, the Na^+/HCO_3^- transporter, and the anion exchange protein, AE2, play important roles in pH regulation.

Na^+,K^+-ATPase is present in the basolateral membrane, [62] and it uses the energy of ATP hydrolysis to exchange Na^+ and K^+ and thus generates the low-Na^+, high-K^+ intracellular environment present in all mammalian cells. A cell negative membrane potential is generated by the presence of K^+ channels in the plasma membranes. [63], [64] The efflux of K^+ through these channels produces a cell negative diffusion potential. Hepatocytes also have multiple Cl^- channels in both the sinusoidal and canalicular membranes. [65] This allows Cl^- to distribute at its electrochemical equilibrium, and this process reduces the membrane potential to approximately -30 to -40 mV, cell interior negative. [66]

Several other transporters are primarily involved in pH regulation. [67] These are the Na^+/H^+ exchanger, NHE-1, [68], [69] and a Na^+-HCO_3^- cotransporter. [70] Both of these regulate intracellular pH in response to an acid load. The Na^+-HCO_3^- cotransporter is quantitatively more important in this response. [71] At the canalicular membrane, a Cl^- channel [72] and the Cl^-/HCO_3^- exchanger AE2 [73], [74] and [75] are present. In bile duct epithelial cells, this combination of a Cl^- channel and Cl^-/HCO_3^- exchanger results in electrogenic Cl^- and HCO_3^- secretion (see later). However, Cl^- is at electrochemical equilibrium in the hepatocyte, and there is thus no driving force for net Cl^- efflux. In hepatocytes, therefore, the AE2 transporter is primarily involved in pH regulation and not in fluid secretion.

Cell volume regulation is also extremely important for hepatocytes. Unlike most other cells, hepatocyte function requires cycles of swelling and shrinkage. After a meal, the concentrations of amino acids and sugars increase in the portal circulation. Hepatocytes take up large quantities of amino acids and other nutrients and consequently swell. [76] They respond to cell swelling by activation of K^+ and Cl^- channels. [77], [78] and [79] This produces a net flux of KCl out of the cell and reduces cell volume. [67] In addition, the Cl^- channels activated by cell swelling are also permeable to organic substrates such as taurine, and efflux of taurine contributes to volume regulation. [80] The mechanisms by which cell swelling activates ion channels are not well understood. Hepatocytes release ATP in response to cell swelling, and this ATP can bind to purinergic receptors on the cell membrane that activate Cl^- channels. [81] In addition, cell swelling directly activates protein kinases, and these play a role in channel activation as well. [82]

Uptake Transporters

Specific transport proteins at the sinusoidal membrane of hepatocytes account for the ability of the hepatocyte to take up substances from sinusoidal blood and to move them into the cells. With few exceptions, the transported molecules do not cross lipid bilayers, and their uptake is entirely determined by the properties of the transport proteins present in the sinusoidal membrane. Differences in the identities and quantities of these account for the different uptake properties of hepatocytes in different species, in different individuals, and at different times in the same individual. The most important uptake transporters are Na^+/bile acid cotransport protein (NTCP), the Na^+-dependent bile acid transporter, [83], [84] and a family of organic anion conjugate transporters known as the OATP family. [85] Members of the OATP family are responsible for the Na^+-independent uptake of bile acids, [44] unconjugated bilirubin, many other organic anions, and even some cationic and amphipathic substances. [10], [86], [87] Other important groups of transporters include the OAT family of anion transporters [88] and the OCT family of cation transporters. [89] These transporters are summarized in Table 16-1, and a schematic representation of their localization is demonstrated in Figure 16-4.

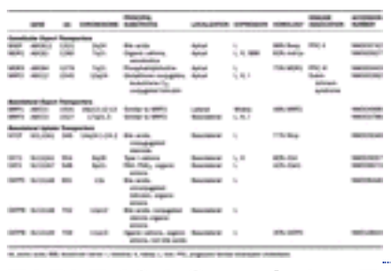

TABLE 16-1 Organic Ion Transport Proteins of the Human Hepatocyte

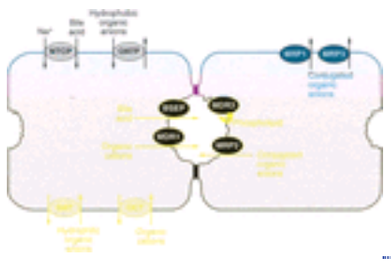

FIGURE 16-4. Organic ion transporters of the hepatocytes. Uptake at the basolateral membrane is mediated by an Na^+/bile acid cotransport protein, NTCP, and three families of organic ion exchanger transporters. The symbol *OATP* represents the organic anion transporter protein family, *OCT* represents the organic cation transporter family, and *OAT* represents the organic anion transporter family. Export from the hepataocyte into the canalicular space results from the ATP-dependent transport proteins BSEP, MRP2, MDR1, and MDR3. The ATP-dependent transport proteins MRP1 and MRP3 transport substrates out of the cells into the sinusoidal blood. See text for details.

Sodium-Bile Acid Cotransport Protein The first liver-specific transport protein to be identified was NTCP. [44], [90] The existence of a coupled Na^+/bile acid transporter was inferred from extensive studies demonstrating that the major fraction of bile acid transport was Na^+ dependent. [91], [92] The molecule responsible for this coupling, Na^+-taurocholate transport protein (Ntcp), was identified in 1989 by expression cloning with rat liver mRNA. [93], [94] Subsequently, a strongly homologous molecule (NTCP) was shown to be present at the basolateral membrane of human liver. [95] Its expression is highly liver specific, it localizes exclusively to the basolateral membrane of hepatocytes, and it is expressed similarly in periportal and pericentral hepatocytes. [96] Human NTCP is a 349-amino acid, 50-kd protein exhibiting a 77% identity with rat Ntcp. [96], [97] The human protein, NTCP, has a higher affinity for taurocholate than does rat Ntcp (K_m of 6 µM versus 25 µM) and also mediates uptake of a variety of bile salts in addition to taurocholate including glycocholate, chenodeoxycholate, glycochenodeoxycholate, taurochenodeoxycholate, and tauroursodeoxycholate. [98] Transport is strongly coupled to Na^+ with a stoichiometry of 2 Na^+ transported for each bile acid molecule. [99], [100] This coupling strategy results in an electrogenic transport process, [101], [102] and [103] which greatly increases the driving force for uptake and increases the maximum intracellular bile acid concentrations that can be achieved. It has been estimated that it can elevate intracellular bile acid concentrations at least tenfold higher than in the sinusoidal blood. [104] NTCP is a member of a small family of Na^+/bile salt cotransporters within the superfamily of Na^+/solute symporters. [105], [106] Human NTCP (Na^+/taurocholate cotransporting polypeptide) was mapped to chromosome 14q 24.1-24.2. [98] In addition, a structurally related protein, ASBT, [107] mediates uptake of bile acids in the

ileum as well as the bile duct and has been identified in rat and human ileum. [39], [54], [108], [109] These Na $^{+}$-dependent bile acid transporters are unique within the superfamily of Na $^{+}$/solute symporters in that they possess only seven membrane-spanning domains. [106], [107] The function of NTCP is critical for bile acid transport, and it is responsible for Na $^{+}$-dependent bile acid transport. Under most conditions, this accounts for one half to two thirds of the total bile acid uptake, and it is critical for achieving the rapid clearance of bile acids from portal blood. NTCP is strongly conserved among all mammalian species examined, and its critical role in uptake is reflected by its being an important target of regulation of expression during cholestasis. [20], [110], [111]

Microsomal Epoxide Hydrolase A second protein, microsomal epoxide hydrolase (mEH), has also been proposed to contribute to Na $^{+}$-dependent bile acid uptake. [112] This protein is present in both the endoplasmic reticulum and the hepatocyte sinusoidal membrane, [113] and it can mediate Na $^{+}$-dependent bile acid transport in reconstituted membrane preparations, [114] as well as in stably transfected MDCK cells. [115] However, unlike NTCP, its role in physiological bile acid uptake is uncertain. This is because its expression in other cell lines did not alter bile acid transport, [116] and it is also because the substrate and inhibitor specificity proposed for mEH does not correspond to that of the native hepatocyte. It is thus possible that mEH may serve as an intracellular bile acid transporter, but its role in sinusoidal bile acid uptake is uncertain.

OATP Family of Transporters The OATP family consists of a large number of related molecules with a broad tissue distribution and substrate specificity. [85], [110] To date, 15 members have been identified, 8 in humans (OATP-A to OATP-F, OATP8, and hPGT), [86], [117], [118], [119] and [120] and 7 in rodents (Oatp1 to Oatp5, OAT-K1/2, and rPGT). [90], [121], [122], [123] and [124] These transporters are classified within the gene superfamily of solute carriers (SLC) as gene family SLC21A. The initial member of this family to be discovered is now called Oatp1 and was identified by expression cloning from rat liver. [125], [126] It accomplishes Na $^{+}$-independent transport of bile acids, conjugated estrogens, conjugated bilirubin, cysteinyl leukotrienes, thyroid hormones, and many other substrates, [125], [127] by a process of anion exchange. [128] In addition to uptake into the cell, Oatp1 mediates the efflux of reduced glutathione (GSH) from hepatocytes into the sinusoid. [129] Because GSH is synthesized in hepatocytes and its intracellular concentrations are much higher than those in sinusoidal blood, efflux of GSH is likely to provide the driving force for electroneutral organic ion uptake. [130] Oatp1 localization is not restricted to liver, and it is present in other tissues as well. [90], [131] It is a 670-amino acid, 80-kd protein expressed at the basolateral membrane of the hepatocytes, the S_3 segment of the proximal tubule, and the apical surface of the epithelial cells of the choroid plexus. Oatp2 is a 661-amino acid, 92-kd protein, expressed at the basolateral membrane of rat hepatocytes, [132] the choroid plexus, [133] the retina, and the endothelial cells of the blood-brain barrier. [124] It also functions as an anion exchanger and mediates the uptake of bile salts, cardiac glycosides, and cyclic proteins. [132], [134] Oatp4 is another rat protein that shares 43% and 44% amino acid identities with Oatp1 and Oatp2, respectively, and is expressed exclusively in the liver, where it mediates the uptake of bile salts, conjugated steroids, and thyroid hormones. [122] Additional family members such as Oatp3, rPGT and OAT-K1/2 are not expressed in the liver. [135], [136] and [137] Unlike the situation for NTCP, in which the protein is directly homologous among species, the human OATP molecules are not the direct homologs of the earlier-identified rodent proteins. [86], [118] This has caused some confusion in the nomenclature of the human OATP proteins. Table 16-1 presents the characteristics of the human OATP proteins and the systematic gene names, as well as the names that are commonly used in the literature. OATP-C, which has also been called OATP2, or liver–specific transporter (LST-1), appears to be the primary organic ion uptake transporter in human liver. [117], [119], [138] It is a 691-amino acid protein that is primarily expressed in the basolateral membrane of hepatocytes and transports bile acids, conjugated bilirubin, conjugated sterols, eicosanoids, and thyroid hormones. Its significance is demonstrated by its ability to transport albumin-bound unconjugated bilirubin, unlike most of the other members of the OATP family. [139] It is most homologous to the rodent transporter Oatp4. OATP8 is another important multispecific transport molecule at the basolateral membrane of human hepatocytes. It has an 80% identity to OATP-C, [140] and it also has a broad substrate specificity mediating transport of bile acids, conjugated sterols, bromosulphophthalein, thryroid hormones, and organic cations. [86] OATP-B, a 643-amino acid protein that is expressed predominantly in the basolateral membrane of the hepatocytes, [86] is the third human liver OATP. It has a more limited substrate specificity than OATP-C or OATP8 and does not transport bile acids. [86] The first human OATP to be identified, OATP-A, is not thought to be an important hepatic transporter. Although it is expressed in the hepatocytes, it is found predominantly in the endothelial cells of the blood-brain barrier, where it transports bile salts, organic anions, conjugated steroids, and numerous drugs. [141], [142] and [143]

Other Uptake Transporters Several other groups of transporters are present in the basolateral membrane of hepatocytes and play a role in uptake. The OAT family comprises a group of transporters that play a role in anion transport in both liver and kidney. [88] The substrate specificity of the OAT family members differs from that of the OATP family in that substrates tend to be more hydrophilic. Nonetheless, there is considerable overlap. OAT1, the initially identified member of the group, is present only in kidney, where it functions as the high-affinity paraaminohypuritic acid transporter. This is the probenecid-inhibitable transporter that is largely responsible for efficient tubular anion secretion. [144], [145] A similar transporter, OAT2, is present exclusively in the liver, [146] a third family member, OAT3, is present in both kidney and liver, [147] and OAT4 is present in kidney and placenta. [148] The relative distribution of OATP and OAT family members between kidney and liver plays an important role in the well-known transport differences of these two organs. More bulky hydrophobic anions (OATP substrates) are preferentially taken up by hepatocytes and are excreted largely in bile rather than in urine. More hydrophilic organic anions (OAT substrates) are preferentially secreted by the renal tubules and are excreted largely in urine rather than in bile. The members of the OAT family have a 12-transmembrane domain structure and function largely as electroneutral anion exchangers. [88] In spite of these similarities, they do not share sequence homology with the OATP family. They do, however, share homology with the organic cation transporters of the OCT family. [149] The organic cation transporters mediate the uptake of small type I cations such as endogenous amines and a wide range of drugs. [89] The rat OCT1 is a 556-amino acid protein that is expressed in the basolateral membrane of the hepatocyte, kidney, colon, and small intestine. [149], [150], [151], [152] and [153] Two homologous human transporters have been cloned. The hOCT1 has a 78% identity with rat OCT1 and is expressed predominantly in the liver, whereas hOCT2 is expressed predominantly in the kidney. [154], [155] These molecules function as electrogenic cation transporters. [151], [156] Although the organic cation transporters appear to play little role in bile formation, their substrates include many important therapeutic drugs and xenobiotics.

Intracellular Movement

After uptake of organic solutes across the basolateral membrane of the hepatocytes, the solutes are transferred to the apical domain within seconds to minutes. [157] Many of the solutes transported by the hepatocytes are hydrophobic organic ions, and as a consequence they tend to bind to proteins, partition into various cellular membrane fractions, and become associated with intracellular organelles. It has been estimated that these interactions reduce the effective diffusion constants for intracellular molecules by a factor of 1000 compared with what would be expected for diffusion in free solution. [158] This intracellular binding reduces the tendency of substrates to efflux back out the sinusoidal membrane, but it also has the potential to reduce the delivery of substrates to the canalicular membrane. Transcellular transport thus requires mechanisms for these molecules to traverse the hepatocyte cytoplasm and to become available as substrate for the canalicular transporters. [159], [160] and [161]

High-affinity intracellular bile acid binding proteins are present in hepatocytes. The bile acid binding proteins are primarily 3a-hydroxysterol dehydrogenases. [162], [163] and [164] These molecules bind bile acids in the low micromolar range and have been cloned from rat and human liver. [165], [166] Other substrates also bind to intracellular binding proteins in high affinity. These include fatty acid binding protein for free fatty acids [167] and glutathione *S*-transferases, previously referred to as ligandin, [168], [169] for bilirubin.

Several functions for intracellular binding of bile acids and other substrates have been proposed. [158], [160] Because the proteins remain in the aqueous phase of the cytoplasm, they may serve to prevent bile acids from partitioning into fixed lipid membranes and organelles. In this case, protein binding serves to increase the diffusion coefficient for these molecules. [170] They may also serve as an intracellular sink preventing reflux of bile acids through the sinusoidal membrane. Lateral diffusion within lipid bilayers, as well as vesicle-vesicle transfer, is another mechanism that plays a role in intracellular bilirubin diffusion. [171] For molecules in which vesicle-vesicle transfer is important, binding proteins may interfere with this process and may actually slow the process of intracellular movement. [160]

Transcytotic vesicular transport also plays a role in hepatic transport in some situations. Certain proteins, particularly monomeric IgA, bind to specific receptors at the sinusoidal membrane and undergo receptor mediated endocytosis, transcellular trafficking, and exocytosis at the canalicular membrane. [172] Other molecules, including bulky organic solutes such as class II cations and proteins such as transferrin, translocate by this mechanism. [173], [174] and [175]

Whether small molecules, such as bile acids, are also packaged in vesicles and are exocytosed is doubtful. Several investigators have shown that a microtubule-dependent pathway is involved in bile acid secretion, [176], [177] and [178] but these results are likely because bile acids induce a vesicle mediated insertion of transporters into the canalicular membrane, [179] and not because the vesicles themselves contain significant amounts of bile acids. [175] This mechanism is discussed in detail later.

Hepatic Copper Transport The hepatic transport of copper also involves a vesicular transport process. Biliary excretion of copper is the exclusive mechanism by which copper is eliminated from the body, and a defect in this process, as occurs in Wilson disease, results in massive accumulation of copper in liver, brain, and other organs. [180] The major copper transport protein is a metal transporting (P-type) ATPase known as ATP7B. This protein is exclusively found in the liver and is

localized primarily in an intracellular trans-Golgi site. [181] Copper transport into this vesicular space is necessary for copper incorporation into ceruloplasmin and other proteins, but how this subcellular localization results in biliary copper excretion is unclear. One possibility is that ATP7B transports copper into a population of intracellular vesicles that then traffic to the canalicular membrane and discharge their contents into the bile. [182], [183] An alternative hypothesis is based on the observation that ATP7B moves away from the trans-Golgi and associates with the canalicular membrane when cellular copper content is elevated. If ATP7B directly inserted in the canalicular membrane under these conditions, it could directly pump copper into the canalicular space. [184] At the present time, this issue remains unresolved.

Canalicular Transport

The secretion of bile salts and other molecules from the cytoplasm of the hepatocytes across the canalicular membrane into the bile canaliculi is the rate-limiting step in bile formation and requires direct energy input. [6], [16] It is achieved by the action of several different ATP-dependent transport proteins. [185] These transport proteins are part of the superfamily of ATP-binding cassette (ABC) proteins and share similar structural and functional characteristics with each other. [186] In addition to canalicular membrane organic ion transporters, this family includes the cystic fibrosis transmembrane transporter (CFTR), [187] the sulfonylurea receptor, [188] and certain bacterial transport proteins. [189] Four different ABC transporters have been shown to play a significant role in canalicular secretion of biliary components. [190]

Bile Salt Exporting Protein Although NTCP can accomplish at most a tenfold increase in bile salt concentration from sinusoidal blood into the cell, biliary bile salt concentrations can be more than one hundredfold greater than that in the cell. In humans this concentrative transport step is accomplished almost exclusively by bile salt exporting protein (BSEP). [191] This molecule was initially identified as a protein of unknown function present exclusively in the liver. It shares significant homology with the multidrug resistance P-glycoptein. It was thus initially designated *sister of P-glycoprotein* or spgp. [192] This protein was subsequently shown to transport bile acids with a substrate specificity and concentration dependence identical to that seen for the bile acid transport process in isolated liver canalicular membranes. [193] Definitive proof that BSEP is the only significant bile salt export protein in human liver was provided by the observation that the genetic cholestatic disorder PFIC2 mapped to the BSEP gene locus on chromosome 2q24. [191], [194] These patients have mutations of BSEP that result in failure of the protein to function and a near complete absence of bile acid export into bile (see later). The rat, mouse, and human BSEP genes have been cloned, and the gene product is exclusively expressed in the liver. [195] Immunofluorescence microscopy demonstrates that the protein is localized in the canalicular membrane and in subcanalicular vesicles. [196] The rat protein is approximately 160 kd and shares almost 50% amino acid homology with the canalicular cation transporter, Mdr1b. [193] Although loss of human BSEP results in a near total elimination of biliary bile acid excretion, [191] a knock-out mouse missing bsep only displayed a 50% reduction in bile acid secretion. [197] This demonstrates that in mouse, unlike in humans, other proteins at the canalicular membrane can transport bile salts. This further demonstrates that the precise molecules that carry out hepatic transport and the relative proportions of each are species specific.

Multidrug Resistance Associated Protein 2 Multidrug resistance associated protein 2 (MRP2) is an ABC transport protein that is primarily expressed in the canalicular membrane of hepatocytes, [198], [199] and it serves as a primary, high-affinity transporter for conjugated organic anions including conjugated bilirubin, [200] glutathione conjugates, and cysteinyl leukotrienes. [201] In addition, it transports other substrates including sulfated bile salts, conjugated estrogens, antibiotics, and other exogenous compounds. [202] MRP2 also transports unconjugated GSH from the hepatocyte into the bile, [130] albeit with a relatively low affinity. [203] However, because intracellular GSH concentrations are high, it is responsible for a significant fraction of canalicular GSH secretion. MRP2 is a 1545-amino acid protein coded by a gene located on chromosome 10q 23-q24. [204] It is a member of a family of closely related transport proteins that differ more in their tissue and membrane localization than in their transport function. [198], [199], [205] In humans, the MRP family consists of six members. MRP2 is the only MRP detected in the apical membrane, but MRP1 and MRP3 are present in the basolateral membranes, where they function as sinusoidal efflux pumps. [202] These become important during cholestasis (see later). MRP2 is specifically absent from the canalicular membrane in the human disease Dubin-Johnson syndrome, [206] as well as in two mutant rat strains, TR-/GY and EHBR. [207], [208] and [209] Although MRP2 is important in organic anion and bilirubin transport, it plays little role in bile formation. Patients with Dubin-Johnson syndrome have an almost complete absence of bilirubin conjugates and glutathione conjugates in bile, they develop a black pigment in their liver, but they are otherwise normal. They have an up-regulation of other MRP family members in the sinusoidal membrane, and as a consequence they are able to eliminate MRP substrates into the blood for eventual renal rather than biliary excretion. [210]

Multidrug Resistance Protein 3 MDR3 is an ABC transport protein that is expressed in high levels in the canalicular membrane of the hepatocyte, where it functions as a phospholipid transporter. [211] Several studies have demonstrated that MDR3 and the homologous protein in mice, mdr2, serve to translocate phosphatidylcholine (PC) from the inner to the outer leaflet of the lipid bilayer of the canalicular membrane. [212], [213] This process is a critical step in the mechanism by which phospholipid is secreted into bile (see later). Human MDR3 and its mouse homolog, mdr2, are 170-kd proteins and are the major ABC proteins of the canalicular membrane. [214], [215] and [216] They were initially identified by homology with the multidrug resistance P-glycoprotein, MDR1. This latter protein transports many cationic drugs, and its overexpression renders malignant cells resistant to many chemotherapy agents. [217] MDR3, a closely related molecule, fails to produce multidrug resistance as a consequence of overexpression. However, knock-out mice with disruption of the *mdr2* gene develop progressive hepatic fibrosis and bile duct destruction and have a complete absence of phospholipid secretion into bile. [218] A similar syndrome, progressive familial intrahepatic cholestasis type III (PFIC III; see later), also occurs in humans with mutations of the MDR3 protein. [219] Defects in this gene also contribute to gallstone susceptibility in association with cholestasis. [220], [221]

Multidrug Resistance Protein 1 MDR1 is a 1280-amino acid, 170-kd protein that is responsible for the secretion of a variety of large hydrophobic compounds, especially organic cations. [217] This transporter was first identified as a protein that becomes overexpressed in some cancer cells and consequently renders these cells resistant to a diverse array of chemotherapy agents. It was subsequently determined that the mechanism of this multidrug resistance is that MDR1 functions as a drug efflux pump with broad specificity for cationic chemotherapy agents. [222] The protein is normally expressed at the apical membranes of several epithelia but most notably in the canalicular membrane of hepatocytes, [214], [223] where it functions as an important mechanism for the secretion of drugs and organic cations into bile. [10], [224] To date, no specific endogenous substrate has been identified for either MDR1 or its mouse homologs mdr1a and mdr1b.

Biliary Lipid Secretion

Lipids make up an important component of bile. Biliary lipid secretion is necessary for maintenance of whole-body lipid homeostasis and prevention of intrahepatic bile acid toxicity. [13] The major lipid components of bile are bile salts, phospholipid primarily as PC, and cholesterol. The monomeric forms of phospholipid and cholesterol have limited aqueous solubility and exist in bile in the form of micelles and vesicles. The mechanism of biliary lipid secretion differs from that of soluble small molecules. The general process is one in which PC and cholesterol are inserted into the canalicular membrane and then are subsequently solubilized from the outer leaflet of the canalicular membrane into bile by a process dependent on bile acid. [12], [13], [225], [226]

Phospholipid secretion depends on several steps. First, cellular PC is inserted into the canalicular membrane. The primary process responsible for this is a membrane-membrane exchange process mediated by the PC transfer protein (PC-TP). [227], [228] and [229] This protein results in the selective addition of PC to the inner leaflet of the canalicular membrane. Flipping of PC from the inner leaflet to the outer leaflet of the membrane is accomplished by the MDR3 protein. [211], [230], [231] and [232] This step is critical, and the absence of a functional “flippase” in the canalicular membrane results in the complete absence of biliary phospholipids in both humans and mice. [218] [219] Phospholipid is ultimately removed from the outer leaflet of the canalicular membrane and appears in bile as small vesicles. This process is dependent on bile salts. Electron microscopic evidence suggests that it may involve direct budding of vesicles off the canalicular membrane, [225], [233] in addition to possible transfer from the canalicular membrane to biliary micelles. [234] Although bile acids are essential for biliary phospholipid secretion, the exact mechanism of this effect has been called into question by the observation that knock-out mice that fail to express BSEP have elevated levels of biliary phospholipid excretion. [197] This result suggests that intracellular bile acid, rather than secreted bile acid, is necessary for PC secretion.

Biliary cholesterol secretion also results from extraction from the canalicular membrane that depends on bile acid. In this case, secreted cholesterol appears to be derived from high-density lipoprotein and not from newly synthesized cholesterol. A hepatic high-density lipoprotein receptor, SR-BI, results in the uptake of cholesterol destined for biliary secretion, [235], [236] but the mechanisms by which cholesterol is inserted into the canalicular membrane and is ultimately solubilized into biliary micelles have not been determined. [226]

Mechanisms of Bile Ductular Secretion

After the process of fluid secretion into the canalicular space, the bile flows through the bile ductular system before its emptying into the duodenum. Far from a passive conduit, the biliary epithelium serves many functions, including secretion and absorption of fluid and electrolytes. [237] In addition, bile ducts are able specifically [52], [238] to absorb bile acids. [239] This serves both to detoxify bile and to amplify bile flow through cholehepatic shunting. [240] The biliary ductules comprise only

3% to 5% of the total liver cell population, but they can secrete up to 40% of total bile flow in humans. [241] Unlike the situation in hepatocytes, fluid secretion by the biliary epithelium is not the product of organic ion secretion. Rather, it is a process of Cl^--dependent HCO_3^- secretion similar to that which occurs in other salt transporting epithelia such as the airway epithelium. [242] Biliary secretion is under intense hormonal control, particularly by the secretagogue secretin, which increases intracellular cyclic AMP (cAMP) stimulating secretion of HCO_3^--rich fluid. Other hormones and neuropeptides such as acetylcholine, somatostatin, gastrin, bombesin, substance P, vasoactive intestinal polypeptide, and endothelin also modulate bile flow. [237], [243] Figure 16-5 diagrams the transport proteins responsible for bile ductular secretion.

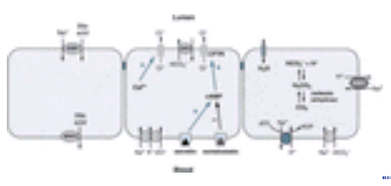

FIGURE 16-5. Bile duct epithelial cell transport. Transport of electrogenic fluid and HCO_3^- results from the involvement of multiple transporters. The $Na^+/K^+/2\ Cl^-$ cotransporter uses the energy of the Na^+ gradient to bring Cl^- into the cell at concentrations above its electrochemical equilibrium. Cl^- is secreted into the lumen primarily through the cAMP-dependent Cl^- channel, CFTR (cystic fibrosis transmembrane conductance regulator). It is exchanged for HCO_3^- by AE2 at the apical membrane. The process is primarily regulated by secretin, which increases cAMP levels in the cell. Bile acids can be absorbed from the lumen by the ASBT transport protein. A water channel, aquaporin-1, is present at the apical membrane. These processes are represented in different cells only for clarity of the figure. See text for further details.

The cholangiocytes are the epithelial cells that line the biliary ductules. They are polarized cells with transcellular transport resulting from the asymmetric localization of transport proteins. The basolateral membrane contains a Na^+,K^+-ATPase that establishes the ionic gradients and a K^+ channel that serves to maintain the intracellular negative potential. [244] An electroneutral $Na^+/K^+/2\ Cl^-$ cotransporter at the basolateral membrane is driven by the Na^+ gradient and results in the accumulation of intracellular Cl^- concentrations greater than that which would be expected by electrochemical equilibrium. [245] This is important because of the presence of the CFTR Cl^- channel at the apical membrane facing the ductular lumen. [246] Because Cl^- is above electrochemical equilibrium, a stimulus, such as secretin, that opens the apical membrane Cl^- channels will result in a process of Cl^- secretion into the lumen. [247], [248] A water channel, aquaporin-1, is present in the apical membrane and allows a water flux to be driven by osmotic forces. [249]

At the same time, the Na^+ gradient across the basolateral membrane drives two processes that tend to alkalinize the cytosol. These are electrogenic Na^+-HCO_3^- cotransport [250], [251] and Na^+/H^+ exchange. [252] The cycle is completed by an apical membrane Cl^-/HCO_3^- exchanger, AE2, which exchanges the secreted Cl^- in the lumen for intracellular HCO_3^-. [74] The net process is one of electrogenic HCO_3^- secretion. The entire system is maintained by the Na^+,K^+-ATPase, and the energy supplied by this transporter is transduced into net electrogenic HCO_3^- secretion from blood to bile, Cl^- recycling into and out of the cell across the apical membrane, Na^+ and K^+ recycling across the basolateral membrane, and passive Na^+ entry into bile through the tight junctions. This process of secretin-stimulated fluid secretion occurs primarily in the larger branches of the intrahepatic ducts, those with diameters greater than 15 µm, and not primarily in the smallest ducts with diameters less than 8 µM. [253] The CTFR is a critical component of this process. It is a cyclic AMP-dependent apical membrane Cl^- channel on which this process relies. Similar to the situation in respiratory epithelia, a defect in this Cl^-channel, as occurs in cystic fibrosis, reduces fluid secretion. [254] Under these circumstances, a Ca^{2+}-dependent Cl^- channel can substitute for CFTR and can allow some biliary secretion to occur. [255]

MECHANISMS OF REGULATION OF BILE FORMATION

A fundamental characteristic of the liver is that it serves multiple different functions and is able to adapt its functional activity to suit physiological and pathophysiological demands. The ability of the liver to function in the production of bile is thus quite variable and under some circumstances can be dramatically reduced. This reduction in the transport activity of hepatocytes and bile ducts manifests itself as cholestasis. Because bile formation is largely a consequence of the activity of organic ion transport proteins, the major mechanisms involved in regulation of bile flow are changes in the function, localization, and expression of these transport proteins. Other changes such as alterations in structure and function of tight junctions [256] and bile duct secretory processes [243] also play a role. This allows the liver to adapt to conditions that require changes in bile flow. The liver is able to modify its transport function by several mechanisms. In the short term (minutes to hours), changes in intracellular signaling result in modifications of transport proteins themselves, [257] as well as in redistribution of transport proteins between intracellular and plasma membrane pools. [179] In the longer term (hours to days), changes in expression of specific transport proteins play the more significant role. [258]

Alterations in Function of Hepatocellular Transporters

Signaling events within hepatocytes and biliary epithelial cells produce rapid changes in transport. [259] NTCP is subject to rapid regulation of its function on several levels. First, because it transports 2 Na^+ ions with each negatively charged bile acid, [99] the net transport is electrogenic and its rate is strongly influenced by changes in the intracellular negative membrane potential. [260] Hepatocytes normally have a membrane voltage of -30 to -40 mV, but this changes in pathological states, [66], [261], [262], [263], [264], [265] and [266] with a consequent increase or decrease in bile acid entry through NTCP.

In addition, NTCP itself is phosphorylated, and its phosphorylation state controls its distribution between intracellular and membrane sites. [267], [268] and [269] The phosphorylation state of NTCP is controlled by a balance of kinase and phosphatase activity and a cAMP-mediated increase in phosphatase activity reduces the phosphorylation state of NTCP. The dephosphorylated molecule is preferentially translocated to the sinusoidal membranes from an intracellular pool. [267]

Other important transport proteins can also be directly phosphorylated, but the importance of phosphorylation to regulation of transport is not clear. Protein kinase C (PKC) phosphorylation sites are present on MRP2, and activity of canalicular multispecific organic anion transport is modulated by PKC activators. [270] However, it is not known whether this effect results from direct effects on the protein or other changes such as membrane trafficking (see later). Oatp1 in rats has also been shown to be phosphorylated, [271] but the consequences of this on transport are not clear. There is additional evidence that phosphatidylinositol 3-kinase plays a role in transporter regulation. It regulates insertion of transporters into the canalicular membrane (see later), and its activation also increases the transport capacity of canalicular membrane vesicles. [272] The mechanism of this stimulation is unknown.

Alterations in Transporter Targeting

A major mechanism that produces rapid changes in the transport capacity of hepatocytes is redistribution of transport molecules between cellular sites. [179], [273], [274] Although this can occur for both the uptake transporters as well as the canalicular membrane efflux pumps, it is a more critical mechanism at the canalicular membrane, where transport capacity is rate limiting for overall bile flow. Redistribution of preformed canalicular transporters occurs rapidly in response to increased intracellular cAMP, [274] elevated intracellular bile acid concentrations, [275], [276] and osmotically induced changes in cell volume. [196], [277], [278]

Intracellular bile acid themselves increase the cellular capacity for maximal bile acid secretion. This process depends on the function of microtubules. [157] Electron microscopic studies of hepatocytes have shown that exposure of isolated hepatocytes to taurocholate induces an increase in the number of subcanalicular vesicles and a transformation of the subcanalicular network from primarily small vesicles to one of elongated tubules. [279] This process results in the insertion of BSEP-containing vesicles into the canalicular membrane [272] and an increase in the capacity of the canalicular membrane to transport bile acids. [280] The four major canalicular membrane transport proteins all actively shuttle between the canalicular membrane and an intracellular “subapical” vesicular pool. [179] Although the canalicular transport proteins undergo dynamic redistribution, the process is quite specific, and other canalicular membrane proteins remain in the canalicular

membrane while transporters are internalized. [179], [275]

Transporter cycling is dependent on the generation of lipid signalizing molecules though the action of phosphatidylinositol-3-kinase. [281] Transporter recruitment to the canalicular membrane is entirely blocked by inhibitors of phosphatidylinositol 3-kinase and the lipid products of phosphatidylinositol 3-kinase themselves directly stimulate transporter insertion. [179] As discussed earlier, phosphatidylinositol 3-kinase therefore plays a dual role in regulation of transport, stimulating transporter insertion and directly modulating transporter activity. The response to cell volume changes also appears to involve phosphatidylinositol 3-kinase. In addition, hepatocyte swelling activates several different members of the MAP kinase family including kinases of the Erk and p38MAPK type. [259]

Dynamic redistribution of canalicular membrane transporters between intracellular and canalicular membrane sites is important for liver function during physiological conditions. Hepatocytes normally undergo cycles of swelling and shrinkage in response to the solute load imposed by meals and subsequent uptake of amino acids and sugars. [282], [283] Because cell swelling causes insertion of MRP2 and BSEP into the canalicular membrane and cell shrinkage causes their internalization from the canalicular membrane, [259] this mechanism is likely to coordinate bile secretion rates with meals. Rapid redistribution of preformed transporters appears to be less important for the uptake transporters at the sinusoidal membrane. Although cAMP-dependent translocation occurs for NTCP, the uptake step is not rate limiting, and this may not play a major role in regulation of bile formation. Transporter translocation has not been shown to be important for regulation of the OATP family of transport proteins.

Regulation of Transporter Gene Expression

The primary mechanism by which the transport function of the liver is regulated is through changes in the expression levels of individual transport proteins. [257], [258] This mechanism plays an important role in the adaptation of the liver to inflammation [284], [285] and bile duct obstruction, [18] and it plays a dominant role in the development of liver transport function in ontogenesis. [26] The mechanisms that control expression of hepatic transport proteins are currently under active investigation, and although much information has been obtained, a complete understanding of how expression is coordinated under varying conditions has not yet emerged.

Transcription of the hepatic transporter genes, like all other cellular genes, is under the control of 5' upstream regulatory element sequences in the genes and the presence of activator proteins in the nucleus that bind to those elements. [286] Transporter mRNA transcription rates are rapidly altered by changes in the amount or function of these nuclear transcription factors. The nuclear localization and DNA binding ability of the transactivator proteins themselves are strongly regulated. This regulation can occur after transcriptional activation of the transcription factors themselves, after proteolysis steps that activate or inactivate factors, or after ligand binding, which creates an active factor complex. [286], [287] The transcription factors controlling transporter gene expression are multiple and interacting, and as a consequence environmental changes result in coordinated changes in expression. [258]

Investigators have demonstrated that bile acids themselves are the endogenous ligands for a particular nuclear receptor, the farnesoid X receptor (FXR). [50], [51], [288] FXR is a cytosolic transcription factor that binds bile acids with low micromolar affinity. [288], [289] On bile acid binding, FXR can complex with the retinoid X receptor (RXR), [290] to form an active transcription factor complex. [49] For genes with an FXR/RXR response element, such as the intestinal bile acid binding protein, [291] bile acids induce expression. Intracellular bile acids can also suppress transcription as for a key enzyme involved in bile acid synthesis, cholesterol 7a-hydroxylase. [292] In this case, bile acid binding to FXR results in formation of an FXR/RXR complex, which then competes for RE binding of another transcription factor (LXR/RXR) and decreases expression. [293] The extent to which this system controls hepatic transporter expression is not yet clear, but retinoid binding protein response elements are present in the NTCP promoter, [294] and they could be down-regulated by bile acids, similar to the situation with cholesterol 7a-hydroxylase.

Regulation of NTCP expression is critical because it controls bile acid entry into the hepatocytes. Its expression is sharply down-regulated in inflammation and other cholestatic situations, and this prevents bile acid–induced cytotoxicity (see later). Promoter elements that have been identified to control NTCP expression are the liver-specific transcription factors Hex [295] and HNF-1 and an uncharacterized footprint B binding protein (FpB BP). [296], [297] Expression is also under the control of signal transducer and activator of transcription 5 (STAT5), [298] and it involves the RXRa/RARa heterodimer. [294] Down-regulation of NTCP expression during inflammation can be explained in rats by an endotoxin-induced down-regulation of HNF-1 and FpB BP. [297] These important effects of endotoxin are likely mediated by cytokines. This is supported by the observation that interleukin-1ß (IL-1ß) down-regulates RXRa/RARa heterodimer activity and NCTP promoter activity. [294] In contrast, the hormone prolactin increases NTCP expression, and this results from a prolactin-induced phosphorylation and activation of STAT5. [298]

Details are less clear about the elements of promoter regulation of the other transporter proteins. Unlike NTCP, BSEP expression is only slightly decreased by whole-animal endotoxin treatment, bile duct ligation, or ethinyl estradiol treatment. [258] Transcription factors that bind to the promoter elements of the *BSEP* gene include C/EBP-ß, the hepatocyte-specific factor HNF-3ß, and the FXR/RXR heterodimer. Because this last transcription complex is directly activated by bile acids, it could potentially modulate coordination of BSEP expression with intracellular bile acid concentration. [258]

Regulation of OATP family expression is complex because of the multiple members of the family. In humans, promoter elements have only been identified for OATP-A, [299] although this family member is now known to be expressed primarily in brain. OATP-C and OATP8 are more significant transporters in liver. [86] OATP-A expression is stimulated by taurocholate in promoter constructs in HepG2 cells, and because OATP-mediated transport is bidirectional, this could enhance sinusoidal efflux of bile acids in cholestasis. Promoter element that have been identified include AP-1, AP-2, AP-3, HNF-1, HNF-3, C/EBP, and the glucocorticoid response element, GRE. [299]

Expression of MRP2, the canalicular organic anion transporter, is rapidly down-regulated in experimental models of cholestasis. [24], [300] This can in part be mediated by IL-1ß, which results in a decrease in the expression of RXRa/RARa heterodimers. [294] Promoter response elements identified in the human MRP2 promoter include AP-1, SP-1, HNF-1, HNF-3ß, and C/EBP. [301], [302] and [303]

Regulation of the canalicular phospholipid transporter, MDR3, has been extensively studied because of its role in disorders of lipid metabolism. [258] Its expression does not appear to be altered by endotoxin or during inflammation, but it can be strongly induced by feeding of hydrophobic bile acids, pharmacological inhibition of cholesterol synthesis, and induction of the transcription factor PPARa. [258], [304] Responsive elements in the 5' UTR of the gene include SP-1, AP-2, and C/EBP. [305]

Cytoskeleton and Tight Junction Changes

Alterations in the structure of the cytoskeleton and tight junctions occur in several conditions in which bile flow is reduced. Actin filaments serve as an intracellular scaffolding mechanism and are necessary for the targeted delivery of vesicles and the maintenance of cell polarity. A loss of the normal uniform actin filament distribution and a clumping of actin filaments around the bile canalicular membrane have been observed in multiple different models of cholestasis including bile duct obstruction and cholestatic bile acids and drugs. [306], [307] Vesicular transport along microtubules mediated by the molecular motor protein kinesin is also inhibited in cholestasis, [308] and these processes together alter transport function by changing the pattern of transport protein insertion and retrieval from the cell membranes.

The paracellular pathway, controlled by the proteins that make up the tight junctional complex, is also altered in cholestasis. [256] Both bile duct obstruction and estrogen-induced cholestasis produce changes in the distribution of the intracellular tight junction protein, ZO-1, [309] and a reduction in the number of claudin strands that compose the tight junctional seal. [310] These effects produce an increase in the permeability of the tight junctions to large molecules. [310] Alterations in the organization of tight junction proteins occur in human cholestatic diseases, [311] and they may contribute to the decrease in bile flow under these conditions.

Regulation of Bile Duct Secretion

Short-term regulation as a consequence of transport protein phosphorylation is the major mechanism of regulation of bile duct secretion. [237], [243] The rate-limiting step for biliary HCO_3^- secretion is the activity of the CFTR Cl^- channel at the apical membrane (see Fig. 16-5). Channel activity of CFTR is controlled by protein kinase A–mediated phosphorylation of its regulatory domain. [187], [312] In the biliary epithelium, a secretin-induced increase in intracellular cAMP is the primary mechanism that activates Cl^- channels and net secretion. [247] In addition, secretin also causes a microtuble-dependent insertion of aquaporin-1 water channels into the apical

membrane further enhancing fluid secretion. [249]

Other hormones and neuropeptides also play a role in regulation of ductular secretion, particularly in modulating the effects of secretin. Somatostatin interacts with somatostatin receptor subtype 2 on the bile duct epithelial cells and decreases cAMP and biliary secretion. [313] Gastrin has no effect on basal secretion, but it inhibits the secretin-induced choleresis. [314] Ductular fluid secretion is stimulated by bombesin, [315], [316] vasoactive intestinal polypeptide, [317], [318] and acetylcholine. [317], [318] It is inhibited by endothelin. [319]

An additional mechanism that regulates bile ductular secretion is the presence of micromolar concentrations of ATP in the ductular lumen. [320] In response to cell swelling and other stimuli, hepatocytes are able to release ATP into the canalicular space. [321], [322] This ATP interacts with purinergic P_{2u} receptors on the apical membrane of cholangiocytes that increase intracellular calcium, activate Cl^- channels, and stimulate secretion. [323], [324] In addition, ATP may be released by the cholangiocytes themselves resulting in a mechanism for both autocrine and paracrine regulation of bile duct function.

MECHANISMS OF CHOLESTASIS

Cholestasis is defined as the cessation or reduction of bile flow in a pathological situation. In many circumstances, this results from a coordinated response and is not merely a manifestation of nonspecific injury. The general principle of the response is that transcellular transport is diminished, but at the same time bile acid accumulation in the cell is minimized. This coordinated response provides for an alternative sinusoidal efflux pathway for toxins, conjugated bile acids, conjugated bilirubin, leukotrienes, and GSH. At the same time, biliary excretion of drugs is preserved and hepatocellular uptake of amino acids is increased, perhaps as a mechanism to support the massive protein synthesis required for the acute phase reaction. Other changes in liver function and structure also occur in many cholestatic settings. These include changes in cytoskeletal architecture, [307] alterations in tight junctional permeability, [310] and a decrease in the fluidity of the canalicular membrane. [325] In this section, we consider the specific changes that occur in several cholestatic situations. Numerous detailed reviews have appeared on this subject. [18], [21], [23], [24], [25] and [26], [284], [326], [327] and [328] Table 16-2 summarizes some of the changes in transporter activities that occur in acquired cholestasis syndromes.

TABLE 16-2 Changes in Transporter Gene Expression Associated with Cholestasis

Inflammatory Cholestasis

Cholestasis is frequently associated with inflammation, in particular that caused by gram-negative bacteremia. Inflammatory cholestasis is mediated primarily by cytokines, such as tumor necrosis factor-a, IL-1, and IL-6, that are released in response to bacterial lipopolysaccharide (LPS) stimulation of activated macrophages and Kupffer cells. The effect of these cytokines has been extensively studied in several experimental models. [329], [330] and [331] The best studied model is intraperitoneal LPS administration to rats. This treatment results in a dramatic decrease in bile flow and bile acid output that lasts several days. Within 3 hours of administration of LPS, Mrp2 redistributes from the canalicular membrane to a population of subapical vesicles. [332] This relocation results in reduced excretion of glutathione conjugates and bilirubin by Mrp2.

In addition to the rapid decrease in the Mrp2-mediated secretion, there is a slower onset of a decrease in bile acid transport. The amount of Ntcp present at the basolateral membrane is decreased, and this occurs primarily from reduced trans- cription. [330], [333] This is mediated by a reduction in transcription factors that bind to response elements in the Ntcp promoter region, specifically hepatocyte nuclear factor 1 (HNF-1 [333]), FpB BP, and the RXRa/RARa heterodimer. [294] These changes result in the impairment of Na^+-dependent bile acid uptake and thus a reduction in the concentration of bile acids within the hepatocyte. Expression of the canalicular bile acid transporter Bsep is relatively preserved compared with that of Ntcp, [334] but overall canalicular membrane excretion of bile acids from the hepatocytes is decreased. At the same time as biliary bile acid excretion is decreased, there is an up-regulation of expression of Mrp1 and Mrp3 at the basolateral membrane. [335] This provides an alternative sinusoidal efflux pathway for organic anions and is partially responsible for the appearance of conjugated bilirubin and bile acids in the plasma of patients with inflammatory cholestasis. Uptake of non–bile acid organic anions is not decreased to the same degree as bile acid uptake. Expression of Oatp1 in rat models is somewhat reduced, [285] but the functional consequences of this are unclear because a decrease in Na^+-independent bile salt uptake does not occur. [330], [333]

In humans, studies have been more limited. In a group of patients with inflammatory cholestasis, mostly patients with cholestatic alcoholic hepatitis, there is also a reduced expression of NTCP, OATP-C, and BSEP. In contrast to the situation in rodents, however, mRNA levels of MRP2 are preserved. [336] Despite these differences between the experimental rodent models and human disease, both situations are characterized by a decrease in transcellular bile acid transport. Bile acid uptake is decreased to a greater degree than canalicular efflux, and a sinusoidal efflux pathway for organic ions and bile salts is increased. This reduces the accumulation of bile acids within the hepatocytes and allows for entry of these compounds into the blood for eventual urinary excretion. The changes in gene expression are summarized in Table 16-2.

Bile Duct Obstruction

Obstructive cholestasis is a pathological condition resulting from obstruction in the extrahepatic bile duct as commonly results from choledocholithiasis or neoplasm. It has been extensively studied in the model of common bile duct ligation in rats. The inability of bile to enter the intestine results in an increase in bile acid concentrations in the bile duct lumen and within the hepatocytes, [337] as well as an increase in the pressure within the biliary tree. In response, expression of Ntcp and Oatp1 at the basolateral membrane is reduced, [338] limiting hepatocellular uptake of toxic bile acids. Short-term common bile duct ligation also results in relocation of Mrp2 from the apical membrane to a subapical vesicular compartment similar to that seen in inflammatory cholestasis. [339] There are also specific mechanisms that decrease canalicular efflux. Mrp2 expression [334] is dramatically decreased, [300] and this impairs secretion of sulfated bile acids as well as conjugated bilirubin. However, Bsep is reduced by only 20%, and therefore some efflux of bile acids into the biliary space continues. [334] This serves to protect hepatocytes from accumulating toxic levels of bile acids.

Several mechanisms further serve to prevent accumulation of toxic compounds intracellularly and in the bile duct lumen. Tight junctional structure is altered with a decrease in junctional strands and a marked increase in paracellular permeability that allows reflux of biliary components into blood. [310] As in inflammatory cholestasis, there is also up-regulation of Mrp1 and Mrp3 at the basolateral membrane of the hepatocytes. [335], [339], [340] and [341] This allows the efflux of bile acids into plasma, thus preventing further hepatocellular toxicity. In the bile duct, there is proliferation of cholangiocytes, [36], [342] as well as an increase in the expression of the ASBT at the apical membrane of the cholangiocyte. [343] This provides a mechanism for the removal of conjugated bile acids from the lumen of the bile duct. Furthermore, up-regulation of Mrp3 expression at the basolateral membrane of the cholangiocytes results in efflux of bile acids. [344] Finally, there is a marked increase in ductal HCO_3^- secretion resulting from up-regulation of secretin receptors. Therefore, although ductal obstruction prevents net bile flow, the compensatory mechanisms result in limitation of bile acid accumulation within hepatocytes and the duct lumen and profound dilation of the obstructed duct.

Estrogen-Induced Cholestasis

Estrogen-induced cholestasis is complex process resulting from changes in gene expression, direct inhibition of transport proteins, and other factors. It can occur with oral contraceptive use and can manifest as intrahepatic cholestasis of pregnancy. This syndrome is characterized by pruritus and cholestasis during the third trimester and accounts for about 20% of pregnancy-associated liver disorders. [345], [346] The administration of the synthetic estrogen ethinyl estradiol to male rats serves as an experimental model to study the pathogenesis of estrogen-induced cholestasis. In this model, there is a dramatic decrease in expression of Ntcp [334] associated with a

reduction in bile flow. Bsep expression is also reduced, but as in the other models of cholestasis, this effect is much smaller than that on Ntcp. [18] The result is impaired bile acid secretion. In addition, decreased expression of Oatp1 has also been observed, [347] which reduces the Na^+-independent uptake of bile acids and organic anions as well.

Conjugated estrogens themselves also are direct inhibitors of bile acid transporters. Ethinyl estradiol 17ß-glucuronide is a direct inhibitor of BSEP. However, it inhibits BSEP only when it is present in the canalicular space. It must therefore first be secreted before it produces its cholestatic effect. [348], [349], [350] and [351] Because it is transported into the canalicular space primarily by Mrp2, it is cholestatic in normal livers, but not in liver lacking expression of Mrp2 such as mutant rats or patients with Dubin-Johnson syndrome.

Lithocholic Acid–Induced Cholestasis

Lithocholic acid (LCA) is a monohydroxyl bile acid derived from bacterial 7a-dehydroxylation of chenodeoxycholic acid. LCA, together with its taurine and glycine conjugates, induces a cholestatic decrease in bile flow in animals and in perfused liver models. Several mechanisms have been postulated, but unlike the situation for other experimental models of cholestasis, there is not yet a detailed understanding of the effects of LCA on transporter expression and function.

LCA infusion produces a rapid cholestatic effect on the liver. It decreases canalicular excretion of both bile acids and organic anions, [352] it alters the distribution of cytoskeletal proteins, [325] it increases tight junction permeability and reflux from the liver into plasma, [352] and it reduces canalicular membrane fluidity by mobilizing cholesterol to the apical membrane. [353] This decreased membrane fluidity may contribute to the inhibition of canalicular transport. Like other highly hydrophobic bile acids, LCA increases intracellular Ca^{2+} and has specifically been shown to activate PKC. [354] These effects likely play a role in the cellular functional changes.

Although LCA is a known cause of cholestasis in experimental models, its significance in humans is unclear. LCA is found in minute amounts in human bile and serum. In human liver, in addition to its conjugation with taurine and glycine, LCA undergoes sulfation resulting in a decrease in hepatotoxicity and cholestasis. It has been shown that LCA, unlike other bile acids, is a high-affinity ligand for the nuclear receptor PXR. [355] LCA binding to PXR up-regulates the expression of the enzyme CYP3A11, which hydroxylates LCA and converts it to a less toxic derivative. In addition, LCA binding to PXR up-regulates expression of Oatp2. In rats, this would increase uptake of LCA, possibly allowing it to be more efficiently removed from blood and detoxified. [355]

Hereditary Cholestasis Syndromes

Several inherited defects in hepatic transport proteins result in clinically significant cholestatic liver diseases (Table 16-3). In addition, they provide enormous fundamental insights into the function of the transporters and the consequences of their failure.

TABLE 16-3 Summary of Hereditary Cholestasis Syndromes

Progressive familial intrahepatic cholestasis (PFIC), also known as Byler disease, is an autosomal recessive disorder that was first described in an Amish kindred. [356] It is now known that there are several distinct subtypes of this disorder, and molecular and genetic studies have identified the genes responsible for three of these. PFIC I is caused by a defect in a protein produced by the familial intrahepatic cholestasis 1 *(FIC1)* gene. This gene maps to chromosome 18q 21-22, and at least five mutations have been identified. [357] The *FIC1* gene codes a P-type ATPase that may be involved in the transport of aminophospholipids. It is expressed in the liver, small intestine, and pancreas, and a defect can cause cholestasis, diarrhea, or pancreatitis.

Benign recurrent intrahepatic cholestasis (BRIC) is a clinically milder variant of PFIC I. It is a recurrent cholestatic disorder of adults that was first described by Summerskill and Walshe in 1959. [358] Houwen and associates [359] mapped the genetic defect in BRIC to the *FIC1* gene. The process by which these mutations lead to cholestasis is not understood. Whereas PFIC I leads to progressive liver disease, BRIC is a milder, nonprogressive disease presenting either in childhood or adulthood. The reason for this variability in phenotypic expression is unknown.

PFIC II is a subtype of Byler disease that is clinically indistinguishable from PFIC I but is caused by a different genetic abnormality. The PFIC II locus has been mapped to the *BSEP* gene on chromosome 2q24 locus. [194] Immunostaining of the liver of these patients shows an absence of BSEP at the canalicular membrane. [191] These patients have a near-total absence of bile acids from the bile and consequently develop bile acid hepatotoxicity as a result of accumulation within the hepatocytes. The relatively severe phenotype and progressive liver failure resulting from absence of BSEP in PFIC II demonstrate the importance of this molecule in preventing the toxic effects of bile acid accumulation in hepatocytes. It is noteworthy, therefore, that BSEP expression is relatively preserved in most acquired cholestatic syndromes. Total loss of BSEP, as in PFIC II, results in severe liver toxicity.

PFIC III is a subtype that presents as a somewhat more aggressive disease, and unlike PFIC I and PFIC II, the affected patients have a high ?-glutamyltranspeptidase level. It is caused by a mutation of the *MDR3* gene on chromosome 7q21, [360] and it leads to a near absence of PC secretion into the bile. Because phospholipids are crucial for forming micelles with bile acids, the absence of biliary phospholipid increases free bile acid concentrations in the biliary tract. The consequences of this are injury and proliferation of bile ductules resulting in the release of ?-glutamyltranspeptidase. *MDR3* mutations are also associated with milder diseases that manifest in adulthood. Studies suggest that defects in MDR3 may be involved in hereditary susceptibility to cholelithiasis in association with cholestasis. [221]

CHAPTER 17

Peter G. Traber

CARBOHYDRATE ASSIMILATION

Carbohydrates are the most abundant of the four major biomolecules, which also include proteins, nucleic acids, and lipids. Carbohydrates include sugars (mono- and disaccharides), starch, and fiber, and they constitute between 40% and 50% of the total daily calories as a source of fuel for humans. The ingestion and assimilation of carbohydrates should be viewed as the first step in carbohydrate homeostasis, which is crucial for the function of all organs. Carbohydrate absorption occurs along the entire length of the alimentary tract. After absorption, the liver, endocrine pancreas, muscle, and fat become the principal sites of carbohydrate homeostasis.

CHEMISTRY AND STRUCTURE OF CARBOHYDRATES

Carbohydrates, or saccharides, are composed of a series of aldehyde and ketone compounds that contain multiple hydroxyl groups. [1] Monosaccharides consist of a single aldehyde or ketone unit, and oligosaccharides contain two to ten monosaccharide units. The most common oligosaccharides available as human fuel sources are the disaccharides lactose and sucrose. Polysaccharides contain many monosaccharide units joined in long linear or branched chains. In biologic systems, carbohydrates serve as sources of fuel, energy stores, intermediates in metabolic pathways, and structural components of cells.

Monosaccharides have the molecular formula $(CH_2O)_n$. The simplest sugar, D-glyceraldehyde, has an n of 3 and one asymmetric carbon. Because of the stereoisomerism of asymmetric carbon atoms, the diversity of chemical structures increases with the addition of each successive carbon atom. The most important monosaccharides used as fuel sources are the hexoses D-glucose and D-galactose (Fig. 17-1A,B). Dihydroxyacetone is the three-carbon ketose that is the precursor of the most important six-carbon ketone sugar, D-fructose (Fig. 17-1C). The stable structure of hexose is as a six-member ring (i.e., pyranoses) that closes in either an a or ß form based on the position of the hydroxyl group on carbon 1 (see Fig. 17-1A,B). Fructose forms a five-membered ring called a *furanose* (see Fig. 17-1C). These ring structures form the building blocks of oligosaccharides and polysaccharides.

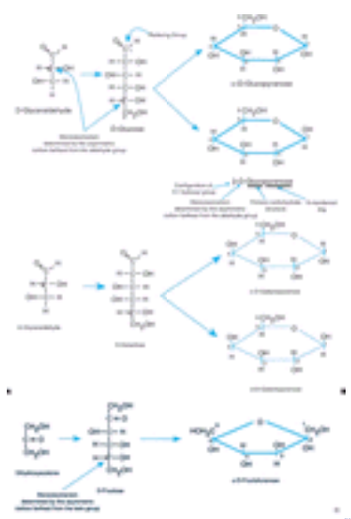

FIGURE 17-1. Carbohydrate structure. Linear and closed-ring forms of the chief nutritional carbohydrates. **A:** D-Glucose. **B:** D-Galactose. **C:** D-Fructose.

The chemical bonds that link monosaccharides to form oligosaccharides and polysaccharides are crucial to the biologic properties of the resultant molecules. Two D-glucose molecules linked by an a(1,4)-glycosidic bond form maltose, a readily digestible oligosaccharide (Fig. 17-2). If the D-glucose molecules are linked by a ß(1,4) linkage, the resultant molecule is cellobiose, the structural building block of cellulose, a compound that is indigestible by human enzymes. The structures of the two major dietary disaccharides, lactose and sucrose, also are shown in Figure 17-2.

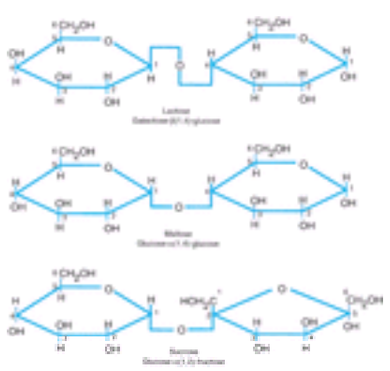

FIGURE 17-2. Structure of the three major nutritional disaccharides: lactose, maltose, and sucrose.

DIETARY CARBOHYDRATES

In Western cultures, 200 to 300 g of carbohydrates account for 40% to 50% of the total daily food energy ingested by humans. [2], [3] and [4] A survey conducted in 1985 showed that in the United States, carbohydrates, fats, and proteins accounted for 47%, 37%, and 16%, respectively, of the total daily ingested calories. [4] More recently, carbohydrate intakes in the United States have varied widely because both high- and low-carbohydrate dietary regimens are advocated. The sources of carbohydrates include complex forms, such as starch, and simple sugars, including disaccharides such as sucrose and lactose and monosaccharides such as glucose and fructose.

Except for lactose, which is found in milk, and small amounts of glycogen contained in meats, all carbohydrates are derived from plants. In fact, most of the glycogen in meat is depleted during the slaughter of the animal and therefore is not available as an energy source when ingested. [5] A number of ingested plant carbohydrates are not digestible by humans, including fiber and a variety of oligosaccharides. [6] These oligosaccharides contain three to eight linked monosaccharides and are ingested mainly as a-galactosides in legumes (e.g., raffinose and stachyose) and fructans (e.g., fructooligosaccharides), which are constituents of some vegetables, such as onions and Jerusalem artichokes.

Starch, a soluble polymeric molecule found in the cell walls of many plants, accounts for 40% to 60% of total ingested carbohydrates, [2] or about 22% of total calories. [4] The two forms of starch, a-amylose and amylopectin (Fig. 17-3), are present in many common foods, including grains (e.g., wheat, rice, barley) and vegetables. a-Amylose is a linear polymer of glucose joined by a series of a(1,4)-glycosidic bonds. Amylopectin is a branched form of a-amylose with a(1,6)-glycosidic linkages at the branch points, which occur every 15 to 25 molecules. [7] The ratio of a-amylose to amylopectin is variable, depending on the source of the starch. The physical form of starch in food is important in the process of digestion. [6] Most starch can be hydrated to form a gel, which gives particular foods their typical consistency. In raw plant foods, starches are enclosed in granular structures that are variably disrupted in food processing or cooking. Starch granules may be more or less disrupted with variable hydration of the starch. These physical characteristics of starch-containing foods have important implications for digestion and absorption.

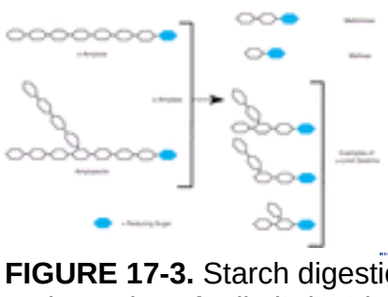

FIGURE 17-3. Starch digestion products. Amylopectin and a-amylose, the two molecular forms of starch, are digested by lumenal a-amylase into maltotriose, maltose, and a series of a-limit dextrins, a few examples of which are shown.

The percentage of simple sugars in Western diets has increased during the past several decades. [2], [4], [5] Sucrose is a natural ingredient of most fruits and vegetables. In addition, purified sucrose, used as table sugar and as a sweetener for many foods, is derived from certain plants that contain a high sucrose content, such as sugarcane, beets, and maple sap. The mean daily intake of sucrose per person in the United States is 41 g per day, or about 9% of the caloric intake and 30% of the carbohydrate intake. [2], [8] Of this ingested sucrose, 67% is added to foods as a sweetener. Lactose, the other main disaccharide, is the major carbohydrate in milk and serves as a food additive in many processed foods. The intake of lactose per person is highly variable depending on race and age, but it can account for up to 10% of the total carbohydrate calories consumed by the population in the United States.

The primary monosaccharides in foods are fructose and glucose. Fruits and vegetables contain various amounts of these two sugars as well as the disaccharide sucrose (Table 17-1). The average daily intake of free glucose per person has been estimated to be 20 g. [2] The main source of fructose in the diet is high-fructose corn syrup, which is added as a sweetener to foods because it is the sweetest of the sugars. [2] For this reason, the mean daily intake of fructose per person in the United States is 16 g; for some persons who ingest large amounts of foods sweetened with high-fructose corn syrup, fructose intake can be up to 150 g per day. [2], [8] The sugar alcohol sorbitol, or D-glucitol, is commonly found in many fruits; however, increasing amounts of sorbitol are being added to foods as a nonnutritive sweetener [2] and may cause gastrointestinal complaints in some persons because of its poor absorption by the small intestine. [9] Other polyols also are being used as food additives, including xylitol, mannitol, lactitol, and maltitol.

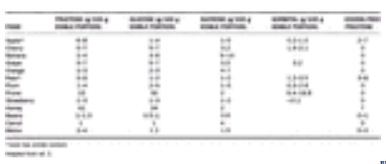

TABLE 17-1 Food Content of Fructose, Glucose, Sorbitol, and Sucrose

Based on the health risks of high-fat diets, it has been recommended that the percentage of carbohydrates in the U.S. diet be increased. [4] There is concern, however, about the type of carbohydrate that will account for the increment in intake. For example, an increase in the fructose intake may have deleterious health consequences, increasing hyperlipidemia and inducing other metabolic changes. [4] Similarly, the ratio of amylopectin to a-amylose may be important because the insulin response and postprandial serum glucose levels after a meal of amylopectin are significantly higher than those after a meal primarily composed of a-amylose. [4] Therefore, the carbohydrate composition of the diet may be of importance for the overall health of the population.

DIETARY FIBER

The typical human diet comprises multiple nondigestible carbohydrates called *fiber*. The amount of fiber in the diet varies widely with the region of the world and the regional dietary customs. Fiber is composed of nonstarch polysaccharides, which are integral structural components of plant cell walls. The wall that surrounds plant cells is a complex structure that differs in chemical composition among plants, in different portions of the same plant, and during developmental processes in the same plant. The highly variable cell wall properties of different plants lead to many varieties of fibers in nature. [10] The structure of many of the fibers in the human diet have not been studied extensively. Fiber can be categorized into soluble and nonsoluble forms, of which representative types are listed in Table 17-2.

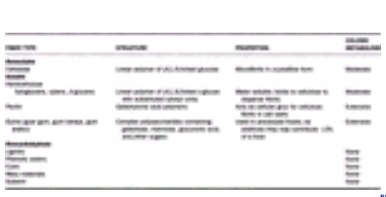

TABLE 17-2 Dietary Fiber

Dietary fiber has numerous effects on metabolism and digestive processes. [10], [11], [12] and [13] Unabsorbed fiber reaching the colon serves as a fuel for colonic bacteria. [13] The degree to which fiber is metabolized by bacteria varies with the type of fiber (see Table 17-2). The bacterial products of fiber metabolism include short-chain fatty acids, hydrogen, and methane. [13], [14] and [15] Short-chain fatty acids serve as a fuel for colonocytes. [16], [17] The fiber content of food affects the rate of intestinal absorption of carbohydrates by several mechanisms. One mechanism is to slow gastric emptying based on the viscosity of the gastric contents. Another is to impede digestion in the intestinal lumen by decreasing the accessibility of starch to enzymes. [10] It is known that the ability of fiber to complex with organic compounds may affect the absorption of certain drugs. [10] Other effects include changes in sterol metabolism [10] and an increase in stool weight. [10], [18]

Evidence suggests that dietary fiber may have a beneficial effect on a number of disease processes, [12], [19] including lipid disorders and colorectal cancer. Studies have shown that water-soluble fiber in the diet reduces low-density lipoprotein levels by about 10%, but it has no effect on the levels of high-density lipoproteins and triglycerides. [20] Based on the results of epidemiologic studies, it has been concluded that an inverse relationship exists between the amount of ingested fiber and the incidence of colorectal cancer. [21], [22], [23], [24], [25] and [26] Cautionary notes have been sounded on the interpretation of the results of these studies because of the possible variance in dietary components and socioeconomic parameters among populations. [23], [27] Although the mechanism of the effect of fiber on the incidence of colorectal cancer is unknown, it is possible that the colonic metabolites of fiber, particularly short-chain fatty acids (e.g., butyrate), are involved in growth regulation. [24], [28]

CARBOHYDRATE ASSIMILATION

Organs throughout the alimentary tract have important roles in the digestion and assimilation of ingested carbohydrates. The most important processes include the enzymatic hydrolysis of starch in the lumen of the intestine, the hydrolysis of oligosaccharides and disaccharides by enzymes located in the apical membrane of enterocytes, and the transport of monosaccharides across the apical membrane of enterocytes. [6], [29] These processes are described in detail in the following sections, and the overall efficiency of the process and the rate-limiting steps for the assimilation of different types of carbohydrates are discussed.

Several ancillary processes have a small overall effect on carbohydrate assimilation. Effective mastication of certain vegetable products is important for lumenal hydrolysis of the starch, which may be located within a layer of waxy cellulose. There is some evidence that the motility of the stomach and small intestine may play a small role in absorption. [30], [31] Overall starch absorption increases if the transit time through the small intestine is slowed by pharmacological means, [30] whereas absorption is diminished if transit is hastened. [30], [31]

LUMENAL PHASE OF DIGESTION STARCH HYDROLYSIS

Initial digestion of starch occurs in the lumen of the alimentary tract and is catalyzed by a-amylase. [31], [32], [33] and [34] This enzyme has a high level of activity for the cleavage of internal a(1,4)-glycosidic linkages. [32] It has no activity for the hydrolysis of a(1,6) linkages, terminal glucose residues, or a(1,4) bonds adjacent to a(1,6) linkages. [32] Lumenal hydrolysis of a-amylose produces maltose and maltotriose, and hydrolysis of amylopectin produces maltose, maltotriose, and a-limit dextrins, which are a series of oligosaccharides containing four or more glucose molecules having an a(1,6) linkage (see Fig. 17-3). [7], [32], [33] In the aqueous environment of the gastrointestinal lumen, the process of starch hydrolysis is efficient and is completed in the proximal jejunum [33], [35]; however, some important characteristics of solid food particles limit starch hydrolysis and allow a percentage of starch to enter the colon undigested.

The a-amylase protein is synthesized and secreted into the alimentary tract by the parotid gland and the pancreas. Salivary a-amylase, which exhibits optimal activity within a narrow pH range of 6.6 to 6.8, initiates starch digestion but is of only minor significance because it is rapidly inactivated in the acid pH environment of the stomach. Short-chain glucose polymers in the diet may stabilize the enzyme and allow maintenance of activity at acid pH. [36] This stabilization phenomenon may help to ensure amylase activity for carbohydrate assimilation in neonates and in patients who have chronic pancreatic insufficiency. [3] In healthy persons, the survival of amylase in the proximal intestine is increased by the presence of nutrients in the lumen. [37] Pancreatic amylase is secreted into the lumen in quantities far greater than are required for the hydrolysis of starch. The completeness of starch hydrolysis is more dependent on the state of the ingested starch than on the amount of pancreatic amylase secreted. For example, the physicochemical properties of different varieties of rice [38] and the preparation of other cereal foods [39] affect the ability of amylase to hydrolyze the starch component of the foods. Amylase concentration becomes limiting for starch hydrolysis only in severe cases of pancreatic insufficiency, in which lumenal amylase activity levels are reduced to below 10% of normal (see Chapter 95). [40] Human milk contains amylase activity, which may be important for carbohydrate digestion in infants. [41]

Amylase proteins are encoded by a clustered gene family located on human chromosome 1 and mouse chromosome 3. [42] In humans, the AMY1 gene is expressed in the parotid gland, and the AMY2 gene is expressed in the pancreas. [43] Purified preparations of the two isoenzymes exhibit identical activities at neutral pH, but their molecular weights differ, as do other biochemical properties. [44] The sequences of the pancreatic and salivary cDNAs are 94% similar, encoding for polypeptides with the same number of amino acids. [45] For additional information on the structure, synthesis, and secretion of amylase, see Chapter 15.

BRUSH BORDER CARBOHYDRASES

Brush border saccharidases are ectoenzymes that are anchored to the apical membrane of enterocytes. These enzymes are responsible for the further breakdown of lumenal hydrolysis products (i.e., maltose, trimaltose, and a-limit dextrins) and ingested disaccharidases. The result of metabolism by these enzymes is the production of monosaccharides that can be transported across the apical membrane. Table 17-3 outlines the characteristics of each enzyme.

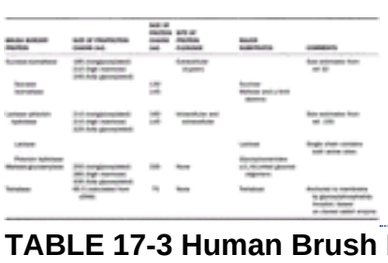

TABLE 17-3 Human Brush Border Proteins with Carbohydrase Activity

Sucrase-Isomaltase

Sucrase-isomaltase (SI) has been one of the most intensively studied membrane proteins; consequently, an enormous amount of literature has accumulated concerning its function, synthesis, processing, sorting, and regulation.

Enzyme Activity SI, a bifunctional disaccharidase with two active sites, constitutes about 10% of the total brush border protein mass. [46] The isomaltase active site hydrolyzes maltose at the a(1,4)-glycosidic linkage and a-limit dextrins at the a(1,6) linkage. [47] Although SI does hydrolyze isomaltose, this natural substrate is not abundant; therefore, the name *a-limit dextrinase* has been suggested in place of *isomaltase*. [48] The sucrase active site cleaves sucrose to glucose and fructose and appears to be the only enzyme in the intestinal tract that can perform this function. The enzyme accounts for 100%, 90%, and 80% of the sucrase, isomaltase, and maltase activity, respectively, in the intestine. [46] One group of investigators has reported that SI is a cAMP-dependent chloride channel on the basis of current inhibition in the presence of antibodies. This intriguing functional characteristic of SI must be confirmed with further research. [49]
Protein Structure The primary structure of the SI molecule was determined by cloning of the complete rabbit, [50] human, [51] and rat [52] cDNAs. The coding sequence of the human SI mRNA is 5481 bases long and encodes a 1827-amino acid polypeptide. [51] The deduced molecular weight of this polypeptide correlates well with the measured molecular weight of the nonglycosylated human SI protein of 185 kd. [53] The nucleotide sequence of rabbit cDNA has 83% overall identity to the human sequence [50], [51] and a similar level of identity in the cloned regions of rat [54] and mouse [55] cDNAs. In both rabbit and human cDNAs, the isomaltase and sucrase

subunits have a high degree of sequence identity. In fact, 13 of 15 amino acids surrounding the aspartate residues at both active sites are conserved, [50], [53] which has led to the hypothesis that the two subunits were formed by a gene duplication event. [47], [50], [56] In addition, SI may be a member of a larger gene family [57], [58] with homology to lysosomal glucosidase. [58] The primary structure of SI predicts a molecular model that can be represented by five different domains (Fig. 17-4). [47], [50], [56] The amino terminus of the molecule forms a short intracytoplasmic domain containing about 12 amino acids. A transmembrane domain of highly hydrophobic amino acids that predicts an a-helical structure serves as the membrane anchor for the molecule; the length of this segment indicates that it can cross the membrane only once. The first portion of the extracellular domain forms a highly hydrophilic segment, or stalk, of about 180 amino acids, including multiple serine and threonine residues, which suggests a high degree of glycosylation. [46], [47], [50], [56] The length of this stalk differs somewhat among species, with that of the rat being longer than that of the rabbit and human. [59] The significance of this finding is unknown. The isomaltase subunit is next, followed by the sucrase subunit, which in the completely processed enzyme is linked to the isomaltase subunit by noncovalent ionic bonding.

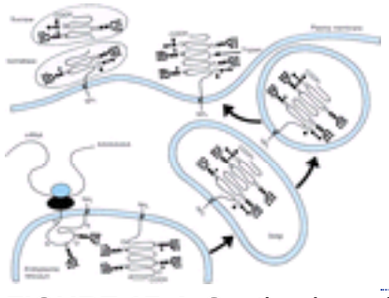

FIGURE 17-4. Synthesis and processing of sucrase-isomaltase. The processing of sucrase-isomaltase, from synthesis of the polypeptide chain on ribosomes to insertion of the protein in the apical membrane.

Synthesis and Processing SI is encoded by a single gene in the human, [59], [60] rat, [59] and mouse. [55] The human gene, which is located on chromosome 3 at locus 3q25-26, [61] is estimated to be about 55 kb in size. [51] As for many eukaryotic genes, the 5'-flanking region of the SI gene has a number of DNA regulatory regions that control initiation of gene transcription. [62], [63] Transgenic mouse experiments show that SI gene expression in the mouse intestine is regulated by many functional *cis*-acting DNA elements. [64], [65] and [66] The elements necessary to direct intestinal epithelial cell–specific expression are embodied in a 201-nucleotide, evolutionarily conserved, 5'-flanking region of the gene. [66] This mouse SI gene promoter directs expression of a reporter transgene to enterocytes in the proper developmental- and differentiation-dependent patterns. Studies with transgenes containing longer segments of the 5'-flanking region of the gene showed that other elements are important for modulating the expression of the SI gene. [65] DNA regulatory elements and associated DNA binding proteins within the evolutionarily conserved SI promoter region have been assessed. [55], [67], [70] At least two types of transcriptional proteins are involved in SI promoter transcription, including hepatocyte nuclear factor 1 (HNF-1), [67], [68] and caudal-related homeodomain proteins (Cdx). [70] The requirement for the HNF-1 binding site has been confirmed in transgenic mice, and the activation of transcription is modulated by the ratio of HNF-1a to HNF-1ß. [68] There is some evidence that GATA factors facilitate maximal transcriptional activation of the SI promoter, [69] although the mechanism remains poorly defined. The interaction of tissue-specific, tissue-restricted, and ubiquitous transcription factors facilitates the transcription of genes in a single cell type. It is not understood how these transcription factors interact with each other or with coactivator proteins to direct the complex patterns of SI gene transcription. Following synthesis and processing, the mature mRNA for SI is translated in the cytoplasm to yield a single protein of the predicted size (see Fig. 17-4). [47], [53] The amino terminus forms a short-membrane anchor that remains embedded in the endoplasmic reticulum (ER) membrane. [47], [71] The amino-terminal intracellular tail of the SI protein is phosphorylated by cAMP-dependent protein kinase, which suggests that phosphorylation affects the physiological function of the protein. [72] The SI protein is used as a model for examining the posttranslational processing of membrane proteins. Glycosylation of proteins is performed by multiple glycosylases present in the ER and Golgi apparatus. [73] Protein *N*-glycosylation and the addition of a branched oligosaccharide to an asparagine residue occur during translation of the protein in the ER. Because this oligosaccharide contains nine mannose molecules, proteins with this modification have been called *high-mannose forms*. This common precursor oligosaccharide may be modified in the Golgi apparatus by the removal of mannose residues and the addition of other sugars. The secondary structure of the protein determines which asparagine-linked oligosaccharides are further modified. *O*-glycosylation occurs at the hydroxyl-group oxygen of serine and threonine residues in the Golgi apparatus. The fully glycosylated SI molecule has a molecular weight of 245 kd, and both *N*- and *O*-glycosylation occur equally on the isomaltase and sucrase subunits. [53] Although these data apply to the human protein, other species show essentially the same pattern of synthesis, with slight differences in the molecular weights of the forms. [71], [74], [75] and [76] The fully glycosylated SI molecule is transported uncleaved to the apical membrane of the enterocyte. Electron microscopic studies suggest that the transport vesicles move from the Golgi apparatus directly to the apical membrane. [77] Cleavage of the molecules into the two subunits (145 kd for isomaltase and 130 kd for sucrase) occurs by tryptic digestion in the lumen of the human intestine. [46], [47], [53] The two subunits remain associated by hydrostatic bonds. In studies using electron microscopy of reconstituted membranes, it was shown that SI exists as a dimer in the membrane. [78] The degradation of SI in the lumen of the intestine is mediated by pancreatic proteases. [79], [80] Understanding of the processing and transport of the SI molecule has been instrumental in elucidating the site of the defect in inherited SI deficiency in humans. [81] The enzymatic deficiency in these persons appears to be related to a number of different defects in glycosylation and intracellular transport, and it may also involve catalytic activity. [81], [82]

Regulation

Spatial and regional regulation. The expression of genes in the intestine exhibits a complex spatial pattern along the vertical (crypt-to-villus) and horizontal (proximal-to-distal) axes. [83] By using sections of frozen tissue to sample villus and crypt cells sequentially, it was demonstrated that there is little sucrase enzyme activity in the crypt, maximal activity in the lower and mid villus, and decreased levels in the villus tip cells. [84] This pattern of enzyme activity is consistent with the localization of SI protein expression that was determined when antibodies became available to study the pattern of SI protein expression by immunohistochemistry. [77] In the mouse, SI protein in the intestinal mucosa is not detectable in crypt cells, but it is expressed from the crypt-villus junction to the villus tip, with a minimal decrease in intensity at the tips. [64] This pattern of expression is generally accepted, although some data derived from monoclonal antibody studies show that SI protein is expressed to some degree in the crypts of the human small intestine. [85] SI mRNA is also first expressed in the upper region of the crypt near the crypt-villus junction. [59], [64], [86] Within only a few cell positions, the levels of SI mRNA are maximal and remain at a similar level about two thirds of the way up the villus; levels decrease toward the villus tip. These data suggest that the major mechanism for regulating the expression of the SI protein along the crypt-villus axis is the steady-state level of SI mRNA; however, posttranscriptional and posttranslational regulation likely plays a role in the expression of functional SI protein along the intestinal crypt-villus axis, [85], [87] and in colon carcinoma cell lines that undergo partial enterocyte differentiation. [88] Experiments in transgenic mice suggest that the complex patterns of SI mRNA expression along the crypt-villus axis most likely result from events associated with transcriptional regulation of the gene. [64], [65] and [66] Many functional differences exist between the jejunum (proximal segment) and the ileum (distal segment) that reflect differences in the expression of different genes, or gradients of gene expression, along the proximal-distal axis of the intestine. For example, SI activity is four- to fivefold greater in the jejunum than in the ileum [87]; however, sucrase mRNA appears to be similar in the two regions. [64], [89] The pattern of glycosylation in the Golgi apparatus differs slightly between the two regions, but the resultant protein levels seem to be unaffected. [87], [89] The major difference in regulation of SI expression between the jejunum and ileum appears to be at the level of mRNA translation. [89]

Developmental regulation. SI has served as a model to examine developmental processes in the intestine because its expression mirrors many of the developmental transitions that occur in the establishment of the adult intestine. [66], [90], [91], [92] and [93] In the human small intestine, SI is expressed between weeks 8 and 14 of gestation, and high-level expression persists through birth and into adulthood. [90] The mechanism for the induction of SI in human small intestine appears to be at the level of mRNA. [90], [94] In rats, mice, and rabbits, the maturation of the small intestine is completed in the neonatal period. [91] At birth, SI enzymatic activity is not detectable, and dramatic induction occurs at the time of weaning. [95], [96] Evidence suggests that activation of the SI gene occurs in two stages. [66] SI mRNA is first detectable at low levels in the mouse fetus after the transition of the endoderm into a simple polarized epithelium. [66] Low levels of SI mRNA expression are maintained until the suckling-weaning transition that occurs in the third week of life, when a dramatic induction of SI mRNA and protein takes place. [66] Transgenic mouse experiments have shown that a short, evolutionarily conserved SI promoter [66] is sufficient to direct the induction of expression at the suckling-weaning transition. These data indicate that transcriptional regulation is responsible for the patterns of expression during development. Moreover, the two stages of SI mRNA expression suggest that epithelial cells can transcribe the SI gene late in fetal development, but missing factors come into play at weaning to allow full expression of the gene. The dramatic induction of SI in the rodent intestine appears to be a genetically programmed event, largely unaffected by the type of ingested food. [91], [92] and [93], [97] Stress in suckling pups or the administration of corticosteroids or thyroid hormone results in premature induction of SI before the normal time of weaning. [91], [92] and [93], [97] It appears that the normal induction of SI at the suckling-weaning transition and the precocious induction of SI by corticosteroids occur through separate molecular pathways. [66], [98] Studies in rodents have shown that differences in corticosteroid regimens significantly affect the response of SI in the developing intestine, [99] which may explain conflicting results obtained in human studies. SI expression in the colon of humans and rodents is transient. [100], [101] and [102] In humans, SI mRNA, protein, and enzymatic activity are found in the colon between weeks 12 and 28 of gestation, concurrent with the histological appearance of villus and crypt structures

resembling those of the small intestine. Expression of the SI gene and these histological features are subsequently lost after gestational week 28 and are absent in the newborn colon. [101] Although this matter remains controversial, [103], [104], [105], [106] and [107] results of studies using the reverse transcriptase-polymerase chain reaction suggest that SI mRNA is not expressed in adult colon. [105] Importantly, SI is expressed in neoplastic tissue from the colon, including adenomas and adenocarcinomas, [103], [104], [105] and [106], [108] which may represent a reversion to a fetal type of regulation of the SI gene. A similar pattern of developmental expression is found in the rodent colon, although the process occurs in the postnatal animal, as it does in small intestine maturation. [109]

Nutritional regulation. Changes in diet have a marked effect on the expression of SI. [87] Starvation leads to a rapid decline in brush border proteins and SI activity. [110], [111], [112], [113] and [114] This decline in SI activity is restored rapidly after refeeding. The type of ingested carbohydrate is important for the regulation of SI expression. Although both starch and sucrose induce SI activity, sucrose is a more potent inducer. [87], [115], [116], [117] and [118] The mechanism of induction of SI in rats appears to be at the level of mRNA. [115] There is evidence that feeding rats fructose, but not glucose, increases transcription of the SI gene and alters the binding of proteins to the promoter. [119] Study of the intestinal cell line Caco-2 has shown that a short promoter region of the human SI gene (nucleotides -370 to +30) can down-regulate SI transcription in the presence of glucose. [120] Although this effect may be related to the neoplastic origin of the cell line, it underscores the complex physiological regulation of SI gene transcription in response to glucose. There is also a circadian pattern to SI activity that is related to meal ingestion; the pattern can be shifted by altering the time of feeding. [87] The short-term regulation of the meal-related diurnal differences is not controlled by food intake, but the long-term regulation of this phenomenon is clearly related to feeding. [87] Research has also shown that glucagon-like peptide 2 can increase the expression of SI in the intact intestine. [121]

Pathophysiological regulation. The levels of SI and other saccharidases may decrease with infection and inflammation. [122] In some cases, a decline in enzyme activity leads to malabsorption of carbohydrates and symptoms of diarrhea, flatulence, and weight loss. In most disease processes, however, the diminished levels of SI are associated with global dysfunction of the small intestine mucosa with abnormal absorption of other nutrients, abnormal absorption of water, and abnormal electrolyte absorption and secretion. Cytokines may mediate the inflammation-related inhibition of SI expression in intestinal epithelial cells in vivo and in intestinal cell lines. [123] Experiments in cell lines suggest that interleukin-6 and interferon-? specifically inhibit SI gene expression. [123] Although most diseases produce a decline in SI activity, diabetes mellitus results in a striking up-regulation of SI activity. [87] This increased function of the small intestine mucosa is not limited to SI activity; monosaccharide transport, amino acid transport, and mucosal hypertrophy also are increased. [87], [124], [125], [126], [127], [128] and [129] The mechanism of SI induction in experimental diabetes in rats appears to be multifactorial. There may be changes in protein degradation, [126] an increase in SI mRNA, [87] and a greater number of SI-expressing cells along the crypt-villus axis. [130] The increase in the absorptive capacity of the small intestine for sugars may be of importance in the pathogenesis of complications associated with diabetes. Administration of acarbose, a drug that inhibits SI, decreases postprandial glucose levels and hemoglobin A_{1c} levels in experimental models of diabetes and in humans with diabetes. [131] Furthermore, diabetic rats given acarbose had less severe diabetic neuropathy than did control animals. [132]

Lactase–Phlorizin Hydrolase

One of the defining characteristics of mammals is that neonates are fed milk produced by their mothers. The major carbohydrate in milk is the disaccharide lactose, which is produced exclusively in the mammary glands by lactose synthase. Brush border lactase is the only enzyme that cleaves lactose into glucose and galactose and is therefore essential for mammalian survival early in life. Lactase has other enzymatic activities, including phlorizin hydrolase, glycosylceramidase, and ß-galactosidase activity. [133] It has been suggested that glycosylceramidase activity may play a role in the digestion of glycolipids. [133], [134]

Structure and Synthesis Lactase–phlorizin hydrolase (LPH) cDNAs and genes from a number of species have been cloned. The human LPH structural gene is about 55 kb long with 17 exons [135] and is located on the long arm of chromosome 2. [136] The human LPH cDNA encodes a single polypeptide chain containing 1972 amino acids. [137] Various lengths of the 5'-flanking regions of the human, [135] pig, [138] and rat [139], [140] LPH genes have been characterized. The LPH promoter is well conserved across species within the first 150 nucleotides from the start of transcription. [138] Nucleotides -1000 to -24 of the pig LPH gene [141] and nucleotides -2038 to -15 of the rat LPH gene [140] are able to direct transcription to the intestinal epithelium in transgenic mice. Studies in intestinal cell lines have identified functional DNA elements in the LPH promoter that interact with nuclear transcription factors. [138], [142], [143], [144], [145], [146] and [147] Both Cdx and HNF-1 proteins bind to promoter elements similar to the SI promoter element, [68], [142], [143], [145], [146] and it appears that these two proteins interact. [143] A single Cdx2 molecule binds to the LPH promoter, whereas the SI promoter binds two Cdx molecules at two closely linked sites. [142] Single Cdx-binding elements are also active regulatory units in the transcription of other intestinal gene promoters. [148] Members of the GATA-type zinc-finger transcription factor family have emerged as important activators of the LPH promoter [68], [145], [146] and appear to interact with HNF-1 in the transcriptional activation of LPH. [68] It is of great interest that transcription factors similar to those that regulate the SI gene promoter may also regulate the LPH gene despite very different patterns of regulation. Analysis of the primary amino acid sequence and multiple biochemical experiments using native LPH protein and cDNA-derived protein from transfected cells have provided a clear picture of the processing and structure of the mature enzyme. Although both LPH and SI are anchored to the apical membrane and have two active sites on the lumenal side of the membrane (Fig. 17-5), their structures differ markedly. The carboxyl-terminal end of the LPH polypeptide is embedded in the plasma membrane, leaving the amino-terminal end in the lumen. The 19 amino-terminal amino acids of the propeptide are cleaved in the ER, leaving the amino-terminal end of the molecule free in the interior of the ER. After synthesis of the polypeptide, the carboxyl-terminal end remains embedded in the membrane and serves as an anchor. This anchor consists of a cytoplasmic domain containing 26 amino acids and a membrane-spanning region containing 19 hydrophobic amino acids. [137] Correct folding of pro-LPH in the ER is dependent on intramolecular disulfide bonds. [149] The prepolypeptide has a fourfold symmetry, and the mature lactase has a twofold symmetry, suggesting that the two domains may harbor the active sites of the enzyme. [137] This is similar to the symmetry of the SI molecule, although the repeated units in LPH are not cleaved. The active sites in the mature protein have been identified: the lactase site at Glu1271 and the phlorizin hydrolyase site at Glu1747. [150]

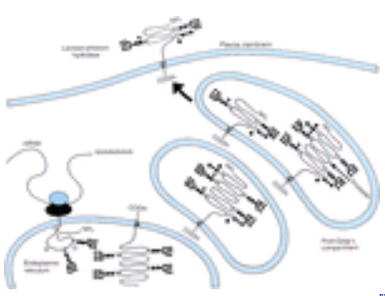

FIGURE 17-5. Synthesis and processing of human lactase–phlorizin hydrolase.

In humans, a single polypeptide precursor of about 210 kd is synthesized from a single mRNA (see Fig. 18-5). [151] The precursor is cotranslationally *N*-glycosylated in the ER and then transported to the Golgi apparatus, where some of the *N*-glycosylated groups are modified and *O*-glycosylation occurs, [151], [152] resulting in a 215-kd high-mannose form and a 225-kd complex glycosylated form of LPH. The glycosylation process is apparently not invariant because the final plasma membrane enzyme exists in two forms, one with *N*-glycosylation only and another with both *N*- and *O*-glycosylation. [152] The latter form is more active enzymatically. [152] The mature LPH enzyme in the brush border represents a cleavage product of the glycosylated precursor molecule. [47], [133], [152], [153] The first cleavage occurs intracellularly at a dibasic residue (Arg734-Leu735), resulting in a 160-kd intermediate form of LPH. [154], [155] The cleaved polypeptide is structurally similar to the mature enzyme, but it is devoid of enzymatic activity. [156] The human enzyme is cleaved before the appearance of the protein on the plasma membrane [151] in a post-Golgi compartment [157] after complex glycosylation. [152], [158] Proteolytic cleavage is not required for enzymatic activity in either polarized [159] or nonpolarized [160] cells, nor for proper sorting to the apical membrane. [159] The human LPH enzyme is cleaved at a second site by extracellular trypsin (Arg868-Ala869) after it is in the brush border membrane, to yield the mature 145-kd form. [154] In contrast to the cleavage of human LPH, that of rat LPH appears to occur on the plasma membrane in several steps. [133], [161], [162]

Regulation Regional differences in the expression of LPH occur along the vertical and horizontal axes of the intestine. In situ hybridization and immunohistochemistry of small intestine tissue from neonatal rats show a complex pattern of expression of LPH mRNA along the crypt-villus axis. [163] Prenatally, LPH mRNA and protein are expressed in all villus-associated enterocytes. [163] Immediately after birth, the LPH mRNA is restricted to enterocytes located at the base of villi, in a fashion similar to the pattern of expression of SI mRNA in the adult intestine. The protein, however, persists throughout all villus enterocytes, suggesting some posttranscriptional regulation of the maturation process. [163] The regulation along the horizontal intestinal axis is complex, involving pretranslational and translational regulation in the proximal and distal intestine. [164], [165] and [166] The developmental regulation of LPH has been studied extensively. [47], [93], [97], [133] In humans, LPH is expressed in fetal small intestine just after the onset of expression of SI. [90], [100] This expression is maintained throughout development and during childhood. LPH is expressed in the neonatal rat colon [101], [167] in the same manner as SI. At some time during childhood or adolescence, LPH activity declines to 5% to 10% of childhood levels in most populations worldwide. [47], [168] The age at which the enzyme disappears varies, depending on the heritage of the individual. Ingestion of milk or milk products by

persons with diminished LPH activity leads to flatulence, abdominal cramps, and diarrhea. [168] In selected human populations, such as those in northern Europe, where dairy cattle have been developed as a continuing source of milk products, intestinal LPH activity persists throughout adulthood. [47], [93], [97], [133] This phenotype is inherited as an autosomal recessive trait, and evidence of intermediate levels of LPH activity has been found in heterozygous persons. [47] Therefore, the aberrant allele in the human population is considered to be the one that leads to persistence of the enzyme, not the deficiency. Support is given to this concept by the fact that in nearly all other species of mammals, LPH activity is lost after weaning. [47], [93], [97], [133] Thus, LPH activity declines at the same time that SI activity increases in the small intestine. [47], [91], [92] The decline in LPH activity is hastened by pharmacological treatment with corticosteroids in parallel with the induction of SI. Hypolactasia in humans appears to involve transcriptional and posttranscriptional mechanisms. [166], [169], [170] and [171] The mechanisms involved in the postweaning decline of LPH activity in many animal species remain uncertain. The clinical syndrome and the mechanisms for hypolactasia are discussed in Chapter 77. LPH activity is sensitive to infectious and inflammatory diseases that affect the intestine. Therefore, after a bacterial, viral, or parasitic infection, residual symptoms resulting from the loss, and slow recovery, of LPH activity may occur. Infection with human immunodeficiency virus type 1 leads to decreased LPH activity and malabsorption of lactose. [172] In adults, LPH activity is resistant to the effects of starvation, [97] whereas in children, malnutrition causes a reduction in LPH mRNA. [173]

Maltase-Glucoamylase

Maltase-glucoamylase is a bifunctional enzyme that is responsible for the removal of glucose from the nonreducing end of short glucose polymers at a(1,4) bonds. [174] Both subunits of the enzyme appear to have the same substrate specificity and activity. The enzyme has low but measurable activity for hydrolysis of a(1,6) bonds. [175] Maltase-glucoamylase accounts for about 2% of the brush border protein and 20% of the total maltase activity in the small intestine. [93] Relatively little is known about the structure of the enzyme, although the human cDNA has been cloned. [176], [177] Much can be learned from a number of careful biochemical studies of enzymes isolated from the small intestine of rats, [76], [178] rabbits, [179] pigs, [175], [180], [181] and humans. [174], [182], [183]

Maltase-glucoamylase purified from human small intestine brush border membranes is a monomeric membrane protein of about 335 kd (others report 355 kd). [182], [183] The protein is synthesized as a polypeptide with a molecular weight of 255 kd, which is rapidly *N*-glycosylated to a 285-kd high-mannose form. [182] Further processing results in *N*-linked complex glycosylation and *O*-glycosylation, producing the mature enzyme. [182] The final sugar content of the molecule is about 30% of the total weight. [174], [182], [183] There is no evidence that proteolytic cleavage occurs intracellularly or extracellularly by pancreatic proteases. [182]

The characteristics of maltase-glucoamylase in other species differ markedly from those of the human enzyme. [175], [180], [181] The pig enzyme has a molecular weight of 240 kd. After insertion into the apical membrane, pancreatic proteases cleave the enzyme into smaller forms of 135 kd and 125 kd. [175], [181] The molecule is anchored to the membrane by an amino-terminal sequence and exists in the membrane as a homodimer. [180] The rat maltase-glucoamylase is synthesized as a polypeptide of 145 kd, which undergoes partial cleavage to yield two subunits with molecular weights of 130 and 145 kd. [72] The functional significance of these structural differences is unknown.

The developmental regulation of maltase-glucoamylase differs somewhat from that of SI and LPH. The enzyme is expressed at significant levels in the small intestine of suckling rats and mice, accounting for all the maltase activity at this developmental time because SI activity is not detectable. [93] At weaning, maltase-glucoamylase activity is induced to adult levels, but the increase in activity is less than that occurring with the induction of SI. [93], [184] Furthermore, pharmacological doses of corticosteroids before weaning lead to precocious induction of the enzyme, but the fold induction is less than that for SI. [93], [185], [186] Expression of maltase-glucoamylase in the human small intestine has not been investigated carefully during development, but the available data show that it is expressed early in development and that expression continues at similar levels after birth and into adulthood.

Trehalase

Trehalose is a disaccharide of glucose that is found in insects, yeast, and mushrooms. The mammalian intestine brush border contains small quantities of an enzyme that is able to hydrolyze this disaccharide. [187], [188] Although the total trehalase protein in the brush border amounts to only 0.1% of the total brush border proteins, it is important for the assimilation of foods that contain trehalose; for example, in persons who are trehalase deficient (as are 8% of Greenlanders), severe diarrhea develops after the ingestion of mushrooms. [187], [188], [189] and [190]

The cDNA for rabbit, human, rat, and mouse intestinal trehalase encodes a protein of 576 to 578 amino acids with a molecular weight of about 65.5 kd. [191], [192] and [193] There are four potential *N*-glycosylation sites in the rabbit cDNA, which may account for the higher molecular weight of the purified protein. [191] The rabbit cDNA encodes authentic trehalase by demonstrating enzymatic activity in frog oocytes injected with synthesized mRNA. [191] The protein is markedly different from the other brush border carbohydrases, because there is a cleaved signal peptide and the protein is fixed to the membrane by a glycosylphosphatidylinositol anchor. [191] It has no homology with other known proteins except for *Escherichia coli* trehalase, which shares 35% amino acid identity. [191] The mRNA for rabbit trehalase is distributed in a pattern commensurate with the expectations from previous studies of enzymatic activity. High levels of a 1.9-kb rabbit mRNA were measured in the small intestine and kidney, with low levels detected in the liver. [191] A 2.1-kb mouse mRNA was found only in the intestine and kidney. [192]

The developmental pattern of trehalase expression in the small intestine mirrors that of SI expression; levels in the human fetus and adult are similar, [93] whereas levels in rodents are very low during the suckling period, with marked induction at weaning. [93], [99], [184] Premature trehalase expression in rodent intestine can be induced with corticosteroids. [99], [184]

Integrated Function of Brush Border Enzymes

The membrane carbohydrases have individual activities for specific disaccharides. They also work to further hydrolyze the products of amylase hydrolysis, which include maltose, maltotriose, and a-limit dextrins. The generally accepted scheme for this process is shown in Figure 17-6. Maltase-glucoamylase has maximal activity for the removal of nonreducing sugars from oligosaccharides (i.e., linear and a-limit dextrins) that have between five and nine glucose molecules. [174] The sucrase and isomaltase subunits are also capable of metabolizing these oligosaccharides. [194] The a(1,6) bonds are resistant to hydrolysis until the adjacent nonreducing sugar is removed. Once the a(1,6) linkage is exposed, isomaltase is able to cleave this bond; glucoamylase also has minimal activity, but its role in completing this reaction is unknown. Hydrolysis of maltose can be accomplished by any of the carbohydrases, although the primary ones are sucrase and glucoamylase. This process yields monosaccharides that then can be absorbed across the epithelium.

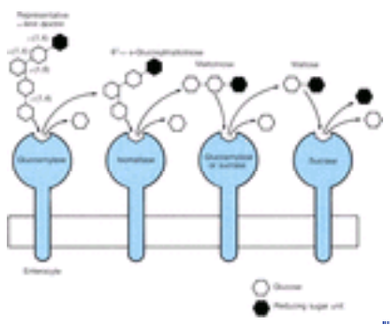

FIGURE 17-6. Overall process of digestion to monosaccharides. The hydrolysis of a-limit dextrins is a collaborative effort between multiple brush border enzymes.

ABSORPTION OF MONOSACCHARIDES

The only carbohydrates that can be absorbed across the epithelial cells of the small intestine mucosa are monosaccharides, or simple sugars. Digestion by

intralumenal and brush border processes is required to present simple sugars to the transport systems in the apical membrane of enterocytes. The transport processes involved in the absorption of monosaccharides across the enterocyte are passive or facilitated diffusion and Na^+-coupled active transport. The sugars that are normally presented to the enterocyte for absorption are glucose, galactose, and fructose. The mechanisms for the transport of each of these sugars has been elucidated, and this knowledge has led to a working molecular model for the absorption of each of these sugars (Fig. 17-7). As discussed in the following sections, these mechanisms and their relative contributions to absorption remain the subject of debate. [195]

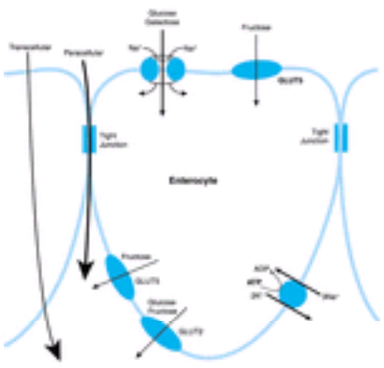

FIGURE 17-7. Transport processes responsible for movement of monosaccharides across intestinal epithelium in the enterocyte. Note that evidence suggests that GLUT2 may exist in the apical membrane when lumenal glucose levels are high (see refs. [195] and [228]).

Na^+-Coupled Glucose and Galactose Transport

The primary process for the active absorption of glucose and galactose is the active cotransport of Na^+ and sugar molecules across the apical membrane (see Fig. 7-7). [52], [196] Many studies of whole intestine mucosa, isolated enterocytes, and membrane vesicles isolated from the apical membrane fragments of the intestinal epithelium have shown that glucose and galactose are transported across the apical membrane in a Na^+-coupled electrogenic process. [52], [196], [197], [198] and [199] The active component of this system is dependent on a Na^+ gradient that is created and maintained by Na_+, K_+-ATPase (see section " Structure and Function of Na+,K+-ATPase in Enterocytes"). The concentration of solute in vitro at which the transport process is at half-maximum, or the enzyme's K_m for the transport of D-glucose, is between 0.2 and 0.5 mmol/L, and the K_m for the transport of extracellular Na^+ is between 2 and 7 mmol/L. [200] Transport studies suggest that there is a stoichiometry of 2 Na^+ for every hexose molecule. [198], [199] The transporter has been estimated to be about 75 kd in size and exists in the membrane as a homotetramer. [199], [201] These data led to a working molecular model of how the transporter may function (Fig. 17-8).

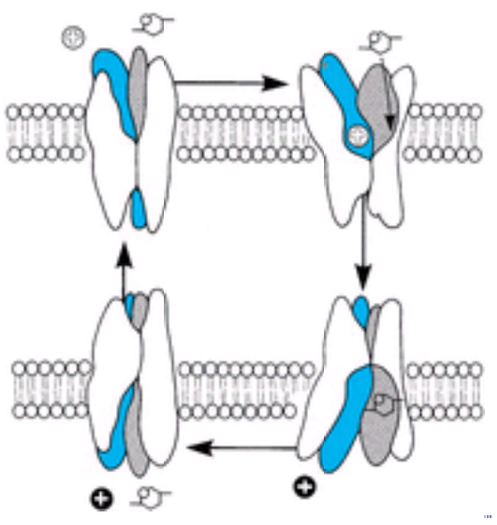

FIGURE 17-8. In the proposed mechanism for Na^+/glucose cotransport across the apical membrane, the transporter complex is likely to be a tetramer. (From Wright EM, Turk E, Zabel B, et al. Molecular genetics of intestinal glucose in transport. J Clin Invest 1991;88:1435.)

Knowledge of the molecular mechanism of this transporter advanced rapidly after cloning of the cDNA encoding the rabbit intestine Na^+/glucose cotransporter SGLT1. [202] The cloned cDNA encodes transport activity with the same relative specificity as the previously characterized native transport system D-glucose > a-methyl-D-glucose > D-galactose > 3- *O*-methyl-D-glucopyranose > > > L-glucose. [202], [203] Furthermore, the transport process in oocytes expressing the protein was found to be electrogenic, [204], [205] like transport of the native protein in the small intestine. The cDNA encodes a protein of 662 amino acids with a predicted molecular weight that correlates well with the biochemically defined size. Computer-aided analysis and biochemical studies have provided a model of the membrane topology of SGLT1 and other cotransporters in this gene family. SGLT1 is predicted to have 14 membrane-spanning domains, with one asparagine-linked carbohydrate group on the third extracytoplasmic loop. [206], [207] and [208]

The importance of the cloned transporter and proof that it is the major, if not the only, Na^+/glucose cotransporter in the intestine was shown in studies of two siblings with hereditary glucose galactose malabsorption, a rare autosomal recessive disease. [209] These two sisters had severe diarrhea in the first days of life that resolved with the elimination of glucose and galactose from the diet. A point mutation was identified in the genomic DNA of both sisters that resulted in a change of amino acid residue 28 from an aspartate to an asparagine. [209] Analysis of DNA from the parents proved that they were heterozygous for the mutation. The mutant mRNA was tested in *Xenopus* oocytes and was found to be nonfunctional for D-glucose transport. The mutant protein was synthesized and processed normally but was nonfunctional. [209] Since the description of the mutation in these two sisters, a variety of mutations in the coding region of the SGLT1 gene have been identified, many of which lead to the expression of proteins that are dysfunctional because of cellular trafficking abnormalities. [52], [210], [211], [212], [213] and [214]

The identification of the cDNA encoding SGLT1 led to additional biochemical analysis of the synthesis and transport properties of this Na^+/glucose cotransporter protein. [215] Inhibition of *N*-glycosylation in mammalian cells transfected with the cDNA decreased glucose transport activity by 80%, suggesting that this posttranslational modification is important for expression of the protein or for protein activity. [215] In vitro analysis of glycosylation showed that of the two potential *N*-glycosylation sites, only aspartate, [248] which resides on the external side of the membrane, is glycosylated. [216] Mutation of this aspartate to a glycine eliminated glycosylation of the protein; however, only a minimal decrease in activity occurred in *Xenopus* oocytes. [216] Glycosylation studies of the native protein suggested that a single *N*-linked residue was glycosylated and that partial deglycosylation did not affect the function of the transporter. [217] These data suggest that a single residue is *N*-glycosylated in the ER followed by modification in the Golgi apparatus. The protein does not require glycosylation for function, but glycosylation may be required for proper processing of the protein in mammalian cells. [215]

The expression and activity of glucose transport in the intestinal brush border are regulated by both short-term and longer-term processes. In the short term, activity of glucose transport is increased by both protein kinase A– and protein kinase C–dependent processes. [200] The mechanism of this enhanced activity is an increase in the number of membrane transporters, mediated by changes in exocytosis and endocytosis of membrane vesicles that contain the transport protein. [200] Study of the

transcriptional regulation of the SGLT1 gene in cell lines has shown involvement of HNF-1 and Sp1 proteins. [218] Longer-term regulation of glucose transport is mediated by changes in the expression of SGLT, which is controlled by changes in nutrient intake. [219], [220] and [221] Nutrient transport in the healthy intestine and in various disease states has been reviewed in the literature. [222], [223]

Facilitative Monosaccharide Transport

D-Glucose that is absorbed across the apical membrane crosses the basolateral membrane as the last step in intestinal absorption by a process of facilitative diffusion (not requiring energy) (see Fig. 17-7). [224] Because glucose is required by every cell in the body, facilitative glucose diffusion is a ubiquitous property of mammalian cells; however, different transport properties and regulatory characteristics are required by different cells. To meet these different requirements, there exists a family of genes (GLUT) that encode facilitative sugar transport proteins. [225], [226], [227], [228] and [229] The GLUT family of genes, their transport properties, and their tissue distributions are outlined in Table 17-4. The two genes that are expressed in the small intestine are GLUT2, the basolateral membrane–associated glucose transporter, and GLUT5, an apical membrane fructose transporter.

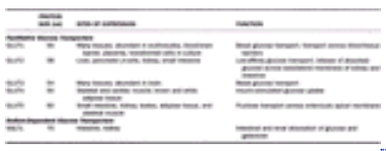

TABLE 17-4 Glucose Transporters

GLUT2 has molecular structural characteristics similar to those of the other members of this family of transporters. [225], [226] and [227] The protein has 500 amino acids with many hydrophobic residues that predict a total of 12 membrane-spanning domains (Fig. 17-9). There is a one long extracellular loop between membrane-spanning domains 1 and 2 that contains an asparagine that is *N*-glycosylated and one long cytoplasmic loop between membrane-spanning domains 6 and 7; the remainder of the connecting sequences for the membrane-spanning domains are short. The association of GLUT molecules has been investigated for several of the genes. GLUT1 appears to be a dimer, whereas GLUT4 appears to exist as a monomer. [225], [226] and [227] It has not been determined whether GLUT2 exists in the membrane as a monomer or as a multimer.

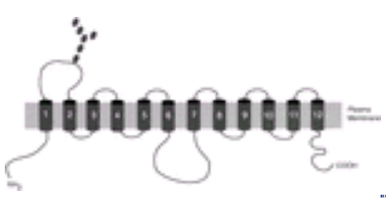

FIGURE 17-9. GLUT2 basolateral glucose transporter. This model of the monomer is suggested by the primary amino acid sequence. (From ref. [225].)

The transport properties of the GLUT2 protein have been studied by expressing it in *Xenopus* oocytes. [225], [226] and [227] The transporter has a high K_m for glucose (17 mmol/L) and is responsible for transport in the liver, kidney, and pancreatic ß-cell, as well as in the intestine. [225], [226] and [227] Therefore, the transporter has a high-level capacity for glucose transport. Evidence suggests that this protein also can transport fructose. The GLUT2 transporter protein is expressed on the basolateral membrane of enterocytes and renal tubular cells. [227] There is evidence that GLUT2 may also reside in the apical membrane and contribute to the facilitated diffusion of glucose, and that this process is regulated by a protein kinase C–dependent pathway. [195], [228]

Fructose Transport and Absorption

Studies in both humans and other animals have shown that there is a saturable, facilitative transport system for fructose in the intestinal epithelium that is less active than the transport system for glucose and galactose. [2], [230] Despite this lower level of activity, the fructose transport capacity of the entire small intestine mucosa is estimated to be large. [2] In vivo studies in humans, however, have shown that most individuals have a capacity for the absorption of fructose that is much more limited than the estimated value. [2] In these studies, hydrogen breath tests have been used to determine the threshold for malabsorption of fructose in test subjects.

The protein responsible for most apical membrane fructose transport is a member of the facilitative monosaccharide transporter family called *GLUT5*. Human [231] and rat [232] cDNAs have a similar predicted amino acid primary sequence: a protein of 502 amino acids with a molecular weight of 55.51 kd in the rat [232] and a protein of 501 amino acids in humans. [231] Analysis of this amino acid sequence suggests that there are 12 membrane-spanning domains, as for the other GLUT molecules. There is also one potential *N*-linked glycosylation site that is predicted to be located on an extracellular loop of protein.

Despite the similar structural characteristics of human and rat GLUT5 molecules, evidence of functional differences was revealed after assessment of GLUT5 in a *Xenopus* oocyte expression system. Human GLUT5 transports fructose and is specifically inhibited by excess fructose but not by glucose. [231] In contrast, the transport of fructose by rat GLUT5 is inhibited by both fructose and glucose, and furthermore, rat GLUT5 is able to transport 2-deoxyglucose. [232] These data suggest that GLUT5 in the rat facilitates the transport of both glucose and fructose, whereas human GLUT5 transports fructose exclusively. The functional significance of these findings requires assessment in the whole animal.

The tissue distribution of GLUT5 also differs between rats and humans. Human GLUT5 mRNA and protein are expressed in the small intestine, kidney, testes, adipose tissue, and skeletal muscle. [233] Rat GLUT5 mRNA is expressed in the small intestine, kidney, and, at lower levels, in the brain, but it is not expressed in adipose tissue, testes, or skeletal muscle. [232]

Little fructose is metabolized in the enterocyte. [2] Fructose is transported across the basolateral membrane and is taken up and metabolized rapidly by the liver, resulting in low postabsorptive blood levels of fructose. [2] Some in vivo experiments in human subjects have raised the question of whether more than one type of fructose transport process exists. [2] These experiments show that malabsorption of fructose in humans can be prevented by the simultaneous administration of glucose. [2] Although there are possible mechanisms by which a single fructose transport process can yield these results, it has been argued that another glucose-responsive system may be present in enterocytes. Fructose likely is transported across the basolateral membrane by GLUT2, [229], [234] and evidence of GLUT5 expression on the basolateral membrane suggests that it too may be a fructose transporter. [235] It is also possible that GLUT2 on the apical membrane transports fructose. [195], [228]

Expression of the GLUT5 protein is regulated by the presence of its substrate. [221] If experimental animals are fed fructose, the expression of GLUT5 mRNA and protein increases an induction process that requires fructose to be in contact with the brush border membrane. [221] Precocious expression of GLUT5 in suckling animals is also induced by lumenal fructose. [236]

Structure and Function of Na^+,K^+-ATPase in Enterocytes

Na^+,K^+-ATPase is found in the membrane of nearly every cell in the animal kingdom and is essential for cell viability. [237] This integral membrane protein uses ATP

energy to transport 3 Na^+ out of the cell and 2 K^+ into the cell, thus maintaining an ionic and electrochemical gradient between the intracellular and extracellular space. Na^+, K^+-ATPase, localized on the basolateral surface of the enterocyte, functions in the absorption of monosaccharides by maintaining low intracellular Na^+ concentrations, thereby providing a large gradient for transport from the intestinal lumen across the apical membrane.

Na^+,K^+-ATPase comprises two proteins: the a and ßsubunits. [237], [238] The a subunit, also called the *catalytic subunit,* is 112 kd in size and contains the binding sites for ATP and cardiac glycosides. The 35-kd ß subunit is required for activity, but its specific function has not been established. Isozymes of the a and ß subunits have a complex pattern of tissue distribution. [238], [239] and [240] The significance of the differential expression of the subunits in various tissues has been evaluated, [240] but the implications for intestinal epithelial function are unknown.

Passive Movement across the Epithelium

Intestinal absorption of glucose continues in a linear fashion when glucose levels exceed those that saturate the Na^+/glucose cotransport system. [195] Therefore, other mechanisms for glucose transport across the enterocyte are thought to exist. Two potential mechanisms for the passive movement of monosaccharides across the intestinal epithelium are paracellular and transcellular pathways (see Chapter 8).

The paracellular pathway allows water and solutes to pass between epithelial cells and has been used to explain the absorption of glucose at high lumenal levels that oversaturate the SGLT1 system. The zona occludens forms a high-resistance seal between epithelial cells, the tightness of which can be altered by physiological processes. [241] One cellular mechanism for altering this intercellular seal may be the contraction of the cellular cytoskeleton that is connected to the zona occludens apparatus, which results in separation of the cells at the tight junction. [241] A trigger for this altered junction permeability is apical membrane Na^+-coupled glucose transport. [241] Therefore, it has been hypothesized that the absorption of glucose may lead to an increase in paracellular permeability and the movement of water and solutes by the paracellular route. [241] At times of high intralumenal glucose concentration, this transport mechanism may be significant.

Passive diffusion of monosaccharides across the apical membrane of the enterocyte (i.e., a transcellular pathway) is very inefficient because sugars are water-soluble molecules that are efficiently excluded by lipid bilayers. Diffusion would be enhanced if there were a facilitated transporter, as there is for the basolateral membrane. As mentioned previously, GLUT2 may be inserted into the apical membrane via a regulated trafficking pathway. [228] This would lead to facilitated diffusion of glucose across the apical membrane, and because GLUT2 is a high-capacity transporter, this could account for linear increases in glucose transport exceeding the capacity of the SGLT1 system.

The contribution of the paracellular pathway versus facilitated diffusion remains controversial. However, it is likely that one or the other predominates because the presence of a facilitative transport protein in the apical membrane would dissipate the glucose gradient that is hypothesized to drive the paracellular movement.

Water Movement Accompanying the Transport of Sugars

Water crosses the intestinal epithelial cell layer as monosaccharides are transported across the cell; this is the rationale for adding glucose to oral rehydration solutions. The mechanism by which water crosses the epithelial cell layer is poorly defined. One hypothesis is that the driving force for water movement is a localized, intracellular osmotic gradient created by the active transport of monosaccharide molecules across the membrane. This mechanism probably is not the major mechanism, however, because the basolateral and brush border membranes of enterocytes are relatively impermeable to water. In some epithelial tissues, such as the renal collecting ducts, specialized transmembrane proteins called *aquaporins* transport water. [242], [243] Aquaporins have not been identified definitively in the intestine, however. Another widely held hypothesis is that most water movement in the intestine occurs by the paracellular route. Because the intestinal epithelium is semipermeable, the tight junctions can act as size-selective pores, allowing the passage of small molecules for which there are no specific transporters, including water. As discussed previously, the paracellular pathway of water movement may be regulated by changes in the epithelial cells. The driving force for this process is also assumed to be osmotic gradients across the epithelial junctions as well as bulk flow.

Wright and colleagues [244], [245], [246] and [247] introduced a revolutionary concept for intestinal water transport. Experiments in *Xenopus* oocytes have shown that SGLT acts as a low-capacity water channel in the absence of glucose. When glucose and Na^+ are present in the extracellular medium, SGLT can cotransport 264 water molecules for every 2 Na^+ and every 1 molecule of glucose. The capacity of this water-transporting system in a human who ingests an average carbohydrate diet is estimated to be 5 L of water per day. Transporters of other molecules, including amino acids, may also use this mechanism of water transport. Interestingly, GLUT2 may also transport water, which would allow apically located GLUT2 to facilitate the movement of water molecules across the apical membrane. [195] Quantitative in vivo experiments will be required to assess the relative contribution of this type of water transport associated with monosaccharide transport and that of paracellular water movement.

SPATIAL LOCALIZATION OF HYDROLYSIS AND TRANSPORT ALONG THE CRYPT-VILLUS AXIS

In a consideration of physiological processes, it is important to recognize that the intestine is lined with a complex epithelium in which each enterocyte does not have the same phenotypic characteristics. The epithelial cells of the small intestine are generated from a fixed stem cell population that has been localized to the lower portion of intestinal crypts. [83], [248], [249] and [250] These stem cells give rise to four primary epithelial cell types that reside in the intestinal mucosa: absorptive enterocytes, goblet cells, enteroendocrine cells, and Paneth cells. [249], [250], [251] and [252] Precursors of absorptive enterocytes in the crypts constitute about 90% of the cells in the crypt compartment, and mature absorptive enterocytes constitute more than 95% of cells located on the intestinal villus. [252] The other three primary phenotypes make up a small, but important, percentage of the total number of cells. Absorptive enterocytes migrate from the crypt compartment to the intestinal villus and are extruded into the intestinal lumen from the villus tip. The migration of cells occurs in a linear fashion, with cells moving vertically from their site of origin in the crypts. [253], [254] and [255] This process occurs over about 3 days in mice and over 4 to 5 days in humans. [248] Therefore, the epithelial lining of the mucosa is renewed continually at a relatively rapid rate.

The phenotype of enterocytes changes as cells move from the undifferentiated crypt compartment to the villus. Changes in phenotype are mediated by the expression or repression of sets of genes. The pattern of expression along the crypt-villus axis for multiple genes involved in carbohydrate assimilation has been determined. These data provide information that indicates where sugar absorption occurs. As discussed previously, a number of investigators have examined the pattern of expression of SI mRNA, protein, and activity along the crypt-villus axis. These studies suggest that there is little SI in crypts and that SI levels are maximal in the mid villus region. LPH gene expression in rodents is remarkably similar to that of SI. [163] In the small intestine of adults who have hypolactasia, LPH protein expression is patchy. [256] GLUT5 mRNA expression along the crypt-villus axis is nearly identical to that of SI mRNA, an intriguing finding inasmuch as GLUT5 transports fructose, one of the major products of SI enzymatic action. [232], [257] The pattern of SGLT mRNA expression in the crypts and lower villus region is the same as that of SI and GLUT5, but in the villus tip cells, expression is maintained at high levels. [257] GLUT2 expression is limited to the basolateral membrane of mature villus enterocytes. [258]

The components of the brush border carbohydrate assimilation system appear to be expressed in a coordinate pattern, suggesting that similar regulatory mechanisms may be involved in directing their expression. The enterocytes located in crypts probably do not normally function in carbohydrate assimilation; however, the expression of proteins involved in sugar assimilation may be expressed earlier along the crypt-villus axis in certain pathological conditions, such as diabetes mellitus. [130] This is an important level of regulation in addition to the level of expression in individual enterocytes.

EFFICIENCY AND RATE-LIMITING STEPS OF CARBOHYDRATE ASSIMILATION

The molecular mechanisms for the biochemical processes involved in carbohydrate absorption are being established, as indicated in the preceding sections; however, the integration of this information for an understanding of the absorption of real food in humans has lagged behind the basic scientific discoveries. Therefore, some controversy, as well as misleading statements, can be found in the literature. In simplistic terms, the efficiency of starch absorption can be related to two factors: the availability of food starch for intralumenal hydrolysis and the activity of the brush border enzymes and transport processes for absorption. A meal of soluble starch is assumed to be completely available for hydrolysis; therefore, the efficiency of absorption is dependent only on the brush border hydrolases and monosaccharide transport processes. Under these conditions, the traditional view has been that D-glucose transport at the apical membrane is the rate-limiting step. In reality, however, all ingested starch is not completely available for lumenal hydrolysis. Therefore, the rate-limiting step may be viewed as being dependent on properties of

the food itself.

A certain portion of starch is not digested or absorbed in the small intestine. [259], [260], [261], [262] and [263] In fact, a small degree of starch malabsorption should be considered a normal physiological phenomenon. [262] The quantity of starch malabsorption after ingestion of a variety of foods has been tested by ileal intubation, [260], [261] in patients with an ileostomy, [263] and by hydrogen breath tests. [259], [261] These experiments indicate that the passage of carbohydrate into the colon is common for many food types. The degree of malabsorption of ingested starch in healthy volunteers ranges from 2% to 20%. [260] The types of compounds that are complexed with starch, as well as the degree of food processing, appear to affect hydrolysis. [259], [264], [265] Sucrose also is partially malabsorbed in otherwise healthy persons, [266] as is lactose in subjects with normal LPH levels. [262] Therefore, the accessibility or contact time of disaccharides to brush border enzymes also may be a limiting factor.

Starch and oligosaccharides that reach the colon cannot be absorbed in the absence of bacteria. [266] Carbohydrates in the colon are metabolized rapidly by the colonic bacterial flora to short-chain fatty acids, including acetic, butyric, and propionic acids, which are absorbed rapidly by the colonic mucosa. [266], [267] and [268] These short-chain fatty acids serve as a primary fuel for colonocytes. [17] The energy derived from the metabolism of carbohydrates in the human colon is as high as 5% to 10% of total energy requirements. [267] Research has been directed at determining whether short-chain fatty acids provide a beneficial fuel during intestinal inflammation. [16], [269], [270]

Another gauge of the availability of starch from different sources is the glycemic index. [271], [272] This index is calculated by measuring the area under the serum glucose curve for 2 hours after a meal and comparing it with the area obtained for a reference food (e.g., glucose, white bread) set at 100%. This index does not assess the completeness of absorption of the available glucose; rather, it measures how rapidly the glucose is absorbed. When this method is used, different foods containing the same amount of total glucose demonstrate a wide range of glycemic indices (Table 17-5). It is difficult to predict what the glycemic index will be for a particular food. Furthermore, the difference between simple and complex carbohydrates is not straightforward because some complex forms (e.g., potato) have higher indices than simple sugars (e.g., sucrose; see Table 17-5). [271] This measure has been found to be useful in the treatment of diabetes mellitus.

FOOD	GLYCEMIC INDEX* (%)
Percentage of response to glucose	
Glucose	100
Corn flakes	80
Rice	72
White bread	69
Corn	59
Oatmeal	49
Kidney beans	29
Percentage of response to white bread	
White bread	100
Whole grain rye	58
Whole meal wheat	99
Rice	83
Spaghetti	66
Potato (russett, baked)	135
Potato (sweet)	70
Apple	53
Banana	79
Pear	47
Raisins	93
Fructose	30
Glucose	138
Honey	126
Maltose	152
Sucrose	86
Whole milk	49
Ice cream	52
Yogurt	52

*Area under 2-hour glucose curve.

TABLE 17-5 Glycemic Index of Selected Foods

According to traditional theories, the absorption of oligosaccharides, including both starch hydrolysate and disaccharides, is dependent on brush border hydrolytic enzyme systems and monosaccharide transport. Sucrose, maltose, maltotriose, and a-limit dextrins are hydrolyzed completely to their component monosaccharides, and the rate-limiting step for absorption is transport of the monosaccharides across the apical membrane. In contrast, the rate-limiting step in the absorption of lactose is hydrolysis by LPH. In vitro studies have questioned these time-honored concepts. The transport of glucose polymer–derived glucose was investigated in rabbit jejunal mucosa by measuring unidirectional glucose flux in the presence and absence of various enzyme inhibitors. [273] The findings suggest that brush border hydrolysis may be the limiting factor in the absorption of glucose polymer–derived glucose. [273] Furthermore, studies in humans have shown that 2% to 4% of ingested sucrose may enter the colon [266]; the level at which sucrose malabsorption occurs is unclear.

One important physical aspect of the lumenal content–enterocyte interface is the unstirred water layer. [274], [275] and [276] This layer is a stationary region of the lumenal fluid that is in contact with the mucosal surface of the intestine. Transport of solute molecules across this region of lumenal fluid occurs by simple diffusion based on concentration gradients. The thickness of this layer has been estimated by using a number of experimental methods. [274], [275] A practical assessment of these data suggests that the thickness of this layer in vivo has been grossly overestimated, and that the contribution of the unstirred water layer to the resistance to oligosaccharide and monosaccharide absorption is much less than previously reported. [276] The thickness of the unstirred water layer may increase in disease states (e.g., celiac sprue) and thereby contribute to malabsorption. [277]

CHAPTER 18

Nicholas O. Davidson

INTESTINAL LIPID ABSORPTION

Dietary lipid represents a major caloric source in most Western cultures. In addition to the 120 to 150 g of lipid consumed each day, the small intestine processes 40 to 50 g of biliary lipid, together with small amounts of lipid contributed by sloughed mucosal cells and bacteria. Tremendous advances have been made in understanding how this process is efficiently coordinated, and the widespread attention given the issues of diet and cardiovascular health has renewed investigation of the role of the small intestine as an active participant in systemic lipoprotein metabolism.

INTESTINAL LIPID BALANCE

The major form of dietary lipid consumed each day is long-chain (>14 carbon atoms) triglyceride, combined with smaller amounts (=10 g/d) of the phospholipid lecithin. The predominant sources of intralumenal lecithin arise from biliary secretion (10–20 g/d) and membrane phospholipid from desquamated intestinal cells. Most Americans consume 200 to 500 mg of cholesterol daily, which, in conjunction with large fluxes of biliary cholesterol (1–2 g/d), constitutes a major source of the body's daily metabolic requirements for this sterol. Plant sterols, principally ß-sitosterol, and shellfish sterols may be substantial dietary lipid components. Each person daily ingests other complex lipids, such as waxes, lipovitamins (i.e., A, D, E, K), lipid-soluble by-products of commercial food processing, and hydrophobic xenobiotics, including potentially toxic insecticides and preservatives. Absorption of intestinal lipids is highly efficient (>95% coefficient of absorption for triglyceride, <5% for ß-sitosterol), and the underlying physiological parameters regulating uptake, intracellular processing, and secretion are distinctive.

INTRALUMENAL LIPID DIGESTION

Intestinal lipid digestion is a complex, multistep process, depending first on the effective dispersion of fat into a stable form with a large surface area. This process is called *emulsification*. Second, several lipolytic enzymes become sequentially adsorbed to this emulsion and, under appropriate conditions, mediate the digestion of long-chain triglyceride, phospholipid, and sterol ester bonds, a process called *lipolysis*. Lipolysis also involves important phase transitions; the controlled, sequential evolution of lipolysis is integral to the successful completion of digestion and solubilization of lipid. These lipolytic products subsequently undergo incorporation into aggregated mixtures of bile salts and biliary lecithin for delivery to the microvillus membrane of the villus cell. This step is called *micellar uptake*, a process that necessitates traversing the aqueous milieu of the small bowel lumen. The physical and apparent barriers limiting this process are considered in subsequent sections.

Intragastric Events

Lipid digestion begins in the stomach with the initiation of emulsification. The interaction of triglyceride droplets with dietary and other intralumenal sources of lecithin is a key step in providing stability to the crude lipid emulsion resulting from the shearing action of gastric peristalsis. Proteolytic fragments resulting from peptic digestion also stabilize the emulsion.

The properties of such emulsions have been characterized in vivo and in vitro by using phase equilibria and magnetic resonance spectroscopy with carbon 13. [1,2] Studies of the initial properties of a model emulsion consisting of triglyceride, phospholipid, cholesterol, and water predict a surface layer of lecithin consisting of about 3% triglyceride by weight and small amounts of cholesterol. [1] Most of the triglyceride is sequestered within the core of this emulsion and exists as a homogeneous oil phase. In this conformation, limited quantities of surface triglyceride are accessible for lipase digestion. The rapid exchange that occurs between core and surface triglyceride molecules continuously exposes new substrate to lipase, facilitating the efficient initiation of lipid digestion.

Intragastric lipolysis is of substantial quantitative importance in humans and experimental animals. Lipase activity has been demonstrated in the gastric contents of neonates born prematurely as early as 26 weeks of gestation and in mucosal biopsy specimens from adults up to 80 years of age, although enzyme activity decreases in persons older than 60 years. [3,4] Estimates based on studies in ruminants and extrapolated to data for humans suggest that normal intragastric lipolysis may account for 20% to 30% of total intralumenal lipid digestion. [4,5] A relative or absolute decrease in pancreatic lipase secretion may increase the percentage contribution of intragastric lipid digestion to more than 90%.

Earlier evidence suggested that two distinct lipases were detectable in human gastric contents: lingual lipase and a gastric lipase principally of fundic origin. [4,5] and [6] Although rodents may have more than one source of gastric lipase activity, this is unlikely to be the case in humans. In one study, the lipase activity was measured in tissue supernatants from numerous regions of the human tongue (including Ebner glands), the pharynx, and the upper gastrointestinal tract. Virtually all the lipase activity was found in the gastric fundus, with less than 0.015% of the total activity attributable to a lingual source. [4] More recent studies [7] have evaluated the specific activity of lipases from gastric content in comparison to the recombinant proteins, finding that although the absolute activity is lower than predicted from in vitro studies, total lipase activity is accounted for by secretion of gastric lipase without the need to invoke an alternative source.

Intragastric lipolysis differs in several important respects from lipolysis in the small intestine. Based on assay of human gastric contents and biopsy of gastric fundic cells, preduodenal lipase activity displays a broad pH range with an optimum of about 4.0 to 5.5 and preferential activity against the 3-position long-chain fatty acid ester bond of triglyceride. [3,4] and [5,8] The major gastric lipolytic products are diglyceride and fatty acid. Activity of the purified enzyme in vitro is inhibited in the presence of bile salts, and a similar effect is observed after bile salts are added to human gastric aspirates, particularly in concentrations greater than 5 mmol/L. [3,8] This suggests that intragastric lipolysis is sensitive to interfacial denaturation, although at the bile salt concentrations typically encountered in neonates (i.e., 1–2.0 mmol/L), in whom intragastric lipolysis may be particularly important, little inhibitory effect is predicted. [3] In addition to its low pH optimum and inactivation by bile salts,

preduodenal lipase is resistant to pepsin and requires no cofactors. [9] At neutral to alkaline pH and in the presence of bile salts, preduodenal lipase is rapidly and extensively degraded by pancreatic proteases, so that it unlikely that it would function effectively in the upper small intestine under normal circumstances. [10] Crystal structure analysis of recombinant human gastric lipase has confirmed these predictions. [11]

In the stomach, crude dietary lipid undergoes emulsification and initiation of lipolysis. This contribution to lipid digestion may assume particular importance in neonates, in whom preduodenal lipase secretion can compensate for a developmental deficiency in pancreatic lipase secretion, resulting in intragastric lipolysis of 60% to 70% of dietary triglyceride. [12] Similarly, triglyceride absorption is maintained at about 50% in children with a congenital absence of pancreatic lipase. [13], [14] Patients with cystic fibrosis and exocrine pancreatic insufficiency typically exhibit various degrees of steatorrhea. [15] In one study, preduodenal lipase activity in five such patients accounted for more than 90% of the total lipase activity measurable at the ligament of Treitz. [15] A notable contributor to the apparent preservation of preduodenal lipase activity in these patients was the low postprandial intralumenal pH of about 4.0 to 5.0, presumably reflecting decreased bicarbonate secretion, which would permit continued lipolysis by gastric, but not pancreatic, lipase. [15] Gastric lipase activity also may play a role after total gastrectomy, when fat malabsorption is not uncommon. [16] At a pH of 5.0 to 6.0, essentially all the liberated fatty acids remain protonated and, with diglyceride, are dissolved in the oil phase of the triglyceride emulsion. This emulsion, containing partially digested triglyceride and its lipolytic products, enters the small intestine, where most intralumenal fat digestion takes place.

Small Intestine Events

Several key events governed by the physicochemical environment of the upper small intestine act in concert to augment the rate and extent of lumenal lipolysis. First, at the duodenal pH of 6.0 to 7.5, the fatty acids released by intragastric lipolysis become ionized. They migrate to the surface of the emulsion, where, as charged particles, they assist in emulsification and help anchor colipase to the triglyceride emulsion. [1] This is an essential step in initiating pancreatic lipase digestion. Second, various hormonal stimuli induce gallbladder contraction, resulting in the entrance of bile into the duodenum. The combination of alkaline pH, adequate Ca^{2+}, bile salts, and lecithin in the presence of lipolytic enzymes initiates a dynamic and dramatic cascade of events.

Lipolytic enzymes encounter the triglyceride emulsion resulting from the gastric processing of ingested fats, and in the presence of appropriate cofactors, ionic conditions, and pH, they accelerate intralumenal lipolysis. [13], [14] and [15], [17], [18], [19], [20], [21], [22], [23], [24], [25], [26], [27], [28], [29], [30], [31], [32], [33], [34], [35], [36], [37], [38], [39], [40] and [41] Pancreatic lipase and colipase are secreted from acini in equimolar amounts. Effective activation of pancreatic lipase requires several interdependent steps. After bile salts clear the lipid emulsion from adsorbed protein, the colipase-lipase enzyme complex attaches to the triglyceride emulsion—colipase physically anchors lipase in an appropriate configuration to expose its active site. To achieve this anchor, colipase binds directly to the triglyceride emulsion and indirectly to the bile salts through micelle formation. The bile salts then bind to the emulsion surface. These interactions are augmented by the presence of ionized fatty acids. [18], [21], [22], [26], [39] Pancreatic lipase activity in vitro is inhibited by bile salts and phospholipid through desorption of surface protein (including lipase) from the lipid emulsion. This inhibitory process is specifically reversed by colipase.

Colipase-dependent anchoring of lipase to the lipid emulsion is further enhanced by phospholipase A_2 digestion of the phospholipid on the surface of the lipid emulsion, allowing exposure of the triglyceride core to the colipase-lipase complex. Phospholipase A_2 digestion requires bile salts and Ca^{2+} for activation, which may further assist colipase-lipase–mediated triglyceride lipolysis by providing a mechanism for removal of the lipolytic products. As previously described, dietary and biliary phospholipids play an important role in stabilizing the crude triglyceride emulsion. The major intralumenal phospholipid is phosphatidylcholine (i.e., lecithin), which is unabsorbable intact and requires hydrolysis by phospholipase A_2 to yield a mole of fatty acid and a mole of lysolecithin per mole of substrate. Lysolecithin has a high aqueous solubility and undergoes rapid diffusion and uptake. The newly generated long-chain fatty acids undergo micellar solubilization and participate in lipolytic product phase formation.

Sterol and lipovitamin esters are largely sequestered within the oily core of the triglyceride emulsion and undergo hydrolysis of their fatty acid ester bonds through the actions of cholesterol esterase. [36], [37] Bile salts are an obligatory component of this reaction, serving as an essential enzyme cofactor and as a vehicle for effective solubilization of the extremely hydrophobic sterol and lipovitamin alcohols.

The dynamic aspects of intralumenal fat digestion have been elucidated in a series of elegant in vitro and in vivo studies. With the use of mixtures of triglyceride, pancreatic lipase, colipase, and bile salts in a buffered solution at duodenal pH of about 6.5, researchers have demonstrated the existence of at least two sequential product phases of triglyceride lipolysis, as visualized by light microscopy. [42] The initial products were contained within a lamellar liquid crystalline phase composed of a shell of birefringent calcium soaps (i.e., a 1:2 mixture of Ca^{2+} and fatty acid) encapsulating an oily core of unhydrolyzed triglyceride. When a similar analysis was conducted at pH 5.0, no product phases were visible, suggesting that because the liberated fatty acids are minimally ionized at gastric pH, calcium soap formation does not occur. [2] Development of this calcium soap phase can be preserved in vitro by performing incubations in the absence of bile salts, suggesting that this may be a transient, intermediate phase of intralumenal lipolysis. [2]

In the presence of bile salts, a second phase is formed, the composition of which varies continuously as a function of the molar ratio of lipolytic products to bile salts. This phase continuum is referred to as the *viscous isotropic phase* and is composed largely of monoglyceride and protonated fatty acid in a 1:1 molar ratio. [42] The initial products of lipolysis, visible 5 minutes after the addition of lipase in vitro, are spherical vesicles 11 to 30 nm in diameter. As lipolysis proceeds to completion, lamellar products accumulate at the surface of unhydrolyzed triglyceride emulsions. In the presence of physiological micellar concentrations of bile salts, multilamellar product phases and lamellar product vesicles are also detected in vitro, with product vesicles averaging 50 to 250 nm in diameter. A similar situation is encountered in vivo; after intralumenal lipid instillation, a rough multilamellar product appears initially (Fig. 18-1), giving way to an abundance of product vesicles as bile salts enter the intestinal lumen, inducing micellar solubilization of lipolytic products for delivery to the microvillus membrane.

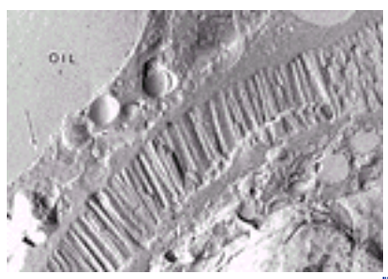

FIGURE 18-1. Morphology of intestinal lipid digestion in vivo. Lamellar product vesicles (*arrows*) are adjacent to a large triglyceride droplet. The product phases are in proximity to the enterocyte brush border. (*Bar* = 500 nM; from Rigler MW, HonKanen RE, Patton JS. Visualization by freeze fracture, in vitro and in vivo, of the products of fat digestion. J Lipid Res 1986;27:836.)

The multilamellar phase of in vitro and in vivo systems appears to correspond to the viscous isotropic phase previously demonstrated by light microscopy. [42] It is proposed that as lipolysis proceeds in the upper small intestine, the lipolytic products (i.e., monoglyceride and fatty acid) initially accumulate to form rough multilamellar phases (e.g., viscous isotropic phase). The density and size of these phases vary according to divalent cation and bile salt concentrations. In the presence of bile salts above a critical micellar concentration, lipolytic products are partitioned into mixed micelles, the size of which reflects the ratio of bile salt to lipolytic product. This process is represented schematically in Figure 18-2. The concordance of the results of in vitro analyses with in vivo experiments indicates the likelihood that this phase transition complex occurs physiologically in humans.

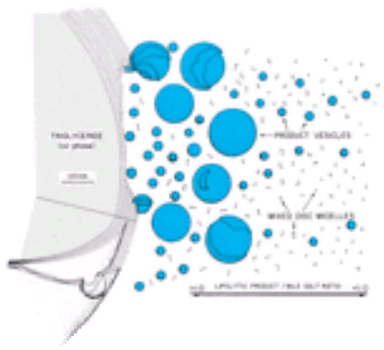

FIGURE 18-2. Accumulation of lipolytic product (LP) lamellae and their subsequent dispersion into vesicles, illustrating the formation of product vesicles whose density and size vary as a function of the LP–bile salt ratios. At high LP–bile salt ratios, large LPs are obtained, and discoidal structures of high flotation density are obtained at higher bile salt–LP ratios. (Adapted from Rigler MW, HonKanen RE, Patton JS. Visualization by freeze fracture, in vitro and in vivo, of the products of fat digestion. J Lipid Res 1986;27:836.)

Micellar Uptake and Delivery of Lipolytic Products to the Brush Border

Adequate lumenal concentrations of conjugated bile salts are a key factor governing the effective solubilization of lipolytic products. Lipolytic products and phospholipid (i.e., biliary lecithin) become incorporated into these aggregates, producing mixed micelles. The more hydrophobic products of lipolysis partition preferentially into the core of the micelles and traverse the aqueous medium of the intestinal lumen by virtue of micellar solubilization. Examples of lipids that depend critically on this mechanism include cholesterol, fat-soluble vitamins, and plant sterols.

In the absence of bile salts at effective micellar concentrations, which can be caused by biliary obstruction, bacterial deconjugation (e.g., bacterial overgrowth), or abnormal small intestine acidity (e.g., acid hypersecretory states), absorption of hydrophobic compounds is reduced virtually to zero. In contrast, absorption of fatty acids and monoglycerides is facilitated by, but is not exclusively dependent on, micellar solubilization. As a result, triglyceride malabsorption is relatively mild (<30%) in patients with total biliary obstruction, in whom lipolysis would be expected to proceed normally but the formation of micelles from lipolytic products would be absent.[43] The explanation presumably reflects the phase equilibria produced after triglyceride digestion. In the absence of bile salts, fatty acids and monoglycerides exist as a lamellar, viscous isotropic phase from which monomeric fatty acids can be delivered to the brush border membrane for uptake.

Effective solubilization of lipolytic products within the bulk phase of lumenal contents is one mechanism by which diffusional resistance to mucosal uptake may be overcome. The diffusion of hydrophobic molecules through this aqueous medium, composed of a dense mucous layer overlying the brush border glycocalyx, and their delivery to the brush border membrane are components of a major rate-limiting process in lipid absorption. One explanation of the behavior of solutes within the bulk phase of lumenal contents is the unstirred layer hypothesis, which predicts that contents in the center of the lumen are ideally mixed while contents at the outermost region of the loop (i.e., closest to the brush border membrane) remain functionally unstirred. Quantitation of this unstirred layer has produced figures for the rat in the range of 100 to 1100 µm.[44], [45] and [46] In contrast, the laminar flow model predicts that solutes would be mixed by a physical process that depends on their relative positions with respect to an ideal central axis of vectorial flow.[47] The essential difference between the two models resides in the assumption that the laminar flow model has fixed physical dimensions derived from the direct determination of solute movement relative to fluid movement in longitudinal and horizontal axes and from the determination of epithelial compared with lumenal resistance to solute movement. The laminar flow hypothesis is supported by the observation that absorption of a variety of probes is independent of lumenal volume.[47] The results obtained in these experimental systems provide a useful basis for understanding lumenal resistance to solute movement in mammalian intestine.

Intestinal brush border membranes contain a heparin-like binding site that mediates specific, saturable, and heparin-displaceable binding of pure pancreatic cholesterol esterase (100-kd peptide) and pancreatic lipase, but not amylase or ribonuclease.[48], [49] These findings imply that binding of lipolytic enzymes may occur at the brush border membrane, obviating the requirement for lipolytic products to traverse an aqueous diffusion barrier. These investigators postulated that in situ lipolysis of cholesteryl ester or triglyceride releases fatty acids, monoglyceride, and free cholesterol in proximity to the brush border membrane, where they undergo rapid uptake.[48], [49]

Lipolysis and Uptake of Phospholipid and Medium-Chain Triglyceride

A triglyceride with fatty acyl groups that have a 6- to 12-carbon chain length is referred to as a *medium-chain triglyceride*. Its lumenal and intracellular metabolism differs in several respects from that of a long-chain triglyceride. First, medium-chain triglycerides form more expanded surface films as emulsions than do long-chain triglycerides, facilitating intragastric lipolysis.[1] Second, as a result of their intrinsically higher aqueous solubility, medium-chain fatty acids released by intragastric and small intestine lipolysis are effectively absorbed by gastric and small intestine epithelium and undergo rapid transepithelial delivery. Third, medium-chain fatty acids do not become activated to their coenzyme A (CoA) derivative for reassembly into complex lipid but rather undergo direct secretion into the portal vein, where they become bound to albumin for transport to the liver.[50], [51] Fourth, although intrinsically more susceptible to lipase digestion than long-chain triglycerides, a proportion of medium-chain triglycerides may be absorbed directly, without prior lipolysis. Direct proof of this last metabolic event is lacking in humans.

The role of phospholipid hydrolysis in the regulation of lipid absorption is unresolved. Rats treated with a competitive phospholipase A_2 inhibitor demonstrated reduced cholesterol and triglyceride transport into lymph,[52] supporting a role for lumenal phospholipid hydrolysis in lipid absorption. Interestingly, although human studies have shown that lumenal phospholipid may interfere with cholesterol absorption, the absorption of triglyceride, phospholipid, or cholesterol was unchanged in phospholipase A_2 -/- mice,[52] suggesting that other lipases may accomplish the task of phospholipid hydrolysis.

Bile Salt Absorption

Micellar lipid delivery involves the disgorgement of micellar contents at the brush border membrane for uptake. Conjugated bile salts are passively absorbed as monomers throughout the upper small intestine, and because of the efficient processes of hepatic uptake after portal vein delivery and reexcretion into bile, they become rapidly available again to participate in micellar lipid solubilization. In addition to passive uptake throughout the small intestine, an active Na^+-coupled uptake process in the mature ileum retrieves more than 95% of the intralumenal bile salts. Ileal absorption of bile salts is mediated through the apical Na^+-dependent bile transporter (ASBT), originally referred to as the *ileal bile acid transporter (IBAT)*.[53] ASBT demonstrates 35% amino acid identity and 63% similarity to the rat liver Na^+-coupled bile acid transporter.[53] Human IBAT cDNA cloning and population screening identified a mutation in a patient with Crohn's disease that abolishes taurocholate transport.[54] Cellular transport of bile acids in the ileal enterocyte is mediated by the ileal bile acid–binding protein (I-BABP), whose gene transcription is tightly regulated by altered bile acid flux through mechanisms involving the nuclear orphan receptor FXR.[55] Bile acid–dependent regulation of gene expression is discussed in detail elsewhere (see Chapter 16). Once delivered across the cytosolic compartment in association with I-BABP, the efflux of bile salts appears to involve transport through a truncated version of ASBT (t-ASBT) that arises through alternative RNA splicing.[56] Alternative RNA splicing results in skipping of exon 2 of the ASBT gene product and produces a frameshift in the alternatively spliced mRNA. This generates t-ASBT, a novel peptide of 154 residues that is expressed in the basolateral membrane of ileal enterocytes and cholangiocytes and functions as an efflux protein.[56]

Colonic Events

Unabsorbed long-chain fatty acids that enter the colon undergo a series of bacterial modifications, principally hydroxylation; they are not absorbed by this organ. In healthy persons, no undigested triglyceride is found in the stool, and the standard fecal fat estimate of approximately 7 g/d reflects the cumulative total excretion of saponification products (i.e., fatty acids) that arises principally from membrane phospholipid and bacteria. Estimates of normal triglyceride fractional absorption (>95%) likely underestimate the astonishing efficiency of this process.

Short-chain fatty acids are the principal aqueous solute in colonic contents, with a total concentration of 100 to 240 mmol/L; of these, over 90% are acetic, propionic, and *n*-butyric acids.[57] Short-chain fatty acids arise from bacterial fermentation of unabsorbed carbohydrate and may be an important energy source for colonocytes in health and disease.[58] Human fecal matter contains about 500 mg of bile salts and 200 to 500 mg of cholesterol and its bacterial degradation products, cholestanol

and cholestanone. [59] Bile salts are principally deconjugated and dehydroxylated in the colon, and in health, a balance is maintained between these daily fecal losses and de novo bile salt synthesis by the liver. [59]

Brush Border Membrane Events

The mechanism of long-chain fatty acid uptake across the intestinal microvillus membrane is incompletely understood. This subject is well covered in two reviews. [60], [61] Although a favorable concentration gradient likely exists for passive diffusion of these lipophils, biochemical evidence suggests the presence of a specific carrier. The cloning and characterization of a family of fatty acid transport proteins (FATPs) [62] led to the identification of FATP4, a protein of about 64 kd that is expressed at high levels in the apical membrane of mammalian enterocytes. [63] The cloning of this family of transporters has fulfilled earlier predictions of the biochemical and kinetic parameters of fatty acid uptake. FATP4 transfection of heterologous cells induces saturable, specific, and temperature- and substrate-dependent uptake of long-chain fatty acids, but not cholesterol or other hydrophobic sterols, suggesting that FATP4 likely is the elusive intestinal fatty acid transporter. [63] The role of other proteins previously thought to be involved in fatty acid transport across the brush border membrane, including the microvillus membrane fatty acid–binding protein (MVM-Fabp), which was subsequently identified as a mitochondrial isoform of aspartate aminotransferase, [64] must now be reexamined. Further information concerning the role of these FATP genes in fatty acid transport by the enterocyte will undoubtedly emerge from gene-targeting approaches.

Cholesterol uptake across the microvillus membrane of small intestinal enterocytes has been postulated to be protein mediated, although the identification of such transporters has been long sought. A breakthrough was the identification of an ATP-binding cassette (ABC)–type cholesterol transporter, ABCA1, whose function is defective in Tangier disease. [65], [66] and [67] Tissues of patients with Tangier disease (including the small intestine) accumulate cholesterol, and their serum contains very low levels of high-density lipoprotein (HDL) as a result of the failure of cholesterol to be transferred to an acceptor HDL particle in the extracellular fluid. ABCA1 is postulated to function as a cholesterol export pump, although whether it is uni- or bidirectional is unclear. In addition, the tissue- and cell-specific distribution of ABCA1 is somewhat controversial. Studies in mice suggest that ABCA1 mRNA is expressed and regulated in the intestine, [68] whereas in situ hybridization studies of baboon intestine suggest that ABCA1 mRNA is located in macrophages in the lamina propria. [69] Accordingly, intestinal expression of ABCA1 protein is yet to be demonstrated, and its membrane topology (i.e., brush border or basolateral) will have to be reconciled with any putative cholesterol transport function. Pending the resolution of these questions, other studies have demonstrated metabolic regulation of distinct components of cholesterol transport. Specifically, nuclear hormone receptors involved in cellular lipid metabolism, including oxysterol receptors (LXRs) that function as obligate partners of retinoid X receptors (RXRs), were demonstrated to regulate cholesterol absorption through the transcriptional induction of ABCA1 expression in the intestine. [68] Mice treated with a synthetic rexinoid, a ligand agonist of RXR, demonstrated up-regulation of ABCA1 expression in the intestine, with decreased cholesterol absorption. [68] Consistent with these observations, ABCA1 -/- mice show mild increases in cholesterol absorption. [70], [71] In contrast, another report suggests that ABCA1 -/- mice generated in a C57 genetic background manifest an increase in cholesterol absorption. [72] These findings considered together suggest as yet unresolved issues concerning an important new mechanism of cholesterol uptake by the human intestine. A further breakthrough in the understanding of brush border events regulating lipid uptake came with the cloning of yet another set of ABC-type transporters whose function is defective in humans with sitosterolemia. Affected individuals absorb large amounts of plant sterols, structurally related to cholesterol, whereas healthy subjects absorb less than 5% of these sterols. This presumably is a consequence of the ability of the enterocyte transporter to discriminate subtle differences in sterol structure. By using a combination of genetic linkage and fine mapping, the locus was narrowed, and candidate genes identified as half-transporters, referred to as *ABCG5* and *ABCG8*, were located on chromosome 2p21. [73], [74] The two genes are arranged in tandem and transcribed in opposite directions, each encoding a half-transporter. Accordingly, these ABC-type transporters are postulated to function as heterodimeric sterol exporters with the ability to discriminate cholesterol from other, related sterols. [73], [74] Investigators postulate that these transporters function in concert, but the relationship of ABCA1 to the function of the ABCG5 and ABCG8 transporters is unknown. Conceivably, these transporters participate in a coordinated manner whereby cholesterol and other sterols are discriminated and selectively transported across the membrane.

INTRACELLULAR EVENTS IN LIPID REASSEMBLY

Intracellular Transport of Long-Chain Fatty Acids

After brush border membrane uptake, long-chain fatty acids and monoglyceride must be translocated across the aqueous cytosolic compartments of the enterocyte and delivered to the smooth endoplasmic reticulum (ER) for incorporation into complex lipid. Directed intracellular trafficking is facilitated by fatty acid–binding proteins (Fabps), members of a larger supergene family that includes several vitamin A–binding proteins and other proteins whose functions are unknown. Mammalian enterocytes express mRNAs for two cytosolic Fabps, intestinal Fabp (Fabpi) and liver Fabp (Fabpl), [75] based on the organ from which each was initially isolated. The mRNAs encoding these proteins are highly abundant, accounting for 2% to 3% of the total intestinal translation products and representing 1% to 2% of the soluble cytosolic protein mass. [76], [77], [78] and [79] Predictions from the cDNA sequence [80], [81] suggest Fabpl is a 127-residue peptide with a molecular weight of 14,273 d, whereas Fabpi mRNA encodes a slightly larger peptide of 132 residues and a molecular weight of 15,124 d, with more than 80% nucleotide and amino acid homology between rat and human genes. [75], [80], [82] Human *FABPL* is located on chromosome 2, and *FABPI* on chromosome 4. [82] Both Fabps are synthesized as obligate intracellular peptides, neither being destined for export. The tissue distribution of the two cytosolic Fabps differs. Fabpi mRNA is essentially confined to the small intestinal enterocyte. When transcript abundance is normalized to that in the small intestine (100%), less than 8% of the small intestine signal is present in colon, and the stomach and the liver express 2% to 4%, respectively. [83] By contrast, Fabpl mRNA is expressed in the liver at 50% to 70% of the level found in the small intestine, and both the stomach and colon express 2% to 6% of the small intestine Fabpl mRNA. [83]

Regulation of the biosynthesis of intestinal and liver Fabps has been studied by means of various techniques. Earlier studies demonstrated that the cytosolic concentration of immunoassayable Fabp increases in a gradient from the villus to the crypt and from the proximal to the distal small intestine. [78] The developmental expression of the two cytosolic Fabps reveals a coordinated increase in Fabpl and Fabpi mRNA abundance in intestinal mucosa after birth, detectable at day 19 of gestation and peaking in adulthood. [83] Complementary approaches of cDNA hybridization and classical protein turnover kinetics have established that Fabpl mRNA abundance and translatable activity are higher in the jejunum of female than of male rats. [76], [77] However, the turnover of newly synthesized Fabpl in female rats is also faster than in male rats, producing no net effect on steady-state cytosolic Fabpl concentrations. There are no sex-related differences in the cytosolic concentration or translatable activity of Fabpi. Clofibrate, a hypolipidemic agent that affects hepatic fatty acid metabolism through peroxisome proliferator activator receptor-a, doubles the intestinal Fabpl mRNA level and protein concentration in the intestine but has no effect on Fabpi.

A consensus of data supports the hypothesis that the two cytosolic Fabps are independently regulated and probably play distinct roles in intracellular fatty acid metabolism. Both Fabps are expressed in *Escherichia coli,* and their structures and ligand-binding affinities have been determined. [84], [85] and [86] Fabpl has a binding capacity of 2 mol fatty acid per 1 mol protein, and Fabpi binds in 1:1 stoichiometry. Further studies have demonstrated that Fabpl exhibits a higher affinity for polyunsaturated fatty acids than for saturated species, and Fabpi exhibits a broadly similar affinity for saturated and polyunsaturated fatty acids. These data support the concept that intracellular Fabps may target substrate fatty acid to selective compartments for incorporation into triglyceride, phospholipid, or cholesteryl or retinyl esters. Fatty acids entering the enterocyte from the basolateral membrane (i.e., plasma derived) are thought to be metabolically distinct from fatty acids absorbed across the brush border. [87] The differences in ligand-binding stoichiometry, underlying mechanisms of conformational interaction, and pH sensitivity may be correlated with their distinctive physiological roles in enterocyte fatty acid trafficking. [84]

The *FABPI* locus was examined in Pima Indians as a possible basis for the linkage observed between markers on chromosome 4q and certain measures of insulin action. [88] A common genetic polymorphism in the coding region of *FABPI* was identified—that is, a single G-to-A transition generating an alanine-to-threonine substitution in the Fabpi protein. [89] The mutant protein demonstrated increased binding of long-chain fatty acids in vitro. [89] Furthermore, expression of the mutant protein in Caco-2 cells resulted in increased transport of both long-chain fatty acids and triglyceride. [90]

Analysis of the role of Fabpi through gene targeting in mice has yielded some surprising findings. Homozygous Fabpi -/- mice absorb fat normally, and male but not female animals gain weight at a faster rate than do wild-type animals when fed either a chow diet or a high-fat diet. [91] Plasma insulin levels were higher in Fabpi -/- mice of both sexes but were not associated with alterations in plasma glucose levels. Thus, the male Fabpi -/- phenotype shows some features of the Pima Indian phenotype previously described. Further study of the metabolic targets of Fabps will undoubtedly reveal new functions for these abundant genes. The fatty acid transport function of these genes has been reviewed recently elsewhere. [92]

Intracellular Transport of Sterols

Intestinal absorption and metabolic processing of dietary and biliary sterols—principally cholesterol—is a major component of the body's homeostatic control mechanisms for regulating sterol uptake. The intestine is the portal of entry of the fat-soluble A, D, E, and K vitamins, and elaborate conservation mechanisms have evolved to ensure constant availability of these essential nutrients, particularly vitamin A.

From the perspective of regulating intracellular cholesterol traffic, the enterocyte receives most of its daily flux of cholesterol from lumenal sources (i.e., dietary and biliary), but it is also capable of de novo cholesterol synthesis from 2-carbon units. The intestinal cell also expresses low-density lipoprotein (LDL) receptors on its basolateral membrane, which facilitate the endocytotic uptake of circulating plasma LDL. [93] The interactions of these sources of intestinal cholesterol and their role in regulating cholesterol metabolism in the enterocyte have been studied extensively.

Cholesterol delivery to various intracellular locations is facilitated by means of its 1:1 stoichiometric association with a specific carrier protein, sterol carrier protein 2 (SCP2). [94] SCP2 was first isolated from rat liver as a 13-kd protein that participated in the intracellular movement of cholesterol within hepatocytes and steroidogenic tissues. [94], [95] Cloning the rat and human SCP2 genes revealed substantially more information. [96], [97], [98] and [99] The rat gene spans 20 to 30 kilobases (kb) and is transcribed into four distinct mRNA species that encode a 58-kd protein, SCPx, and a smaller, about 14-kd protein, SCP2. [98] SCP2 is expressed in rat small intestine enterocytes [100] and colocalized to the subapical region with the peroxisomal marker PMP70, suggesting that SCP2 is indeed a peroxisomal protein, not a mitochondrial protein, as previously thought. [101] SCP2 gene expression in the rat is subject to tissue-specific and developmental regulation with a temporally distinct pattern of increase in SCP2 mRNA abundance in the liver and small intestine in the neonatal period. [102] The function of SCP2 may involve peroxisomal catabolism of methyl-branched fatty acyl-CoA, as inferred from the study of gene-targeted mice. [103] These mice demonstrated alterations in peroxisomal morphology associated with hypolipidemia and neuropathy with accumulation of phytanic acid. Other studies have suggested roles for SCP2 in cholesterol efflux [104] and biliary cholesterol secretion. [105]

Intracellular Transport and Metabolism of Vitamin A

All mammals require vitamin A for effective cell growth and differentiation. The two major sources of this nutrient are carotenoids, principally ß-carotene from plants, and retinyl esters derived from animal tissues. Carotenoids must be converted, after uptake into the enterocyte, into retinol. This conversion is a two-step procedure involving cleavage by 15,15'-dioxygenase to yield two molecules of retinaldehyde, which is subsequently reduced to retinol. [106] Dietary retinyl esters must first undergo hydrolysis to retinol before absorption, and although details are lacking, the evidence suggests that ß-carotene and retinol are absorbed into the enterocyte by passive diffusion.

The intestine synthesizes specific binding proteins that provide a mechanism by which cellular vitamin A is stored and delivered for esterification before secretion in the form of retinyl ester. There are at least four intracellular cellular vitamin A–binding proteins in mammals, including cellular retinol-binding protein I (CRBP I), cellular retinol-binding protein II (CRBP II), and cellular retinoic acid–binding protein types I and II (CRABP I and CRABP II). [107] These intracellular vitamin A–binding proteins are distinct from the serum retinol-binding protein RBP. [108]

The genes that encode these proteins form part of a supergene family that has at least 11 known member products, including the Fabps, adipocyte 422 protein, and myelin P2 protein. The two principal intracellular vitamin A–binding proteins of relevance to the intestine are CRBP I and CRBP II. These two peptides exhibit extensive amino acid and nucleotide homology, and the genes for both are located on human chromosome 3. [109] The tissue distribution of the two mRNAs is distinct, with CRBP II gene expression virtually confined to the enterocyte and CRBP widely distributed among vitamin A–responsive cells; CRBP immunoreactivity in the gut is confined to the submucosa and lamina propria. [110], [111]

CRBP II is abundant, representing about 1% of the soluble protein in rat jejunum and 0.4% of the soluble protein in human proximal small bowel. [112] The highest levels are detected in villi of the proximal small bowel, illustrating a striking gradient vertically (i.e., villus to crypt) and horizontally (i.e., jejunum to ileum). Studies further suggest that CRBP II undergoes developmental regulation, with peak mRNA abundance occurring just before birth, at 21 days' gestation in the rat. [111] This finding is compatible with the observation that cellular retinol flux undergoes changes along the villus-crypt axis. Cloning and sequencing of the retinoic acid receptor gene suggest that this new member of the steroid-thyroid hormone receptor gene family may function as a vertebrate morphogen. [113] Further elucidation of the structure of its intestinal homolog may provide important insights into the factors controlling cellular maturation and differentiation. Gene-targeting studies should provide conclusive information concerning the role of CRBP II.

Retinol is secreted by the enterocyte in the form of retinyl ester, predominantly in the hydrophobic core of triglyceride-rich lipoproteins. The mechanism by which intestinal retinol undergoes esterification has been the subject of considerable debate. Potential mechanisms include the reversible action of pancreatic cholesterol esterase, microsomal conversion using acyl-CoA:cholesterol acyltransferase 1 or 2 (ACAT1 or ACAT2), or acyl-CoA:retinol acyltransferase (ARAT). [114] The latter two enzymes have been favored because of the observed fatty acid specificity of the esterification reactions as evidenced by gas-liquid chromatographic analysis of human and rat lymph retinyl esters. [106] The role of ACAT enzymes is discussed further in the next section.

When retinol is presented as a complex with CRBP II, microsomes are able to use endogenous acyl donors and synthesize retinyl esters with a fatty acid composition strikingly similar to that described for rat lymph. [51], [115] Moreover, retinol–CRBP II complexes are unavailable for acyl-CoA–directed esterification, but retinol complexed to albumin is effectively esterified in an acyl-CoA–driven reaction. The rates of retinyl ester production by rat intestinal microsomes using this acyl-CoA–independent mechanism are calculated to be more than 1 µmol/d, which is more than sufficient to meet physiological requirements. These observations suggest that a major function of CRBP II may be to direct intestinal retinol to an appropriate milieu for esterification. [51], [115] Retinol targeted to a non–acyl-CoA–driven reesterification process would permit distinct metabolic compartmentalization. Although direct evidence is lacking, this mechanism could obviate competition between retinol and other intracellular lipid components, such as cholesterol for acyl-CoA donors.

Intestinal Cholesterol Metabolism

Dietary and biliary sources provide the 1 to 2 g of cholesterol that enters the intestinal lumen each day. Biliary cholesterol is essentially all free sterol, but 10% to 20% of dietary cholesterol is cholesteryl ester that must undergo hydrolysis before absorption. As previously discussed, intestinal cholesterol uptake is likely to involve one or more ABC-type transporters (ABCA1, ABCG5, and ABCG8) whose interactions may regulate the net influx of sterols. Membrane cholesterol transport may require interaction with protein components capable of mediating specific interactions with sterol acceptors, such as SCP2. From the brush border, cholesterol is transported, presumably by SCP2 and other acceptor proteins, to the smooth ER for reesterification. Although up to 25% of cholesterol may be secreted from the enterocyte and transported in mesenteric lymph as free cholesterol, most intracellular cholesterol destined for export undergoes reesterification.

Cholesterol esterification in the intestine is mediated by one of two ACAT enzymes. ACAT1 is expressed in numerous sites, with high levels in the adrenal cortex, macrophages, and sebaceous glands. [116] Intestinal cholesterol absorption, as well as hepatic and intestinal ACAT activity, were normal in the ACAT1 -/- mice, suggesting that another enzyme may function in the intestine and liver. [117] As suspected, a second ACAT gene (ACAT2) was subsequently identified whose expression is limited to the intestine and liver and whose function has recently been suggested through gene targeting in mice. [118] These mice demonstrated reduced cholesterol absorption and were protected against dietary cholesterol-induced hypercholesterolemia and cholesterol cholelithiasis. The intestine and liver of these animals also failed to accumulate cholesteryl ester when challenged with a dietary cholesterol load. [118] The results of experiments with ACAT2 -/- mice suggest that hepatic and intestinal cholesterol metabolism is regulated by distinct cholesterol-esterifying enzymes compared to other tissues.

The available evidence suggests that several discrete metabolic compartments exist for intestinal cholesterol. Absorbed lumenal (i.e., dietary and biliary) cholesterol appears to regulate ACAT2 activity and may be the preferred substrate. Newly synthesized cholesterol plays an important role in delivering cholesterol for cell membrane biosynthesis, perhaps in part related to growth needs but distinct from the diet-related export demands of the enterocyte. The factors that regulate LDL internalization and the role that this source plays in the traffic of intracellular cholesterol are unresolved and together form a focus of active investigation.

Intestinal Triglyceride Synthesis and Metabolism

Triglyceride is the most abundant lipid processed by the intestine and is almost completely absorbed by the enterocyte after intralumenal lipolysis. Approximately 75%

of absorbed lumenal fatty acids are resynthesized into triglyceride and secreted by the enterocyte as lipoprotein. [119], [120] The remaining 25% serve as substrate for phospholipid and other intracellular lipid resynthesis events or undergo transport to the liver bound to albumin through the portal vein. [50], [121], [122] The intestine also synthesizes and secretes triglyceride during fasting, with estimates of 10% to 40% of circulating plasma triglyceride being derived from the intestine after an overnight fast. [123]

There are two major pathways for intestinal triglyceride synthesis. The glycerol-3-phosphate pathway is the major route during periods of limited availability of lumenal monoglyceride and fatty acid. [123], [124] The substrates for triglyceride synthesis through this pathway, glycerol-3-phosphate and lysolecithin, are derived from glucose metabolism (i.e., dihydroxyacetone phosphate) and biliary phospholipid, respectively. [123], [125] The importance of biliary phospholipid as a substrate for triglyceride synthesis is highlighted by the fact that 75% of the fatty acids in infused lecithin are incorporated into secreted triglyceride during fasting. [126]

Enzymes catalyzing triglyceride synthesis through the monoacylglycerol pathway are located in the smooth ER, in contrast to the enzymes of the glycerol-3-phosphate pathway, which are located in the rough ER. [127], [128] Although the liver also contains monoacylglycerol acyltransferase, the intestinal form of the enzyme appears to be distinct based on substrate specificity, thermolability, and susceptibility to various detergents. [129] The intestinal enzyme is stereospecific in that almost 90% of 2-monoacylglycerol is converted into 1,2-diacylglycerol. [130] The molecular cloning of acyl-CoA:diacylglycerol acyltransferase (DGAT) has provided a new avenue for the investigation of triglyceride synthesis. [131] Structural and biochemical studies of DGAT were hitherto impossible because DGAT is an integral membrane protein. With the availability of reagents, these and other questions, including the tissue- and cell-specific distribution (ubiquitous with high levels in liver and intestine), were addressed. [131] After DGAT was cloned, its function was established by gene targeting in mice. The DGAT -/- mice demonstrated both resistance to obesity and defective lactation. However, intestinal triglyceride absorption was normal, although the livers of mice fed a high-fat diet accumulated less triglyceride. [132] These findings imply the presence of another DGAT enzyme involved in triglyceride synthesis in certain tissues, including the small intestine, perhaps analogous to the multiple ACAT enzymes that mediate cholesterol esterification.

Intestinal Phospholipid Synthesis and Metabolism

Phospholipids, particularly phosphatidylcholine (i.e., lecithin), are essential components of cell membranes. Lecithin is also a key component of lipoproteins, providing a surface coat for the inner core of triglyceride and cholesteryl ester. There are two major synthetic pathways for phospholipid in the enterocyte: the phosphatidic acid–phosphorylcholine pathway and the reacylation of absorbed lysolecithin. [126], [133], [134] and [135] Phosphatidylethanolamine is methylated in a third pathway in the liver, but this mechanism is not important in the intestine. [136]

The quantitative importance of either pathway for intestinal phospholipid synthesis is unknown. [137], [138] Lysophosphatidylcholine acyltransferase is more responsive to lipid feeding than choline phosphotransferase, suggesting that the lysolecithin reacylation pathway may be more important postprandially. [139] During periods of fasting and low levels of lumenal lecithin, the phosphatidic acid–phosphorylcholine pathway is the main synthetic route. [126], [138] Postprandially, with higher levels of biliary and dietary lysolecithin available, there is increased synthesis of lecithin through the reacylation pathway. During very high rates of experimental lecithin infusion into the lumen of the rat intestine, lymphatic chylomicron-phospholipid is exclusively derived from the infused lecithin through the reacylation pathway. [138]

INTESTINAL LIPOPROTEIN ASSEMBLY AND SECRETION

Enterocyte Morphology and Pathways of Lipoprotein Assembly

The morphology of the intracellular events occurring during lipid absorption has been studied extensively in human and rat intestine (Fig. 18-3). [140], [141] and [142] Serial electron micrographs reveal that large droplets of lipid form near the microvillus membrane 5 to 10 minutes after lipid instillation into the intestinal lumen. These droplets represent resynthesized triglyceride in and adjacent to the smooth ER. The overall process of chylomicron assembly and secretion is coordinated through the sequential action of several co-dependent steps (Fig. 18-4). The enzymes involved in triglyceride and phospholipid synthesis are located in the smooth and rough ER. [137] There may be metabolically distinct pools of intracellular triglyceride, one pool destined for chylomicron secretion derived from the 2-monoglyceride pathway, and another, not destined for immediate export, derived from the phosphatidic acid pathway. [122] In addition, there is evidence for the sequential assembly of chylomicrons and their compartmentalization based on different transport rates through the secretory apparatus. [143], [144]

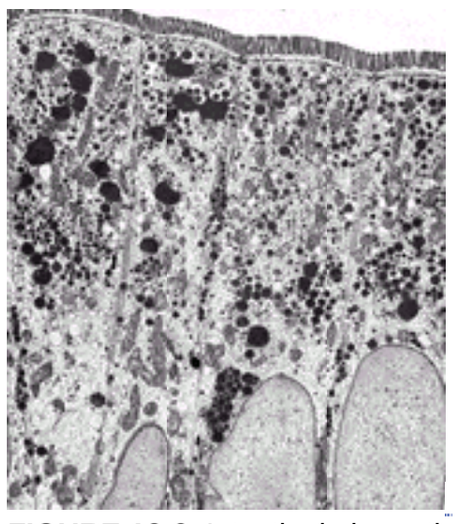

FIGURE 18-3. Intestinal absorptive cells after lipid feeding. This electron micrograph, taken 2 hours after lipid feeding, shows the apical cytoplasm to be engorged with osmiophilic droplets bounded by smooth endoplasmic reticulum. Golgi zones and intracellular spaces contain chylomicron-size particles. (Original magnification ×8000; adapted from ref. [141].)

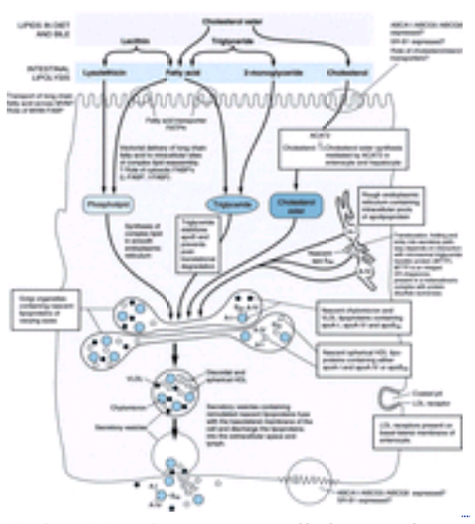

FIGURE 18-4. Intracellular pathways of intestinal lipoprotein assembly. Lumenal lipids are absorbed across the microvillus membrane and transported to the smooth endoplasmic reticulum, where they serve as substrates for the synthesis of triglyceride, lecithin, and cholesteryl ester—the lipids of nascent lipoproteins.

Apolipoproteins from the rough endoplasmic reticulum are mobilized during lipoprotein formation onto lipid to form nascent lipoproteins in Golgi organelles. Lipoproteins are remodeled in the Golgi organelles and the secretory vesicles. These secretory vesicles fuse with the basolateral membrane of the enterocyte and release the nascent lipoproteins into the lymph.

Apolipoproteins synthesized in the rough ER are transferred onto newly synthesized lipid, as evidenced by the decrease in apo B immunostaining in the rough ER and a corresponding increase in apo B immunostaining in the smooth ER after lipid feeding. [145] The distribution of apolipoproteins within the enterocyte is such that during fasting, about 90% of apolipoprotein is not bound to lipoprotein, but remains associated with the ER. [146] Lipid feeding mobilizes 5% to 10% of this apolipoprotein from the non–lipoprotein-bound pool onto newly assembled lipoproteins. [147] The mechanism by which apolipoproteins associate with lipids to form nascent intracellular lipoproteins is likely to involve the microsomal triglyceride transfer protein (MTTP). Other studies have suggested that microtubules may be involved in intracellular lipid transport. [148]

The Golgi apparatus membranes, which are located close to the nucleus of the cell, become filled with lipid droplets corresponding in size to chylomicrons and very-low-density lipoprotein (VLDL)–like particles after lipid feeding (see Fig. 18-3 and Fig. 18-4). In the liver, lipid and apolipoproteins are added to nascent lipoproteins in both the ER and the Golgi organelles (Fig. 18-5), and similar remodeling probably occurs in the intestinal enterocyte. [149] Golgi organelles are thought to be precursors to secretory vesicles, which are larger vesicles filled with lipid droplets of various sizes that represent nascent forms of intracellular lipoproteins before secretion. [142] These secretory vesicles fuse with the basolateral membranes and release nascent lipoproteins into the extracellular space and mesenteric lymph. [141], [142] The limiting rate during chylomicron formation and secretion appears to be the rate at which lumenal triglyceride is absorbed, not the rate of apolipoprotein synthesis. [146], [150] Secretion rates of apolipoprotein in the proximal and distal rat small intestine appear to be similar, although distal intestine has been shown to transport lipid more slowly than proximal intestine. [150] After lipid infusion directly into human jejunum and ileum, no morphologic differences between enterocytes from the two sites are seen, suggesting similar fat absorption and lipid secretion in the proximal and distal bowel. [151] Functional differences, however, may exist in the capacity of the ileum to transport large quantities of lipid, as inferred from the reduced expression of most genes involved in lipid transport and lipoprotein assembly.

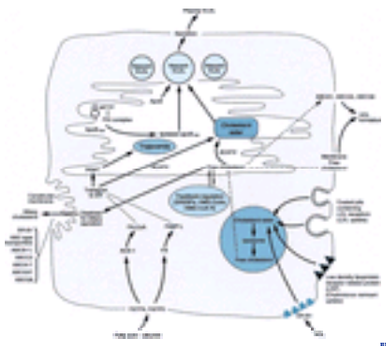

FIGURE 18-5. Intracellular pathways of hepatocyte lipoprotein assembly and secretion. Several distinct pathways are involved in the complex regulation of hepatic lipid flux. Fatty acid uptake by the hepatocyte is carrier mediated and results in fatty acid delivery to acyl-CoA synthase (ACS-1) and also to liver fatty acid–binding protein (Fabpl). Fatty acids are delivered to the endoplasmic reticulum (ER) for assembly into complex lipid (cholesteryl ester and triglyceride). Key enzymes involved in these reactions include acyl-CoA:cholesterol acyltransferase 2 (ACAT2) and acyl-CoA:diacylglycerol acyltransferase (DGAT), respectively. The newly synthesized triglyceride is transferred to the nascent apo B protein by the microsomal triglyceride transfer protein (MTTP), which is an ER chaperone. MTTP exists bound to protein disulfide isomerase and is required for lipidation of apo B. These particular features of hepatic lipoprotein assembly are indistinguishable from those in the small intestine. Other apolipoproteins are added to the nascent very-low-density lipoprotein (VLDL) particle, including apo E, which is not expressed in the enterocyte. The VLDL particle is directed through the Golgi apparatus for secretion into plasma. Cholesterol entry into the hepatocyte involves lipoprotein uptake by several different receptors. In humans, most lipoprotein cholesterol is carried by low-density lipoprotein (LDL), and the LDL receptor accounts for most receptor-dependent cholesterol uptake. Other receptors are shown to indicate their role in high-density lipoprotein (HDL) uptake: class B scavenger receptor (SR-B1) and LDL receptor–related protein (LRP), chylomicron remnants. In addition, several members of the ABC transporter family likely play a role in cholesterol secretion, both into bile and into the systemic circulation. However, it is as yet unclear whether the expression of these HDL transporters (ABCA1, ABCG5, and ABCG8) is polarized in the hepatocyte and what if any role they play in the delivery of cholesterol into bile.

As alluded to previously, there are many similarities in intestinal and hepatic lipoprotein assembly and secretion, but also important points of divergence. These are summarized in Figure 18-5.

Regulation of Intestinal Apolipoprotein Gene Expression

Apolipoproteins are the protein components of lipoproteins, the vehicles by which water-insoluble lipid is transported through the aqueous medium of plasma. Lipid secretion from the enterocyte is largely in the form of chylomicrons and VLDLs. The liver secretes VLDLs but not chylomicrons (see Fig. 18-5), for reasons that are incompletely understood. Both chylomicrons (>100 nM) and VLDLs (30–90 nM) are large, lipid-rich particles that transport neutral lipid from its site of synthesis or reassembly to other tissues for use as an energy substrate or for the delivery of cholesterol. VLDLs and chylomicrons have a distinctive pattern of apolipoproteins associated with their surface, apolipoproteins that play a large role in directing the particles to the appropriate receptors and enzymes involved in their metabolism.

There are at least six apolipoprotein genes, whose presence in the small intestine has been demonstrated by immunologic detection of the final gene product or by hybridization to an appropriately sized transcript (Table 18-1). Of these apolipoprotein genes, three are expressed abundantly (i.e., apo A-I, apo A-IV, apo B), and these are discussed in this chapter. For further information, the reader is referred to excellent reviews of the molecular genetics of apolipoproteins and the structure-function and evolutionary aspects of apolipoprotein genes. [152], [153], [154], [155] and [156]

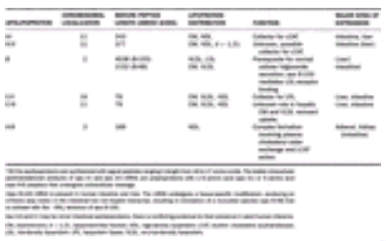

TABLE 18-1 Human Intestinal Apolipoproteins*

Apolipoprotein gene structure in mammals shows a high degree of conservation, with four of the six genes expressed in human small intestine showing distinct similarities; the structure of the apo B gene and predicted structure of the apo A-IV gene are quite different. The major apolipoproteins demonstrate such structural conservation that they are predicted to have arisen from a common ancestral gene. [157] The basic organization is a four-exon, three-intron gene structure; the exception is apo A-IV, which lacks an intron in the 5' noncoding region of the corresponding mRNA. [158] The observed structural similarity in the genes reflects structural conservation in the gene products, in which multiple repeats of 22 amino acids confer a marked a-helical amphipathic secondary structure that contributes to their essential function as lipid-binding proteins. [159], [160] Like most proteins destined for export, all the intestinal apolipoproteins are synthesized with signal peptides that are cotranslationally cleaved, and the stable posttranslational forms of apo A-I and apo A-II mRNA contain an additional prosegment that undergoes extracellular

cleavage. [157], [161], [162]

Apo A-I is an abundant intestinal mRNA that codes for about 1% to 2% of newly synthesized protein in the rat. [161] In humans, apo A-I is the major protein component of HDL and is the principal cofactor for the enzyme lecithin:cholesterol acyltransferase (LCAT), which is responsible for plasma cholesterol esterification. [163], [164] Several studies suggest that the intestine synthesizes about half of the body's daily input of this apolipoprotein. [165] Attention given to the importance of HDL as a protective factor against atherosclerosis and evidence demonstrating that ambient serum levels of apo A-I may be an even more potent predictive factor have focused attention on factors that influence the biosynthesis of apo A-I. [166]

Studies of the rat suggest that apo A-I is synthesized throughout the small intestine, with the highest levels produced in the proximal jejunum and a nadir reached in the terminal ileum. [167] Additional rat studies have demonstrated that intestinal apo A-I synthesis and mRNA content are unaltered after acute triglyceride feeding or after 3 to 6 weeks of sustained exposure to diets containing widely discrepant quantities, 0% to 30% by weight, of triglyceride. [168] Intestinal apo A-I synthesis does not respond to diets composed of butter fat or corn oil, and dietary cholesterol augmentation has no effect, suggesting that, at least in this species, intestinal apo A-I gene expression appears to be largely constitutive. Apo A-I synthesis demonstrates regional sensitivity to the removal of biliary lipid components, with no effect observed in the jejunum but marked suppression in the ileum. [167] The molecular basis and physiological consequences of this regional heterogeneity are unknown.

Intestinal apo A-I gene expression undergoes marked induction during development, with an increase in mRNA abundance occurring at birth, presumably with the onset of suckling; subsequent mRNA levels appear to remain relatively constant until adulthood. [161] Intestinal apo A-I gene expression may be sensitive to alterations in thyroid hormone status, with such changes mediated at a translational or posttranslational level. [169]

Apo A-IV expression constitutes another abundant intestinal mRNA species, coding for as much as 3% of newly synthesized protein. [170] Its distribution in plasma differs from that of apo A-I and all the other members of this gene family in that it circulates largely unbound to lipoproteins, although about 25% of the plasma apo A-IV in humans is associated with HDL. [163] Its regulation within enterocytes is also distinct from that of apo A-I, as it is responsive to cellular triglyceride flux. [167], [171] The synthesis rates and mRNA abundance of jejunal and ileal apo A-IV double within 4 to 6 hours of ingestion of a fat bolus, and under fasting and postprandial conditions, the proximal to distal gradient of synthesis rates and mRNA abundance is maintained. [171] Further studies demonstrated striking developmental induction of intestinal apo A-IV mRNA abundance, with a greater than 20-fold increase occurring at birth, followed by a gradual decline over the ensuing 14 days. [172] The intestine is the major synthetic and secretory source of apo A-IV, and although no specific function has yet been attributed to this protein, studies suggest that it may act as a potential cofactor for LCAT, although less effectively than apo A-I. [173] Studies in rats have suggested that apo A-IV may be a factor in regulating food intake, and in this regard, its effects appear to be centrally mediated. [174] Transgenic mice expressing high levels of human apo A-IV in the intestine demonstrated no alterations in food intake. [175] Another promising area for investigation was suggested by the demonstration that human apo A-IV transgenic mice bred into the atherosclerosis-susceptible apo E–deficient strain were protected against atherosclerosis. [176]

Apo C-III is a minor intestinal apolipoprotein whose mRNA codes for less than of 0.5% total protein synthesis. [177] Its gene is localized on chromosome 11 between and in a reverse orientation to the apo A-I and apo A-IV genes. [178] Apo C-III probably functions in regulating the hepatic uptake of remnant lipoprotein particles. Studies have demonstrated that, like apo A-IV, apo C-III is regulated after increases in intestinal triglyceride, with accumulation of mRNA and its translational product. [177], [178]

Apo A-II, apo C-I, and apo C-II are minor intestinal apolipoproteins; their regulation has not been studied extensively. [170], [179], [180] Apo D mRNA codes for a protein found in human plasma in association with HDL, whose function is partially understood. This mRNA has been demonstrated in human intestine, [181] but its regulation mechanism is unknown in the gut.

Apo B is synthesized in mammalian enterocytes and hepatocytes as an obligate component of triglyceride-rich lipoproteins (e.g., chylomicrons, VLDL). Based on a centile score in human plasma, two major molecular forms of apo B are found: apo B-100 (~512 kd) and an unglycosylated form, apo B-48 (~241 kd). [182] These isoforms are synthesized in an organ-specific fashion as a result of posttranscriptional RNA editing (described in the following paragraph). Apo B plays an essential role in the assembly of lipoproteins within the liver and small intestine. In addition, apo B-100, the major protein component of circulating plasma LDLs, expresses a domain in its carboxyl terminus that mediates the high-affinity interaction with the LDL receptor and plays a central role in cholesterol catabolism. [183], [184] Because this domain is absent from apo B-48, intestinal lipoproteins such as chylomicrons, which contain apo B-48, are catabolized through a different receptor, referred to as the *chylomicron remnant receptor*. [152]

Mammalian apo B is the product of a single gene that has been mapped in humans to chromosome 2. [152] Its genomic organization is distinct from that of all other apolipoprotein genes. Apo B has 29 exons; exon 26 spans 7572 bases, so that it is one of the largest mammalian exons studied. [152], [183] The underlying mechanism for the organ-specific production of apo B-100 and apo B-48 has been the focus of considerable study. A single apo B gene is transcribed into a 14-kb mRNA in the liver and small intestine. In the liver, this apo B mRNA contains a genomically templated CAA codon that encodes a glutamine residue in apo B-100. In the small intestine, apo B is transcribed into an mRNA in which a site-specific deamination of the cytidine residue in this codon produces a UAA or translational stop. [157], [185] As a result of posttranscriptional RNA editing, intestinal apo B mRNA is translated as a truncated protein that is colinear with the amino-terminal 48% of apo B-100. [157], [185] Apo B mRNA editing occurs in the human small intestine but not in the liver. [157], [185], [186] In contrast, rat and mouse livers contain edited and unedited species of apo B mRNA and secrete apo B-100 and B-48. [187] Apo B mRNA editing is developmentally regulated in the human small intestine and is subject to hormonal and nutritional modulation in the rat liver. [187], [188] and [189] The functional consequence of intestinal apo B mRNA editing is that intestinal chylomicrons (apo B-48) are cleared from the circulation within 30 minutes, and LDL particles (e.g., apo B-100) have a half-life longer than 2 days. [190] Apo B mRNA editing can thus be viewed as an adaptive mechanism for the rapid delivery of intestinal triglyceride to the liver.

The underlying molecular mechanisms have been elucidated and involve protein factors that mediate site-specific deamination in the context of a distinct AU-rich RNA motif. [188] The catalytic subunit of the apo B mRNA editing enzyme, apobec-1, has been cloned and is expressed exclusively in the human small intestine. [191], [192] Apobec-1 knock-out mice phenotypically express exclusively apo B-100. [193] There was no apparent defect in intestinal lipid absorption, suggesting that apo B-100 and apo B-48 can function interchangeably as regards intestinal lipoprotein assembly and secretion. [193], [194]

Despite its evident requirement in the assembly and secretion of triglyceride-rich lipoproteins, intestinal apo B synthesis is not regulated in response to dietary triglyceride augmentation but may be regulated by various components of bile. [195], [196] Intestinal apo B synthesis is decreased in the rat after removal of biliary lipid and reexpressed after introduction of components such as fatty acids and bile salts. The postulated mechanism appears to be the provision of substrate (i.e., fatty acid) for microsomal triglyceride assembly that presumably reaches a threshold level at which intestinal apo B synthesis is reexpressed. Augmentation of the triglyceride flux above this putative threshold produces no further change in apo B synthesis. Regulation of apo B synthesis and posttranslational stability in the context of triglyceride availability has been reviewed. [197]

The developmental regulation of apo B gene expression in the rat is different from that of apo A-I or apo A-IV. [198] After an increase at birth, apo B levels decline until day 8, when a second increase occurs, followed by a second decline to a nadir at age 24 to 35 days. After the second decline, expression increases to adult levels. Apo B RNA editing also is developmentally regulated in mammalian small intestine. [186], [187], [189], [199]

The major evidence that apo B is essential to the process of triglyceride-rich lipoprotein secretion has been derived from studies of humans with syndromes of defective chylomicron assembly and secretion and abnormal apo B gene expression (Table 18-2). The prototype of such syndromes is abetalipoproteinemia, an autosomal recessive condition characterized by mild fat malabsorption and several systemic abnormalities, including ataxia, acanthocytosis, and retinitis pigmentosa. [200]

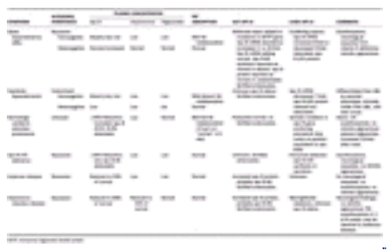

TABLE 18-2 Syndromes of Defective Chylomicron and Very-Low-Density Lipoprotein Secretion

Parents of the affected persons are obligate heterozygotes but manifest normal levels of plasma apo B and no evidence of fat malabsorption. Conclusive studies demonstrated that the molecular basis for abetalipoproteinemia is a defective MTTP gene. [201] Earlier studies of the intestine of two homozygous patients with abetalipoproteinemia revealed an absence of immunoreactive apo B, a finding in contrast to the report of quantitatively normal amounts of immunoreactive apo B-48 (and apo B-100) epitopes in another patient with this disorder. [202], [203] The molecular heterogeneity of abetalipoproteinemia is exemplified by divergent reports of absent or normal apo B-48 synthesis by intestinal explant cultures. [204], [205] Other studies of the livers of two patients with abetalipoproteinemia revealed increased amounts of apo B mRNA, findings that should be contrasted with other work reporting fivefold decreased levels of apo B mRNA. [206], [207] Studies of intestinal apo B mRNA in abetalipoproteinemia have demonstrated an increased abundance of a normally edited transcript. [206], [208] The most reasonable conclusion is that abetalipoproteinemia is a heterogeneous condition in which triglyceride accumulation within hepatocytes and small intestinal cells is accompanied by inconsistent alterations in apo B gene expression. It bears emphasis that apo B mRNA abundance was unaffected in a murine model of abetalipoproteinemia generated through conditional gene targeting of the *Mttp* allele in embryonic stem cells. [209] The molecular basis for abetalipoproteinemia is different from a genetically distinct entity referred to as *hypobetalipoproteinemia*. [210], [211] The distinguishing features in hypobetalipoproteinemia include autosomal codominant inheritance and low plasma apo B levels in obligate heterozygotes. Studies have shown a sevenfold decrease in hepatic apo B-100 mRNA levels, compared with a sixfold increase in abetalipoproteinemia and a reduced intracellular apo B-100 mass. [211] Hypobetalipoproteinemia may represent a translational abnormality with an unstable or an abnormal apo B mRNA.

Patients with several other syndromes have various degrees of fat malabsorption and are unable to assemble and secrete triglyceride-rich lipoproteins from enterocytes or hepatocytes. These syndromes are summarized in Table 18-2 and collectively form the basis for investigating the molecular details of apo B assembly and processing and its requisite involvement in chylomicron secretion. [200], [201], [202], [203], [204], [205], [206], [207] and [208], [210], [211], [212], [213], [214], [215], [216], [217] and [218]

Characterization of Intracellular Intestinal Lipoproteins

Lipoproteins are multimolecular aggregates of lipid and protein, with a configuration that allows the transport of intensely hydrophobic lipid through the aqueous milieu of cellular cytosol and plasma compartments. The apolar lipid core of the particle contains triglyceride and cholesterol ester, and the surface coat is composed of cholesterol, lecithin, and apolipoproteins. The intestine assembles and secretes chylomicrons, VLDL, HDL, and perhaps LDL (see Fig. 18-4). Chylomicrons (80–500 nm) are assembled during periods of lipid absorption and have been isolated from within intestinal Golgi organelles. Intracellular chylomicrons are composed of 13% to 25% protein and 75% to 85% lipid, two thirds of which is triglyceride. [146], [168], [219] In contrast, extracellular chylomicron composition in lymph and plasma is greater than 95% lipid, 90% of which is triglyceride. [220], [221] The major apolipoproteins on the surface of intracellular chylomicrons are apo B-48, apo A-I, and apo A-IV. These proteins are synthesized within the enterocyte.

VLDL-size particles (25–80 nm) are assembled in the enterocyte during fasting and lipid feeding. Apolipoproteins comprise about 15% of intracellular VLDL—apo B-48, apo A-I, and apo A-IV. As with chylomicrons, the lipid moiety of VLDL is largely triglyceride and phospholipid. [219] The compositional resemblance of chylomicrons and VLDL suggests that these particles represent a size continuum of the same type of lipoprotein whose volume depends on the availability of intracellular triglyceride. [222] There appear to be separate pathways for chylomicron and VLDL assembly, based on the demonstration of chylomicrons and VLDLs in different Golgi organelles, together with studies showing selective inhibition of chylomicron secretion despite persistent VLDL secretion. [223], [224]

Lipoprotein particles of the size of LDL have been isolated from within enterocytes and partially characterized. [146] The particles contain newly synthesized apo A-IV and apo B and trace amounts of apo A-I. The lipid composition is 40% phospholipid and 31% triglyceride. In rats given galactosamine, which profoundly reduces the hepatic synthesis of lipoproteins, there appear to be intestinally derived particles of the size of LDL in mesenteric lymph. [225] However, these data should not be construed to indicate that the intestine is normally a source of plasma LDL.

HDL particles, although too small to be seen in electron micrographs of unfractionated enterocytes, have been isolated within Golgi vesicles of rat enterocytes. [226] Intracellular HDL particles have been visualized as spherical 6- to 13-nm particles. Compositional analysis has revealed two distinct populations, one containing apo A-I and A-IV and the other containing apo B-48 as the surface apolipoprotein. The particles are composed of 70% protein and 30% lipid, one half of which is phospholipid. Whether the HDL particles that contain apo B-48 are metabolic precursors to chylomicrons is unknown, as is their fate.

Mesenteric lymph contains a population of discoidal and spherical HDL particles that are secreted from the intestine. [227], [228] Discoidal particles make up about 50% of fasting levels of lymph HDL; these particles are enriched in apo A-I and phospholipid relative to plasma HDL. Apo A-I on these HDL particles is metabolically derived by de novo intestinal synthesis. Metabolic labeling experiments in rats provide good evidence that discoidal HDL particles are synthesized within enterocytes and do not simply reflect lipolytic products of triglyceride-rich lipoproteins or ultracentrifugation artifacts. [227] Spherical lymph HDL particles are also relatively protein- and phospholipid-enriched compared with plasma HDL particles, and they contain core cholesteryl ester that appears to have an intestinal source (i.e., ACAT derived) rather than a plasma (i.e., LCAT derived) source, as evidenced by the high ratio of saturated to unsaturated fatty acid esters. [227] These spherical particles resemble intracellular HDL particles.

Further evidence that newly synthesized HDL particles are secreted by the intestine comes from examination of the specific activity of lipoprotein phospholipid after administration of choline-labeled bile lecithin. [229] The phospholipid of lymph HDL has a lower specific activity than VLDL phospholipid, indicating that the two particles are derived from distinct synthetic pathways. [229]

Mesenteric Lymph Lipoproteins

Studies of rats have characterized the principal species of intracellular apolipoproteins. After secretion into the lymph compartment, several alterations occur in apolipoprotein composition, largely as a result of the passive exchange of surface protein components with lipoproteins in lymph. [220] It is likely, although unproved, that a similar situation exists in humans. Rat mesenteric lymph chylomicrons and human chyluric chylomicrons demonstrate a striking degree of homology in their apolipoprotein compositions. [220] In addition to apo B-48, apo A-IV, and A-I, human and rat lymph-derived chylomicrons contain substantial quantities of albumin, apo E, and apo C. Human chyluric and pig intestinal lymph chylomicrons also contain a peptide of a size compatible with apo B-100, suggesting that apo B-100 transfers onto lymph chylomicrons or, more likely, that hepatic VLDL (containing apo B-100), secreted into the cisterna chyli, contaminates the chylomicron fraction. [228], [230]

The presence of discoidal HDL in mesenteric lymph and in perfusates from rat liver, but not in plasma, suggests that this form of lipoprotein is secreted directly into lymph. It is postulated that discoidal HDL becomes rapidly converted to a spherical morphology after the action of LCAT, which converts free cholesterol to cholesteryl ester and enriches the core of these particles with hydrophobic lipid. [227] During fasting, 75% to 85% of lymph apo A-I is in the HDL fraction. [147], [231], [232] Essentially all apo B in fasting lymph is in the chylomicron-LDL fraction. [147] During lipid feeding, 25% to 50% of apo A-I and 67% to 100% of apo B in lymph is in chylomicrons and VLDL. [147], [233]

Lipid Effects on Intestinal Lipoprotein Assembly and Secretion

Triglyceride Effects on Apolipoprotein Synthesis and Secretion There is no consensus regarding the regulatory effect of triglyceride feeding on human intestinal apolipoprotein synthesis. Some studies suggest that acute triglyceride feeding increases apo A-IV synthesis, but not apo A-I or apo B-48 synthesis. [167], [171], [195], [234] Similarly, chronic triglyceride feeding has no affect on the synthesis of apo A-I or apo B-48. [168] Older studies based on the immunofluorescence or immunoperoxidase

staining of apo A-I, apo A-IV, or apo B demonstrated an increase in intracellular apolipoprotein content in response to triglyceride feeding, which can be interpreted as being consistent with increased synthesis. [232], [235], [236] It may be that alterations in the intracellular location of apolipoproteins, as occurs during lipid absorption, account for differences in staining characteristics. Reports of enterocyte apolipoprotein content after lipid absorption have shown increased, decreased, and unchanged apo A-I and apo B content. [167], [236], [237] and [238] Considered together, the available evidence suggests that only apo A-IV gene expression is responsive to alterations in mucosal triglyceride flux. In this regard, cell culture studies have suggested that apo A-IV synthesis is regulated transcriptionally through the secretion of leptin. [239] These findings, however, have not been confirmed in rats, the results showing no adaptation to chronic high-fat intake and no relation to serum leptin levels. [240] The secretion of apolipoproteins A-I, A-IV, and B into the lymph, unlike their intracellular content or synthesis, increases during lipid feeding. [232], [233], [234], [235], [236], [237] and [238], [241], [242] During lipid absorption, however, lymph flow rates and the transfer of proteins from plasma to lymph increases. Thus, conclusions about enterocyte synthesis based on lymph apolipoprotein measurements are difficult to interpret. [231], [233], [242], [243] The effect of lipid on intestinal apolipoprotein secretion has been studied extensively. In patients with chyluria, in whom intestinal lymph is directly secreted into urine, apo A-I and apo A-IV increase after lipid feeding. [244] Examination of human thoracic lymph after lipid feeding has shown an increase in secretion of pro–apo A-I. [245] However, when plasma apolipoprotein levels are experimentally reduced in rats treated with ethinyl estradiol, only apo A-IV increases in lymph during triglyceride absorption, suggesting that the observed postprandial increases in apo A-I and apo B-48 may be the result of plasma filtration. [246] The issue of increased intestinal secretion or plasma filtration of apo B-48 and apo A-I remains unsettled. A unifying hypothesis is needed to account for the apparently conflicting observations of increased lymph apolipoprotein secretion without accompanying changes in intestinal apolipoprotein synthesis rates after a fatty meal. [146] Such a hypothesis may be derived from the observation that a large intracellular pool of apo A-I and apo B is principally microsomal and not associated with lipoprotein. After a fatty meal, a significant shift occurs, increasing by twofold to threefold the lipoprotein-associated fractions of both apolipoproteins, which are then destined for export, while producing minimal changes (<10%) in the total intracellular pool size of apolipoproteins. [146]

Triglyceride Effects on Lipoprotein Composition The fatty acid composition of chylomicron triglyceride mirrors the composition of triglyceride in the intestinal lumen. [222], [247], [248] The size of secreted chylomicrons is affected by the quantity and type of lipid absorbed. The more triglyceride that is absorbed, the larger the chylomicrons. [247] The composition of the triglyceride also affects the size of chylomicrons. In general, chylomicrons increase in size as the lipids contained within them become less saturated. [247] When saturated fats such as palmitate are fed, smaller chylomicrons are secreted into lymph than when unsaturated fatty acids are fed, although this observation has not been consistent. [222], [233] The presence of unsaturated fatty acids also affects the composition of chylomicrons in that there is less apo B-48 on chylomicrons containing unsaturated triglyceride. [233] During active lipid absorption, the uptake of free fatty acids from plasma into the enterocytes and the incorporation of these fatty acids into newly synthesized triglyceride are increased. [85] Triglyceride feeding affects the triglyceride component of lipoproteins and the phospholipids. The fatty acid composition of lymph lipoprotein phospholipids at least partially reflects the fatty acids present in the intestinal lumen. This observation is consistent with the concept that phospholipids are in part derived from lumenal triglyceride during triglyceride feeding. [229] Phospholipids are synthesized de novo during triglyceride feeding, suggesting that reacylation of absorbed lysolecithin and the phosphatidic acid–cytidine diphosphate choline pathways contribute to lipoprotein phospholipid. Triglyceride feeding also increases the phospholipid content of lymph HDL. [229], [249]

Effect of Bile Diversion and Fasting Reduced intestinal lipid flux has been produced experimentally by using a combination of bile diversion and fasting. The lack of biliary lipid, bile salts, and exogenous lumenal lipid reduces triglyceride output in lymph by 85% and results in the almost total disappearance of VLDL from Golgi organelles. [231] Apo A-I synthesis in jejunal enterocytes after bile diversion is similar to that observed in fasted animals, although ileal enterocytes exhibit lower rates of synthesis. [167] Reinfusion of bile salts alone fails to prevent the decrease in ileal apo A-I synthesis. Apo B-48 synthesis, which is dramatically suppressed in jejunal and ileal enterocytes after bile diversion, is reexpressed in jejunal, but not ileal, enterocytes after intralumenal administration of sodium taurocholate. [195] The bile salt–dependent reexpression of apo B biosynthesis in rat enterocytes can be reproduced by infusion of lysolecithin or fatty acid alone, and it is apparent that this regulation is at a translational or posttranslational level because total apo B mRNA abundance is unaltered. [196] Studies examining intestinal microsomal triglyceride concentration indicate an association between the reexpression of jejunal apo B biosynthesis and microsomal triglyceride content, suggesting that a threshold level of triglyceride may be required for the stable elaboration of intestinal apo B-48. [196] Consistent with the dramatically reduced secretion of triglyceride after bile diversion, intestinal synthesis of apo A-IV is also reduced. [250] The phospholipid composition of lymph HDL during bile diversion is similar to that of non–bile-diverted controls, suggesting that intestinal HDL phospholipid is not derived from exogenous sources. [229] In the absence of dietary fat, the intestine contributes 11% to 40% of the total plasma triglyceride, 10% to 15% of apo B, 50% of plasma apo A-I, and almost 100% of apo A-IV. [157], [222], [249], [251], [252], [253] and [254] Under fasting conditions, intracellular apolipoprotein and VLDL particles can be localized to enterocytes, and newly synthesized apolipoprotein can be isolated from enterocytes and lymph. [145], [168], [255] Intestinal VLDL and HDL are also found in lymph during fasting, with the lipid presumably arising from bile and sloughed, digested enterocytes.

Effect of Phospholipid Absorbed phospholipid comes from bile (10–20 g/d) and from exogenous dietary phospholipid (5–10 g/d). Endogenous sources of lipoprotein phospholipid include de novo synthesized lecithin and the preformed intracellular pool of phospholipids. Lecithin is the predominant phospholipid in lipoproteins. Lecithin infusion results in the intracellular synthesis of triglyceride and lecithin and the incorporation of these lipids into secreted lipoproteins. Infusion of lecithin without triglyceride leads to newly synthesized triglyceride and subsequent VLDL secretion. [229], [256] Most of the infused phospholipid is reassembled into triglyceride through the intracellular hydrolysis of lysolecithin to glycerol-3-phosphate and subsequent reassembly to triglyceride through the phosphatidic acid pathway. [125], [257] Infusion of triglyceride and phospholipid similarly leads to newly synthesized chylomicron triglyceride, which is derived in part from the infused lecithin. Approximately 75% of the fatty acids in infused lecithin occur in lymph triglyceride. [256] The addition of lecithin during high rates of triglyceride infusion increases lymph triglyceride secretion, suggesting that adequate amounts of phospholipid must be available to serve as the surface coat for newly synthesized triglyceride to be secreted as a chylomicron. [258] If biliary lecithin is eliminated during high-dose triglyceride infusion, the effect on lipoprotein phospholipid is variable. Some researchers observed a decrease in secretion, but others reported no change. [229], [258], [259] and [260] At normal rates of triglyceride infusion, there is no decrease in lymph phospholipid secretion after bile diversion. [229], [258] Infusion of lecithin decreases cholesterol secretion. [229], [258] In fasting animals, the phospholipid compositions of VLDL and HDL in lymph resemble those in bile. [229] Elimination of bile that contains 16:0 fatty acids significantly decreases the 16:0 species from lymph lipoproteins in fasted animals. [229] In triglyceride-fed animals, the VLDL and HDL phospholipid compositions mirror the fatty acids in the infused triglyceride. [229] Bile diversion does not significantly affect the composition of lipoprotein phospholipid in fed animals.

Effect of Cholesterol Feeding Only a small percentage of cholesterol recovered in lymph is of exogenous origin. [248] In general, the consequence of increased dietary cholesterol is increased cholesterol content in all lymph lipoproteins. In monkeys, during the experimental infusion of diets with a high cholesterol content, there is an increase in thoracic duct total lymph cholesterol mass. [261] The amounts of free and esterified cholesterol increase, although there is preferential esterification of the absorbed (i.e., lumenal) cholesterol in the lymph chylomicron and VLDL fractions, which leads to a proportionally greater rise in esterified cholesterol than in free cholesterol in the lymph. [262] In rats chronically fed diets containing high levels of cholesterol, mesenteric lymph cholesterol redistributes to an intermediate-density lipoprotein fraction (1.006–1.030 g/mL), in which there appears a particle that is triglyceride- and cholesteryl ester–enriched, with apo A-I and apo B as the major apolipoproteins. [263] Alterations in the composition of ingested triglyceride may affect cholesterol absorption in the rat. Animals fed large concentrations of unsaturated fatty acids demonstrated increased cholesterol absorption, with the excess recovered in the lymph VLDL fraction. [222] These results have not been substantiated in controlled studies of humans. [264]

Metabolic Fate of Intestinal Lipoproteins

The small intestine synthesizes and secretes a variety of lipoprotein particles, principally triglyceride-rich lipoproteins—chylomicrons and VLDL—and HDL. The metabolic fate of each of these particles is distinct and has been the focus of considerable investigation. Chylomicrons enter the lymphatic circulation through fenestrations in the capillary endothelium and immediately undergo a series of modifications to their surface protein composition. The principal surface proteins of nascent intracellular intestinal chylomicrons are pro-apo A-I, apo A-IV, and apo B-48. After entering the lymph compartment, apo E, apo C-II, and apo C-III transfer from the surface of filtered plasma HDL by passive exchange, a process during which chylomicron apo A-I, apo A-IV, and phospholipid are transferred into HDL. [248] Most (50%–75%) of apo A-IV is transferred into the lipoprotein-free fraction of lymph and plasma, [241] where it displays fractional turnover kinetics distinct from those of HDL-associated apo A-IV. [265] As previously described, apo A-I is synthesized and secreted in the form of a stable propeptide containing a 6–amino acid prosegment. [161] This prosegment, which terminates with paired glutamine rather than paired basic residues, [161] is cleaved extracellularly in both lymph and plasma compartments by a metal-dependent protease. [266] The metabolic fate of chylomicron surface apolipoproteins A-I and A-IV appears to be distinctive. These apolipoproteins are thought to contribute substantially to the circulating pool of HDL apolipoprotein. In view of the importance of HDL as an epidemiologic marker of coronary artery disease susceptibility, [166] increased understanding of the physiological parameters governing chylomicron surface catabolism is of clinical importance. After completion of the surface exchange reactions (note that apo B-48 does not participate in these reactions and therefore can be used as a marker of an intestinally derived lipoprotein), chylomicrons are transported to the capillary beds of peripheral tissues, where the core triglyceride undergoes hydrolysis mediated by lipoprotein lipase. [267] Apo C-II is a critical cofactor in activating lipoprotein lipase, and its deficiency is associated with severe hypertriglyceridemia and chylomicron accumulation. [268] Apo C-II is synthesized in both liver and intestine in humans and circulates predominantly with triglyceride-rich lipoproteins. [269] After catabolism of the core triglyceride, the resulting chylomicron particle undergoes substantial modification; most of the surface apolipoproteins are lost, with the notable exception of apo E and apo B-48. This particle is referred to as a *chylomicron remnant* and is transported to a number of sites, including the liver, where it is thought to bind to a cell

surface receptor. The evidence suggests that apo E may be the cognate ligand. [270] This receptor displays characteristics distinct from the LDL (i.e., apo B, apo E) receptor. [270] Metabolic studies of patients with homozygous familial hypercholesterolemia and study of an animal model of familial hypercholesterolemia, in which there is also virtually complete deficiency of LDL receptors, demonstrate normal chylomicron uptake, indicating that at least two populations of lipoprotein receptors recognize apo E–containing particles. [271], [272] A cell surface receptor that resembles the LDL receptor and epidermal growth factor precursor has been identified and is referred to as the *LDL receptor–related protein (LRP)*. [273] LRP functions as an apo E receptor, has an estimated molecular mass of 503 kd, and is translated from a 15-kb transcript. [273] The tissue distribution of the LRP transcript (liver > brain > lung > intestine) suggests that the receptor—if it functions as a chylomicron remnant receptor—may play a more widespread role in tissue cholesterol delivery than previously supposed. Indeed, targeted disruption of LRP in mice leads to embryonic lethality, necessitating the use of the Cre-lox P recombinant system to inactivate LRP to ascertain its role in chylomicron remnant uptake. [274]

Hepatic uptake of triglyceride-rich lipoprotein remnant particles is also modulated by the presence of C apolipoproteins on the lipoprotein surface. Substantial inhibition of remnant uptake occurs with particles containing apo C-II, particularly isoform 2. [275] This finding, based on in vitro studies of the perfused rat liver, has been extended to a study of chylomicron catabolism in persons with apo C-III and apo A-I deficiency, in whom chylomicron catabolism was unusually rapid. [276]

The regulation of plasma HDL metabolism differs from that for chylomicron and LDL metabolism. Plasma HDL is directly secreted from the liver and intestine and is derived from the catabolism of triglyceride-rich lipoproteins. [226], [277], [278] The identification of a class B scavenger receptor (SR-B1) as the long-sought HDL receptor has generated considerable interest in HDL metabolism. [279] Another transporter family, related to the ABC-type transporters, has been identified in patients with low HDL levels as the defective gene in Tangier disease (see previous discussion of ABCA1 in section “ Brush Border Membrane Events”). [65], [66] and [67]

LIPID ABSORPTION IN MALABSORPTIVE STATES

The process of intestinal lipid absorption requires a critical interaction of several distinct elements, disturbances in any of which may become rate limiting to the overall process. A key feature of intestinal lipid absorption is the substantial functional reserve that compensates for minor limitations in some of the critical phases of this process and that limits the extent of malabsorption. For example, the enormous functional capacity of the exocrine pancreas for secreting lipase delays the appearance of lipid malabsorption in pancreatic insufficiency until relatively late in the destructive process. In infants with cystic fibrosis, the preservation of gastric lipase secretion limits the effects of pancreatic insufficiency.

The formation of lipid micelles is critical to effective absorption, and decreased intralumenal bile salt concentrations, resulting from uncompensated ileal losses or bacterial deconjugation in the proximal small intestine, produce malabsorption of lipid. Clinically, the extent of fat malabsorption may be complicated by the coexistence of several defects, such as mucosal damage and villus blunting, together with bile salt deconjugation in small intestine bacterial overgrowth. Processing and intestinal lipoprotein secretion by the enterocyte may be defective. In the setting of diffuse structural diseases, such as celiac sprue, defective enterocyte function can produce severe fat malabsorption.

CHAPTER 19

Vadivel Ganapathy, Malliga E. Ganapathy, and Frederick H. Leibach

PROTEIN DIGESTION AND ASSIMILATION

The digestion and assimilation of proteins differ from that of carbohydrates and lipids in a number of aspects. Unlike the carbohydrates in the diet, which consist of quantitatively significant amounts of monosaccharides (e.g., glucose and fructose) and disaccharides (e.g., sucrose and lactose), in addition to polysaccharides (e.g., starch and glycogen), dietary amino acids are ingested predominantly as proteins. The amount of free amino acids and small peptides is very low in the normal diet. Dietary carbohydrates are absorbed by the enterocytes exclusively as monosaccharides. Therefore, the polysaccharides and disaccharides in the diet must be digested in the intestinal lumen completely to monosaccharides before absorption can occur. In contrast, the digestion of proteins in the intestinal lumen is incomplete, resulting in the generation of a mixture of free amino acids and small peptides in which peptides predominate. A major portion of protein digestion products is absorbed by the enterocytes as small peptides, which are subsequently digested to free amino acids inside the enterocytes. Thus, in addition to the specific transport systems in the intestine for monosaccharides, distinct transport systems exist in this organ for free amino acids and small peptides. Furthermore, unlike dietary carbohydrates, which consist predominantly of only three structurally different monosaccharides (glucose, galactose, and fructose), dietary proteins comprise a much greater number of structurally and physicochemically diverse amino acids. Consequently, the enzymes and transport systems involved in the digestion and absorption of proteins outnumber those involved in the digestion and absorption of carbohydrates. Moreover, unlike dietary lipids and their digestion products, which are highly hydrophobic, dietary proteins and their digestion products are largely hydrophilic. Therefore, bile salts, which play an obligatory role in the solubilization of dietary lipids to facilitate their digestion and assimilation, do not play any direct role in the digestion and assimilation of dietary proteins. However, bile salts and bile salt–facilitated fat digestion may influence protein digestion indirectly because bile salts and fat digestion products in the intestinal lumen are important modulators of cholecystokinin secretion, a process with profound influence on the secretion of pancreatic enzymes involved in protein digestion.

ASPECTS OF DIETARY PROTEINS

The recommended daily allowance for dietary proteins in humans, when expressed per kilogram of body weight, declines in an age-dependent manner. [1] In adults, this value is 0.75 g/kg; it is twice as much in newborns. The recommended daily allowance for dietary proteins increases during illnesses such as sepsis and during trauma; it also increases in women during pregnancy and lactation. The protein content of the average daily American diet is 70 to 100 g, which is more than adequate to meet the recommended daily allowance. Dietary proteins are required for two purposes: (1) to provide the amino acids that are nutritionally essential under all conditions (i.e., methionine, threonine, tryptophan, valine, isoleucine, leucine, phenylalanine, histidine, and lysine) and the amino acids that are conditionally essential under specific physiological and pathological conditions (i.e., cysteine, tyrosine, glutamine, and arginine); and (2) to provide nitrogen for the synthesis of nutritionally nonessential amino acids and other metabolically important nitrogen-containing compounds. The nutritive value of various dietary protein sources depends on their content of the nutritionally essential amino acids as well as on their digestibility. Proteins from animal sources have a high content of nutritionally essential amino acids. Egg and milk proteins are routinely used as reference standards for comparison of protein quality. Proteins from certain specific plant sources are “incomplete” because they lack or contain only limited amounts of some of the essential amino acids. However, by complementation with plant proteins, which contain the missing amino acids, it is possible to overcome this deficit in a complete diet. [2] Just as the essential amino acid content varies, the digestibility of different proteins also varies considerably. Protein digestibility is influenced by the type of protein and by the method of food processing before ingestion. Generally, plant proteins are less digestible than animal proteins. The relative contributions of animal proteins and plant proteins in the daily intake of dietary proteins differ markedly between developed and developing countries. [3] For example, in North America and Western Europe, animal proteins contribute about 60% to 70% to the total proteins in the diet. In contrast, this contribution is as low as 20% in Africa, the Middle East, and the Far East.

In addition to the proteins in the diet, substantial amounts of endogenous proteins enter the gastrointestinal tract and are digested and assimilated just like the dietary proteins. These endogenous proteins arise partly from the saliva and the gastric, biliary, pancreatic, and intestinal secretions and partly from desquamated epithelial cells of the gastrointestinal tract. The secretions account for about 20 to 30 g of endogenous proteins per day, and desquamated cells account for an additional 30 g per day. [4]

DIGESTION OF PROTEINS

The digestion of proteins occurs in two phases defined by the site of digestion along the gastrointestinal tract: a gastric phase and an intestinal phase. For the sake of convenience, the intestinal phase can be subdivided into a lumenal phase, a brush border phase, and an intracellular phase, again defined by the exact location of digestion in the intestine. The overall scheme of protein digestion in the gastrointestinal tract is depicted in Figure 19-1.

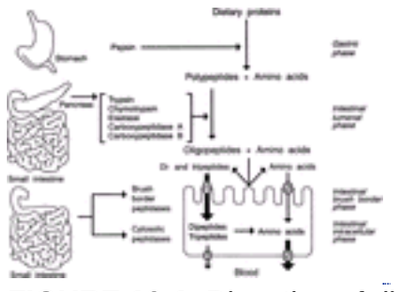

FIGURE 19-1. Digestion of dietary proteins and absorption of digestion products in the gastrointestinal tract. *1,* Transport system for dipeptides and tripeptides; *2,* transport systems for free amino acids.

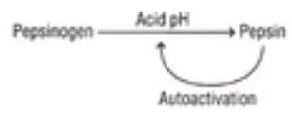
Gastric Phase

Protein digestion begins in the lumen of the stomach with the action of proteases elaborated by the gastric cells. These enzymes, called *pepsins,* belong to the category of carboxyl proteases that are active at acid pH. The carboxyl groups of two anionic amino acid residues in the enzymes play an obligatory role in the catalytic activity. The enzymes are secreted as inactive precursors into the gastric lumen (i.e., pepsinogens), where they are autocatalytically activated to pepsins

under acidic conditions (Fig. 19-2). Two different pepsinogens are known to be present in humans. Pepsinogen A or I, the more abundant of the two forms, is secreted by chief cells found in the fundus and body of the stomach. The less abundant form, pepsinogen C or II (also known as *progastricsin*), is secreted by chief cells found throughout the entire stomach. There are five isoenzyme forms of pepsinogen A and two isoenzyme forms of pepsinogen C. Pepsinogens possess an amino-terminal region that is positively charged because of the high content of cationic amino acids. At neutral or alkaline pH, this region is folded in pepsinogens in such a way that it masks the catalytic site. This inactive state is stabilized by electrostatic interaction between the cationic amino-terminal region and the acidic amino acids in pepsinogens, which are ionized at neutral or alkaline pH. In the acidic environment of the gastric lumen, these acidic amino acids are protonated, so that electrostatic interaction is destabilized, uncovering the catalytic site. The unmasked active site removes the amino-terminal region, consisting of about 40 amino acids, from pepsinogens by autocatalytic digestion to generate the active forms of the enzymes, the pepsins. Pepsins A and C exhibit similar substrate specificity. They are endoproteases that hydrolyze internal peptide bonds in proteins and liberate large peptide fragments. Pepsins act preferentially on peptide bonds formed by the amino group of the aromatic amino acids phenylalanine and tyrosine, as well as by the branched-chain amino acid leucine (Fig. 19-3). The peptide bonds formed by the carboxyl group of these amino acids are also somewhat susceptible to digestion by pepsins. The action of these enzymes on proteins in the gastric lumen results in a mixture of large polypeptides, smaller oligopeptides, and small amounts of free amino acids.



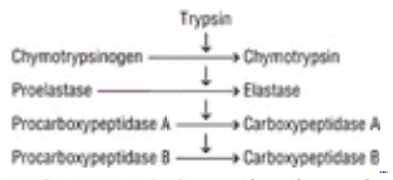


FIGURE 19-2. Activation of gastric and pancreatic zymogens.

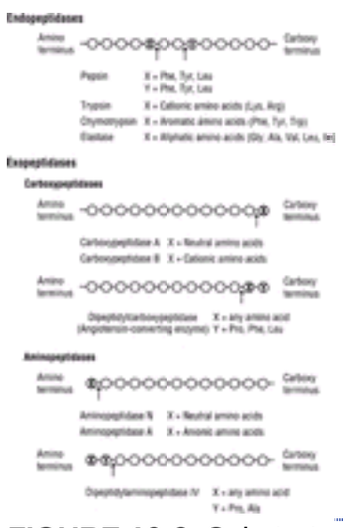

FIGURE 19-3. Substrate specificity of proteases and peptidases involved in the digestion of proteins in the gastrointestinal tract.

Gastric juice contains HCl and thus has a pH of less than 2. The acid pH aids the digestive action of pepsins in three ways: (1) Proteins are denatured, rendering them more susceptible to proteolytic attack; (2) pepsinogens are autocatalyzed to active pepsins; and (3) the catalytic mechanism mediated by the carboxyl groups of the two anionic amino acid residues in the active site of pepsins is effective. Pepsins are not catalytically active at a pH above 4. Therefore, the digestive action of pepsins on proteins is restricted to the stomach. The acidic stomach contents are neutralized by the pancreatic and intestinal secretions when they enter the duodenum, leading to the inactivation of pepsins.

The products of protein digestion by pepsins in the stomach lumen may play an essential role in modulating gastric functions, such as acid and pepsinogen secretion and gastric emptying. These products may also act as stimulants for the release of cholecystokinin in the duodenum, thus influencing pancreatic secretion. Despite the apparent functional consequences of the action of pepsins on proteins, the gastric phase is not essential for overall protein digestion inasmuch as protein digestion and assimilation are not significantly impaired by partial or total gastrectomy.

Intestinal Phase

The intestinal phase of protein digestion consists of three stages: the lumenal phase, the brush border phase, and the intracellular phase (see Fig. 19-1). The lumenal and the brush border phases take place before the protein digestion products are absorbed into the enterocytes across the brush border membrane. In the intracellular phase, the absorbed peptides are digested inside the enterocytes. Protein digestion comes to an end at this stage. The final products of digestion leave the enterocytes across the basolateral membrane and enter the portal circulation.

Lumenal Phase The lumenal phase of protein digestion in the small intestine is mediated by pancreatic proteases and peptidases. This phase begins in the duodenum, where the pancreatic juice enters the small intestine. The exocrine pancreas produces three endoproteases and two exopeptidases, and each of these enzymes is synthesized and secreted as an inactive precursor (i.e., a zymogen). The inactive forms of the three endoproteases are trypsinogen, chymotrypsinogen, and proelastase. The inactive forms of the two exopeptidases are procarboxypeptidase A and procarboxypeptidase B. Activation of these inactive zymogens is initiated in the duodenum by enteropeptidase (also known as *enterokinase*), an enzyme associated with the brush border membrane in the duodenum. Enteropeptidase is an integral membrane protein and consists of a heterodimer linked with disulfide bonds. [5] The heavy chain is anchored to the brush border membrane, and the light chain contains the catalytic site. The enzyme initially is synthesized by the enterocytes as a single polypeptide precursor and then is processed to the heterodimeric form by a hitherto unidentified mechanism. The only known substrate for enteropeptidase is trypsinogen. The action of enteropeptidase on trypsinogen results in the proteolytic removal of a hexapeptide from the amino terminus of trypsinogen, generating trypsin, the catalytically active form. This is the key step in the activation of pancreatic proteases because trypsin thus generated can activate trypsinogen autocatalytically and can also activate the remaining pancreatic zymogens (see Fig. 19-2). The action of trypsin leads to the conversion of chymotrypsinogen to chymotrypsin, proelastase to elastase, procarboxypeptidase A to carboxypeptidase A, and procarboxypeptidase B to carboxypeptidase B. Trypsin, chymotrypsin, and elastase are endoproteases capa- ble of hydrolyzing the internal peptide bonds in proteins and polypeptides. The substrate specificities of these enzymes are given in Figure 19-3. Trypsin hydrolyzes peptide bonds formed by the carboxyl group of cationic (i.e., basic) amino acids (lysine and arginine); chymotrypsin hydrolyzes peptide bonds formed by the carboxyl group of aromatic amino acids (phenylalanine, tyrosine, and tryptophan); and elastase hydrolyzes peptide bonds formed by the carboxyl group of aliphatic amino acids (glycine, alanine, valine, leucine, and isoleucine). Carboxypeptidase A and carboxypeptidase B are exopeptidases, capable of hydrolyzing the terminal peptide bonds on the carboxyl terminus of polypeptides. These two enzymes contain zinc at their active sites. Carboxypeptidase A cleaves carboxyl terminal peptide bonds if the amino acid at the terminus is a neutral amino acid (aromatic or aliphatic), and carboxypeptidase B cleaves carboxyl terminal peptide bonds if the amino acid at the terminus is a cationic amino acid (lysine or arginine) (see Fig. 19-3). These two enzymes thus release free amino acids from polypeptides. Pancreatic endoproteases

and exopeptidases function in a highly complementary manner to carry out the efficient digestion of proteins. Chymotrypsin and elastase generate oligopeptides that contain neutral amino acids at their carboxyl terminus, and these peptides become the preferential substrates for carboxypeptidase A. Trypsin generates oligopeptides that contain cationic amino acids at their carboxyl terminus, and these peptides become the preferential substrates for carboxypeptidase B. The action of these pancreatic enzymes on proteins in the intestinal lumen produces a mixture of oligopeptides and free amino acids, of which oligopeptides constitute a major portion (60%–70%) of the total amino nitrogen.

Brush Border Phase The amino acids generated by the concerted action of pancreatic enzymes on proteins are absorbed as such into the enterocytes across the brush border membrane. In contrast, the oligopeptides undergo further hydrolysis by the action of a battery of peptidases associated with the brush border membrane, resulting in a mixture of free amino acids, dipeptides, and tripeptides, before absorption. [6] The intestinal brush border membrane is particularly rich in aminopeptidase activity. Aminopeptidases are exopeptidases that are capable of hydrolyzing the terminal peptide bonds on the amino terminus of oligopeptides. This provides functional complementation to the carboxypeptidases present in the pancreatic juice. In addition to several aminopeptidases, the intestinal brush border membrane also contains endopeptidase and dipeptidase activities. The two major aminopeptidases associated with the intestinal brush border membranes are aminopeptidase N and aminopeptidase A. The substrate specificity of these two enzymes is given in Figure 19-3. Aminopeptidase N hydrolyzes the amino-terminal peptide bond of oligopeptides if the amino acid at the terminus is a neutral amino acid. Aminopeptidase A, in contrast, hydrolyzes the amino terminal peptide bond of oligopeptides if the amino acid at the terminus is an anionic amino acid. In addition to these enzymes, two other peptidases are associated with the intestinal brush border membrane. Dipeptidylcarboxypeptidase is an exopeptidase (also called *angiotensin-converting enzyme*) that hydrolyzes the peptide bond adjacent to the carboxyl-terminal peptide bond. Dipeptidylaminopeptidase IV is also an exopeptidase, but it hydrolyzes the peptide bond adjacent to the amino-terminal peptide bond. Thus, unlike aminopeptidase N and aminopeptidase A, which release free amino acids from oligopeptides, dipeptidylcarboxypeptidase and dipeptidylaminopeptidase IV release dipeptides from oligopeptides. The substrate specificities of these two enzymes are such that the dipeptides released are generally of the X-proline type, where *X* represents any amino acid (see Fig. 19-3). Animal studies have established unequivocally the essential role of dipeptidylcarboxypeptidase and dipeptidylaminopeptidase IV in the intestinal assimilation of oligopeptides. [7], [8], [9], [10] and [11]

Intracellular Phase The end products of protein digestion by gastric and pancreatic proteases and by peptidases associated with the intestinal brush border membrane comprise a mixture of free amino acids and small peptides. The peptides consist primarily of two to six amino acids. Of the total amino acid content in the intestinal lumen, the peptide-bound amino acids represent a predominant fraction. The absorption of free amino acids into the enterocyte across the brush border membrane is mediated by a number of distinct amino acid transport systems. Peptides consisting of two or three amino acids are absorbed intact across the brush border membrane by a specific peptide transport system. The peptides, once inside the enterocyte, are hydrolyzed to free amino acids in the cytoplasm by various intracellular peptidases. The peptidases exhibit a preference for dipeptides and tripeptides as their substrates. The similarity between the substrate specificities of the intracellular peptidases and the peptide transport system is of functional importance because the transport system makes the peptide substrates available for the intracellular peptidases by importing them across the brush border membrane from the intestinal lumen. The intracellular peptidases that have been characterized in detail include an aminotripeptidase, which releases the amino acid present at the amino terminus of tripeptides, and several dipeptidases, which show differential substrate specificities toward dipeptides containing specific amino acids. [6] Among the dipeptidases, iminodipeptidase (also called *prolidase*) is of special interest because of its restricted specificity toward dipeptides of the X-proline or X-hydroxyproline type. Peptide bonds formed by the imino acids proline and hydroxyproline in proteins are generally resistant to hydrolysis by proteases and peptidases involved in the digestion of proteins in the intestinal lumen. Consequently, the imino acids exist to a large extent as iminodipeptides in the lumen, which are transported intact into the enterocyte by the peptide transport system. These dipeptides are then efficiently cleaved by the intracellular prolidase. The amino acids, which are either transported as such into the cell in the free form or generated inside the cell by the action of intracellular peptidases, exit the cell across the basolateral membrane by way of specific amino acid transport systems to enter the portal circulation.

ABSORPTION OF PROTEIN DIGESTION PRODUCTS

Peptide Absorption

The intestinal brush border membrane possesses a specific transport system that accepts dipeptides and tripeptides as substrates. Free amino acids are not recognized by this system. The most interesting feature of this transport process is that it uses a transmembrane electrochemical H^+ gradient rather than a transmembrane electrochemical Na^+ gradient as the driving force. [12], [13] The physiological significance of this feature is obvious because there is evidence for the existence of an acid pH microclimate on the lumenal surface of the intestinal brush border membrane that creates a H^+ gradient across the brush border membrane in vivo. This acid pH microclimate is generated and maintained by the combined action of the Na^+/H^+ exchanger in the brush border membrane and Na^+,K^+-ATPase in the basolateral membrane of the enterocyte (Fig. 19-4). Another interesting and functionally important feature of the intestinal peptide transport system is its broad substrate specificity. This system accepts as substrates dipeptides as well as tripeptides consisting of neutral amino acids, anionic amino acids, and cationic amino acids. Apparently, there is only a single peptide transport system in the intestine that is capable of handling the large number of chemically and structurally diverse di- and tripeptides that are expected to be generated from the digestion of dietary proteins.

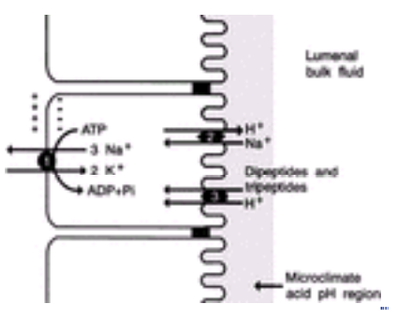

FIGURE 19-4. Generation of an electrochemical proton gradient across the intestinal brush border membrane. *1*, Na^+,K^+-ATPase; *2*, Na^+/H^+ exchanger; *3*, H^+/peptide cotransporter.

The peptide transporters from rabbit, rat, mouse, and human small intestine have been cloned. [14], [15], [16], [17] and [18] The human protein consists of 708 amino acids, with a predicted core molecular size of 79 kd. Hydropathy analysis of the primary amino acid sequence shows the presence of 12 transmembrane domains. The gene for this protein is located on human chromosome 13. This transporter is a member of a superfamily of H^+-coupled peptide transporters expressed in animals, yeast, bacteria, and plants. [19] In situ hybridization [20] and immunolocalization [21] studies in laboratory animals have shown that the peptide transporter is expressed in the small intestine (duodenum, jejunum, and ileum), but not in the esophagus, stomach, colon, or rectum. In the small intestine, the expression is restricted to the absorptive epithelium. Studies of cloned intestinal peptide transporters have established that the transporter recognizes a variety of neutral, anionic, and cationic dipeptides as substrates. [22], [23] and [24] This explains the broad substrate specificity of the intestinal peptide transport system. The mechanism of the transport process is a simultaneous translocation of H^+ and peptide substrate involving a single H^+-binding site on the protein. [25], [26]

Amino Acid Absorption

The absorption of free amino acids from the intestinal lumen into the enterocytes is mediated by amino acid transport systems expressed in the intestinal brush border membrane. [27] Several distinct amino acid transport systems have been functionally characterized in the intestinal brush border membrane, and these transport systems exhibit significant overlap in substrate specificity. The differences between the processes of peptide absorption and amino acid absorption are interesting to note in terms of the number of physiologically occurring amino acids and peptides and the number of transport systems that are involved in their absorption. About 20 different amino acids constitute dietary proteins. Absorption of these amino acids in the free form is mediated not by a single amino acid transport system but by several distinct amino acid transport systems. In contrast, the theoretically possible number of structurally different dipeptides and tripeptides arising from dietary proteins during the digestive process is several times greater than the number of structurally distinct amino acids (400 dipeptides and 8000 tripeptides). Nevertheless, a single peptide transport system mediates the absorption of all these diverse peptides. Another notable difference between the peptide and amino acid absorptive processes is in the energetics. The energy source for the peptide transport process is the electrochemical H^+ gradient; a Na^+ gradient is not directly involved. In contrast, several amino acid transport systems are dependent on the Na^+ gradient as the driving force. Some amino acid transport systems, however, are independent of any ion gradient.

The different amino acid transport systems known to be present in the intestinal brush border membrane, their substrate specificities, and their dependence on the Na^+ gradient are given in Table 19-1. The major transport system responsible for the absorption of neutral amino acids across the intestinal brush border membrane is the Na^+-dependent system B°. The molecular nature of this transport system has been elucidated. [28], [29] The human system B° protein is made up of 541 amino acids and is predicted to contain 10 transmembrane domains. The gene coding for this protein is located on human chromosome 19. Immunolocalization studies have established unequivocally that the system B° protein is restricted to the brush border membrane of the absorptive epithelial cells in the small intestine. [30] Glutamine is a high-affinity substrate for system B°, a fact bearing physiological significance because of the well-known relevance of this amino acid to the maintenance of intestinal structure and function and to the treatment and prevention of critical illness. [31], [32] and [33]

TRANSPORT SYSTEM	SUBSTRATES	NA^+-DEPENDENT
B°	Neutral amino acids	Yes
$B^{0,+}$	Neutral amino acids, cationic amino acids	Yes
X^-_{AG} or EAAT3	Anionic amino acids	Yes
IMINO	Imino acids	Yes
$b^{0,+}$	Neutral amino acids, cationic amino acids, and cystine	No
y^+ or CAT1	Cationic amino acids	No

CAT, cationic amino acid transporter; EAAT, excitatory amino acid transporter.

TABLE 19-1 Amino Acid Transport Systems in the Intestinal Brush Border Membrane

System $B^{0,+}$ is also present in the brush border membrane. This unique amino acid transporter mediates the Na^+- and Cl^--coupled electrogenic transport of neutral as well as cationic amino acids across the brush border membrane. [34] The gene coding for this recently cloned transporter is located on human chromosome X. [35], [36] Interestingly, this transporter is expressed predominantly in the ileum and the colon, not in the proximal part of the small intestine. [36] System $B^{0,+}$ is a transporter not only for amino acids but also for carnitine [37] and several nitric oxide synthase inhibitors. [36]

A separate transport system present in the intestinal brush border membrane is specific for anionic amino acids. X^-_{AG} (i.e., the transport system for the negatively charged amino acids aspartate and glutamate) is also Na^+ dependent. The protein, which has been cloned from rabbit small intestine, [38] contains 524 amino acids and 10 putative transmembrane domains. Its human ortholog also has been characterized. [39] Because this transporter is also expressed in glutamatergic neurons in the brain, where it functions in the neuronal reuptake of glutamate (an excitatory amino acid), system X^-_{AG} is currently classified as a member of the excitatory amino acid transporter (EAAT) family. The glutamate transporter expressed in the intestinal brush border membrane is known as EAAT3.

Another transport system in the intestinal brush border membrane recognizes neutral and cationic amino acids as high-affinity substrates. This system, $b^{0,+}$, is Na^+ independent, and interestingly, it also recognizes the disulfide amino acid cystine as a substrate. System $b^{0,+}$ is a heterodimer consisting of a light chain and a heavy chain. [40], [41] The light chain possesses 12 putative transmembrane domains and exhibits a membrane topology typical of most transport proteins. The heavy chain is responsible for directing the recruitment of the light chain specifically to the enterocyte brush border membrane. It may also have a modulatory role in the transport function. [42] The genes coding for the heavy chain and the light chain are located on human chromosomes 2 and 19, respectively. [43], [44]

System y^+ is a Na^+-independent amino acid transporter with a preference for cationic amino acids. [45] There are at least four subtypes within the cationic amino acid transporter (CAT) gene family: CAT1, CAT2, CAT3, and CAT4. Of these, only CAT1 is expressed in the intestine. This transporter, in contrast to system $b^{0,+}$, does not interact with cystine. System IMINO is a Na^+-dependent transporter with specificity toward the imino acids proline and hydroxyproline. The molecular identity of system IMINO remains unknown.

FATE OF ABSORBED PROTEIN DIGESTION PRODUCTS

At the end of the intracellular phase of protein digestion in the enterocyte, after the absorption of small peptides and free amino acids from the intestinal lumen across the brush border membrane, free amino acids constitute the predominant form of the protein digestion products in the enterocyte cytoplasm. It is probable, however, that a small but significant portion of the protein digestion products may exist in the form of small peptides that are absorbed by way of the brush border membrane peptide transporter but are resistant to hydrolysis by intracellular peptidases. Free amino acids in the cytoplasm of the enterocyte enter into various metabolic pathways, such as degradation, conversion into other amino acids, and incorporation into cellular proteins; they also enter the portal circulation by way of specific amino acid transport systems in the basolateral membrane. Glutamine, glutamate, aspartate, and arginine are preferentially used by the enterocyte as metabolic fuel.

The intestinal basolateral membrane possesses a set of amino acid transport systems that are different from those in the brush border membrane (Table 19-2). [27] The amino acid transport systems in the basolateral membrane function to export amino acids from the enterocyte into the portal circulation during the periods of feeding. They also participate in the import of amino acids from the portal circulation into the enterocyte for cellular metabolism when amino acids are not available from the intestinal lumen, such as between meals. Of the amino acid transport systems present in the basolateral membrane, systems y^+L and A are of particular importance. System y^+L is an amino acid exchanger that mediates the efflux of cationic amino acids from the intestinal cells into the blood coupled to the Na^+-dependent influx of neutral amino acids from the blood into the intestinal cells. [40], [41], [45] This transport system is also a heterodimer, consisting of a light chain and a heavy chain, the former mediating the actual transport function and the latter facilitating the recruitment of the light chain to the basolateral membrane. [41] System A is a Na^+-coupled transporter for neutral amino acids, including glutamine, that plays a role in the entry of amino acids from the blood into the intestinal cells for use in cellular metabolism. System A consists of at least three subtypes, amino acid transporter 1 (ATA1), ATA2, and ATA3. [46], [47] and [48] Of these, ATA1 and ATA2 are expressed in the small intestine. The intestinal basolateral membrane also possesses a peptide transport system that may or may not be identical to that in the brush border membrane. This transport system facilitates the exit of hydrolysis-resistant small peptides from the enterocyte into the portal circulation.

TRANSPORT SYSTEM	SUBSTRATES	NA^+-DEPENDENT
A	Neutral amino acids and imino acids	Yes
ASC	Small neutral amino acids (e.g., Ala, Ser, Cys)	Yes
asc	Small neutral amino acids (e.g., Ala, Ser, Cys)	No
L	Neutral amino acids	No
y^+L	Cationic amino acids	No
	Neutral amino acids	Yes

TABLE 19-2 Amino Acid Transport Systems in the Intestinal Basolateral Membrane

PHYSIOLOGICAL AND CLINICAL SIGNIFICANCE

Compelling evidence exists for the absorption of protein digestion products predominantly in the form of small peptides rather than free amino acids. Therefore, the physiological importance of the intestinal peptide transport system in the maintenance of protein nutrition is clearly evident. In addition, the intestinal peptide transporter has been shown to interact with several pharmacologically relevant drugs that possess peptide-like chemical structures. These drugs are efficiently absorbed from the intestinal lumen after oral administration by way of the peptide transporter. Consequently, the peptide transporter in the intestine is an important determinant of the bioavailability of orally active peptidomimetic drugs. Examples of peptidomimetic drugs that are absorbed in the intestine by way of the peptide transporter include several ß-lactam antibiotics (e.g., cephalexin, cefadroxil, cefradine, and ceftibuten), angiotensin-converting enzyme inhibitors (captopril and

lisinopril), the antitumor agent bestatin, inhibitors of renin and thrombin, and prodrugs such as valacyclovir, valgancyclovir, and a-methyldopa-Phe. [49]

The peptide transport process in the intestine also has potential for therapeutic applications. Peptide-based formula solutions have many advantages over amino acid–based elemental solutions for enteral nutrition. [50] The efficacy of peptide-based enteral solutions is facilitated by the intestinal peptide absorptive process. The osmolality of these solutions can be kept low while amino acid content and composition are maintained. Furthermore, amino acids are absorbed more efficiently and more evenly from peptides than from an equivalent mixture of free amino acids. Another clinical application of the peptide transport system is the practice of including heat-labile and water-insoluble amino acids such as glutamine, cysteine, and tyrosine in the form of peptides in enteral solutions to promote their absorption.

REGULATION OF AMINO ACID AND PEPTIDE ABSORPTION

The capacity of the small intestine to absorb protein digestion products changes significantly under various physiological and pathological conditions. The underlying mechanisms of these changes may be nonspecific, such as alterations in the absorptive surface area; or specific, such as alterations in the number and activity of particular transporters. The transport systems responsible for the absorption of amino acids and peptides are present in the small intestine even before birth in several animal species, including humans. The ability of the small intestine to absorb amino acids and peptides, when expressed per wet weight of intestinal tissue, is maximal at birth and during early development, decreasing thereafter with age. Several hormones have been shown to alter the intestinal amino acid and peptide transport systems. Somatostatin and vasoactive intestinal polypeptide inhibit these transport processes, whereas epidermal growth factor, neurotensin, cholecystokinin, and secretin enhance them. Studies of cultured cells indicate that various intracellular second messengers regulate the intestinal peptide transporter. In Caco-2 cells, a human intestinal cell line, the peptide transporter is stimulated by insulin [51] and inhibited by protein kinase C [52] and cyclic adenosine monophosphate (cAMP). [53] However, because there is evidence of direct coupling between the peptide transporter and the Na^+/H^+ exchanger via the transmembrane H^+ gradient in Caco-2 cells, [12], [54] it is not clear whether the observed effects of insulin, protein kinase C, and cAMP on peptide transporter activity are direct or mediated indirectly by alterations in the activity of the Na^+/H^+ exchanger.

In animal studies, the expression of the intestinal peptide transporter also has been shown to be modulated by dietary protein content and protein digestion products. [55], [56] Even though the peptide transporter is expressed along the entire small intestine, the diet-induced changes in the expression of the transporter are specific to certain regions. A high-protein diet increases the steady-state levels of the transporter-specific messenger RNA in the middle and distal regions of the small intestine. The expression of the brush border peptidases dipeptidylcarboxypeptidase and dipeptidylaminopeptidase IV, which release dipeptides from oligopeptides, are also enhanced by a high-protein diet, again only in the middle and distal regions of the small intestine. This coordinated regulation of the peptide transporter and the peptidases that generate the substrates for the transporter is likely to be of physiological importance. Similarly, the protein digestion products, particularly certain specific dipeptides and amino acids, also enhance the expression of the peptide transporter in the intestine.

PROTEIN-ENERGY MALNUTRITION

Protein-energy malnutrition represents the most common type of malnutrition seen primarily in developing countries. This condition is classified into two subtypes: kwashiorkor and marasmus. In kwashiorkor, intake of protein is inadequate, but energy intake in the form of carbohydrate and fat is adequate. In marasmus, the intake of both protein and energy is inadequate. The crucial clinical features that differentiate these two subtypes are the degree of body wasting and the presence or absence of edema. Kwashiorkor is characterized by edema and a body weight 60% to 80% of that expected for the given age. This condition is also associated with fatty liver. Inadequate protein intake in the presence of adequate energy in kwashiorkor results in decreased hepatic synthesis of blood proteins and ß-lipoprotein. Decreased protein levels in the blood cause edema, and decreased ß-lipoprotein in the liver causes defective handling of lipids, leading to fatty liver. Marasmus is characterized by the absence of edema and less than 60% of the expected body weight for the given age. Both conditions manifest a decreased cell-mediated immune response that reduces the ability to fight infection.

DEFECTS IN DIGESTION AND ABSORPTION OF PROTEINS

A number of defects, primary as well as secondary, associated with the impairment of protein digestion and assimilation are known to occur in humans (Table 19-3).

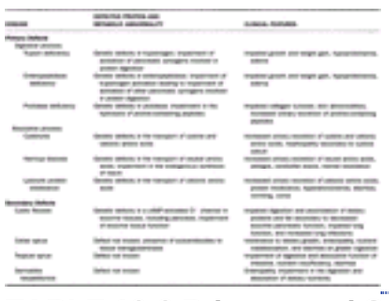

TABLE 19-3 Primary and Secondary Defects Associated with an Impairment of Protein Digestion and Assimilation

Primary Defects

Defects in the digestion of proteins can be caused by genetic diseases involving the expression and activity of any of the proteases or peptidases necessary for the digestive process. Cases of a genetic deficiency of pancreatic trypsinogen have been reported. [57], [58] Because trypsin is a key player in the activation of other pancreatic zymogens (e.g., chymotrypsinogen), a deficiency of trypsinogen results in a marked impairment of protein digestion, noticeable in early infancy. Infants with trypsinogen deficiency fail to gain weight and present with hypoproteinemia and edema. These infants improve dramatically if fed protein hydrolysates instead of intact proteins. Several cases have been reported of a genetic deficiency of enteropeptidase, [59] an intestinal enzyme responsible for the activation of trypsinogen. Infants with enteropeptidase deficiency present with symptoms similar to those observed in cases of trypsinogen deficiency, which include failure of growth, hypoproteinemia, and edema. Because a deficiency of enteropeptidase leads to impairment of trypsinogen activation and consequently to an impairment of the activation of other pancreatic protease zymogens, the digestion of proteins is markedly affected in these patients. Treatment with activated pancreatic enzymes results in improvement of protein digestion and assimilation. Genetic defects in enteropeptidase and trypsin cause impairment not only in protein digestion but also in the digestion of fat. This is because trypsin is obligatory for the activation of procolipase to colipase, a protein necessary for the hydrolytic action of pancreatic lipase on dietary triglycerides after emulsification with bile acids. Similarly, because pancreatic proteases play an essential role in the intestinal absorption of vitamin B_{12}, genetic defects in enteropeptidase and trypsin may also interfere with the absorption of this vitamin.

With the exception of enteropeptidase deficiency, no other documented inheritable defects in peptidases are associated with the intestinal brush border membrane in humans. However, a mutant rat strain is available that exhibits a genetic deficiency of dipeptidylaminopeptidase IV. [11] These mutant rats are apparently normal with no alteration in growth rate if fed a diet with protein constituents with a modest proline content. [11] However, if the dietary protein source is changed to gliadin, a proline-rich protein, the enzyme-deficient mutant rats experience a significant weight loss, whereas wild-type rats do not. These studies show that, as a result of the unique substrate specificity of dipeptidylaminopeptidase IV, a functional role for this enzyme becomes evident under physiological conditions only if the diet contains proline-rich proteins. These observations also point to the physiological advantage of the presence of multiple peptidases in the intestinal brush border membrane with significant overlapping substrate specificities.

Inheritable deficiency of the intracellular dipeptidase prolidase is known in humans. [60] In healthy persons, this enzyme is expressed not only in the intestine but also in several other tissues, such as the kidney; its functions are multiple, including an important role in collagen turnover. It is therefore not surprising that manifestations of prolidase deficiency are pleiotropic. However, no information is available on the intestinal assimilation of proteins in these patients. It is likely that prolidase deficiency does not lead to detectable alterations in the intestinal assimilation of proteins under normal dietary conditions, as seen in the mutant rat strain lacking dipeptidylaminopeptidase IV.

Defects in the absorption of protein digestion products can be caused by diseases involving the expression and activity of amino acid and peptide transport systems in the intestine. Several inheritable amino acid transport defects have been identified in humans. Cystinuria is an autosomal recessive disorder characterized by the increased excretion of cationic amino acids (lysine and arginine) and cystine. [61] The disease is associated with a defect in the renal reabsorption of these amino acids. A similar defect also occurs in the small intestine, leading to impaired absorption of cationic amino acids and cystine from the intestinal lumen. This suggests that an identical transport system is involved in the absorption of these amino acids in the kidney and the intestine. The primary clinical problem associated with the disease is nephropathy resulting from renal stones enriched in cystine. This disulfide derivative is poorly soluble in water (300 mg/L). In cystinuria, the concentration of cystine is greater than this solubility level in the renal tubule because of defective reabsorption, and cystine stone formation results. The amino acid transporter $b^{\circ +}$ is defective in cystinuria. This disease is caused by mutations in either the light chain [44] or the heavy chain [40] of the heterodimeric transporter $b^{\circ +}$. Thus, two genes, one on chromosome 2 (heavy chain) and the other on chromosome 19 (light chain), are associated with cystinuria. Because system $b^{\circ +}$ is present primarily in the brush border membrane of the intestinal and renal tubular epithelial cells, the transport defect in cystinuria is restricted to this membrane. Therapeutic strategies are directed toward facilitating cystine excretion in the urine by increasing urine volume, alkalinizing the urine to increase cystine solubility, and using penicillamine, which reacts with cystine to form a more soluble mixed disulfide.

Hartnup disease is also an autosomal recessive disorder of amino acid transport, but this condition is associated with impaired absorption of neutral amino acids (Ala, Ser, Cys, Thr, Gln, Asn, Val, Ile, Leu, Met, Phe, Tyr, and Trp) in the kidney and the intestine. [62] Consequently, this disease is associated with the hyperexcretion of several neutral amino acids in urine. The symptoms of the disease, which include photosensitive skin rash, ataxia, and neurological complications, are similar to those of pellagra (i.e., niacin deficiency). These symptoms occur despite an apparently normal dietary intake of niacin but disappear in response to niacin therapy. In humans, endogenous synthesis of niacin from the neutral amino acid tryptophan contributes significantly to normal niacin requirements. In Hartnup disease, the endogenous synthesis of niacin is most likely impaired because of defective intestinal absorption of tryptophan coupled with defective renal reclamation of tryptophan. Because people in industrialized nations generally consume a nutritious diet rich in protein, the disease is relatively benign, except for symptoms of niacin deficiency, cerebellar ataxia, and occasional psychological problems. However, in developing or underdeveloped nations, where suboptimal protein intake is common, the disease is characterized by more severe clinical symptoms, including mental retardation. The amino acid transport system B° has been suggested as one of the prime candidates for the amino acid transport defect seen in Hartnup disease because of its specificity toward neutral amino acids and its known expression in the intestine and the kidney. [28], [29] The amino acid transport defect in Hartnup disease is restricted to the brush border membrane of the intestinal and renal tubular epithelial cells. The finding that system B° is associated exclusively with the brush border membrane of these cells [30] supports the hypothesis that Hartnup disease is caused by defects in the gene coding for this transporter.

Interestingly, persons with cystinuria or Hartnup disease usually do not show obvious symptoms of protein malnutrition, despite the clearly established defects in the intestinal absorption of specific amino acids. This was puzzling until it was discovered that intestinal absorption of the affected amino acids (i.e., cationic amino acids in cystinuria and neutral amino acids in Hartnup disease) is normal if the amino acids are given in the form of dipeptides. [63], [64], [65] and [66] Because protein digestion products are absorbed across the intestinal brush border membrane mainly in the form of small peptides, these individuals obtain significant amounts of the affected amino acids through the peptide transport mechanism despite the amino acid transport defect in this membrane. These observations are of historical importance in peptide transport research because they provided early indisputable evidence that the transport mechanisms available for free amino acids and peptides in the intestine are different. [67]

Lysinuric protein intolerance is an autosomal recessive disorder caused by impaired absorption of the cationic amino acids lysine and arginine in the intestine and the kidney. [68] The absorption of ornithine, also a cationic amino acid, is impaired as well. Persons with this disease show decreased plasma levels and increased urinary excretion of these three amino acids. Deficiency of arginine and lysine, which are essential amino acids, causes impairment of protein synthesis, resulting in growth retardation and neurological complications. In addition, because arginine and ornithine are the amino acids involved in the urea cycle and hence in the elimination of ammonia, patients with this disease exhibit decreased urea cycle activity and consequently hyperammonemia. Dietary intake of protein induces diarrhea, vomiting, and, in extreme cases, coma. Treatment strategies, which are related to the prevention of hyperammonemia, include dietary protein restriction and ornithine supplementation. The intestinal and renal handling of cystine is not affected in lysinuric protein intolerance, indicating the difference between the molecular defects associated with this disease compared to cystinuria, which also involves the renal and intestinal absorption of cationic amino acids. The transport defect in lysinuric protein intolerance is restricted to the basolateral membrane in the intestinal and renal epithelial cells. [69] The transport of cationic amino acids across the brush border membrane of these cells is not affected. Linkage analysis [70] assigned the gene for lysinuric protein intolerance to the long arm of chromosome 14. The transport system defective in this disease is $y^{+}L$, as supported by its localization to the basolateral membrane of the intestinal and renal tubular epithelial cells and also by the location of the gene coding for the light chain of this heterodimeric system on chromosome 14. Mutations in this gene have been identified in patients with lysinuric protein intolerance. [71], [72]

Secondary Defects

Impairment of protein digestion and absorption occurs as a secondary defect in several diseases, including cystic fibrosis, celiac sprue, tropical sprue, and dermatitis herpetiformis. In cystic fibrosis, the primary defect occurs in the CFTR (cystic fibrosis transmembrane conductance regulator) protein, a cAMP-regulated Cl^{-} channel. The defective function of this protein leads to complications involving diverse organs, such as the lung, pancreas, gastrointestinal tract, and sweat glands. In the exocrine pancreas, the absence of the Cl^{-} channel in the apical membrane of pancreatic ductal epithelial cells results in failure to secrete salt and water into the duct. This leads to the retention of digestive enzymes in the pancreas and, ultimately, the destruction of pancreatic tissue. Pancreatic insufficiency associated with this disease causes impairment of the digestion and assimilation of protein and fat. Celiac sprue, or gluten-induced enteropathy, is characterized by an inability to tolerate gluten, a protein found in wheat and rye. The dietary intake of gluten induces abnormalities in the intestinal structure, characterized by blunting and flattening of the villi, which reduces the mucosal surface area and results in a deficiency of enterocyte-associated digestive enzymes and transport proteins. This causes a generalized impairment of the digestive and absorptive function of the intestine. Celiac sprue is a genetic disease, and immunoglobulin A antibodies to endomysium, a structure of the smooth muscle connective tissue, are specific indicators of the disease. The endomysial autoantigen has been identified as the tissue transglutaminase. [73] Interestingly, gliadin, which is the major protein component of gluten, is a preferred substrate for this enzyme. Tropical sprue is a serious gastrointestinal disease also characterized by a generalized impairment of the digestive and absorptive function of the intestine. A disease of unknown etiology, it occurs among the residents of tropical areas. The gastrointestinal manifestations of tropical sprue are strikingly similar to those observed in celiac sprue. Dermatitis herpetiformis is another malabsorption syndrome associated with blunting and flattening of the mucosal villi and consequently impaired digestion and absorption of dietary nutrients.

CHAPTER 20

Charles H. Halsted and Bo L. Lönnerdal

VITAMIN AND MINERAL ABSORPTION

WATER-SOLUBLE VITAMINS

Folate and vitamin B_{12} (cobalamin) have complex and different mechanisms of absorption, and each has a broad range of clinical effects. Because these vitamins are interactive metabolically, many of the clinical signs of deficiency are similar, even though their structures, food sources, and modes of absorption are dissimilar (Table 20-1).

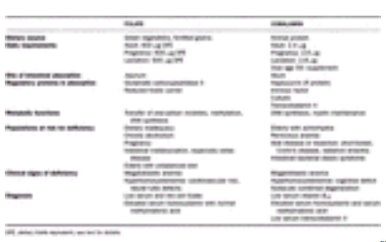

TABLE 20-1 Comparison of Folate and Cobalamin

Folate

Sources Folate in the form of oxidized folylmonoglutamate, or folic acid, contains a pteridine ring linked to *p*-aminobenzoic acid and glutamic acid. Folates appear in the diet and in endogenous storage as folylpolyglutamates with up to six additional glutamates in ?-peptide linkage to folylmonoglutamate. Whereas the term *folic acid* refers to the oxidized monoglutamyl form of the vitamin, reduction in the 5-, 6-, 7- and 8-positions and methylation at the 5-position of the pteridine ring produce 5-methyltetrahydrofolate (5-MTHF), the circulating form of the vitamin. Dietary sources of folate include green leafy vegetables (i.e., foliage), orange juice, grains (in particular, breakfast cereals that are fortified with folic acid), and organ meats such as liver. The Dietary Reference Intake (DRI; formerly referred to as the *Recommended Dietary Allowance [RDA]*) for folate from all sources is now quantified in dietary folate equivalents (DFEs). This term accounts for the fact that monoglutamyl folic acid that is marketed as a vitamin supplement or as a fortifier in the diet is 1.7 times more available than the natural food folates that occur as folylpolyglutamates in the diet. [1] In calculating DFEs, the amount of supplemental folic acid is multiplied by 1.7 and added to the amount of folate present in the mixed diet. The DRI for folate is set at 400 µg of DFE per day for adults, 600 µg/d during pregnancy, and 500 µg/d during lactation. Since 1998, all grain products in the United States have been fortified with folic acid at 1.40 mg/kg to ensure a daily intake equal to or more than the DRI for folate. This mandated fortification of the food supply has lowered the incidence of folate deficiency in the United States from 10% to less than 1% of the population. [2]

Folate Absorption and Homeostasis Folates are absorbed in the duodenum and upper jejunum. During the process of intestinal absorption, dietary folylpolyglutamates are hydrolyzed at the epithelial cell (enterocyte) brush border membrane, followed by active transport of the folylmonoglutamate derivative into the absorbing enterocyte. Studies that followed the movement of labeled compounds across the human jejunum during jejunal perfusion or when excreted in the urine after oral administration demonstrated the importance of the hydrolytic step, because the absorption of monoglutamyl folic acid was about 85%, compared to the 50% absorption of complex dietary folylpolyglutamates in adult human volunteers. [3] The 85:50, or 1.7:1, ratio of the absorption of the two different folates provides the basis for the DFE calculation. Two intestinal proteins—glutamate carboxypeptidase II (GCP II, formerly known as *folate conjugase* or *hydrolase*) and the reduced folate carrier (RFC)—are required, respectively, for the sequential hydrolysis of dietary folylpolyglutamates and the transport of folylmonoglutamate derivatives across the enterocyte brush border and basolateral membranes. GCP II has been characterized in pig and human intestine and expresses a brush border membrane protein with molecular size of 120 kd that contains a single 5' membrane-spanning domain and an extracellular catalytic domain. GCP II shares an identical sequence with two other proteins: brain *N*-acetylated a-linked acidic dipeptidase and prostate-specific membrane antigen. [4] In its functionally active enzyme form, purified human intestinal GCP II has an optimal pH of 6.5 and a K_m value of 0.6 µmol/L and is an exopeptidase that releases intermediate products of folylpolyglutamates in stepwise fashion ending with the folylmonoglutamate derivative. [5] By contrast, human RFC is a 65-kd brush border membrane protein with 12 membrane-spanning domains that operates at an optimal pH of 5.0 and a K_m value of 0.5 to 1.5 µmol/L. [6] Studies that used isolated intestinal brush border membrane vesicles defined a saturable carrier system for monoglutamyl folates with a preference for reduced and methylated forms and capable of either H^+ cotransport or anion exchange. During folate transport through the absorbing enterocyte, pteroylmonoglutamate is reduced and methylated, and 5-MTHF is transported across the intestinal basolateral membrane by the RFC to the portal vein and the liver. The uptake of 5-MTHF by hepatocytes involves both liver plasma membrane–binding and carrier-mediated transport into the cell. The binding step is regulated in part by the folate receptor or folate-binding protein (FBP), a 37-kd protein that operates at a pH of 6.5 to 7.5 and a K_m value in the nanomolar range. FBP is attached to the membrane by a glycosylphosphatidylinositol anchor. [7] 5-MTHF transport obeys the kinetics of the RFC, which also expresses its activity in the liver plasma membrane. [8] Within the hepatocyte, 5-MTHF uptake is followed by conversion to the folylpolyglutamate form for storage and metabolism. About 10% of the liver folate pool undergoes biliary secretion as 5-MTHF to an enterohepatic folate circulation, while much of the remaining passes into the systemic circulation. [9] The urinary excretion of 5-MTHF is regulated by filtration and then efficient reuptake by renal tubular epithelial cells via both FBP and RFC. [10] About 1% of the total body folate pool is excreted daily in the urine and 0.1% in the feces. [11]

Folate Functions Folates serve as substrates or cofactors in the transfer of single-carbon moieties in amino acid metabolism and in nucleic acid synthesis (Fig. 20-1). In the methyltransferase pathway, 5-MTHF, which is derived from both dietary and endogenous sources, is the substrate for the methionine synthase reaction that, with cobalamin cofactor, generates methionine from homocysteine. In the alternate salvage pathway, methionine is generated from betaine and homocysteine by way of the betaine homocysteine methyltransferase (BHMT) pathway. Methionine is converted to *S*-adenosylmethionine (SAM) by methionine adenosyltransferase (MAT), an enzyme produced by two genes; *MAT1A* expressed in the liver and *MAT2A* expressed in nonhepatic tissues, and in the liver in alcoholic hepatitis and carcinoma. [12] About 6 to 8 g of SAM is present in a healthy liver. Through many reactions that include DNA methylation and the synthesis of phosphatidylcholine, SAM is metabolized to *S*-adenosylhomocysteine (SAH), which is also generated from homocysteine through the reversible SAH hydrolase (SAHh) reaction. SAM regulates the synthesis of glutathione by up-regulating cystathionine ß-synthase and the homocysteine transsulfuration pathway. SAM also provides negative regulatory feedback to the methylene tetrahydrofolate reductase (MTHFR) reaction that converts 5,10-MTHF to 5-MTHF. Thus, adequate SAM ensures sufficient 5,10-MTHF as

substrate for thymidylate synthase, which ensures the nucleotide balance of deoxyuridine monophosphate and deoxythymidine monophosphate for DNA synthesis. According to these metabolic interactions, hyperhomocysteinemia, or elevated circulating homocysteine, results from either folate or cobalamin deficiency, but may also be caused also by genetic polymorphisms that reduce the activities of cystathionine ß-synthase methionine synthase, or MTHFR. Levels of SAM are reduced through decreased methionine production by methionine synthase or oxidative inactivation of MAT, [13] whereas SAH, a product of homocysteine, inhibits SAM methylation reactions. [14] The consequences of reduced levels of SAM include decreased DNA methylation and nucleotide imbalance with DNA instability, and decreased glutathione production and oxidative defense. Considerable evidence suggests that SAM deficiency is an integral component in the pathogenesis and clinical expression of alcoholic liver disease. [15]

FIGURE 20-1. Interactions of folate, methionine, and choline metabolism. *BHMT,* betaine homocysteine methyltransferase; *CBS,* cystathionine ß-synthase; *CDP-choline,* cytidine diphosphorylcholine; *choline-P,* phosphoryl choline; *DNMTs,* DNA methyltransferases; *dTMP,* deoxythymidine monophosphate; *dUMT,* deoxyuridine monophosphate; *GSH,* glutathione; *MAT,* methionine adenosyltransferase; *MS,* methionine synthase; *5-MTHF,* 5-methyltetrahydrofolate; *5,10-MTHF,* 5,10-methylenetetrahydrofolate; *MTHFR,* methylenetetrahydrofolate reductase; *PC,* phosphatidylcholine; *PE,* phosphatidylethanolamine; *PEMT,* phosphatidylethanolamine methyltransferase; *SAH, S*-adenosylhomocysteine; *SAM, S*-adenosylmethionine; *SAHh,* SAH hydrolase; *THF,* tetrahydrofolate; *TS,* thymidylate synthase.

Clinical Expressions of Folate Deficiency Because folate ultimately is required for maintaining nucleotide balance during DNA synthesis, its deficiency is expressed by increased apoptosis and by compensatory increased proliferation of cells with rapid turnover in the blood-forming bone marrow and in the intestinal mucosa. Bone marrow megaloblastosis and macrocytosis of red cells and enterocytes are a reflection of deficient DNA synthesis with production of immature and dysfunctional cells that translates clinically to macrocytic anemia and, potentially, diarrhea. As indicated in Figure 20-1, folate deficiency also affects the methionine metabolic cycle, resulting in hyperhomocysteinemia. In addition to megaloblastic anemia, several common clinical conditions have been linked to folate deficiency with abnormal DNA metabolism and hyperhomocysteinemia.

Anemia and diarrhea. The clinical expression of overt folate deficiency is megaloblastic anemia, with findings of macrocytic red blood cells with increased mean corpuscular volume and hypersegmented neutrophils in the peripheral blood. Macrocytic enterocytes were identified in small intestinal biopsy specimens from alcoholic patients with folate-deficient megaloblastic anemia. [16] Furthermore, experimental folate deficiency combined with ethanol intake in humans is associated with abnormal fluid and electrolyte transport in the intestine, which may explain in part the clinical finding of diarrhea in alcoholic patients with chronic folate deficiency. [17], [18]

Folate deficiency and neural tube defects. Neural tube defects are errors of fetal spinal cord development that occur within the first 2 weeks of pregnancy and result in anencephaly and spina bifida. Neural tube defects occur at a rate of 1 to 2 per 1000 live births and probably more frequently in spontaneous abortions. The association of neural tube defects with folate deficiency is based on findings that red cell folate levels in early pregnancy correlate with the risk for delivery of a child with a neural tube defect [19] and on the results of trials in which neural tube defects were prevented by using pre-pregnancy supplemental folic acid. [20] About 20% of infants with a neural tube defect and their mothers have a homozygous C677T mutation of the MTHFR gene, which together with dietary folate, regulates the level of 5-MTHF. [21] The advent of folic acid fortification of the U.S. food supply is expected to significantly reduce the risk for neural tube defects.

Cardiovascular disease. A metaanalysis of 15 studies of proven coronary artery disease showed that an increment of 5 µmol/L in the serum level of homocysteine above the normal range constitutes a coronary heart disease risk similar to an increase in total cholesterol of 20 mg/dL above normal. [22] A multicenter European survey showed that hyperhomocysteinemia exerts a 2.6- to 8.2-fold multiplicative effect on conventional coronary disease risks, including hyperlipidemia, smoking, and hypertension. [23] Hyperhomocysteinemia also is an established risk factor for carotid artery narrowing and occlusive strokes. [24] The results of ongoing prospective trials designed to demonstrate decreased cardiovascular risk with folic acid supplementation are pending.

Colon cancer. A prospective sigmoidoscopic and dietary survey of more than 20,000 health professionals found that the ingestion of diets high in folate was protective against the development of colonic adenomas, whereas a relatively low-folate diet together with the consumption of more than two alcoholic drinks per day increased adenoma risk twofold. [25] In a 6-year follow-up study of more than 40,000 male health professionals, the same investigators found a threefold increased risk of colorectal cancer in alcohol consumers ingesting a low-folate diet, whereas a high-folate diet was protective against colorectal cancer despite alcohol consumption. [26]

Causes of Folate Deficiency

Dietary deficiency. In a landmark self-experiment, removal of folate from the diet was followed by a fall in red blood cell folate and eventual megaloblastic anemia after 140 days. [27] Populations at risk for dietary folate deficiency include young, frequently dieting women, pregnant women who fail to take folate supplements, and the economically deprived, who often include elderly persons with degenerative diseases. Body stores of folate are sufficient for about 4 months; therefore, before folic acid supplementation of the U.S. food supply, the risk for dietary folate deficiency was high in these susceptible populations.

Intestinal malabsorption of dietary folate. Diseases of the intestinal mucosa, such as celiac disease and tropical sprue, affect both folate digestion by GCP II and transport by RFC. [3], [28] Many drugs affect folate absorption and contribute to the risk for folate deficiency. For example, sulfasalazine inhibits both the hydrolysis and transport of folylpolyglutamates, [29] and patients receiving this drug for ulcerative colitis should receive folic acid supplementation. Although the risks for folate deficiency from newer salicylate-releasing antiinflammatory drugs are not known, it has been shown in vitro that the inhibitory property of sulfasalazine on GCP II activity requires both the salicylate and sulfa components. [30] Whereas serum folate levels decrease after exposure to the anticonvulsant phenytoin (Dilantin), [31] a well-conducted study demonstrated that a therapeutic concentration of phenytoin in the intestinal lumen does not block folate absorption. [32]

Chronic alcoholism. Low serum folate levels occur in more than three fourths of chronic alcoholics, and megaloblastic anemia in at least one third. The diet of alcoholics is typically poor in folate; furthermore, alcohol impairs folate absorption and accelerates urinary folate excretion, and the alcohol metabolite acetaldehyde triggers an oxidation reaction that destroys the folic acid molecule. [33], [34] Because chronic liver disease reduces folate stores, the combination of these factors accelerates the risk for the development of folate deficiency in patients with alcoholic liver disease. [35]

Genetic abnormalities. A number of polymorphisms in folate regulatory genes have been described that are related to folate deficiency or increased folate requirement. Examples include C677T and A1298C polymorphisms in MTHFR that are associated with elevated homocysteine levels and an increased incidence of neural tube defects. [21], [36]

Assessment of Folate Deficiency Folate deficiency should be suspected in any anemic patient with an elevated mean corpuscular volume of red blood cells, and then confirmed by a low level of serum or red cell folate. Each of the latter tests can be performed by radioisotope binding assay. The serum folate level is more labile, whereas the red cell folate is a more accurate measure of tissue stores. Measurement of the plasma homocysteine level is a more sensitive functional assay for folate deficiency because 5-MTHF is the substrate for the methionine synthase reaction that converts homocysteine to methionine. However, because cobalamin is an essential cofactor for this reaction, its deficiency is also reflected by an elevated homocysteine level as well as by the same tissue expressions found in folate deficiency (see Fig. 20-1 and Table 20-1). Therefore, folate deficiency can be defined metabolically by a high homocysteine level and normal vitamin B_{12} status as described in the next section.

Vitamin B_{12} (Cobalamin)

Structure, Nomenclature, and Metabolic Functions Vitamin B_{12}, or cobalamin, contains a central cobalt atom surrounded by a planar corrin ring that is formed from four reduced pyrrole rings linked together and attached at a right angle to a nucleotide containing ribose, phosphate, and 5,6-dimethylbenzimadazole. In its active coenzyme forms, the cobalt atom is bound to specific moieties, resulting in methylcobalamin and adenosylcobalamin, whereas cyanocobalamin is the pharmaceutical and interchangeable form of the vitamin. There are only two known enzymatic reactions that require cobalamin and serve to bind it in tissues. Methylcobalamin is the cofactor for methionine synthase and participates in the transfer of the methyl group from 5-MTHF to homocysteine, rendering methionine and tetrahydrofolate (see Fig. 20-1). Thus, cobalamin deficiency disturbs folate metabolism and results in the same abnormalities of cellular regeneration as in folate deficiency, most commonly megaloblastic anemia, and in hyperhomocysteinemia. Adenosylcobalamin is involved in mitochondrial fatty acid metabolism as a cofactor for methylmalonyl-coenzyme A (CoA) mutase in the conversion of methylmalonyl-CoA to succinyl-CoA, so that cobalamin deficiency also uniquely results in elevation of serum methylmalonic acid. [37] In this section, the term *cobalamin* is used to describe dietary sources, metabolic pathways, and clinical manifestations of deficiency. The term *vitamin* B_{12} is used to describe the pharmacological and supplemental forms of the vitamin.

Dietary Sources and Requirements Because cobalamin originates from intestinal bacterial synthesis, it appears in the human diet exclusively bound to animal proteins. The usual sources of cobalamin include meat, fish, shellfish, poultry, eggs, milk, and milk products. The adult DRI is 2.4 µg/d (2.6 µg during pregnancy and 2.8 µg during lactation), which accounts for an average 50% absorption from all dietary sources. Because cobalamin absorption declines with aging, persons older than 50 years are advised to take supplements containing vitamin B_{12} or to ingest food that is fortified with vitamin B_{12}, such as most breakfast cereals. [37]

Intestinal Absorption, Metabolism, and Excretion of Cobalamin

Cobalamin absorption. The intestinal absorption of dietary animal protein–bound cobalamin involves gastric, upper intestinal, and ileal stages, and an enterohepatic circulation (Fig. 20-2). The initial two steps of the gastric phase require an acid pH. In the presence of gastric acid and pepsin, cobalamin is released from its protein bond and then transferred to R-binding protein (haptocorrin) that is present in saliva and gastric juice. The release of cobalamin and its transfer to R factor is optimal at pH 1 to 1.3, a level not achieved by achlorhydric individuals, who include most persons older than 65 years. Similarly, patients using proton pump inhibitors such as omeprazole do not absorb food-bound protein normally [38] and are presumably at risk for cobalamin deficiency. The third gastric step involves the secretion of an additional cobalamin-binding protein, intrinsic factor (IF), from acid-secreting parietal cells. However, IF is ineffective as a cobalamin binder at the acid pH of the healthy stomach, and it follows the haptocorrin-cobalamin complex into the duodenum. Here, the complex is degraded by pancreatic proteases, and at the neutral pH of the duodenum, cobalamin is quickly bound to the protease-resistant IF and in this state traverses the small intestine to the ileum.

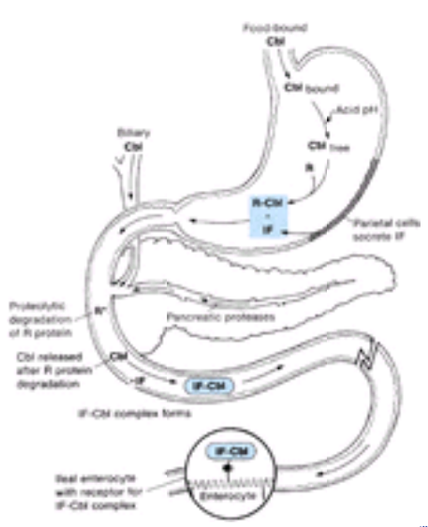

FIGURE 20-2. Sequential steps in the gastrointestinal absorption of dietary protein-bound cobalamin (*Cbl*). Gastric acid is required to liberate both methylcobalamin and adenosylcobalamin from dietary protein. In the acidic gastric environment, cobalamin is then bound to salivary R proteins, whereas gastric parietal cells secrete intrinsic factor (*IF*). After neutralization of the gastric contents in the upper duodenum and pancreatic protease digestion of the R-cobalamin complex, free cobalamin then binds to IF. After transfer to the terminal 50 cm of ileum, the IF-cobalamin complex interacts at the microvillus surface with a specific ileal receptor.

According to retrospective studies in patients with ileal resections of various lengths, at least 50 cm of the terminal ileum participates in the ileal transfer of cobalamin. [39] Ileal absorption of cobalamin requires several binding proteins and may take up to 6 hours for completion. The cobalamin-IF complex is bound to a specific membrane receptor on the ileal enterocyte in the presence of ionized calcium at a neutral pH. Characterization of the cobalamin-IF receptor, named *cubulin,* described a 460-kd glycoprotein that is present on the epithelial surface and colocates with an endocytic receptor, called *megalin,* in both ileal and renal tubular cells. [40] Subsequent transfer across the ileal enterocyte involves endocytic cleavage of the cobalamin-IF complex and then binding of cobalamin to transcobalamin II (TCII). TCII is a 43-kd protein with molecular homology to IF that is synthesized in ileal enterocytes and carries cobalamin out of the ileal mucosa to the circulation. [41] The TCII-cobalamin complex, or holotranscobalamin, accounts for 20% of all circulating cobalamin and is essential for its transport to all tissues. About half of the endogenous circulating pool of cobalamin, or 1.4 µg, is secreted into the bile daily, from which half again undergoes enterohepatic cycling and the other half, 0.7 µg/d, is excreted in the stool. Endogenous cobalamin is secreted into the duodenum bound to biliary haptocorrin; it is then released by pancreatic trypsin and rapidly bound to IF for subsequent passage to the ileal receptor site for intestinal reabsorption.

Clinical Expressions of Cobalamin Deficiency Because folate and cobalamin are required as substrate and cofactor for the methionine synthase reaction, the clinical expression of cobalamin deficiency as megaloblastic anemia and hyperhomocysteinemia is indistinguishable from that of severe folate deficiency. However, because cobalamin is also required in the methylmalonyl-CoA mutase reaction, its deficiency may be expressed in the nervous system as subacute combined degeneration of the posterior columns of the spinal cord, which is characterized by loss of position and vibratory sensation in the lower extremities. Cobalamin deficiency has more subtle and frequent effects on the central nervous system that include neuropsychiatric disorders such as ataxia, paresthesias, memory loss, cognitive dysfunction, and more severe dementia, in the absence of anemia. [42]

Causes of Cobalamin Deficiency Cobalamin deficiency has many potential causes owing to the complexity of the mechanisms of its absorption processes.

Dietary inadequacy. The daily requirement of cobalamin (2.4 µg/d) is very small compared to its body pool size (1–2 mg); therefore, it takes many years to become deficient from dietary inadequacy alone. Only true vegans are at risk for dietary cobalamin deficiency, as cobalamin is present in dairy products and in most multivitamins.

Abnormal gastric events. Because gastric acid is required for the release of food-bound cobalamin as the first step in cobalamin absorption, achlorhydric individuals are at risk for cobalamin deficiency. Studies have demonstrated that achlorhydria of aging is the most common cause of cobalamin deficiency in the United States. About 15% of ambulatory individuals older than 65 years are cobalamin deficient, according to the criteria of elevated methylmalonic acid and homocysteine levels and a serum cobalamin level of less than 300 pg/mL. [43] Gastric infection with *Helicobacter pylori* may predispose to more severe malabsorption of food-bound cobalamin. [44] Because cobalamin deficiency secondary to achlorhydria is caused by malabsorption of food-bound dietary cobalamin but not of unbound crystalline pharmaceutical vitamin B_{12}, its deficiency in elderly persons can usually be prevented by supplemental oral vitamin B_{12}. Similarly, gastric bypass surgery for obesity is associated with food-bound cobalamin malabsorption secondary to achlorhydria, and responds to oral doses of 350 µg of crystalline vitamin B_{12} supplement per day. [45] Pernicious anemia is an autoimmune disorder characterized by the absence of IF in the gastric juice and is associated with achlorhydria and hypergastrinemia. Antibodies to parietal cells can be found in 85% of cases, and blocking and binding antibodies to IF occur in 70% and 50% of cases, respectively. The type A atrophic gastritis of pernicious anemia involves the fundus and upper body of the stomach, in contrast to the more common type B atrophic gastritis of elderly patients, which involves the lower stomach and antrum. According to one survey, the rates of pernicious anemia among elderly men and women are 2.7% and 1.4%, respectively, with a somewhat greater incidence in African Americans than in whites. [46] Because patients with pernicious anemia lack IF, in addition to being achlorhydric, they can absorb neither crystalline cobalamin nor dietary food-bound cobalamin and must be treated with parenteral vitamin B_{12}, usually in monthly 1000-µg doses. Because IF is also required for the absorption of endogenous cobalamin in the enterohepatic circulation, cobalamin deficiency develops more rapidly in patients with untreated pernicious anemia than in strict vegans or elderly persons with achlorhydria.

Abnormal duodenal and jejunal events. Persistent duodenal hyperacidity may inactivate pancreatic trypsin and prevent the transfer of cobalamin from gastric haptocorrin (R factor) to IF; thus, it is not surprising that cobalamin deficiency is a recognized component of the Zollinger-Ellison syndrome. [47] Although cobalamin malabsorption was described in 50% of patients with pancreatic insufficiency, its deficiency is rare in this condition. [48] During passage through the jejunum, the IF-cobalamin complex is susceptible to bacterial cleavage or uptake, and cobalamin deficiency with macrocytic anemia is a recognized risk factor for bacterial stasis syndromes that occur with intestinal blind loops, strictures, and motility disorders such as scleroderma and diabetic visceral neuropathy. Intestinal infestation with the fish tapeworm *Diphyllobothrium latum,* which is found in rural Finland, also causes cobalamin deficiency through competition for the cobalamin-IF complex.

Abnormal ileal events. Because cobalamin-IF receptors are located on enterocytes in the distal 50 cm of ileum, diseases or surgical resection involving this length of small bowel are usually associated with cobalamin malabsorption and deficiency. These include Crohn's disease, radiation enteritis, severe celiac disease, and human immunodeficiency virus infection, and the short-bowel syndrome secondary to surgical removal of terminal ileum. Resection of the ileocecal valve increases the risk for cobalamin deficiency by permitting intestinal bacterial overgrowth. Because the terminal ileum is the site for both dietary cobalamin absorption and the reabsorption of endogenous cobalamin from its enterohepatic circulation, cobalamin deficiency may become evident within several months of surgical resection of more than 50 cm of terminal ileum. Two drugs, colchicine and *p*-aminosalicylic acid, may cause cobalamin deficiency by inhibiting its uptake by the ileal mucosa. [49], [50]

Genetic causes of cobalamin malabsorption. Congenital deficiency of IF results from the failure of its synthesis by gastric parietal cells. The gastric mucosa and acid secretion are normal and IF antibodies are absent in this condition. Cobalamin deficiency is usually apparent between the ages of 1 and 5 years. [51] Defective cobalamin transport by ileal enterocyctes (Imerslünd-Grasbeck syndrome) has been recognized most often in Finland and other Scandinavian countries. It is clinically evident in early childhood but has also been described in young adults. [52] These patients have normal gastric function and ileal histology. This autosomal recessive disease represents failure of synthesis or membrane insertion of cubulin and is expressed in both the ileum and renal tubule by the early onset of cobalamin deficiency and proteinuria. Congenital TCII deficiency is also autosomal recessive and has been described rarely in several families. It is expressed in the first year of life with pancytopenia and megaloblastic anemia. [52]

Measurements of Cobalamin Status Cobalamin deficiency should be suspected in any person who presents with macrocytic anemia and an elevated mean corpuscular red cell volume. However, because most cases of cobalamin deficiency are expressed as neuropsychiatric abnormalities, particularly as cognitive loss in the aged, it is important to suspect and detect deficiency even in the absence of hematologic abnormalities. Cobalamin is conventionally measured in the serum by a radioassay with high specificity and sensitivity. Normal values depend on the laboratory and generally range from 200 to 250 pg/mL. However, based on a comparative study in which serum elevation of the metabolite methylmalonic acid was used as the gold standard, an upper limit of at least 300 pg/mL has been recommended. [43] Although more expensive, the most accurate assessment of cobalamin status is by serum level measurement of its metabolites homocysteine and methylmalonic acid. [53] Cobalamin deficiency is distinguished by elevation of serum methylmalonic acid, as folate deficiency also elevates homocysteine owing to its role as substrate in the methionine synthase reaction. [54] Because metabolically effective circulating cobalamin is bound to TCII, measurement of serum holotranscobalamin is considered a more precise indication of cobalamin status than is the serum cobalamin assay. Difficulties in standardizing the holotranscobalamin assay may be resolved by the development of an immunodetection test. [55]

Clinical Tests of Cobalamin Absorption The etiology of cobalamin deficiency can be assessed by the Schilling test through measurements of urine excretion of label after oral administration of a physiological amount (0.5–2 µg) of radioactive ^{57}Co-cobalamin. Because a 1000-mg tissue-saturating ("flushing") dose of parenteral cobalamin is given 2 hours later, the cumulative appearance of the label in the 48-hour urine excretion is representative of the intestinal absorption of the radioactive cobalamin. To screen all possibilities for malabsorption, two approaches can be used. The food cobalamin test measures the first gastric phase of acid release of protein-bound cobalamin. [56] Practically, the egg yolk cobalamin absorption test (EYCAT) requires initial incubation of labeled cobalamin with egg yolk followed by oral administration and the flushing dose; normal results are usually greater than 2% excretion of the label. Although not universally available, only the EYCAT will distinguish cobalamin deficiency secondary to achlorhydria because achlorhydric patients are incapable of absorbing food-bound cobalamin but are capable of absorbing the widely available unbound crystalline form of cobalamin. The time-honored and widely available Schilling test of crystalline cobalamin absorption is designed to detect and define etiologies that include IF deficiency, as in pernicious anemia, ileal malabsorption, and bacterial stasis. Cobalamin deficiency should first be treated because ileal macrocytosis may impair cobalamin absorption. If the result of stage I of the Schilling test is normal (usually >9% recovery in a 48-hour urine collection), pernicious anemia is ruled out and cobalamin deficiency may be secondary either to diet, as in strict vegans, or to gastric achlorhydria, as occurs in the elderly. If the stage I result is abnormally low, pernicious anemia is confirmed by correction of the test result by provision in stage II of an exogenous source of IF together with the labeled cobalamin. A persistently abnormal stage II test result can be attributed to abnormal ileal absorption or intestinal bacterial competition for the cobalamin-IF complex. This issue can be resolved by the stage III test, in which the absorption of labeled cobalamin is improved or corrected after 2 weeks of oral antibiotic suppression of intestinal bacteria. Although based on physiological principles, the full battery of Schilling tests is cumbersome, requires accurate and complete patient urine collection, and therefore may produce false-positive results.

Other Water-Soluble Vitamins

Several other water-soluble vitamins are relevant to the practice of gastroenterology and hepatology. These include vitamin C (ascorbic acid), thiamin, pyridoxine, niacin, and riboflavin. Each is considered separately, with emphasis on requirement, mechanism of absorption, diagnostic tests, and clinical expression of deficiency (Table 20-2).

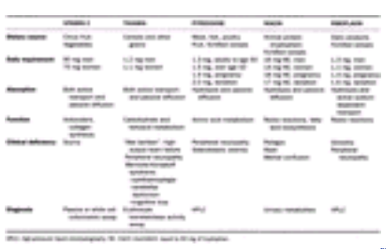

TABLE 20-2 Other Water-Soluble Vitamins

Vitamin C The term *ascorbic acid* derives from the antiscorbutic properties of vitamin C (prevention or treatment of scurvy). Vitamin C is found abundantly in citrus fruits and many vegetables. The DRI of vitamin C is 90 mg/d for men and 75 mg/d for adult women, with an additional 35 mg/d for smokers, in whom vitamin C turnover is increased. [57] Vitamin C functions as both a reducing agent and an antioxidant, as a cofactor for metalloenzymes, and as an electron donor in enzymes involved in collagen, carnitine, and catecholamine synthesis and in tyrosine metabolism. Vitamin C is absorbed equally well from natural foods and supplements by active, sodium-dependent transport at low concentrations and by passive diffusion at high concentrations. [58] The percentage of vitamin C absorbed decreases with increasing intralumenal concentrations and falls to less than 50% after the ingestion of 1g, with a resultant risk for osmotic diarrhea. [59] The maximal tissue saturation of vitamin C is achieved in healthy persons with oral intakes of 90 to 150 mg/d, and excess absorbed vitamin is metabolized to oxalate or excreted in the urine. In human metabolic turnover experiments in subjects deprived of vitamin C, the body pool decreased by 3% per day, with the development of signs of scurvy from the 55th day onward. [60] In modern medicine, scurvy is found in alcoholics, patients with severe celiac disease, severely anorectic patients, and persons who smoke heavily. The sequential clinical signs of scurvy relate to increased capillary fragility and include bruising of the skin, bleeding gums, and a characteristic perifollicular hemorrhagic rash in the lower extremities. In more extreme cases, scurvy results in joint effusions, vascular instability, and death. Vitamin C is assessed by a colorimetric assay; serum levels represent recent intake, whereas white blood cell levels represent tissue stores. [61]

Thiamin Thiamin, in its active form as thiamin pyrophosphate, is involved in carbohydrate metabolism as a coenzyme for pyruvate dehydrogenase and for the decarboxylation of a-ketoacids. Thiamin is present in fortified or whole grain cereals and breads, and in pork. The DRI for thiamin is 1.2 mg for men and 1.1 mg for women (1.4 g during pregnancy and lactation). [62] Thiamin is absorbed by a dual process in the jejunum. At low concentrations (0.2–2.0 mM), thiamin is absorbed by an active Na^+-dependent transport that involves phosphorylation, and at higher concentrations, it is absorbed by passive diffusion. [63] The body pool size of thiamin is about 30 mg, with a half-life of 9 to 18 days, and plasma and red cell levels are sustained by rapid urinary excretion of excess absorbed thiamin. Thiamin deficiency occurs during extreme malnutrition of any cause and is common in persons with chronic alcoholism because of a combination of poor intake and reduced absorption. Ethanol interferes with Na^+, K^+-ATPase–mediated active transport across the basal enterocyte membrane that drives thiamin absorption. [64] The clinical signs of thiamin deficiency are related to the heart and the nervous system. Classical wet beriberi, which often accompanies starvation, is characterized by cardiomyopathy with high-output cardiac failure, whereas the main sign of dry beriberi is progressive stocking-glove polyneuropathy of the lower extremities. Additional neurological features of thiamin deficiency occur mainly in chronic alcoholics and are classified under the Wernicke-Korsakoff syndrome as nystagmus and ocular paresis, cerebellar dysfunction with a wide-based gait, and global confusion. [65] Because body stores of thiamin are regulated by carbohydrate metabolism, the administration of intravenous glucose to a malnourished patient may precipitate an acute demand for residual endogenous thiamin with resultant overt thiamin deficiency made manifest by cardiac failure and confusion. Thiamin status is most accurately assessed by a functional assay of erythrocyte transketolase (ETKA) before and after the addition of thiamin pyrophsophate. [61]

Pyridoxine Pyridoxine, or vitamin B_6, is a coenzyme for many amino acid reactions and exists in six forms: pyridoxine, pyridoxal, pyridoxamine, and the phosphorylated forms of each. Its main food sources include meat, fish, poultry, noncitrus fruits, and fortified cereals. The DRI is 1.3 mg/d for adult men and women; it rises to 1.5 mg/d for those older than 50 years, 1.9 mg for pregnant women, and 2.0 mg for women who are lactating. [66] The phosphorylated forms of pyridoxine are absorbed by hydrolysis by brush border alkaline phosphatases, followed by passive transport of nonphosphorylated forms through the enterocyte. Phosphorylation is completed in the liver, and the principal circulating form is pyridoxal phosphate (PLP) in a complex with albumin. The body pool size of pyridoxine is 60 to 100 mg. Pyridoxine deficiency is one of the common features of chronic alcoholism and, owing to the role of pyridoxine in heme synthesis, presents with microcytic sideroblastic anemia, peripheral neuropathy, cheilosis, and glossitis. Pyridoxine deficiency in alcoholism is caused by hepatic degradation of the PLP-protein complex by acetaldehyde followed by rapid urinary excretion of the unbound vitamin. [67] The more than twofold elevation of serum aspartate aminotransferase relative to alanine aminotransferase characteristic of patients with alcoholic hepatitis may be caused by the greater requirement of the latter enzyme for PLP. [68] Because pyridoxine is an essential cofactor for cystathionine ß-synthase in the transsulfuration elimination pathway of homocysteine (see Fig. 20-1), its deficiency contributes to hyperhomocysteinemia in elderly patients and other susceptible individuals. Pyridoxine toxicity was described in women in whom severe sensory neuropathy of the hands and fingers developed after ingestion of 2 to 6 g/d for 2 months for premenstrual stress. [69] Plasma PLP can be measured by high-performance liquid chromatography (HPLC). [61]

Niacin Niacin is expressed biologically by its two coenzymes, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which are involved in redox reactions, the oxidation of fuel molecules, and fatty acid biosynthesis. Dietary niacin requirements are based on nicotinic acid, nicotinamide, and tryptophan, which is metabolized to niacin such that 60 mg of tryptophan is equivalent to 1 mg of niacin. Dietary niacin is derived from animal protein as tryptophan, and from enriched or whole grain cereals and bread. The DRI of niacin is 16 mg of niacin equivalents (NEs) for men and 14 mg for women, with 18 mg for pregnancy and 17 mg for lactation. [70] Niacin is absorbed as NAD from the upper small intestine. Pellagra, the classical disease of niacin deficiency, is

brought about by insufficient dietary animal protein as a source of tryptophan and is manifested by mental confusion, a characteristic scaly red rash of sun-exposed areas, and diarrhea. Still prevalent in certain developing countries where animal protein is scarce, pellagra is occasionally identified in chronically alcoholic patients, usually in association with other vitamin deficiencies. Niacin in doses exceeding 1 g/d is often used in the treatment of hyperlipidemia. The common toxic side effects of flushing and exacerbation of peptic ulcer disease are greatly minimized by use of a controlled-release preparation. [71] Niacin status is assessed by measurement of the urinary ratio of its metabolites, *N*-methyl-2 pyridone-5 carboxamide and *N*-methylnicotinamide. [61]

Riboflavin Riboflavin, or vitamin B_2, exists in coenzyme forms as flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), each of which is involved in redox reactions. The food sources of riboflavin include milk, other dairy products, and fortified cereals. The DRIs for riboflavin are 1.3 mg for men, 1.1 mg for women, 1.4 mg for pregnant women, and 1.6 mg for lactating women. [72] Dietary FAD and FMN are released from food protein by gastric acid, then hydrolyzed by intestinal phosphatases. [73] Intestinal riboflavin transport is regulated by a Na^+-independent, carrier-mediated system. [74] Riboflavin deficiency is manifested by intense glossitis, seborrheic dermatitis, and peripheral neuropathy and may occur with alcoholism, celiac disease, and anorexia of any cause. Riboflavin status is assessed by HPLC of urine or by colorimetric measurement of erythrocyte glutathione reductase before and after the addition of FAD. [61]

FAT-SOLUBLE VITAMINS

Vitamins A, D, E, and K are unlike the water-soluble vitamins by virtue of their diverse nonenzymatic functions, prolonged storage and greater risk for toxicity, and absorption processes similar to those of dietary lipids in general. Like dietary triglycerides, fat-soluble vitamins are solubilized in the duodenal lumen in the presence of bile and pancreatic enzymes, and are then maintained within the lipophilic core of mixed micelles. Pancreatic esterases release fat-soluble vitamins from their esters in the presence of bile salts. Together with triglyceride-derived fatty acids, fat-soluble vitamins are released from micelles at the enterocyte brush border membrane. The absorption of vitamins E and K is decreased in the presence of high doses of vitamin A, whereas vitamin A absorption may be enhanced in the presence of high doses of vitamin E. [75] At high doses, vitamins A and E can be absorbed directly from water-miscible emulsions. [76] Within proximal enterocytes, fat-soluble vitamins are incorporated into chylomicrons for secretion into lymphatics and ultimate uptake by the liver. Intestinal, biliary, and pancreatic diseases that affect dietary lipid absorption also decrease the absorption of fat-soluble vitamins and promote their deficiencies. Table 20-3 summarizes the sources, requirements, functions, subsequent mechanisms of absorption, and clinical features of each fat-soluble vitamin.

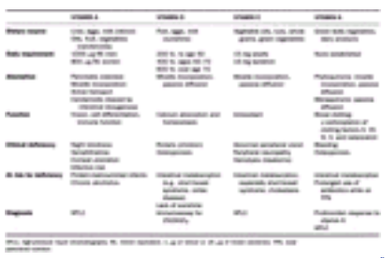

TABLE 20-3 Fat-Soluble Vitamins

Vitamin A

Vitamin A includes provitamin dietary carotenoid precursors of retinol and dietary retinol in its esterified form. Retinol is found exclusively in liver, eggs, and milk products; carotenoids are present in oils, fruits, and vegetables. Within the intestinal lumen, dietary retinyl esters are hydrolyzed by a specific pancreatic esterase to retinol, which is incorporated into micelles, then transported into enterocytes by a specific carrier protein. Transport is active and saturable at low concentrations, and passive at high concentrations. Within the enterocyte, retinol is transported by retinol-binding protein (RBP) to the smooth endoplasmic reticulum for reesterification, incorporation into chylomicrons, and subsequent transport as retinyl esters via lymphatics to the circulation and liver.

Dietary carotenoids undergo the same micellar incorporation as retinol and are passively transported across the cell membrane. Within the enterocyte, each molecule of pure ß-carotene is cleaved by ß-carotene dioxygenase to two molecules of retinol, which are esterified. Retinyl esters are stored in the liver as fat droplets in hepatic stellate cells, and after hydrolysis, they circulate as retinol bound to RBP. Carotenoids that reach the liver intact are transported with very-low-density lipoprotein (VLDL) and are converted to retinoids by tissue dioxygenases. [77]

Because the overall availability of purified ß-carotene in oil is only half that of retinol, the retinol activity equivalent (RE) of supplemental ß-carotene is considered to be 2:1. Considering the average 8% (1/12) availability of dietary ß-carotene in mixed vegetable and fruit diets, its RE is estimated at 12:1 × 2, or 24:1. In other words, after absorption and bioconversion, 24 µg of mixed dietary carotenoids is required to yield the same amount of retinyl esters as 1 µg of dietary retinol. [77] The DRIs for vitamin A are 400 to 700 µg RE for children, 1000 µg RE for adult men, and 800 µg RE for adult women. [77]

The biologic functions of vitamin A include the maintenance of vision through the conversion of retinal to rhodopsin, which enhances rod membrane potential for transmitting light signals to the optic nerve. Vitamin A is also essential for gene expression and cell differentiation during embryonic development, cell-mediated immune responsiveness, and spermatogenesis. The signs of vitamin A deficiency include failure of dark adaptation (night blindness), a follicular hyperkeratotic rash of the extremities, and impaired resistance to infections. Vitamin A deficiency occurs worldwide in protein-malnourished children, in whom night blindness and xerophthalmia develop with the appearance of conjunctival white deposits (Bitot spots), eventual corneal ulceration, scarring, and permanent blindness. Decreased hepatic RBP synthesis is a prominent feature of protein-calorie malnutrition and is the principal cause of vitamin A deficiency in malnourished children. International vitamin A supplementation programs have enhanced innate immune function and significantly reduced life-threatening infections in children worldwide. [78] According to levels in liver biopsy specimens, vitamin A deficiency is nearly universal in patients with alcoholic liver disease because of the effect of the microsomal CYP2E1 ethanol-oxidizing enzyme on enhancing the catabolism and biliary excretion of hepatic retinoids. [79] In the setting of chronic alcoholism, vitamin A deficiency may potentiate the development of esophageal squamous cell cancer. [80] On the other hand, the signs of supplemental vitamin A hepatotoxicity are enhanced by alcoholism, and excessive alcohol consumption interferes with the metabolism of supplemental ß-carotene and may enhance the propensity for lung cancer in alcoholic persons who smoke. [81] Vitamin A toxicity can occur with prolonged daily ingestion of 25,000 to 50,000 IU in easily obtained over-the-counter supplements and can result in liver failure, headache, vomiting, and a desquamating rash. [82]

Vitamin A status is measured by HPLC of plasma or serum by a method that is applicable to both vitamins A and E. RBP can be measured by radial immunodiffusion kit assay (The Binding Site, San Diego, California). The relative dose-response assay is used in field studies and consists of measuring RBP before and after a standard oral dose of vitamin A. Because apo-RBP accumulates in the liver during vitamin A deficiency, an increase of circulating RBP is indicative of vitamin A deficiency. [61] However, plasma RBP is also decreased in severe protein-calorie malnutrition, acute and chronic infection, and trauma. Liver biopsy is the gold standard for assessment of vitamin A status; however, it should be performed only if clear clinical indications of deficiency are present. The dichotomy of normal serum levels but low hepatic levels of vitamin A was demonstrated in a study of patients with liver disease of different etiologies. [79]

Vitamin D

Vitamin D is the generic term for a group of sterols that regulate calcium absorption and homeostasis. The forms of vitamin D include vitamin D_3 (cholecalciferol), which is the natural active form of the vitamin, and vitamin D_2 (ergocalciferol), its synthetic form. Vitamin D_3 is a provitamin that is synthesized in skin from endogenous 7-dehydrocholesterol on exposure to sunlight and is found in the diet in oily fish, egg yolks, and fortified milk. Persons living in temperate and tropical climates receive most of their vitamin D_3 by synthesis in the skin; vitamin D deficiency is more common in more northern or southern geographic areas, where sunlight is less constant. [83] The DRI for vitamin D is not precise and depends on the degree of exposure to the sun. The DRI for healthy adults ages 50 years and younger is 200 IU (equivalent to 5 µg/d), 400 IU/d for persons ages 50 to 70, and 600 IU/d for those older than 70 years. [84]

Like other fat-soluble vitamins, dietary vitamin D is absorbed after micellar solubilization in the upper intestine and by passive diffusion across the enterocyte membrane, then is incorporated into chylomicrons for entry into the circulation via lymphatics followed by uptake by the liver. [84] Two hydroxylation steps are required

for the activation of vitamin D. 25(OH)D_3 is synthesized in the liver and is both the principal circulating form and the substrate for 1a,25(OH)$_2D_3$, the active form of the vitamin that is synthesized in the proximal renal tubular cells. Renal 1-hydroxylase is tightly regulated by circulating levels of parathyroid hormone, calcium, and 1a,25(OH)$_2D_3$. Thus, 1a,25(OH)$_2D_3$ levels are increased by relative hypocalcemia that raises the level of parathyroid hormone. The main action of 1a,25(OH)$_2D_3$ is to maintain the circulating calcium level through regulation of its intestinal uptake, whereas postabsorptive circulating calcium regulates bone resorption by suppressing the release of parathyroid hormone. 1a,25(OH)$_2D_3$ also regulates gene transcription by interacting with vitamin D membrane receptors (mVDRs) and nuclear receptors (nVDRs) in many different tissues. [85]

Dietary vitamin D deficiency reduces calcium absorption, secondarily increasing parathyroid hormone and the risk for osteomalacia in adults or rickets in children, which is compounded by dietary calcium deficiency. On the other hand, osteoporosis in postmenopausal women and elderly men is caused by a lack of estrogen or androgen-derived estrogen, which increases bone resorption and thereby enhances serum calcium levels, resulting in reduced parathyroid hormone secretion and, thus, reduced renal production of 1a,25(OH)$_2D_3$. Consequently, calcium absorption and the serum levels of 25(OH)D_3 and 1a,25(OH)$_2D_3$ decline with aging, all of which contribute to the risk for bone loss in the elderly. In patients with malabsorption diseases characterized by decreased biliary secretion and micelle formation, such as primary biliary cirrhosis or the short-bowel syndrome, or by decreased mucosal lipid absorption, such as celiac disease, vitamin D and calcium are also malabsorbed, and combinations of osteomalacia and osteoporosis develop prematurely. For example, elevated gliadin antibody levels of celiac disease were tenfold more common among osteoporotic than nonosteoporotic Swedish adults. [86] Vitamin D toxicity can occur by excessive over-the-counter use of a vitamin D supplement and is characterized by hypercalcemia, nephrocalcinosis, and extremely elevated serum levels of 25(OH)D_3. [87]

Vitamin D deficiency is assessed by the findings of decreased circulating levels of 25(OH)D_3 and 1a,25(OH)$_2D_3$. [61] Decreased urinary calcium excretion, elevated serum parathyroid hormone, bone-derived alkaline phosphatase, and urinary hydroxyproline are all indicative of increased bone resorption in vitamin D deficiency. The rate of bone loss and the severity of osteoporosis can be partially alleviated by providing supplemental vitamin D in a dose of up to 800 IU/d together with supplemental calcium. [88] The amount of vitamin D required to treat deficiency in intestinal fat malabsorption syndromes is not established; one study demonstrated failure to increase serum levels of 25(OH)D_3 with single vitamin D_3 doses as high as 50,000 IU. [89] Nevertheless, it is worth providing large doses of vitamin D three times weekly to such patients while monitoring carefully for elevated levels of serum 25(OH)D_3 and urinary calcium excretion.

Vitamin E

Vitamin E comprises eight tocopherols, of which two, a- and ?-tocopherol, are significant to human nutrition. The predominant natural form of vitamin E is the *RRR* isomer of a-tocopherol. The major food sources of vitamin E are polyunsaturated vegetable and seed oils, whole grains, nuts, and green leafy vegetables. The DRIs of vitamin E are 6 to 11 mg for children, 15 mg for adults of all ages, and 19 mg for lactating women. [90]

The intestinal absorption of dietary vitamin E includes deesterification by pancreatic esterases, followed by bile-dependent incorporation into intralumenal micelles, subsequent passive diffusion into enterocytes, and incorporation into chylomicrons for transfer to the lymphatics and the circulation. After peripheral hydrolysis of chylomicrons, vitamin E returns to the liver with chylomicron remnants and then is transferred by hepatic a-tocopherol transfer protein (a-TTP) to *RRR*-a-tocopherol in combination with VLDL. After peripheral hydrolysis of VLDL, *RRR*-a-tocopherol is transferred to high- or low-density lipoprotein (HDL or LDL). [91] Subsequent transfer to tissues follows uptake of these lipoproteins. Plasma levels of a-tocopherol are determined by HPLC and vary according to the total plasma lipid concentration, [92] or, because a-tocopherol is transported with HDL and LDL, as a ratio to total cholesterol. [61]

The primary function of a-tocopherol is as a potent antioxidant of lipids. During antioxidant reactions, a-tocopherol accepts the free radical and becomes oxidized, and then is regenerated by vitamin C or glutathione. Vitamin E may also modulate cell-mediated immune function in elderly patients, [93] and may play a preventive role in coronary heart disease through its antioxidant effect on LDL. [94]

Vitamin E can be measured by a HPLC assay that is applicable also to vitamin A. [61], [95] Because vitamin E is ubiquitous in the diet, its deficiency occurs mainly in patients with malabsorptive disorders involving the biliary circulation, pancreas, and intestinal mucosa. Because their vitamin stores are lower, infants and children with biliary atresia or other causes of cholestasis acquire vitamin E deficiency more rapidly than do older children and adults with malabsorption diseases, including cystic fibrosis, cholestatic liver disease, short-bowel syndrome, and celiac disease. [96] Patients with chronic hemolytic anemia may become deficient in vitamin E owing to its overutilization, whereas acute hemolytic anemia may develop in preterm infants fed diets high in polyunsaturated fatty acids and pro-oxidant iron. Vitamin E deficiency is manifested also by neurological damage involving the posterior columns, cranial nerves, brainstem, and peripheral nerves, and by retinal damage, presenting clinically with loss of balance, peripheral neuropathy, or visual field defects. [97] A water-soluble form of vitamin E, *RRR*-a-tocopherol glycol (Aquasol E), is better absorbed than the dietary, fat-soluble natural vitamin and hence is more effective in the treatment or prevention of vitamin E deficiency in malabsorption diseases such as short-bowel syndrome. [76]

Vitamin K

Vitamin K incorporates dietary phylloquinone from plants and menaquinones that are synthesized by intestinal bacteria. The main dietary sources of phylloquinone are leafy green vegetables; dairy products are minor sources. There is no precise DRI, and the average intake of vitamin K is 120 mg in men and 90 mg in women. [98] Menaquinone is absorbed by passive diffusion from the distal ileum in the presence of bile salts, and less efficiently from the colon. [99] In contrast, dietary lipid-soluble phylloquinone undergoes micellar incorporation, after which it is transported into the enterocyte by active saturable transport system. [100] Comparative studies of the forms of vitamin K in the liver suggest that menaquinone from bacterial synthesis provides substantially less vitamin K than dietary phylloquinone.

Vitamin K facilitates the posttranslational ?-carboxylation of proteins involved in blood clotting: prothrombin and factors VII, IX, and X. The presence of ?-carboxyglutamic acid (Gla) residues is essential for calcium binding, as required in blood clotting. [101] Vitamin K also enhances ?-carboxylation of osteocalcin, and vitamin K deficiency contributes to osteoporosis, whereas vitamin K supplementation has been shown to prevent bone fractures. [102]

Vitamin K deficiency can be assessed by a prolonged prothrombin time that responds to parenteral vitamin K administration and by direct measurement of circulating phylloquinone by HPLC. [61] The clinical settings of vitamin K deficiency include the combination of dietary inadequacy and antibiotic use, such as may occur in patients with sepsis receiving total parenteral nutrition; patients with malabsorption syndromes, including hepatobiliary diseases associated with cholestasis, short-bowel syndrome, Crohn's disease, and celiac disease; and patients on prolonged antibiotic regimens. [103]

MINERALS

This section begins with discussion of the absorption of the macrominerals, calcium and magnesium, which always are present in biologic systems in the divalent form and do not undergo any redox reactions. Iron, the most abundant trace element, is discussed next. Iron occurs in several physiologically different forms, has complex absorption mechanisms, and undergoes several oxidation-reduction reactions during its normal metabolism. Finally, the absorptive mechanisms for zinc and copper are presented. Table 20-4 summarizes the dietary sources, requirements, absorptive mechanisms, functions, and clinical features of each of these minerals.

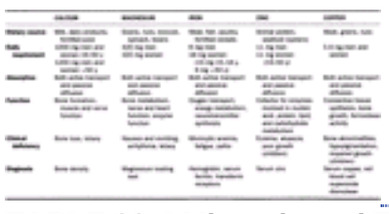

TABLE 20-4 Minerals and Trace Elements

Calcium

Sources and Bioavailability Although diet previously provided the major part of the daily calcium intake, recognition of the importance of calcium in osteoporosis and bone health has changed this pattern. Calcium supplements and fortified beverages and foods are now commonly used and are needed to meet the recently increased dietary requirements. Milk and other dairy products are good dietary sources and often provide up to 75% of dietary calcium. Meat products provide some calcium bound to protein, whereas calcium in plants usually is associated with organic anions, such as phytate and oxalate. The DRI is 1000 mg/d for adults (19–50 years), 1300 mg/d for teenagers and young pregnant and lactating women, [84] and 1200 mg/d for adults older than 50 years. The bioavailability of calcium from milk, dairy products, and meat is high, perhaps because the smaller peptides formed during digestion keep calcium in an absorbable, soluble form. [104] In contrast, phytate, uronic acid, and particularly oxalate, which are present in cereals, fruits, and vegetables, reduce the absorption of calcium. [105], [106] Fiber that contains phytate has been shown to have a negative effect on calcium absorption. However, the results have not been consistent and vary among different types of dietary fiber, possibly because of different contents of phytate. It appears that some forms of calcium supplements are less bioavailable than others. The most absorbable form is calcium citrate malate; calcium is somewhat less available from calcium carbonate and calcium triphosphate. [107] Although not directly affecting calcium absorption, high intakes of caffeine and protein have a negative effect on calcium balance by increasing urinary losses. [105] Furthermore, when supplements are taken with or close to a meal or if calcium-fortified foods are consumed, the absorption of calcium will be the net result of interactions between enhancers and inhibitors of calcium absorption present in the meal. Finally, there is strong homeostatic regulation of calcium absorption that may be more profound than the dietary factors discussed above.

Absorption and Homeostasis Calcium is absorbed both actively in the duodenum and passively by diffusion in the ileum. [106] Some absorption also occurs in the colon. [108] Calcium must be ionized at a low pH in the stomach. In patients with achlorhydria, the absorption of calcium from calcium carbonate is decreased compared to that in control subjects with normal gastric pH. [109] In this study, however, the achlorhydric patients absorbed calcium from skim milk to the same extent as subjects with normal stomach acidity, possibly because of the solubilizing effect of milk peptides, which is not as pH-dependent. Antacids can therefore also reduce calcium uptake. Active absorption via calcium-binding protein (CaBP) dominates at low levels of calcium intake, whereas passive diffusion makes a significant contribution to net calcium uptake at high levels of intake. [110] Active transepithelial calcium transport, which is largely localized to the upper part of the duodenum, is dependent on vitamin D (1,25[OH] $_2$D $_3$) and consists of three mechanisms. First, brush border uptake occurs down a steep electrochemical gradient from the lumen to the cytoplasm through calcium channels that are not voltage gated. [106] Second, calcium ions are transported through the enterocyte by carrier-mediated facilitated diffusion from the brush border membrane to the basolateral membrane. [111] This step has been described as rate-limiting in calcium absorption. Diffusion of calcium ions is very low in the absence of the cytosolic CaBP, calbindin D $_{9k}$, and transcellular calcium transport increases in a linear fashion according to the cellular content of calbindin. [112] Another CaBP, calbindin D $_{28k}$, is also induced by vitamin D, but it binds four calcium ions, whereas calbindin D $_{9k}$ binds two. [113], [114] In vitamin D–deficient cells, calcium enters the cell but stays at the brush border membrane, showing the strong need for calbindins for effective cellular translocation. [114] The third mechanism is extrusion of Ca^{2+} through the basolateral membrane, which is mediated by calcium ATPase and the Na^{+}/Ca^{2+} exchanger, occurs against an electrochemical gradient, and consequently requires energy. [115] Calcium interacts with the cytoplasmic region of ATPase and, through a phosphorylation-induced conformation change in the enzyme, is transported across the membrane via a channel formed by the transmembrane regions of ATPase. Vitamin D has some effect on both the uptake and extrusion phases by increasing the gene expression of membrane-bound calcium ATPase. [116] The passive absorption of calcium occurs by paracellular diffusion down a chemical gradient in all sections of the small intestine. [106] This pathway accounts for the major part of calcium absorption when intake is adequate or high, and is associated with down-regulation of the active transport of calcium. Passive diffusion of calcium also occurs in the colon. In rats, the contribution of the colon to net passive uptake of calcium in the entire tract has been estimated at 11%, whereas its contribution to active transport may account for 7%. [106] Similar values for humans are not available, but it has been shown that total calcium uptake by the colon in the human adult is substantial. [117] Homeostatic regulation of calcium absorption is achieved primarily by up- and down-regulation of active transport. [106] During pregnancy, calcium absorption increases significantly, which may be a response to the high fetal requirement. Lactation, however, does not appear to result in a similar increase in calcium absorption.

Disorders of Calcium Homeostasis Intestinal absorption appears to decrease with age, possibly because of lower circulating concentrations of 1,25(OH) $_2$D $_3$ or decreased responsiveness of the intestine to vitamin D. [118] Consequently, increased calcium intake is recommended for older persons to prevent bone loss. Gastrointestinal disease, such as celiac or Crohn's disease, often results in osteomalacia, usually as a consequence of vitamin D deficiency. [119] Cholestasis and ileal disease disrupt the enterohepatic circulation of bile salts, which in turn reduces micelle formation, leading to decreased lipid and vitamin D absorption. Increased fat excretion in the malabsorption diseases also causes losses of calcium bound to fatty acids. Gastric surgery often disturbs calcium absorption, resulting in osteomalacia as a late complication. [119] Disorders of thyroid hormone metabolism also affect calcium homeostasis through effects on parathyroid hormone. [120] In hyperthyroidism, calcium absorption is decreased secondary to suppression of parathyroid hormone secretion and its effect of renal hydroxylation of 25(OH)D $_3$, caused by increased bone resorption and serum calcium concentrations. In hypothyroidism, the hydroxylation of vitamin D to its active form 1,25(OH) $_2$D $_3$ in the kidney is lowered, resulting in lower calcium absorption. Similarly, renal disease can result in lower production of 1,25(OH) $_2$D $_3$ and thus decreased calcium absorption. Therefore, 1,25(OH) $_2$D $_3$ is used in the treatment of chronic renal disease. However, type I renal acidosis and nephrotic syndrome also cause calcium malabsorption, [121] but in these diseases, vitamin D administration is ineffective and treatment with alkali is required, suggesting a negative effect of acidosis on calcium absorption. Drugs can also affect calcium absorption. Whereas some drugs like glucocorticoids and phenytoin directly inhibit calcium absorption in the intestine, chlorothiazide and other diuretics increase the renal reabsorption of calcium and thereby decrease parathyroid hormone secretion and 1,25(OH) $_2$D $_3$ synthesis, indirectly reducing calcium absorption. Other drugs increase calcium absorption. Pharmacological doses of estrogen can enhance calcium absorption by reducing bone resorption and secondary hyperparathyroidism. [122] Vitamin D intoxication also increases calcium absorption. [123]

Magnesium

Sources and Bioavailability Magnesium is abundant in plants; whole grains, nuts, seeds, broccoli, spinach, and beans are good sources of magnesium. Dairy products and meat also contribute significantly to our daily magnesium intake. Recently, the intake of mineral water high in magnesium has become common, and mineral water is now a considerable source of magnesium for many individuals. The newly set DRI for magnesium is 420 mg/d for adult men, which is usually met by most men, and 320 mg/d for women, [124] whose magnesium intake is frequently less than the DRI. Based on disappearance data, the per capita availability of magnesium suggests an intake of about 350 mg/d, although this intake differs considerably from intake data that show about 180 to 200 mg/d for women and 250 to 300 mg/d for men. [125] Increased magnesium intake has been advocated for fertile women, particularly during pregnancy.

Absorption and Homeostasis Studies in experimental animals show that magnesium absorption occurs primarily in the ileum and the colon, whereas less is absorbed in the duodenum. [126] Human studies over a wide range of magnesium intakes show a saturable curve that is indicative of an active transport mechanism, as well as a linear function that is compatible with passive diffusion. [127] Studies in children also show evidence for carrier-mediated intestinal transport of magnesium. [128] Perfusion studies in humans show magnesium absorption in the jejunum and ileum, [129] and also substantial absorption in the colon. Absorption of magnesium in adults with a normal dietary intake of magnesium is about 21% in men and 27% in women. [130] Magnesium homeostasis is largely regulated by control of renal excretion, but increased absorption of magnesium in the intestine during low levels of dietary intake contributes to homeostasis.

Deficiency Magnesium deficiency secondary to low dietary intake is uncommon and difficult to diagnose because of a lack of reliable markers. [131] Serum or plasma magnesium is relatively tightly regulated and does not reflect tissue levels well. The magnesium content of mononuclear cells and urinary levels are not very reliable markers and are not used in clinical settings. [131] Loading tests are more reliable, but also more tedious. Congenital primary hypomagnesemia is an uncommon disorder that is correlated to a specific defect in the intestinal absorption of magnesium. [128], [132] Hypomagnesuria, hypocalcemia, hypokalemia, and tetany often occur in association with convulsions, [133] which are corrected with the administration of magnesium. The hypocalcemia of magnesium deficiency is caused by an inhibition of the exchange between bone calcium and serum magnesium, resulting in decreased responsiveness of osteoclast parathyroid hormone receptors. [134] Magnesium deficiency eventually inhibits parathyroid hormone secretion and thus decreases the renal production of 1,25(OH) $_2$D $_3$, thereby decreasing the intestinal absorption of calcium. Vitamin D does not correct the hypocalcemia, whereas correction of magnesium levels restores calcium levels to normal. Experimentally induced symptomatic magnesium deficiency in human volunteers consistently resulted in very low levels of plasma magnesium (10%–30% of control values), low urinary and fecal magnesium levels, hypocalcemia, and hypokalemia. [131] Gastrointestinal problems (nausea, vomiting), arrhythmia, and personality changes were common. Most subjects had abnormal neuromuscular function after 4 to 14 weeks of consuming the low-magnesium (~10 mg/d) diet. All symptoms vanished when magnesium was given, with serum magnesium normalizing quickly and serum calcium and potassium more slowly. Clinical conditions that contribute to magnesium depletion include malabsorption syndromes, [135] such as celiac disease, inflammatory bowel disease, and other immune diseases involving villous atrophy; intestinal bypass or resection; gastrointestinal infections; and renal dysfunction, such as may be caused by metabolic disorders, tubular disease, and nephrotoxic drugs and diuretics, and which may result in excessive magnesium losses. [136] Several endocrine disorders also cause magnesium depletion, [137] including diabetes mellitus, hyperparathyroidism with hypercalcemia, and hyperthyroidism. Alcoholism often leads to poor magnesium status, [138] and protein-calorie malnutrition has also been reported to involve impaired magnesium nutrition. [139] Magnesium depletion often occurs in uncontrolled clinical conditions. However, changes in magnesium concentrations in tissues and serum often reflect secondary or tertiary causes of depletion. [131] Potassium depletion, protein catabolism, and chronic acidosis all lower

cellular magnesium levels and, consequently, levels of magnesium in muscle and bone. [131]

Iron

Sources, Forms, and Bioavailability The human diet contains two fundamentally different forms of iron: heme iron and nonheme iron. These forms are absorbed and metabolized differently, and dietary factors have different effects on their absorption. [140] Heme iron is present as myoglobin and hemoglobin in meat, poultry, and fish. The absorption of heme iron is higher than that of nonheme iron. In iron-replete individuals, the efficiency of heme iron absorption is usually about 20% to 25%, whereas the absorption of nonheme iron is about 3% to 10%, depending on the diet. Heme iron absorption is relatively unaffected by dietary factors, whereas food components may have widely different effects on the absorption of nonheme iron. The presence of globin and heme as components of hemoglobin and myoglobin in animal protein in the diet has been shown to increase heme iron absorption. Similarly, a low iron status may enhance heme iron absorption, but only to a relatively modest degree. Ascorbic acid has a strong enhancing effect on nonheme iron absorption, [141] whereas phytate, tannins, and other polyphenols are inhibitory. [142] Calcium has been shown to inhibit iron absorption in some short-term radioisotope studies, [143] but not in others. [144] Long-term studies of infants, children, and lactating and postmenopausal women given high daily doses of calcium (500–1000 mg) for 6 to 12 months, however, failed to show any effect on iron status as assessed by hemoglobin or serum ferritin levels. [145], [146] and [147] It is therefore possible that homeostatic mechanisms adapt after an initial inhibitory effect of calcium on iron uptake, and no negative effect on iron status occurs. The DRI for iron is 8 mg/d for men and women older than 50 years; it is 15 mg/d for young women ages 15 to 18 years and 18 mg/d for older premenstrual women. [148]

Absorption and Homeostasis Heme and nonheme iron are absorbed via different pathways and are affected to different degrees by dietary components, physiological conditions, and iron status. The mechanisms underlying heme iron absorption are not yet fully understood. The uptake into the intestinal mucosal cell has been suggested to occur via putative "heme receptors" that have not yet been characterized, [149] or by intercalation of the hydrophobic heme group via the lipid bilayer of the brush border membrane. [150] Once within the cell, heme oxygenase breaks down the heme group, releasing iron for incorporation into intracellular ferritin or for export out of the cell. [151] Hence, once heme is broken down, the released iron becomes part of the nonheme iron pool. Several mechanisms involved in the mucosal regulation of nonheme iron absorption have been discovered (Fig. 20-3). Duodenal cytochrome *b* (Dcytb) was discovered in the small intestine of rats and found to reduce ferric iron (Fe^{3+}) to the more absorbable ferrous (Fe^{2+}) form. [152] It is known that rodents can absorb ferric iron well, supporting a role for this ferrireductase in iron absorption. Humans, however, do not absorb ferric iron well, [140] although ferrireductase activity has been measured in human duodenal mucosa. [153] Therefore, despite its presence in human small intestine, Dcytb may have only a limited role in iron absorption.

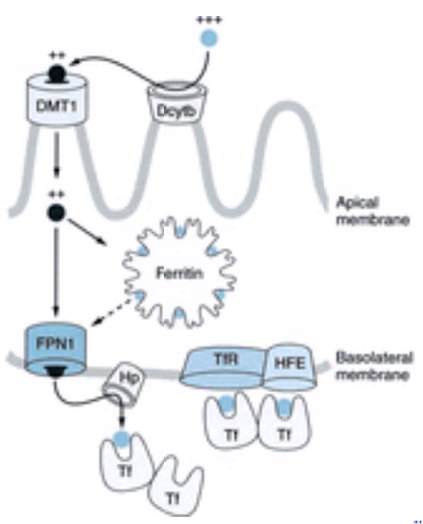

FIGURE 20-3. Suggested mechanisms for the regulation of iron absorption by the mucosal cell. *Dcytb*, duodenal cytochrome b; *DMT1*, divalent metal transporter 1; *FPN1*, ferroportin 1; *HFE*, hemochromatosis gene product; *Hp*, haephestin; *Tf*, transferrin; *TfR*, transferrin receptor.

Divalent metal transporter (DMT1; also called *DCT1* or *Nramp2*) is located in the brush border membrane and is involved in the regulation of iron uptake by the enterocyte. Its expression is up-regulated during iron deficiency and down-regulated in situations of iron excess. [154] The protein is primarily located in the villus tip cells, with less present in the crypt cells. The gene for this protein was found in mutant mice with microcytic anemia (mk), [155] and in the anemic Belgrade rat. [156] Originally, this protein was found by expression cloning in *Xenopus* oocytes, and several cations, including Fe^{2+}, Zn^{2+}, Cu^{2+}, Cd^{2+}, Co^{2+}, Mn^{2+}, Ni^{2+}, and Pb^{2+}, were found to be transported by DMT1. [157] However, it is not certain that oocytes with DMT1 perform the normal functions of a cell–that is, the functions that would occur in vivo. In another study, manganese was found to affect DMT1 expression in cultured Caco-2 cells, but zinc was far less effective. [154] Thus, under physiological conditions, this "divalent metal" transporter may transport only a few trace elements, while others are transported by other carriers. Inside the mucosal cell, the expression of ferritin is regulated by the intracellular concentration of iron. [158] Iron binds to iron regulatory proteins, which are sequence- and structure-specific RNA-binding proteins, which change conformation on binding iron. When the iron status is low, iron regulatory proteins a have high affinity for the iron-responsive element of ferritin mRNA and block protein synthesis. Thus, the rate of ferritin synthesis is low when the iron status is low. When iron is present in excess, the iron regulatory protein conformation does not allow binding to the iron-responsive element, and ferritin synthesis increases. In contrast to ferritin, transferrin receptor (TfR) mRNA contains five iron-responsive elements in the 3' UTR (untranslated region), [159] whereby its stability is regulated, and also a rapid turnover determinant. When the iron regulatory protein binds to the TfR mRNA, the interaction between ribonuclease and the rapid turnover determinant is hindered and TfR mRNA synthesis decreases. This coordinate regulation of ferritin and TfR synthesis, which occurs at the mRNA level, is an excellent means for the cell to respond to varying iron status. The TfR is located both in endosomal compartments and in the basolateral membrane, with the transferrin-binding structural feature being on the outside of the cell, allowing transferrin in portal blood to interact with the TfR. A novel protein capable of exporting iron out of the enterocyte was discovered simultaneously by three research groups and was called *ferroportin 1 (FPN1),* [160] *iron-regulated transporter 1 (IREG1),* [161] and *metal transporter protein 1 (MTP1),* [162] respectively. There is so far no consensus on which name should be used. This iron exporter is up-regulated during iron deficiency and down-regulated during iron excess, [161] and it is likely to be a key protein in normal mucosal iron homeostasis. A membrane-bound protein of 62 kd, it has ten transmembrane regions and contains iron-responsive elements. [162] Fe^{2+} must be oxidized to Fe^{3+} to become incorporated into transferrin in the portal vein. Hephaestin, a copper-dependent enzyme with activity similar to that of ceruloplasmin, was discovered by positional cloning in the sex-linked anemia (sla) mouse mutant, which has a block in intestinal iron transport. [163] This protein is likely to have some influence on human intestinal iron metabolism, but the human homolog has not yet been described, and its quantitative significance is unknown.

Disorders of Iron Homeostasis Hereditary hemochromatosis is an autosomal recessive genetic disorder of defective regulation of iron absorption that leads to severe iron overload in various tissues of the body, particularly the liver. [164] The gene frequency usually is about 1 in 300, but it varies with ethnicity and is highest among Northern Europeans. To prevent cirrhosis of the liver, patients are either phlebotomized regularly or given chelation therapy, usually with desferrioxamine. Studies of patients with hereditary hemochromatosis have revealed that the vast majority of these individuals (>95%) have a mutation in the HFE gene. [165] This gene is expressed at low levels in most tissues, including the small intestine, and appears to be involved in the appropriate down-regulation of iron absorption that normally occurs when iron stores are high. The HFE protein is similar to major histocompatibility complex (MHC) class I proteins. [166] A missense mutation (C282Y) affects a highly conserved cysteine residue, involving a disulfide bond within the MHC I proteins. This causes a defect in HFE protein trafficking and cell surface expression as a consequence of the inability of the defective HFE protein to bind ß $_1$-microglobulin. [167] HFE must interact with ß $_1$-microglobulin to regulate iron absorption, which is illustrated by the finding that iron overload develops in ß $_1$-microglobulin–deficient mice. [168] The HFE knock-out mouse shows all the signs of human hereditary hemochromatosis, which supports the critical role of this protein in the regulation of iron absorption. [169] HFE has been shown to bind directly to the transferrin receptor, [167] suggesting that the regulatory role of HFE may be mediated by an interaction with this protein. Sickle cell disease and ß-thalassemia are also genetic disorders that lead to abnormal iron metabolism. Whereas hereditary hemochromatosis is characterized by the preferential loading of iron into parenchymal cells, in sickle cell disease or ß-thalassemia, iron first accumulates in the reticuloendothelial cells. [170] Clinically, the primary cause of mortality in hereditary hemochromatosis is cirrhosis and hepatocellular carcinoma, whereas in ß-thalassemia, it is cardiomyopathy. [171] In comparison with patients who have ß-thalassemia, patients who have sickle cell disease are relatively spared the toxicity of iron overload. Whether these different outcomes are a consequence of differences in expression of the iron transporters in the intestine and liver has not yet been explored.

Deficiency and Excess Iron deficiency is the most common single nutrient deficiency worldwide, afflicting some 800 to 1000 million people in both less developed and industrialized countries. It is estimated that 500 to 600 million persons have iron deficiency anemia. In adults, this anemia results in impaired immune function and energy metabolism, producing lethargy. [172] In infants and young children, iron deficiency anemia also causes delays in cognitive function and motor development. [173] Whether these developmental delays are reversible is still not clear, but most studies suggest that they are irreversible. Prevention of iron deficiency is therefore a

high priority from a public health perspective. Iron deficiency usually is diagnosed by the serum ferritin concentration, which is directly proportional to body iron stores. When the body becomes depleted of iron, serum ferritin values decrease. A ferritin value below 12 µg/L usually is used as the cutoff for iron deficiency and has been shown to correlate with a lack of stainable iron in the bone marrow. If iron deficiency progresses, hematopoiesis becomes impaired, resulting in microcytic anemia. Because serum ferritin increases during infection and inflammation, resulting in a falsely high value, the circulating serum TfR level is now under evaluation as an additional test for iron deficiency. [174] When iron stores decrease, the cellular synthesis of TfR increases and is reflected in serum TfR concentrations. TfR is not affected by infection and may therefore better reflect tissue iron needs. [174] However, it is not yet known whether other factors affect the TfR, and furthermore, the several commercial kits yield very different results, so that interlaboratory comparisons are difficult. It may therefore take some time before this assay will become part of the clinical routine. Lack of dietary iron or poor iron bioavailability is by far the most common cause of iron deficiency, but chronic gastrointestinal blood loss, malabsorption secondary to mucosal disease (e.g., celiac disease), bypass of the proximal intestine, and achlorhydria can also lead to iron deficiency. Although iron deficiency is common in many populations, particularly children and fertile women, iron overload can also occur in a significant proportion of individuals. Besides hereditary hemochromatosis, iron-loading anemias, such as homozygous thalassemia and sideroblastic anemia, also cause iron overload. [175] Therefore, an overly zealous approach to providing iron to large population groups may harm a growing number of individuals with already large iron stores. Concern has also been raised that high iron stores, although not yet characterized as iron overload, can lead to increased free radical formation and chronic disease. It has been shown that Finnish men with elevated serum ferritin levels (>200 µg/L) have a significantly higher risk for coronary heart disease and non–insulin-dependent diabetes than men with normal (<200 µg/L) serum ferritin levels. [176], [177] Other studies yielded conflicting results, and a recent metaanalysis did not find a significantly increased odds ratio. [178] However, the likelihood of confounders in such epidemiologic studies is high, and further studies are needed to resolve this issue.

Zinc

Sources, Forms, and Bioavailability The daily dietary intake of zinc, which usually is about 10 to 15 mg, generally meets the requirement of men but is often marginal for women, particularly during pregnancy and lactation. [179] The DRI for men is 11 mg/d; for nonpregnant women, 8 mg/d; for young women ages 18 years and younger and for pregnant and lactating women, 13 and 14 mg/d, respectively; and for women ages 19 to 50 years and older than 50 years, 11 and 12 mg/d, respectively. [180] The best dietary sources of zinc are meat, meat products, and seafood. Whole grains and cereals also are relatively high in zinc, but bioavailability often is low because of the presence of phytate. [181] The use of zinc supplements has become more popular, particularly because of its perceived beneficial effect in the prevention and treatment of the common cold. Multivitamin/mineral tablets now often contain zinc, and some cereal products are fortified with zinc. Most forms of zinc are well absorbed, although zinc is less available from zinc oxide as a result of its low solubility. Phytates in cereals and legumes have a strong inhibitory effect on zinc absorption as a consequence of their chelating properties. [181] Because humans cannot digest phytate, zinc bound to phytate is unabsorbable and lost in the feces. Recent attempts to increase the bioavailability of zinc from human diets include alternative food processing (e.g., fermentation), phytase treatment, and the development of genetically modified cereals that are lower in phytate. [182], [183] and [184] All these approaches aim to lower the phytate content of the food. Calcium can lower zinc bioavailability, most likely by forming insoluble calcium-zinc-phytate complexes. However, under some circumstances, calcium can also increase zinc absorption. [185] The protein content of the diet is positively correlated to zinc absorption, most likely because of the formation of amino acids and small peptides that facilitate zinc uptake by the enterocyte. [186] Iron in high doses can reduce zinc absorption from oral supplements, [187] but this does not occur when both are given with a meal. [188] Thus, this interaction may be of some concern when multivitamin/mineral tablets are taken on an empty stomach, but not otherwise.

Absorption and Homeostasis The efficiency of zinc absorption from the diet usually is about 15% to 35% in adults. [189] Active transport dominates at low or normal intake, whereas passive diffusion contributes more significantly at high intake. [190] The extent of the homeostatic regulation of zinc in humans is not well known, but studies in experimental animals suggest that it occurs, although not to the same extent as for iron. [181] The mechanisms underlying the regulation of zinc absorption have long remained elusive. It was known that the low-molecular-weight (~6 kd) protein metallothionein (MT), which also binds copper and cadmium, [191] is present in the cytosol of the enterocyte. However, zinc induces MT only at very high intakes, so that this protein an unlikely regulator under physiological conditions. However, zinc-binding proteins likely play important roles in the trafficking of zinc across the mucosal cell. Zinc transporter 1 (ZnT-1) appears to be involved in the export of zinc across the enterocyte basolateral membrane, [192], [193] whereas ZnT-2 and ZnT-4 are involved in the flux of zinc in the endosomes, possibly regulating intracellular trafficking of zinc. These membrane transporters all have six transmembrane-spanning domains and a conserved histidine-rich region predicted to have a cytoplasmic loop that is likely to bind zinc. [192], [194] ZnT-1 was localized to the basolateral membrane, and ZnT-2 was found in acidic vesicles that accumulate zinc. [195] Overexpression of ZnT-1 supports its role in zinc export. [192] Although higher levels of ZnT-1 mRNA were found in zinc-supplemented rats, [193] direct functional evidence is still missing. ZnT-2 is more responsive to zinc than ZnT-1. Experiments showing zinc sequestration by endosomal vesicles during overexpression of ZnT-2 suggest that this transporter may be important for controlling intracellular transport of zinc by the enterocyte. [195] In rats, ZnT-2 mRNA levels closely correlate with zinc intake. ZnT-4 appears to colocalize with ZnT-2, suggesting some redundancy, but ZnT-4 mRNA is not responsive to changes in zinc status. All three transporters were found primarily in villus cells, much less frequently in crypt cells. The ileum was the major site for ZnT-1; ZnT-2 was found in rat duodenum and jejunum, and ZnT-4 in all parts of the small intestine. [193] Few studies to date have been conducted in intact animals, so that it is difficult to evaluate the physiological significance of these transporters in zinc absorption and homeostasis. Whether MT is involved in this regulation or plays more of a bystander role also needs to be evaluated further. MT expression was found to be closely correlated with ZnT-2 expression, and the ZnT-2 promoter may have multiple metal response elements, similar to the MT promoter. A superfamily of human zinc transporters has been found. [196], [197] Transfection of K562 cells with zinc importer protein (hZIP1 or hZIP2) increased the cellular uptake of zinc. Because these proteins are localized in the plasma membrane and because primarily zinc influx is affected, these transporters may also be responsible for zinc uptake by the enterocyte. Other transition metals decreased zinc uptake, suggesting that these proteins also may transport other cations. [196]

Deficiency and Excess Zinc is a cofactor for a wide diversity of enzymes and transcription factors. Severe zinc deficiency affects many metabolic pathways and tissues, impairing growth, development, reproduction, and immune function. [198] However, severe zinc deficiency is rare and usually is seen only in patients with acrodermatitis enteropathica; marginal zinc deficiency, in contrast, despite problematic status assessment, is likely to be common. [199] The diagnosis of milder forms of zinc deficiency is difficult in part because the plasma zinc level is affected by many factors other than zinc. [198] The response to zinc supplementation is therefore often used as an indicator of zinc status. Supplementation trials have shown positive effects on the growth of infants and children, [200] pregnancy outcome, [201] and diarrheal disease, [202] demonstrating that several population groups are vulnerable to subclinical zinc deficiency. This is particularly the case in developing countries, and strategies to prevent zinc deficiency worldwide are currently under way. The risk for zinc toxicity and the likelihood of achieving excessive dietary intakes of zinc are both low. [198] Patients at some risk for excessive zinc intake are those being treated with oral zinc supplements, such as for acrodermatitis enteropathica or Wilson disease (see section “ Copper”). The effects of such treatment do not appear to be acute; rather, the copper status is impaired with its long-term consequences.

Disorders of Zinc Homeostasis Acrodermatitis enteropathica is an inborn autosomal recessive disorder of zinc metabolism manifested by eczema, dermatitis, anorexia, compromised immune function, and poor growth. [203] The gene frequency is about 1 in 10,000. Symptoms usually occur when infants are weaned as a consequence of the low zinc intake and bioavailability from infant formula and weaning foods, combined with rapid growth. [204] Referral to a dermatologist is common, but the only effective treatment is zinc supplementation. Patients require daily doses of zinc, usually 30 to 50 mg, and higher doses during periods of rapid growth, such as at puberty. If doses are too high, however, copper deficiency can result, causing other clinical problems [205]; therefore, both the zinc status and the copper status of these patients must be monitored. The defective mechanism underlying acrodermatitis enteropathica is still not known. It is described as a disorder of zinc absorption; however, malabsorption may be a secondary problem resulting from mucosal damage caused by local zinc deficiency, as patients treated with zinc appear to absorb zinc normally. [205] It is likely instead that zinc efflux out of the enterocytes into the intestinal lumen is abnormally high, thereby causing an intracellular zinc deficiency. Whether the expression of any of the zinc transporters (ZnT-1, -2, -4; hZIP1, 2) is dysregulated in patients with acrodermatitis enteropathica has not yet been explored.

Copper

Sources and Bioavailability Copper is relatively abundant in meat, grains, and nuts; milk and dairy products are low in copper. [206] However, copper intakes are relatively close to the DRI (0.9 mg/d for men and women), [207] and some concern has been raised that copper status may be suboptimal in vulnerable groups. Environmental factors, such as soil, water source, fertilizer use, processing, and cooking, also affect the copper content of the diet. For example, tap water occasionally has high copper levels because of copper plumbing and well water sometimes has high copper levels, and certain groups, particularly infants and children, may have copper intakes that are excessive. [208] Thus, some concern regarding copper nutrition is warranted. Copper absorption from the diet usually is high, and few dietary components strongly affect its bioavailability. [209] High intakes of iron or zinc, however, may lower the copper status if the ratio between these elements and copper remains high for a long period. [210] Thus, multivitamin/mineral supplements that contain iron and zinc, but not copper, may negatively affect copper status. Ascorbic acid has been shown to lower copper absorption in animals by reducing well-absorbed divalent (cupric) to monovalent (cuprous) copper, which is not as well absorbed. [211] However, in human studies, young adult volunteers given high levels of ascorbic acid daily (600 mg) showed no change in copper status. [212] Whether even higher doses of ascorbic acid, such as those sometimes advocated for prevention of the common cold (>1000 mg/d), affect copper absorption and status is not yet known. Other organic acids in foods, such as lactic, citric, malic, and acetic acids, slightly enhance copper absorption, most likely by affecting its solubility by

chelation. [211]

Absorption and Homeostasis Copper absorption is mediated by both active transport and passive diffusion. [211], [213] Animal studies suggest that the duodenum is the major site of absorption, but some absorption also occurs in the stomach and ileum. [214] Human studies show that copper intake affects copper absorption. [215] Copper homeostasis is mediated in part by bile copper excretion; about 15% of the copper excreted in bile is reabsorbed through the enterohepatic circulation. [211] Cellular copper homeostasis is maintained by a delicate balance of copper uptake and efflux, which are mediated by highly conserved membrane proteins. [216] Copper-transporting P-type ATPases are involved in the intracellular trafficking of copper as well as in the export of copper out of the cell. [217] Cytoplasmic low-molecular-weight copper-binding proteins act as chaperones, steering copper ions to their incorporation into the proper apoproteins. [216] The expression of a human gene, *CTR1* (copper transporter 1), was shown to increase the cellular uptake of copper in yeast cells. [218] The involvement of Ctr1 in cellular copper metabolism was demonstrated by increased copper uptake by human fibroblasts transfected with the human *CTR1* gene. [219] The Ctr1 protein appears to be vital for normal copper metabolism because the *CTR1* knock-out mouse was embryolethal. [220] Mice heterozygous for *CTR1* exhibit tissue-specific defects in copper accumulation and in the activities of copper-dependent enzymes. Supplementation of the pregnant mice with copper did not rescue the homozygous knock-out embryos, suggesting that they cannot acquire copper because they lack the membrane-bound Ctr1 protein, and furthermore, there is no alternate transport system for copper. [220] Ceruloplasmin and hephaestin are copper-dependent enzymes involved in iron homeostasis (see previous section), and the heterozygous *CTR1* knock-out mice had decreased tissue levels of iron, most likely a consequence of impaired delivery of copper to its apoproteins. Interestingly, patients with the very rare genetic disorder aceruloplasminemia have normal copper metabolism but suffer from the consequences of impaired iron metabolism. [221] Studies of human intestinal Caco-2 cells in culture suggest two pathways of copper absorption. [222] At low levels, copper uptake and efflux are closely coupled, and little copper is stored in the cell. Conversely, at high levels, copper uptake and efflux are buffered by a large storage compartment. The molecular regulation of these events is not yet known but should be explored in light of the newly discovered transporters.

Disorders of Copper Homeostasis Menkes disease is an X-linked recessive disorder of copper absorption; copper deficiency occurs at a very young age. [223] The incidence of Menkes disease is 1 in 50,000 to 1 in 100,000 live births. Symptoms include pallor, lax skin, bone fractures, osteoporosis, altered pigmentation of skin and hair (secondary to low levels of melanin formation), growth failure, mental retardation, and microcytic anemia (secondary to low levels of ceruloplasmin/haephestin activity). Oral treatment with copper is ineffective, and patients often die at a young age. The gene was identified by work on mouse models of Menkes disease, [224] and the defective protein is one of the P-type ATPases, ATP7A or Menkes (MNK) protein, which is involved in cellular copper metabolism, particularly the export of copper out of the cell. [217], [225] Thus, copper is blocked in the enterocyte, and little copper is transported into the systemic circulation, resulting in severe copper deficiency. In Wilson disease, excessive amounts of copper accumulate in the body, particularly in liver and brain, and clinical symptoms include liver cirrhosis, eye lesions (Kayser-Fleisher ring), kidney malfunction, and neurological problems. [226], [227] Despite very high levels of copper in the liver, serum levels of copper and ceruloplasmin are low. Treatment has classically been chelation therapy with drugs such as penicillamine and trientine, but high oral doses of zinc (40–50 mg/d) are also effective because they inhibit copper absorption. [228] Wilson disease is an autosomal recessive disorder, occurring in 1 in 30,000 live births. This disorder of copper metabolism has also been shown to be caused by a defective transporter, in this case ATP7B or the WD protein. [229] Copper absorption per se does not appear to be dysregulated in these patients; rather, tissue copper metabolism, particularly in the liver, is affected, causing an excessive cellular accumulation of copper. The outcome for these patients, if treated, usually is good, although continuous monitoring of copper, zinc, and iron status is necessary.

Deficiency and Excess The significance of human copper deficiency was recognized by clinical studies of infants recovering from malnutrition. [230] Risks for copper deficiency include low iron stores in the liver of premature infants, a rapid growth rate, malabsorption syndromes, and increased copper losses, [231] but the deficiency usually is not precipitated unless the dietary intake of copper also is low. [208], [230] Low serum levels of copper and anemia, which is refractory to iron because of low ferroxidase/haephestin activities, are manifestations of copper deficiency and are accompanied by neutropenia, bone abnormalities, hypopigmentation of hair and skin, impaired growth, and an increased incidence of infections. [232] Decreased phagocytic capacity of neutrophils and impaired cell immunity affect the immune system. [233] Acute copper toxicity is rare and usually is caused by the consumption of contaminated foods or beverages, or by the accidental or deliberate ingestion of large quantities of copper salts. [234] Symptoms include nausea, vomiting, and diarrhea. Chronic toxicity is also rare but seems to occur in geographic clusters. Indian childhood cirrhosis has been reported in families that were consuming milk boiled or stored in brass or copper containers. [235] Children consuming such milk may ingest up to 1 mg of copper per kilogram per day, which is enough to explain the observed liver damage. Infants and children in the Austrian Tyrol were reported to have died of liver cirrhosis secondary to chronically high levels of copper intake. [236] In these cases, inheritance followed the typical pattern of a mendelian recessive trait, suggesting that these individuals were particularly sensitive to copper exposure. This was supported by the observation that many children who had received similar levels of copper had no liver damage. Sporadic cases have been reported in other areas, and some of these cases have occurred in consanguineous marriages. Cases were much more frequent in boys, and a genetic origin is possible. Whether a genetic disorder of copper metabolism is present in patients with liver cirrhosis is not known, but the possibility should be explored in light of the new findings of copper transporters in humans.

CHAPTER 21

David H. Alpers and Samuel Klein

GENERAL NUTRITIONAL PRINCIPLES

BASIC NUTRITIONAL PRINCIPLES

Body Composition

The human body consists of 35 components that are organized into five levels of increasing complexity: atomic (e.g., nitrogen, potassium), molecular (e.g., water, protein), cellular (e.g., body cell mass, intra- and extracellular fluid), tissue (e.g., skeletal muscle, adipose tissue), and whole body (e.g., weight, height). A healthy, lean man is composed of 55% to 60% water, 15% to 20% fat, 15% to 20% protein (one half in skeletal muscle), 1% glycogen (four fifths in muscle, one fifth in liver), and 4% minerals. [1] Although sophisticated techniques are available to measure each body component, the definitions of some commonly used terms can be confusing. *Fat mass* represents all body triglycerides, which are present in adipose tissue, muscle, and liver. *Adipose tissue* is about 83% fat (e.g., triglyceride), 15% water, and 2% protein. *Fat-free mass* refers to total body mass minus total fat mass. *Lean body mass* is defined as total body mass minus adipose tissue. The body also can be divided into cellular and extracellular mass. *Body cell mass* is defined as the cellular components of all tissues (35%–45% of the body weight in normal men, 30%–40% in women) and can be measured by total exchangeable potassium. [2] *Extracellular mass* is defined as the heterogeneous group of tissues and fluids supporting the body cell mass.

Diet for Normal People

Many guidelines have been developed over the years for general use by the U.S. population for health maintenance and disease prevention. Although these have been published at different times and represent the input of a large number of experts with diverse interests, all expert panels have reported remarkably simple and consistent recommendations for healthy adults. Two of these guidelines are widely disseminated and are current. *Nutrition and Your Health: Dietary Guidelines for Americans, 2000* combines the guidelines of the U.S. Department of Agriculture and the U.S. Department of Health and Human Services. [3] This publication offers ten guidelines for a healthy diet (Table 21-1).

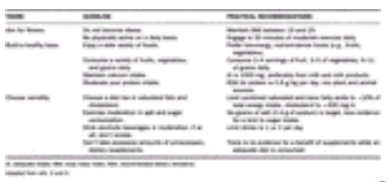

TABLE 21-1 Dietary Guidelines for Adult Americans, 2000

The *American Heart Association Dietary Guidelines Revision 2000* sets forth the recommendations of the American Heart Association. [4] This report recommends four goals for the population that fit well with the guidelines from the U.S. Department of Agriculture (see Table 21-1). The Healthy Eating Pattern goal suggests consuming a variety of fruits, vegetables, and grain products. The Healthy Body Weight goal suggests matching energy intake with energy needs and limiting the consumption of foods with a high caloric density. The Desirable Blood Cholesterol and Lipoprotein Profile goal limits intake of foods high in saturated fatty acids and cholesterol, substituting grains and sources of unsaturated fatty acids, such as vegetables, fish, legumes, and nuts. The Desirable Blood Pressure goal recommends limiting dietary salt intake and alcohol consumption, reinforcing the need for maintaining healthy body weight. Metaanalyses of randomized trials of the effect of reducing sodium on blood pressure concluded that a direct relationship exists for hypertensive persons. [5]

Vegetarian diets accomplish many of the recommendations because these diets lower the risk for the development of coronary artery disease, type II diabetes, and hypertension. [6] The recommendations listed in Table 22-1 are generalized for all Americans, but special considerations may be needed for African Americans and other minority groups. For example, the diets of middle-aged African Americans appear to be lower in calcium, iron (for women), folate, and zinc. [7] The condition of being overweight is more prevalent in African American women and in Hispanic Americans. Americans from the Asian and Pacific Rim countries tend to have diets lower in dairy products and calcium, although in second- and third-generation families, these differences are likely to disappear.

The approach to macronutrient intake of all the dietary recommendations is similar. [3], [4], [8], [9] and [10] The report on macronutrients of the Standing Committee on the Scientific Evaluation of Dietary Reference Intakes, Food and Nutrition Board, Institute of Medicine has been available since 2002. Until that time, the ecommendations for energy and protein intake were supplied by the 1989 tenth edition of *Recommended Dietary Allowances (RDAs)*. [10] All sources recommend maintaining a healthy weight. Standards for such weight have varied from those of the more restrictive *1979 Body Build Study* [11]—which does not allow for age-related weight changes and relates desirable body weight to a low mortality rate—to other measures of ideal weight, such as the RDAs, [10] the measures of the Fogarty Center Conference on Obesity, [12] and the average weights in the United States, which allow for slight increases with age. The guidelines suggest balancing energy intake and physical activity to maintain appropriate weight, and avoiding diets that are excessive or severely restricted in kilocalories. It is worthwhile to calculate the estimated resting energy expenditure (REE) and the activity-related energy requirement. REE is best estimated from the World Health Organization equation, but the Harris-Benedict equation has the advantage of greater simplicity, even though it is less accurate at the extremes of weight (Table 21-2). For estimates of overall energy use, the RDA figures are simple and useful (Table 21-3). These estimates of energy expenditure vary in both directions by 20%. Also, snacks and alcohol intake must be added to the estimated dietary intake.

Harris-Benedict Equation[33]	
Men = 66 + (13.7 × W) + (5 × H) − (6.8 × A)	
Women = 665 + (9.6 × W) + (1.8 × H) − (4.7 × A)	
Owen et al.[37]	
Men = 879 + (10.2 × W)	
Women = 795 + (7.18 × W)	
World Health Organization[48]	

AGE (y)	MALE	FEMALE
0–3	(60.9 × W) − 54	(61.0 × W) − 51
3–10	(22.7 × W) − 495	(22.5 × W) + 499
10–18	(17.5 × W) + 651	(12.2 × W) + 746
18–30	(15.3 × W) + 679	(14.7 × W) + 996
30–60	(11.2 × W) + 879	(8.7 × W) + 829
>60	(13.5 × W) + 987	(10.5 × W) + 596

W, weight (kg); H, height (cm); A, age (y).

TABLE 21-2 Formulas for Estimating Resting Energy Expenditure

LEVEL OF ACTIVITY	ACTIVITY FACTOR (× REE)	AVERAGE ENERGY EXPENDITURE* (kcal/kg per day)
Very light		
Men	1.3	31
Women	1.3	30
Light		
Men	1.6	38
Women	1.5	35
Moderate		
Men	1.7	41
Women	1.6	37
Heavy		
Men	2.1	50
Women	1.9	44

*Estimated from World Health Organization equations for median weights of persons ages 19 to 74 years; activity factor 1.0 = 24.0 kcal/kg for males, 23.2 kcal/kg for females.

REE, resting energy expenditure.

Adapted from ref. 10.

TABLE 21-3 Calculation of Energy Requirement

Regarding protein intake, the available guidelines recommend a moderate intake, not to exceed two times the RDA and not to provide more than 20% of total calories. There is no evidence that intake above the RDA (0.8 g/kg per day) is beneficial. Moreover, because most protein sources are rich in fat, a high protein intake would increase fat intake. All the guidelines recommend a diet with an abundance and variety of vegetables (3–5 servings) and fruits (2–4 servings), plenty of grains (6–11 servings), and sugar in moderation. They recommend the increased intake of complex carbohydrates and fiber as found in whole grain products, fruits, and vegetables. Such intake would provide 55% or more of the total daily energy intake. A corollary to the recommendations on carbohydrates is that the diet be low in fat, especially saturated fat, and cholesterol, to reduce the risk for atherosclerotic heart disease. In addition to a reduced total fat intake, the diet should have no more than 30% of calories from fat, no more than 10% of calories from saturated fat and *trans* fatty acids, and no more than 300 mg of cholesterol per day. The intake of polyunsaturated fats should be increased, up to 10% of total calories, because they have a cholesterol-lowering effect and are a rich source of vitamin E. This recommendation reflects the now large data sets that show favorable blood lipoprotein patterns in individuals who consume moderate amounts of total fats that are predominantly polyunsaturated. [3], [13] Finally, most guidelines suggest an Adequate Intake (AI) of calcium (1300 mg/d for adolescents, 1000 mg/d for adult men and nonpregnant women ages 19 through 50, and 1200 mg/d for adults older than 50 years). [13] Milk contains the highest concentration of calcium (280–300 mg/8-oz cup). There is as yet no convincing evidence that additional protective effects to prevent osteopenia are conferred by ingesting calcium over the recommended AI. Salt (NaCl) should be limited to 6 g/d or less, and alcohol to 1 oz of pure alcohol per day (1 oz is the equivalent of two cans of beer, two small glasses of wine, or two average cocktails).

The implementation of the published recommendations depends on two other federally supported guidelines. The RDA [10], [13], [14], [15] and [16] is the level judged to be high enough to ensure an adequate intake for the majority of the normal population, not the minimal intake necessary to avoid negative balance. The values for the RDA vary with age and gender. These values should not be confused with the U.S. RDAs, standards set by the U.S. Food and Drug Administration in 1973 for the purposes of food labeling for the entire population. The term *U.S. RDA* has been replaced by *Reference Daily Intake (RDI)* and *Daily Reference Value (DRV)*. The latter provided for total and saturated fat, cholesterol, total carbohydrates, dietary fiber, sodium, potassium, and protein—nutrients for which no U.S. RDA was available. The RDI and DRV are now the basis for the daily values that appear on all food labels, and reflect DRVs and RDIs for a 2000-calorie reference diet. The new recommended dietary intake levels are called *Dietary Reference Intakes (DRIs),* a collective term that includes the Estimated Average Requirement (EAR), the Recommended Dietary Allowance (RDA), the Adequate Intake (AI), and the Tolerable Upper Intake Level (UL) (Table 21-4). [13], [14], [15] and [16] These have been developed by the Institute of Medicine in the United States along with Health Canada. The EAR is the daily nutrient intake value estimated to meet the requirements of half of an age- and gender-specific group. It often is derived from balance studies and is used in setting the RDA, the intake level sufficient to meet the nutrient needs of most people within a given life-stage and gender group. The RDA also includes a factor to account for variation within the group, usually estimated at 10% (i.e., coefficient of variation, or CV). If not enough data are available to calculate an EAR, AI is used, based on observed intake consistent with good health. The UL is the maximum amount of a nutrient that can be ingested without posing a health threat and was included because so many nutrients are now ingested at levels far exceeding those possible from the diet.

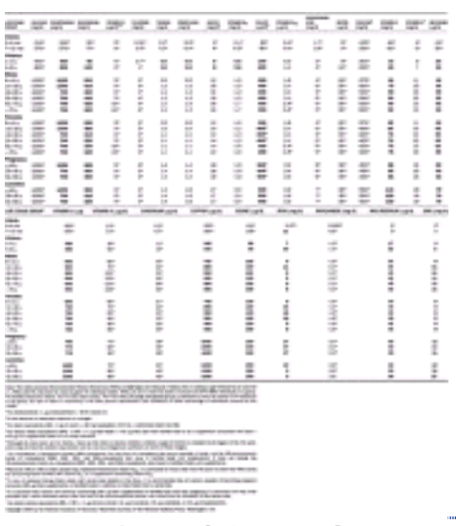

TABLE 21-4 Dietary Reference Intakes: Recommended Intakes for Individuals

These guidelines account for group and in some cases individual variability, but they are not meant for use in patients with either acute or chronic diseases. Rather, they should be used as baseline estimates for planning individual nutrient intake. Such adjustments are particularly important in diseases characterized by malabsorption or catabolism, in contrast to simple lack of intake. Confirmation of sufficient nutrient provision can then be monitored by tests specific for each macro- or micronutrient (see Chapter 53).

The food guide pyramid, recommended to implement the dietary guidelines in Table 21-1, has replaced the four basic food groups by dividing fruits and vegetables, to which are added breads (with cereal, rice, and pasta), milk products, and meat (with poultry, fish, dry beans, eggs, and nuts) to make five groups (Fig. 21-1). [17] The concept assumes that meals are built on a basis of grains, fruits, and vegetables, and supplemented with low-fat milk products and other protein sources in the meat group. The food pyramid comes with a warning to use fats and sweets sparingly. To limit fat and cholesterol intake, it is important to remember that ground beef, the single largest source of dietary fat in the United States, still contains more than half of its calories as fat after cooking; a single egg contains more than 200 mg of cholesterol, and 70% of the calories in regular cheese are from fat.

FIGURE 21-1. U.S. Department of Agriculture food guide pyramid. (From ref. [18].)

The practical aspects of providing advice using the food pyramid (or any other educational system) involves a knowledge of the number of servings in the diet, and what counts as one serving. The range of servings provided by the food pyramid are spread over the average range of energy intake, from 2200 to 2800 kcal/d (Table 21-5). The sizes of the servings are smaller than most people realize and do not include the addition of fats or oils in the calculation of daily energy intake. For example, one bread serving would be one slice of bread or 1/2 cup of cooked rice or pasta; one serving of vegetables is 1/2 cup of chopped, raw, or cooked vegetables; one piece of fruit or 3/4 cup of juice is one serving; 1 cup of milk or 11/2 to 2 oz of cheese is one serving; and 21/2 to 3 oz of cooked lean meat, poultry, or fish or 1/2 cup of cooked dry beans is one serving. [18]

TABLE 21-5 How Many Servings Are Needed Each Day?

Chemoprevention of Gastrointestinal Cancers One of the special applications of dietary recommendations for healthy people is to prevent gastrointestinal cancers. The general recommendations for such diets are similar to those that support health in the entire population. However, it has been estimated that about one third of all cancers are related to diet, and that most colorectal cancer in the United States might be prevented by dietary alterations. [19] Although epidemiologic data have suggested associations between overall diets or environment and the risk for cancer incidence or mortality, it has proved difficult to identify the dietary components that might influence such risks, and to demonstrate their benefit in a prospective fashion. [20], [21] and [22] Table 21-6 summarizes many of the data associating risks for cancer with dietary components. Very few of the associations reported have been convincing. When dietary components have been identified and tested prospectively, the data, in general, are negative, even when premalignant end points are examined, such as colorectal polyps. [23]

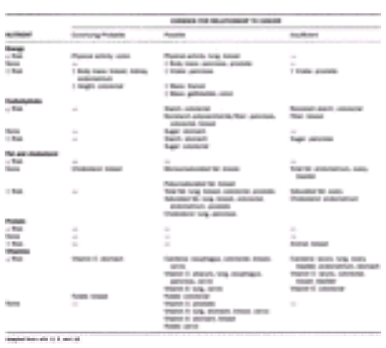

TABLE 21-6 Nutrition, Food, and Cancer Prevention

Epidemiologic evidence (case control and cohort studies) also suggests that people with cancer have a lower intake of raw, fresh, leafy green, or cruciferous vegetables, as well as raw or fresh fruits, especially citrus fruits. [24] Although the ingestion of such foods has increased in the United States, the average intake is less than 0.7 servings of vegetables or fruits per day. Moreover, a large cohort study (Iowa Women's Health Study of more than 40,000 women) showed no protective effect of vegetables or fruits on colorectal carcinoma incidence, except for garlic. [23] The antioxidant vitamins A, C, and E are among those compounds thought to be responsible for the possible effects of vegetables and fruits on carcinogenesis. The same large cohort study analyzed the effect of these three vitamins on colorectal cancer incidence and found that vitamins A and C had no effect. [23] An association of total (i.e., supplemental and dietary) and supplemental vitamin E with a decreased incidence was found, but dietary vitamin E intake alone was not correlated. Other studies have tested the addition of individual or combinations of vitamins (or ß-carotene) on the incidence of colorectal adenoma formation but have not found much efficacy. [19] The other dietary component that has been most extensively studied is fiber. Two extensive reviews have examined the descriptive and case control studies of the association of dietary fiber with colorectal cancer. [25], [26] Most studies showed some correlation, suggesting a protective effect of fiber. In the Health Professionals Follow-up Study involving men, a 64% reduction in cancer was noted in those with the highest quintile of fiber intake (>28.3 g/d) compared to those with the lowest intake (<16.6 g/d). [27] However, results from two large studies of women, the Nurses Health Study [28] and the Iowa Women's Study, [29] showed no effect. Prospective studies suggest that an effect of fiber may occur only in men. A number of interventional studies using fiber supplements have been performed, but the results are inconclusive. [19], [25], [26] The data regarding the effect of other dietary components on the incidence of colorectal cancer or adenomas are too fragmentary or incomplete to permit strong recommendations. [19] Some evidence suggests an effect of folate, and its role is being tested in interventional studies. Alcohol (>30 g/d) may increase the incidence of adenomas in the distal colon and rectum. Although many case control and cohort studies suggested that calcium protected against the development of colorectal cancer, other studies with larger cohorts showed no effect. The results of interventional studies are conflicting, and the end point used has been colonic cell proliferation, not adenoma or carcinoma incidence. In summary, some data implicate an increased intake of dietary fat and red meat and a decreased intake of vegetables, fruits, and fiber in colorectal carcinogenesis. The interventional recommendations include altering those components, which is precisely the recommendations for the diets to maintain the health of people in the United States. [3], [4] Because most people eat less vegetables, fruits, fiber, and calcium than what is needed to meet the RDAs, it is reasonable to promote these diets for general health.

Energy Metabolism

The human body continuously consumes energy for the maintenance of ionic and osmotic gradients, cell transport, nerve conduction, intermediary metabolism, biosynthesis, heat generation, and the performance of involuntary and voluntary mechanical work. Energy is provided largely by the mitochondrial production of high-energy phosphate bonds generated by the oxidation of fat, carbohydrate, and protein. After the hydrolysis of carbohydrates to simple sugars, fats to fatty acids and glycerol, and proteins to amino acids, most of these small molecules are converted to the acetyl unit of acetyl-coenzyme A (CoA), generating a small amount of ATP in the process. Acetyl-CoA is a common breakdown product of the three macronutrients. Acetyl-CoA, carrying most of the chemical energy of the original macronutrients, enters the citric acid cycle and undergoes oxidative phosphorylation, which are the final common pathways in the oxidation of food molecules (Fig. 21-2). Many amino acids enter the citric acid cycle as a-ketoglutarate or oxaloacetate rather than as acetyl-CoA.

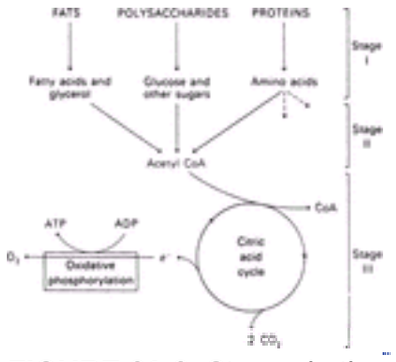

FIGURE 21-2. Stages in the extraction of energy from foodstuffs. (From Stryer L. Biochemistry, 3rd ed. New York: WH Freeman, 1988:325.)

A portion of the energy released during substrate oxidation is not used to perform work and is dissipated as heat. Therefore, energy production is traditionally measured in terms of heat production. One kilocalorie (kcal), equal to 4.184 kilojoules (kJ), is the amount of heat required to raise the temperature of 1 kg of water by 1°C. Normally, body temperature is carefully maintained within narrow limits so that heat production equals heat loss. Energy production can be determined directly (direct calorimetry) by measuring the transfer of heat from the body to water circulating in specially designed chambers or suits. Energy production also can be measured indirectly (indirect calorimetry) by measuring carbon dioxide (CO_2) production and oxygen (O_2) consumption, because the amount of heat produced during substrate oxidation is proportional to the amount of CO_2 produced and O_2 consumed. [30] The relationship between CO_2 production and O_2 consumption can be used to estimate the relative oxidation of different substrates. [31]

Dietary carbohydrates, fats, and proteins can be used as fuel soon after their ingestion, or they can be stored by the body for subsequent oxidation. Endogenous energy stores (Table 21-7), which are continuously being mobilized and oxidized, become a critical source of fuel during postabsorptive conditions and when energy intake is inadequate to meet energy demands. The largest source of endogenous energy is triglyceride in adipose tissue, which is uniquely designed to store fuel. Triglycerides have a high energy density and release 9.4 kcal/g when oxidized. Adipose tissue is composed almost entirely of triglycerides in an oil form, which constitutes 85% of adipocyte weight. In comparison, glycogen, the other major source of endogenous fuel, generates only 4.1 kcal/g on oxidation. Glycogen takes up a considerable amount of space because it is stored in liver and muscle tissue as a gel containing 2 to 4 g of water for every gram of glycogen. [32] The mobilization of adipose tissue yields 6 to 8 kcal/g, whereas the mobilization of glycogen yields only 1 to 2 kcal/g. The energy stored in the adipose tissue of a lean man can provide enough fuel for him to survive 2 months of total energy restriction, [33] whereas the energy present as liver glycogen is consumed within 24 hours of fasting. Certain cells and tissues, such as the brain, prefer glucose as a fuel, and others, such as bone marrow, erythrocytes, leukocytes, renal medulla, eye tissues, and peripheral nerve tissue, require glucose because they cannot oxidize fatty acids. None of the macronutrients are completely absorbed; some are excreted in the feces. Based on the average digestibility of fat (95%) and carbohydrate (97%), the digestible energy derived from fat is 9.0 kcal/g, and that from carbohydrate is 4.0 kcal/g.

TISSUE	FUEL	ENERGY (kcal)
Adipose tissue	Triglyceride	140,000
Muscle	Glycogen	2000
	Triglyceride	3000
Liver	Glycogen	300
	Triglyceride	500

TABLE 21-7 Body Energy Stores

Components of Energy Expenditure Total energy requirements include the sum of REE, the thermic effect of physical activity (TEPA), the thermic effect of feeding (TEF), and adaptive thermogenesis (AT). REE is the energy consumed while lying quietly awake in the postabsorptive state. Normally, REE accounts for about 70% of total daily energy expenditure. Energy requirements of different tissues and organs are heterogeneous, however. Energy consumption by the body's most metabolically active organs—the brain, liver, kidney, and heart—accounts for 60% of REE; these constitute only 5% of total body mass (Table 21-8). In contrast, adipose tissue, which accounts for about 20% and 30% of body weight in lean men and women, respectively, consumes less than 5% of REE.

	MASS		ENERGY EXPENDITURE	
TISSUE	g	% Total	kcal/d	% Total
Gut	2000	3	300	13
Brain	1400	2	400	18
Liver	1600	2.2	440	19
Heart	300	0.4	235	10
Kidneys	300	0.5	200	10
Adipose tissue	14,000	20	70	4
Skeletal muscle	28,000	40	400	18

TABLE 21-8 Postabsorptive Energy Requirements

REE is related to body weight across mammalian species; REE is proportional to the three-fourths power of body weight (weight $^{0.75}$). [34] Several equations have been used to estimate resting energy requirements in humans based on measurements of REE in normal subjects (see Table 21-2). [35], [36], [37] and [38] These equations generate values that are usually within 10% of measured values in normal healthy volunteers but are less accurate in persons who are at extremes of weight (i.e., very lean or obese) or who are ill. Starvation and severe hypocaloric feeding decreases the resting metabolic rate to values 15% to 20% below that expected for actual body size, whereas illness and injury can increase energy requirements. Physical activity usually accounts for 15% to 20% of total energy expenditure. The precise contribution of TEPA to total energy expenditure depends on the intensity and duration of activities. At rest, skeletal muscle accounts for 20% of total energy requirements. However, during moderate- to high-intensity aerobic exercise, energy consumed by working muscles can increase more than 50-fold, causing a 15-fold increase in total energy expenditure. The TEF represents the energy costs of digestion, absorption, transport, metabolism, and storage of nutrients, and it also may involve AT. Eating or infusing nutrients increases the metabolic rate by about 5% to 10% of the ingested or infused calories and depends on the specific foods consumed. Normally, 12% to 20% of the energy in ingested protein, 6% to 12% of carbohydrate energy, and 2% to 3% of fat energy is expended. AT is a proposed mechanism for wasting excess energy to maintain a constant body weight despite fluctuating amounts of energy intake, or for maintaining body heat during exposure to different environmental temperatures. [39] It has been proposed that energy expenditure and heat production for AT and TEF involve brown adipose tissue, a specialized, highly vascularized, thermogenic tissue innervated by sympathetic nerves. [40] Brown adipose tissue is packed with large mitochondria possessing an uncoupling protein that uncouples ATP synthesis from respiration. [41], [42] In this situation, the rate of substrate oxidization does not depend on the availability of ADP precursor, and the reaction can continue at high rates, permitting even small quantities of brown adipose tissue to increase heat production markedly. Radioimmunoassays for the uncoupling protein have demonstrated the presence of brown adipose tissue in humans of all ages [42]; other studies suggest that uncoupling protein expression also can be induced in white adipose tissue. Although it has been estimated that as little as 50 g of brown adipose tissue can contribute 10% to 15% of the energy turnover in humans, [41] the physiological importance of AT in energy metabolism in humans is not clear.

Proteins

Proteins are composed of amino acids joined together by peptide bonds. Twenty different amino acids are commonly found in human proteins. Differences in the sequences of amino acids in proteins permit diverse structures and functions; proteins serve as enzymes, carriers, receptors, hormones, and structural elements. The amino acid sequence determines the location of sites for covalent attachment of carbohydrate and ultimately determines the protein's three-dimensional configuration and specific function. Nitrogen is also present in the body in the form of free amino acids. Free amino acids are in a dynamic state with those being incorporated into tissue proteins, those undergoing catabolic reactions, and those used for the synthesis of other nitrogen-containing compounds. [43]

Protein Quality Protein quality is related to its ability to support metabolic homeostasis and growth, which is determined by amino acid content and bioavailability. Some amino acids (histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, valine, and possibly arginine) are considered essential because their carbon skeletons cannot be synthesized by the body. These amino acids must be consumed in the diet for normal function and survival. Other amino acids (glycine, alanine, serine, cysteine, cystine, tyrosine, glutamine, glutamic acid, asparagine, and aspartic acid) are nonessential because their carbon skeletons can be produced endogenously. In general, the greater the ratio of essential to nonessential amino acids, the better the quality of protein. The ability to digest protein and absorb its component amino acids also affects protein quality. True absorption ranges from 97% to 99% for proteins in meat, milk, and eggs, to 75% for proteins

in potatoes and navy beans. [44], [45] Protein bioavailability also can be affected by food preparation. For example, some lysine is lost by heating in the presence of reducing sugars. In contrast, heating increases the bioavailability of soy protein by inactivating the trypsin inhibitor present in soybeans. [46] In general, the proteins of egg, milk, fish, red meat, and poultry are high in biologic value, and the protein in wheat gluten is low. [44], [45], [47]

NITROGEN BALANCE Nitrogen balance is the difference between intake and output. Nitrogen is excreted primarily in the urine as urea, creatinine, porphyrins, ammonia, and uric acid. The relative proportions of these compounds can vary, but urea usually accounts for about 80% of urinary nitrogen. During fasting conditions, urinary nitrogen reaches a low level of about 2 mg/kcal of REE or about 40 mg/kg of body weight. Approximately 1 to 3 g of nitrogen is normally lost per day from fecal and other sources. [16] Fecal nitrogen losses reflect unabsorbed protein in the diet and in intestinal secretions and sloughed epithelial cells. The amount of endogenous protein that normally enters the intestinal lumen is about 50 g/d. Absorption of exogenous and endogenous protein is so efficient that fecal nitrogen is normally only 1 to 2 g/d. Minor amounts of nitrogen are lost through intact skin, nasal secretions, semen, menstrual fluid, and hair cuttings. Nitrogen balance can be used to estimate protein balance because about 16% of protein consists of nitrogen, and it is assumed that almost all body nitrogen is incorporated into protein or amino acids. A positive balance (i.e., intake greater than losses) represents a net increase in total body protein, whereas a negative balance (i.e., losses greater than intake) demonstrates net protein catabolism. One gram of nitrogen represents about 6.25 g of protein, which is equivalent to 30 g of hydrated lean body mass. Nitrogen balance is affected by protein intake and quality, energy intake, and nutritional status. Inadequate energy intake increases protein requirements. When protein intake is suboptimal, nitrogen balance can be improved by increasing energy intake. Therefore, nitrogen balance reflects both protein intake and energy balance. Most normal adults can maintain nitrogen equilibrium by ingesting 0.5 g of high-quality protein per kilogram of body weight per day. The range of recommended intake for adults is 0.5 to 0.8 g/kg per day, [10], [43], [48], [49] which provides a margin of safety to allow for decreased biologic availability and increased requirements in subsets of the population. The average protein in a Western diet has only 75% of the biologic value of egg protein. [43], [50] Intravenously administered amino acids are as effective in promoting nitrogen balance as oral protein. [51] Infancy is a time of intense growth, and the protein requirements per unit of body weight for infants are higher than those for adults. The normal infant also requires a higher proportion of essential to nonessential amino acids. [52] The growth spurt of adolescence, the only extrauterine period during which growth velocity increases, occurs between 10 and 13 years of age for American girls and between 12 and 15 years of age for American boys and contributes about 15% of final adult height and 50% of adult weight. [53] The guidelines for protein and calorie needs in infancy, childhood, and adolescence are summarized in Table 21-9. The nutritional demands of a normal pregnancy average 80,000 kcal (i.e., 300 kcal/d) and 950 g of protein (i.e., 3.5 g/d). The U.S. National Research Council RDA for pro-tein during pregnancy is 60 g/d, representing an increase of 10 g/d over the RDA for nonpregnant women 25 years of age or older. [10] For lactating women older than 25 years of age whose average daily output of milk is 850 mL, a protein intake of 65 g/d in the first 6 months and 62 g/d in the second 6 months is recommended by the National Research Council. [10] Slightly lower values are recommended for younger women. [10] Modified versions of these figures are available in the Dietacy Reference Intakes for Energy, Carbohydrates, Fiber, Fat, Protein and Amino Acids (macronutrients), 2002 (see legend to Table 21-9).

TABLE 21-9 Dietary Reference Intake Values for Energy and Protein in Individuals by Life Stage Group

Protein Metabolism Body proteins exist in a state of constant flux, with protein synthesis and breakdown occurring simultaneously. Normal daily protein turnover is 1% to 2% of total body protein and results largely from the degradation of muscle and hepatic proteins. Protein degradation involves the enzymatic hydrolysis of protein to its constituent amino acids. More than 75% of the amino acids released by protein breakdown are reused for the synthesis of new proteins; the remaining amino acids are oxidized. Proteases within cell lysosomes are responsible for most protein degradation. [54], [55], [56], [57] and [58] However, proteases are also found in plasma membranes and in the cytosol. The carbon skeletons of amino acids can be oxidized for energy or used for synthesis of glucose, ketone bodies, or fatty acids. [2] Nitrogen can be released as ammonia into the bloodstream and delivered to the liver, where it is converted to urea. The metabolism of amino acids involves the transfer of nitrogen between organs from the periphery to the liver (Fig. 21-3). The liver is a workhorse for amino acid metabolism and is the site of synthesis for urea and plasma proteins. It is the main site of catabolism for the essential amino acids, with the exception of the branched-chain amino acids leucine, isoleucine, and valine, which are degraded in muscle and kidney.

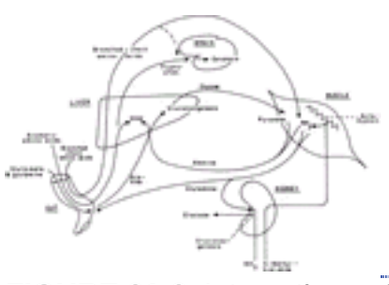

FIGURE 21-3. Interactions of organs in the metabolism of some major amino acids. (From Munro HN. Interactions of the liver and muscle in the regulation of metabolism in response to nutritional and other factors. In: Arias IM, Popper H, Schachter D, et al., eds. The liver: biology and pathobiology. New York: Raven Press, 1982:677.)

Skeletal muscle preferentially takes up the branched-chain amino acids after each meal and is the primary site of metabolism for these amino acids. Although leucine, isoleucine, and valine constitute only 8% of dietary amino acids, they make up 60% of the amino acids in the systemic circulation. [59], [60] When muscle proteins are catabolized, the branched-chain amino acids undergo transamination, yielding alanine, glutamine, and branched-chain keto acids. The keto acids are used by the muscle as fuel, and alanine and glutamine are exported and taken up predominantly by the liver and intestine, respectively. [59] These two amino acids account for more than 50% of the total amino acid nitrogen released from muscle. [60], [61] and [62] The kidneys also take up glutamine, which is the major substrate for renal ammonia production. [63]

Lipids

Lipids are a heterogeneous group of compounds that are soluble in organic solvents. Lipids include triglycerides (fat), sterols, glucolipids, phospholipids, and fat-soluble vitamins. These compounds serve as a source of energy, structural components of cell membranes, carriers of essential nutrients, and precursors for steroid hormone, prostaglandin, thromboxane, and leukotriene synthesis. Dietary lipids are composed mainly of triglycerides, which contain mostly saturated and unsaturated long-chain fatty acids with a 16- to 18-carbon chain length.

Lipid Metabolism The use of fat as a fuel requires the hydrolysis of triglyceride to free fatty acid and glycerol and the tissue uptake of free fatty acids for subsequent oxidation. Hormone-sensitive lipase within adipocytes hydrolyzes adipose tissue triglycerides and releases free fatty acids into the bloodstream, where they are bound to plasma proteins and delivered to other tissues. Lipoprotein lipase at the lumenal surface of the capillary endothelium hydrolyzes plasma triglycerides and releases free fatty acids for local tissue uptake. Fatty acids are transported across the cell membrane by passive diffusion, facilitated diffusion, and active transport. Membrane and cytosolic fatty acid binding proteins are important in transporting fatty acids across the cell membrane and in directing fatty acids from the cell membrane to different metabolic sites. This intracellular fatty acid transport system enhances fatty acid uptake by maintaining a fatty acid concentration gradient and prevents potentially toxic interactions between fatty acids and intracellular organelles. Long-chain fatty acids are delivered across the outer and inner mitochondrial membranes by a carnitine-dependent transport system. Inside the mitochondria, fatty acids are degraded by ß-oxidation to acetyl-CoA, which enters the tricarboxylic acid cycle (see Fig. 21-3). Ketone bodies are produced solely by the liver and are generated by the partial oxidation of fatty acids. Ketone body production increases when the rate of fatty acid production is much greater than the rate of fatty acid oxidation, such as during starvation or uncontrolled diabetes mellitus. In these conditions, ketone bodies become an important fuel and are released into the bloodstream for delivery to extrahepatic tissues. Ketone bodies represent a water-soluble fuel derived from water-insoluble fatty acids. Ketone bodies can cross the blood-brain barrier to replace glucose as the major fuel for the brain, sparing plasma glucose for consumption by other tissues. [64] The biosynthesis of fatty acids is mediated by fatty acid synthase, a multienzyme complex embodied in a single polypeptide chain. It

elongates the molecule by sequential addition of two carbon units and stops with the formation of palmitic acid, a 16-carbon fatty acid. The formation of malonyl-CoA from acetyl-CoA is the committed step in fatty acid biosynthesis and the most important step of regulation. The enzyme that catalyzes this step, acetyl-CoA carboxylase, is stimulated by citrate. Citrate is abundant when ATP and acetyl-CoA are abundant, a condition appropriate for fat synthesis. Palmitoyl-CoA, the end product of fatty acid synthesis, antagonizes the activation of acetyl-CoA carboxylase by citrate.

Essential Fatty Acids Most fatty acids can be synthesized by the liver, but humans lack the desaturase enzyme needed to produce the n-3 double bond (between carbons 3 and 4 counted from the methyl end) and the n-6 double bond (between carbons 6 and 7) in the fatty acid series. Essential fatty acids are important constituents of cell membranes and precursors of the eicosanoids. [65] Arachidonic acid (C20:4, n-6), a precursor of eicosanoids, prostaglandins, leukotrienes, prostacyclins, and thromboxanes, is synthesized from linoleic acid. [65], [66] Vegetable oils, such as corn, soybean, sunflower, peanut, and cottonseed oils, are rich sources of linoleic acid. [65], [66] Linoleic acid (C18:2, n-6) should constitute at least 2% and linolenic acid (C18:3, n-6, 9, 12) at least 0.5% of the daily energy intake to prevent the occurrence of essential fatty acid deficiency, usually manifested as a specific alteration in the plasma fatty acid profile and a skin rash. An elevated ratio of triene to tetraene (>0.4) is characteristic of essential fatty acid deficiency as a result of increased production of eicosatrienoic acid, a fatty acid containing three double bonds (i.e., triene) derived from oleic acid (C18:1), as well as from decreased arachidonic acid production, a tetraene derived from linoleic acid elongation. [67], [68] Essential fatty acid deficiency is rare in adult humans because of sufficient essential fatty acids stores in adipose tissue. However, continuous infusion of lipid-free total parenteral nutrition (TPN) can cause abnormalities of the triene-to-tetraene ratio within 10 days because of increased plasma insulin concentrations, which inhibit lipolysis and the release of essential fatty acids. [68]

Fish Oil Fish oils are ?-3 polyunsaturated fatty acids (PUFAs) found in marine animals, particularly fatty fish, such as herring, salmon, bluefish, and tuna. [69], [70] Epidemiologic studies suggest a possible protective effect of fish oils against cardiovascular disease. [71], [72] In sufficient doses, fish oil prolongs the bleeding time and decreases the production of the proaggregating substance thromboxane A_2. [73], [74], [75] and [76] The significant hypotriglyceridemic effects of fish oils have been confirmed repeatedly in healthy persons and in those with various hyperlipidemic states, but the long-term effects may be less striking. [75], [76], [77], [78], [79], [80], [81] and [82] The effects on serum cholesterol and low-density lipoprotein (LDL) levels have varied. [69], [82], [83] Animal models suggest that fish oils have an inhibitory effect on coronary atherosclerosis and intimal hyperplasia. [69], [73], [74] The ?-3 fatty acids generally suppress cellular inflammatory responses by changing the end products of eicosanoid synthesis. [69], [80], [84], [85] and [86] Dietary supplementation with fish oil suppresses the production by monocytes of the polypeptide cytokines interleukin-1 (IL-1) and tumor necrosis factor (TNF), suggesting an additional mechanism by which fish oils may exert an antiinflammatory effect. [84], [87]

Carbohydrates

Carbohydrates, which constitute most of the earth's organic matter, are important sources of metabolic fuel. In the United States, carbohydrates normally account for about 50% of ingested calories; approximately 60% is complex carbohydrate, primarily starch, and most of the remainder is sucrose and lactose. [88] About 10 to 20 g of indigestible carbohydrate (i.e., soluble and insoluble fibers) are consumed daily. They all undergo hydrolysis to yield glucose and other simple sugars. Some cells and tissues, such as erythrocytes, leukocytes, renal medulla, eye tissues, and peripheral nerve tissue, do not have the capacity for citric acid cycle activity and require glucose as a fuel for anaerobic glycolysis. The brain prefers glucose as a fuel. Daily glucose requirements include 40 g/d for anaerobic tissues and 140 g/d for the brain. [89]

Absorbed glucose that is not directly oxidized can be stored as energy in the form of glycogen or fat, which requires approximately 5% and 25%, respectively, of the original substrate oxidative energy potential. Glycogen is a branching, long-chain polymer of glucose molecules with water and electrolytes between the chains. It is found in most tissues but is stored significantly only in the liver and skeletal muscle. The primary function of hepatic glycogen, about 100 g in a normal adult, is to maintain blood glucose levels. Plasma glucose is an essential fuel for glucose-dependent tissues. Glycogen in skeletal muscle serves to supply glucose to the muscle itself during physical activity.

Glycolysis The conversion of glucose to pyruvate in the cytosol of cells is known as *glycolysis,* a process that results in the generation of ATP but does not require oxygen. Pyruvate represents a major metabolic junction; it can be reduced to lactate, transaminated to form alanine, or enter the mitochondria and undergo carboxylation to oxaloacetate or oxidative decarboxylation to acetyl-CoA (Fig. 21-4).

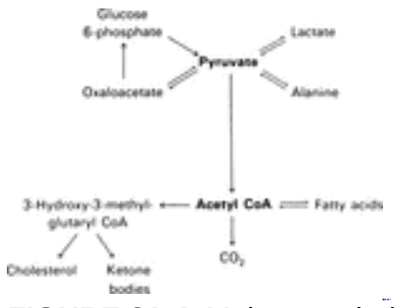

FIGURE 21-4. Major metabolic end products of pyruvate and acetyl-coenzyme A in mammals. (From Stryer L. Biochemistry, 3rd ed. New York: WH Freeman, 1988:633.)

Citric Acid Cycle and Oxidative Phosphorylation The citric acid cycle (i.e., tricarboxylic acid cycle, Krebs cycle) represents a series of reactions that occur in mitochondria. Carbohydrates, lipids, and amino acids enter the cycle after being metabolized to acetyl-CoA and are completely oxidized to CO_2 and water. Vital biosynthetic intermediates are produced by the cycle, and it plays a major role in gluconeogenesis, lipogenesis, and amino acid transamination and deamination. As acetyl-CoA is oxidized, reduced nicotinamide adenine dinucleotide (NADH) and reduced flavin adenine dinucleotide ($FADH_2$) are formed, which transfer the electrons to the respiratory chain in the inner mitochondrial membrane. In the mitochondria, the transfer of high-energy electrons from NADH or $FADH_2$ down the electron transport chain is coupled to the generation of ATP, a process known as *oxidative phosphorylation*. Glycolysis (i.e., anaerobic respiration) yields a net of only two ATPs per molecule of glucose, whereas aerobic metabolism (i.e., citric acid cycle and oxidative phosphorylation) yields 36 ATPs for each molecule of glucose oxidized.

Glucose Production Hepatic glycogenolysis is responsible for most of the glucose produced endogenously in the fed and postabsorptive states. Other mechanisms for glucose production are active and become critically important when hepatic glycogen is depleted, such as during prolonged starvation and endurance exercise. Gluconeogenesis is the process by which glucose is synthesized from noncarbohydrate precursors, lactate, glycerol, and most amino acids (principally alanine). Gluconeogenesis occurs primarily in the liver, but the kidneys also produce glucose, especially during prolonged fasting. The Cori and glucose-alanine cycles provide mechanisms for generating plasma glucose for glucose-dependent tissues from 3-carbon intermediates released from peripheral tissues. [90] The Cori cycle (or lactic acid cycle) resynthesizes glucose that has been partially metabolized to lactate by peripheral tissues. Lactate produced principally by muscle, erythrocytes, and adipose tissue is transported to the liver and kidneys, where it is converted to glucose (gluconeogenesis) and released into the bloodstream. The glucose-alanine cycle shuttles glucose from the liver to muscle and alanine from muscle to liver. In this cycle, pyruvate is transaminated to alanine, which is transported to the liver and converted to glucose, which is then returned to muscle through the bloodstream.

Fiber

The accepted definition of dietary fiber is plant cell wall components that resist digestion by enzymes of the small intestine, including both polysaccharides and noncarbodydrate components. The polysaccharide compounds in dietary fiber, which are the structural and matrix components of plant cell walls, consist primarily of cellulose, hemicelluloses, and pectins, [91] as well as fructooligosaccharides and resistant starches. Cellulose is a ß1-4 polymer of glucose and the main structural component of plant cell walls. Hemicellulose consists of branched polymers of pentose and hexose sugars. Other noncellulose polysaccharides include pectins, which are complex mixtures of colloidal polysaccharides, and several polysaccharides not associated with the cell wall, including mucilages and gums. These compounds are branched polymers containing many uronic acids that hold water and form gels. They are highly branched in growing plants and become less branched as the support structure develops. They act as adhesives and are insoluble in the unripe fruit, becoming soluble only as the fruit matures. Undigested oligosaccharides, such as those associated with flatus (e.g., stachyose and raffinose), are soluble and not included in the definition of fiber.

Fructooligosaccharides are mixtures of ß-D-fructose monomers linked by ß2-1 linkages. These molecules include inulin-type fructans (linear polymers) and levans (branched fructans) and are present in many edible plants, such as wheat grains and members of the onion family. The daily consumption of oligofructoses by North American populations is estimated at 1 to 12 g, slightly more in Western Europe. [92] The ß-C2 linkage makes these polymers resistant to hydrolysis by human digestive enzymes, and they are fermented and metabolized in the colon to short-chain fatty acids. This colonic fermentation produces a change in the microflora, enhancing

bifidobacteria and decreasing *Bacteroides* organisms, clostridia, and other anaerobes. Fructooligosaccharides are the best studied of the prebiotics, defined as "a nondigestible food ingredient that beneficially affects the host by selectively stimulating the growth or the activity of one or a limited number of bacteria in the colon and thus improves host health." [93]

Resistant starches (RSs) are defined as starches that enter the colon. RS1 is physically inaccessible starch because of the particle size or entrapment in food. RS2 and RS3 are resistant to amylase action because of the compact (unbranched) structure, by being either unbranched (RS2) or made retrograde (RS3)—that is, altered during processing. [94] Most resistant starches are produced during food preparation. Intake of such starches on a Western diet is estimated at 5 to 10 g/d.

Other components of dietary fiber include polyphenols (especially flavonoids) and other cell wall–associated nonpolysaccharide substances. Polyphenols are products of plant metabolism and range from single-ring phenols to highly polymerized compounds, such as tannins and lignins. Only lignins are currently included in the determination of dietary fiber, although they constitute about 12% of plant organic compounds. Lignins include a group of phenylpropane polymers of varying sizes, as they are continuously polymerized as the plant ages. They reinforce the cellulose support structure and inhibit microbial cell wall digestion. Lignins are thus resistant to all anaerobic digestion systems and are not partially metabolized in the colon, as are the cell wall polysaccharides. They represent only a small part of the human diet (~0.2%).

Phenolic acids and aldehydes, such as vanillin, are common, but the most common of the plant phenolics are flavonoids, consisting of two aromatic rings linked through three carbons that form an oxygenated heterocyclic ring. [95] Flavonoids and other polyphenols are ubiquitous in plants and beverages. They are found in tea and contribute to the bitterness of that and other beverages. [14] Polyphenols usually account for less than 1% of the dry matter of plants, but they can reach concentrations of 4000 to 7000 mg/mL in red wines and fruit juices. [95] The dietary intake of polyphenols in the United States is 1 to 1.1 g/d, with flavonoids accounting for about 4% of the total. Like other fiber components, polyphenols are degraded and their metabolites are absorbed in the colon, but the effect of these compounds on short-chain fatty acid production and microflora is dependent on the type of compound and the microorganisms present. Polyphenols bind proteins and precipitate them in the intestinal lumen, and they can decrease the absorption of nitrogen, fat, and some minerals, including iron.

Interest in polyphenols has generally focused on their antioxidant properties, particularly on carcinogens and LDL oxidation. Some evidence suggests that moderate consumption of tea, a rich source of flavonoids, may protect against several forms of cancer, cardiovascular diseases, and kidney stone formation. [96] The blacker the tea, the more the polyphenols have been oxidized, lowering the possible effective role of these compounds. Herbal teas are not true teas (*Camellia sinensis*) and have a much lower flavonoid content. Tea contributes more than 60% of dietary flavonoids, onions about 13%, and grapes, apples, red wine, and dairy products most of the rest. The consumption of one to two cups of tea a day has been associated with health benefits in epidemiologic studies, [96] including decreased mortality from stroke in men (50%) and from cancer of the mouth, pancreas, colon, esophagus, skin, lung, prostate, and bladder (20%–40%). These data show only associations, not causation, and the results must be confirmed by prospective intervention studies of the type that have failed to show an effect of total dietary fiber.

Phenolics can, under some conditions, act as pro-oxidants. [97] Their antioxidant properties are dependent on solubility and chelating potential, among other properties. Thus, it is not possible yet to recommend the consumption of large amounts of phenolics as foods or supplements until more data are available.

The heterogeneity of dietary fiber has inspired numerous classification schemes, including those based on source, chemistry, structure, water solubility, detergent solubility, physiochemical properties, and physiological actions. *Crude fiber* was a term commonly used until the early 1970s. It refers to the residue of plant material that remains when food is extracted by dilute acids and alkalis. Although crude fiber is the measurement still referred to in most food tables, it underestimates by 80% to 90% the amount of material in foods that is undigestible by human digestive enzymes. [98]

The physiological effects of dietary fibers on gastrointestinal function are complex because of their heterogeneity and the changes in the lumenal environment along the gastrointestinal tract. Combinations of fibers may have effects that differ from those of individual purified preparations, and the same purified fiber can have different effects depending on how finely or coarsely it is ground. The quantitative measurements of the fiber content of foods alone does not always allow prediction of their biologic action.

Many physical properties of dietary fiber are physiologically important, including hydratability, viscosity, ion exchange properties, and adsorptive capacity. *Hydratability* relates to the ability of a fiber to form viscous gels. It is a function of the physical and chemical composition of the fiber, including particle size, the age of the plant, and the chemical properties of the surrounding solvent. [99] Some dietary fibers, such as lignins and pectins, have a significant capacity to bind and exchange ions, particularly calcium, iron, magnesium, zinc, and phosphorus, and to adsorb materials such as bile salts, proteins, and bacterial cells. [99]

Fermentation of fiber by colonic bacteria generates volatile short-chain fatty acids, acetate, propionate, and butyrate, which serve as a systemic fuel and as the preferred energy substrate of colonocytes. [100] In general, water-insoluble fibers (e.g., wheat bran, bagasse) are less subject to fermentation and hold more water than do the water-soluble fibers (e.g., vegetable fiber, pectins, gums). Therefore, water-insoluble fibers have a greater effect on stool mass than water-soluble fibers. However, the ingestion of degradable fiber stimulates bacteria growth and generates a fecal mass composed largely of bacteria. Although the total number of bacteria can be affected by diet, there is no convincing evidence that dietary changes produce major changes in the composition of colonic microflora. [101]

The rate of gastric emptying and the rate of digestion and absorption are influenced by fiber components. Guar gum and pectins increase the viscosity of the chyme and slow gastric emptying, but particulate fibers (e.g., wheat bran) appear to promote more rapid gastric emptying. [98] Fiber can decrease or increase mouth-to-anus transit time depending on fiber type, particle size, and bulk-forming capacity. [102] Intestinal transit time and stool bulk are inversely related. A large particle size (e.g., coarse wheat bran) produces a greater increase in stool bulk and a greater decrease in transit time than does a small particle size (e.g., finely ground bran). The mechanism by which fiber decreases colonic transit time is unknown but may be related to an increase in colonic peristalsis secondary to increased fecal mass. [102]

Epidemiologic observations, made initially in Africa, led to the hypothesis that dietary fiber and increased stool output can decrease the risk for Western gastrointestinal diseases, such as colon cancer, diverticulosis, cholelithiasis, appendicitis, constipation, and hemorrhoids. [103] However, data from epidemiologic studies may be influenced by confounding variables; a cause-and-effect relationship between dietary fiber and disease prevention has not been proved. [99], [25], [26], [104] Dietary fiber may prevent colon carcinoma by several mechanisms: a decrease in colonic transit time, so that the time that colonic mucosa is exposed to carcinogens is shortened; adsorption of carcinogenic sterols or other carcinogens; dilution of potential carcinogens by increasing stool volume; and alteration of the relative number of anaerobic and aerobic bacteria in the colon. Fiber may prevent diverticula by increasing lumenal bulk, which decreases intralumenal pressures by maintaining a larger-diameter lumen and eliminating closed segments during contractions.

Several studies have suggested that wheat bran promotes the formation of a less lithogenic bile by expanding the pool of bile salts, increasing the amount of chenodeoxycholic acid in the bile salt pool and decreasing the levels of deoxycholic acid in the pool. Other studies suggest that only specific dietary fibers—pectins, but not lignins or oat bran—are capable of lowering the lithogenic index in healthy persons. [104]

The treatment of irritable bowel syndrome with a high-fiber diet (especially a diet that includes wheat bran and commercial fiber supplements) has produced conflicting results. [105] It has been suggested that those patients whose major symptom is constipation are the ones most likely to benefit from increased fiber intake. Several studies have shown that bran and other fiber supplements are effective in preventing constipation, but the side effects include flatulence, distention, and bloating, perhaps related to a long colonic residence time and bacterial fermentation. [106]

Fiber may prevent and treat hemorrhoids by decreasing straining during defecation. Straining causes engorgement of the vascular cushion lining the distal rectum and anal canal, making them more vulnerable to shearing stress. The passage of hard fecal masses through the anal canal exacerbates these shearing forces and displaces the vascular cushion caudally, where it may be trapped temporarily by contraction of the anal sphincter. [107] A trial of fiber is a reasonable initial therapeutic approach for many patients who have hemorrhoids.

Adverse Effects of Fiber Consumption A high-fiber diet is generally safe and well tolerated. Bloating and flatulence are the most common side effects. More serious adverse events, such as obstruction of the esophagus and small intestine and volvulus in the small bowel and sigmoid colon have been reported. [104] Increasing dietary fiber intake does not cause long-term mineral and trace element depletion in populations consuming adequate diets. [98], [103] The effects of fiber on minerals and trace elements are of greatest concern in populations whose diets may be unbalanced in the relative proportion of fiber and micronutrients. For example, dwarfism observed in Iranian children was found to be caused by zinc deficiency induced by eating an unleavened bread, which is high in fiber but also in phytate, which binds

zinc. [104]

Micronutrients: Minerals and Vitamins

The RDAs and AIs are based on the amount of a nutrient needed for an individual to avoid deficiency, or on the average daily amount that populations must consume to prevent deficiency (see Table 21-4). Statistically, the RDA is set as two standard deviations above the mean requirement, so that 97% of healthy persons are covered. The RDAs thus exceed the needs of many healthy persons. They are established only for healthy persons. RDAs were never intended as guidelines for therapy. For some nutrients (e.g., sodium, chloride, potassium), the evidence for daily requirements is much lower than the content of the average diet in the United States. The Food and Nutrition Board has provided an estimated minimal requirement for these nutrients (Table 21-10). New guidelines for these electrolytes will be published in the near future and are available through the National Academy Press (e.g., see ref. [16]). RDIs and DRVs were established in 1973 for the purposes of food labeling and are derived from the 1989 RDAs for micronutrients. [18] What appears on food labels are neither DRVs nor RDIs but daily values, reflecting the recommendations for a 2000-calorie reference diet.

AGE	WEIGHT kg	WEIGHT lb	SODIUM (mg)	CHLORIDE (mg)	POTASSIUM (mg)
Up to 5 mo	4.5	10	120	180	500
6–11 mo	8.9	20	200	300	700
1 y	11	24	225	350	1000
2–5 y	16	35	300	500	1400
6–9 y	25	55	400	600	1600
10–18 y	50	110	500	750	2000
Older than 18 y	70	154	500*	750	2000*

* The minimum requirement does not allow for prolonged losses by vomiting, diarrhea, or excessive dieting. The Food and Nutrition Board of the National Academy of Sciences has recommended a daily sodium intake of 6 g or less, or a sodium intake of 2.4 g, 4.8 times the minimum requirement. The National Research Council recommends a high intake of potassium-containing fruits and vegetables, even though the average U.S. adult diet contains 3.5 of g potassium, nearly twice the minimum requirement. This recommendation takes into account the supposed benefits of increased dietary potassium in hypertension and of dietary fiber in preventing colonic malignancy.

Adapted from ref. 10. New recommendations are expected to be published in 1990.

TABLE 21-10 Estimated Minimum Requirements for Healthy Persons for Sodium, Chloride, and Potassium

Minerals

Sodium. Sodium, the principal cation in extracellular fluid, is necessary for maintenance of intravascular fluid volume and membrane potentials. [18], [108], [109], [110] and [111] Total body sodium ranges from 48 to 60 mEq/g and is dependent on body size. A 70-kg man has about 83 to 97 g of sodium in his body, about one fourth of which is in the skeleton and cannot be exchanged. The kidney regulates sodium excretion by aldosterone action in the distal tubule in response to intravascular volume. Obligatory sodium losses are small compared with body stores. Minimal fecal and urinary losses per day are about 23 mg (1 mEq). There is no RDA for sodium at this writing, but the estimated minimal requirement for adults is 500 mg (22 mEq) daily. Because almost all sodium is absorbed, renal regulation of excessive sodium absorption is crucial. Sodium is abundant in foods, not only as the chloride salt but as the bicarbonate, glutamate, phosphate, caseinate, benzoate, nitrate, propionate, sulfate, and citrate salts, among others. It is also present in many condiments, such as catsup, meat tenderizer, prepared mustards, olives, pickles, sauces, butter, margarine, and salad dressings. Water softeners can increase the water content of sodium. Medications may contain sodium, although only a few contain enough to cause a problem. Deficiency from inadequate intake alone is rarely encountered. Increased losses from the gut (e.g., vomiting, diarrhea, or drainage) or kidney (e.g., diuresis, salt-wasting renal disease, adrenal insufficiency) or excessive perspiration are the usual causes. Approximate mean concentrations of sodium in various fluids (in millimoles per liter) are sweat, 30 to 70; saliva, 10 to 20; gastric juice, 70; bile, 145; pancreatic juice, 130; jejunal secretion, 115; ileal secretion, 100; and normal stool, 5.

Potassium. Potassium is the primary cation in intracellular fluid, in which its concentration is 140 to 160 mEq/L. [11], [109], [110], [111] and [112] The 2% of total body potassium present in the extracellular fluid is important in influencing resting membrane function, particularly in the cardiac muscle. The kidney is the major site of potassium excretion, which is normally regulated not by filtered load but by the action of aldosterone and systemic pH in the distal tubule. It is absorbed efficiently in the upper intestine but secreted in the colon, another aldosterone-sensitive tissue. Colonic secretion is aided by the electronegativity of the lumen. As with sodium, the amount lost in the stool is volume dependent. Because excretion is so highly regulated by the kidney, no RDA has been established at this writing, but the estimated minimum daily requirement for adults is 2000 mg (51 mEq), and most adults consume 50 to 150 mEq daily. Abundant food sources (i.e., >200 mg per portion) include meats and fish, vegetables (especially potatoes), nuts, fruits, and milk. Most salt substitutes use potassium chloride to replace sodium chloride and contain about 2000 mg of potassium per teaspoon.

Calcium. Calcium is the most abundant cation in the body. About 99% resides in bone; the other 1% is a crucial mediator for neural transmission, myocardial function, excitation and contraction of muscle, coagulation, cell division, maintenance of intercellular tight junctions, and enzyme function. [13], [113], [114], [115], [116] /SUP>and [117] Many factors affect the intestinal absorption of calcium: lumenal pH, lumenal binders, transit time, the presence in the diet of the few foods that are rich in calcium, and vitamin D status. [13], [116] The process is relatively inefficient in that only about 33% of the daily calcium requirement is absorbed by the intestine. There is an obligatory loss of calcium each day from the intestine and kidney. During periods of growth or new bone formation, the calcium requirement increases. The risk for a negative calcium balance is great, especially during childhood, adolescence, pregnancy, or lactation. The new RDA for adults is 1000 mg/d (see Table 21-4), but typical diets in the United States provide only about 750 mg/d. [13] Unlike many of the other new RDAs, these recommendations are meant not as nutrient requirements for individuals, but as reflections of national policy. Thus, they describe optimal intake for populations. The debate continues regarding the need for calcium guidelines based on the relationship between calcium intake and bone health. [118] The RDA was raised for adolescents to 1300 mg/d, based on increased bone growth during this life stage. The increased recommendation in older persons to 1200 mg/d is based on decreased calcium absorption in that group. Milk and dairy products are the richest source of calcium (providing about 60% of dietary calcium), and it is most bioavailable in those sources in the form of calcium citrate. Each 8-oz cup of milk contains about 280 to 300 mg of calcium. Green leafy vegetables are a good source, but the bioavailability is more irregular than that in milk products because the calcium is present as the phytate, oxalate, or other organic anion salt. These salts are poorly ionized and absorbed. The single universal requirement for calcium intake at each life stage without reference to intake of protein, sodium, or phytate has been challenged, based on the observation that calcium intakes are low in parts of the world where fracture rates are low, but protein intake also is low, whereas phytate intake is high. [119] Other rich dietary sources are fish with edible bones, such as sardines and salmon. Lumenal calcium is most actively transported in the duodenum, but in humans, most calcium is absorbed in the ileum. [116] About 150 to 300 mg is secreted into the lumen each day. [111] After glomerular filtration, about 98% of calcium is reabsorbed by the renal tubules. [117] Half of serum calcium is protein bound, 10% is complexed with anions, and 40% is ionized and physiologically active. [114] Normal levels of serum calcium are tightly regulated by the action of parathyroid hormone and vitamin D and are not related to total body stores, except when deficiency is severe. Bone density is not a sensitive indicator of calcium deficiency, but it is a measure of body stores and can detect a decrease in bone mass of more than 1% to 2%. [120] Ionized serum calcium is a measure of the hormonally regulated calcium concentration. Under most circumstances, ionized serum calcium reflects body stores, but when acutely altered, it may be low in the presence of normal total body calcium. [121]

Magnesium. Magnesium is the second most abundant intracellular cation. About 70% of the total is in bone, and the rest is in soft tissues. Less than 1% is in extracellular fluids, where 20% to 30% is bound to protein. [108] Serum magnesium levels do not closely mimic body stores. The magnesium concentration in cells is high, like that of potassium, but magnesium leaves the cells less readily. Magnesium is important for neuromuscular transmission, and it is an essential cofactor in many enzyme reactions, including oxidative phosphorylation and nucleic acid synthesis. It also plays a role in wound healing, myocardial contractility, membrane stability, and coagulation. [122], [123], [124] and [125] The RDA averages about 350 mg (29 mEq) for adults 400 to 420 mg for men and 310 to 320 mg for women. The typical adult diet in the United States provides 20 to 40 mEq/d. Food sources are well distributed, but nuts, cereals, seafood, meats, legumes, and green vegetables are rich food sources. [122], [123] Like that of calcium, the intestinal absorption of magnesium is relatively inefficient (i.e., 30%–40%), and most absorption occurs in the ileum. However, magnesium differs from calcium in that there is very little obligatory intestinal loss, so magnesium balance is maintained even with a very low dietary intake if no abnormal losses occur. Loss from the body occurs in regulated function, mostly through the kidney (2%–3% of the filtered load). [122], [123], [124] and [125] Serum magnesium is the standard for assessing body stores, but it is falsely elevated by hemolysis and does not always reflect either intracellular stores or active extracellular ionized magnesium. [18], [121]

Phosphorus. Phosphorus is the major intracellular anion (100 mmol/L). [125], [126] and [127] It is essential for normal membrane function, regulation of enzyme systems, and generation and storage of energy. It affects the delivery of oxygen to tissue by regulating the concentration of 2,3-diphosphoglycerate in red blood cells. However, 80% to 85% of total body phosphorus resides in bone. The requirements for phosphorus parallel those of calcium. The new RDA is only 700 mg/d for adults, somewhat below the DRI for calcium, although daily intakes in the United States range from 1000 to 1500 mg. Like magnesium, urinary phosphorus excretion does not reflect a low dietary intake, so balance studies are misleading. Moreover, the efficiency of phosphorus absorption varies with the food source and the dietary calcium-to-phosphorus ratio. In general, if protein intake is adequate, so is phosphorus intake. [13] Phosphorus is a constituent of all cells and is abundant in most foods, especially meats, dairy products, and carbonated beverages. The absorption of phosphorus requires hydrolysis of the organic phosphates in food by intestinal alkaline phosphatase and is promoted by the action of 1,25-dihydroxyvitamin D_3. Net absorption is 60% to 80% of ingested phosphorus. The kidney adjusts phosphate excretion over a wide range, so deficiency from low intake or malabsorption is rare. In fact, reabsorption can increase to 99.8% if the dietary intake of phosphorus is low. [125]

Iron. Unlike the those of the minerals previously discussed, the body stores of iron are not regulated by increased or decreased excretion, but rather by control of the rate of intestinal absorption, which is increased during deficiency. Daily losses normally occur from the gastrointestinal tract, skin, and urine. Fecal losses predominate, ranging from 6 to 16 mg/d, most of which is unabsorbed dietary iron. About 1 mg of endogenous iron is lost in the stool per day. Additional losses occur from the uterus in women, amounting to 0.5 to 1.0 mg/d averaged over a whole month. The requirements for iron per kilogram of body weight are highest during infancy (because of low body stores), periods of rapid growth (adolescence and pregnancy), and periods of excessive loss (menstruation). The RDA assigned by the 2001 DRI Committee for all age groups of men and postmenopausal women is 8 mg/d; the RDA for premenopausal women is 18 mg/d. [16] The recommended intake during pregnancy is 27 mg/d. At birth, even the child of an iron-deficient mother has normal stores because the fetus has priority for available iron. Milk is a poor dietary source of iron, but the AI for infants ages 0 to 6 months has been set at 0.27 mg/d, based on the daily amount of iron in ingested milk (~0.35 mg/L). It is assumed that milk intake and requirements correlate with body size. Therefore, this AI may not be sufficient for infants with a lower milk intake. Three months after birth, the requirement for iron increases because of growth, and the RDA of 11 mg/d for infants ages 7 to 12 months assumes that feedings complementary to milk are in place. It is during this period that the infant is most at risk for iron deficiency. During adolescence, the hemoglobin level rises 0.5 to 1.0 mg/dL per year, requiring 50 to 100 mg of iron per year, and 300 mg during adolescence. Food iron is available in a variety of red meats, nuts, seeds, and egg yolks. Milk products, potatoes, and fresh fruit are poor sources. Iron in vegetables varies according to growth conditions of the plant. Heme iron in vegetables is not so readily available for absorption as that in meat; it also requires reduction to the ferrous state (by ascorbic acid) for maximal absorption. However, heme iron accounts for only about 10% of dietary iron in the United States. The iron content of some foods (e.g., bread flour) is increased by fortification. Vegetarians are at risk for dietary iron deficiency because of the more limited absorption of nonheme iron. Iron is involved in many reactions as a cofactor for enzymes (heme or otherwise) and as a major constituent of heme as an oxygen-carrying cofactor. Iron is absorbed primarily in the duodenum and upper jejunum. The major transmembrane iron transporter is Nramp2, now called *divalent metal transporter DMT1*. [128] The absorption of inorganic iron is enhanced by gastric acid, ascorbic acid, and other organic acids, including the amino acids histidine, lysine, and cysteine, which form iron chelates. [16], [129] Absorption is decreased when iron forms an insoluble complex in the lumen with dietary phytates or phosphates, or with antacids or other medications. About 10% of iron is absorbed normally, but in deficiency this can increase to 30%. After absorption, iron is stored as ferritin in the liver, spleen, and bone marrow. The functional compartment of iron (hemoglobin, myoglobin) accounts for most of the total body iron, ranging from about 2180 mg to 2750 mg for average women and men, respectively.

Zinc. The body contains 1.5 to 2.5 g of zinc, so that it is the second most abundant trace mineral after iron. Although the turnover of isotopic zinc in adults is 6 mg/d, balance studies show that 12.5 mg of dietary zinc is needed to maintain positive balance. [16] The daily loss of 2.5 mg/d is mostly in feces, and absorption ranges from 20% to 40%, depending on the fiber content of the diet (inversely related). The 2001 DRI Committee report set the RDA at 9 and 8 mg for girls and boys ages 9 to 13 years, respectively, and at 8 and 11 mg/d for adult women and men, respectively. [16] The RDA for pregnancy is 13 mg for adolescents and 11 mg for women older than 18 years. One more milligram is added per day during lactation. Like other divalent cations, zinc is absorbed inefficiently along the entire length of the small intestine. A series of zinc transporters have been identified and are thought to be important in absorption, including ZnT-1, which is expressed in duodenal and jejunal villi. [130] Zinc absorption is decreased by lumenal binders (phosphate and others), as is the absorption of calcium and magnesium. [131] Inorganic iron, especially when ingested as a supplement, impairs inorganic zinc absorption. [132] Absorption can be enhanced, however, by animal proteins and sulfur-containing amino acids, as well as by hydroxy acids. [133] Zinc absorption may be increased during states that increase demand for the mineral, including infancy, pregnancy, and lactation. Zinc plays a critical role in the growth and function of cells. It is a cofactor for many enzymes that participate in the metabolism of carbohydrate, fat, and protein. [16] It is necessary for cell growth and proliferation, sexual maturation, reproduction, and dark adaptation and night vision, and it may play a role in wound healing and immune defenses. Finally, it may activate or inhibit enzymes, modify membrane functions, or bind to DNA transcription factors.

Copper. Copper is an essential trace mineral for humans. Estimates of copper requirements are based on balance studies, fecal and other losses, and absorption at each life stage. [16] Obligatory losses for adults are about 580 µg/d, and absorption averages about 25%. Most absorbed copper is excreted in bile, although some biliary copper is reabsorbed via an enterohepatic circulation. [134] When intestinal and biliary losses occur, the copper requirement increases. The AI for infants is based on intake of milk (120 µg/L) and is set at 200 µg for infants ages 0 to 6 months and 220 µg/d for infants ages 7 to 12 months. The RDA has been set at 900 µg/d for men and women 19 years of age or older. [16] The liver contains about one third of the body stores of copper, mostly in enzymes, including ceruloplasmin, cytochrome oxidase, superoxide dismutase, tyrosinase, lysyl oxidase, and histaminase. [135] Copper is important for normal skeletal and nervous system development, erythropoiesis, leukopoiesis, and iron absorption, and as an antioxidant. Copper absorption and intracellular metabolism are complex. A high-affinity copper transport protein, hCtr1, may transport copper across the apical enterocyte membrane. [136] The Menkes disease protein, MNK, is a membrane-associated P-type ATPase that is required for copper secretion into the portal vein. Hephaestin is a multicopper oxidase that is a membrane-bound analog of ceruloplasmin required for iron (but not copper) secretion from the intestine. [137] Absorbed copper is transferred in plasma to ceruloplasmin and albumin, and it is taken up by the liver via hCtr1-mediated transport. It is distributed to various cellular compartments by a series of small cytoplasmic copper chaperones. [136] In all tissue but the liver, MNK mediates copper efflux in the Golgi apparatus and subsequently in the plasma membrane, as the protein moves to the plasma membrane. In the liver, the Wilson disease protein, WD, is similarly placed and may serve similar functions.

Other trace minerals. Selenium is an essential part of the antioxidant system of glutathione peroxidase. [15], [138] Thus, its function is linked with that of vitamin E. Chromium potentiates the action of insulin at the cell receptor level and plays a role as a cofactor for insulin. [139] Manganese is a cofactor for many enzymes with widely varying functions, from superoxide dismutase to hydrolases and kinases, but a deficiency state in humans has not been identified. [16] Iodine is an essential component of the thyroid hormones and is thus integral to their function. [16], [18] Fluoride is concentrated in bones and teeth and is required for normal growth. The major source of fluoride is now fluoridated water. Although deficiency of most of these minerals occurs in humans, the occurrence of such deficiency is unusual in developed countries. For this reason, they are used primarily as TPN supplements. Vanadium, nickel, cobalt, tin, and silicon are considered essential in mammals because deficiencies have been produced experimentally, but human deficiencies have not been reported. [16] Other elements, including cadmium, lead, boron, aluminum, arsenic, mercury, strontium, and lithium, have not yet been proved essential. Most of these elements, with the exception of boron, are probably present in sufficient quantities as contaminants in TPN solutions. [140]

Vitamins

Thiamin (B_1). Thiamin is essential for the function of many enzyme systems and plays a major role in energy production. Thiamin pyrophosphate is a coenzyme in the oxidative decarboxylation of a-ketoacids to aldehydes, and it catalyzes transketolase activity in the pentose phosphate cycle. It is important for nucleotide synthesis and provides cofactors for fatty acid synthesis. Blood pyruvate levels increase with thiamin deficiency. The requirement usually is related to the intake of energy, especially carbohydrate. The RDA for adults is 0.5 mg for every 1000 kcal in the diet. [14] Allowances are based on the effects of varying dietary thiamin and the relationship with signs of clinical deficiency or with urinary excretion of thiamin or serum transketolase activity. Thiamin is synthesized by many plants. It is abundant in all foods and is added to many commercial baked products and cereals. Because thiamin is lost easily in the cooking and processing of food, its content in food varies according to preparation.

Riboflavin (B_2). Riboflavin is a major component of two essential coenzymes: flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN). It forms the active portion of these coenzymes that are involved in biologic oxidations. Riboflavin requirements are linked with protein or energy intake, like those for thiamin. However, unlike the requirements for thiamin, those for riboflavin are unrelated to food energy intake. The RDA is set at 1.1 mg/d and 1.3 mg/d for adult women and men, respectively. [14] Requirements have been assessed by measuring urinary excretion and by observing signs of deficiency. Riboflavin is available in all leafy vegetables, in meats and fish, and in milk and eggs. The average Western diet contains about 2.7 mg/d. The vitamin can be lost in food processing and by the action of ultraviolet light. Absorption is efficient from the small intestine, and riboflavin is excreted from the kidney unmetabolized.

Niacin (B_3). The term *niacin* encompasses nicotinic acid and its amide form, nicotinamide. It is a component of two coenzymes, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which participate in more than 50 metabolic reactions. Humans can synthesize about 1 mg of niacin from 60 mg of the amino acid tryptophan. Deficiency depends on the limited availability of niacin and tryptophan. [141], [142] The RDA is reported in niacin equivalents (NEs) (1 NE = 1 mg of niacin = 60 mg of tryptophan). The RDA has been estimated at 14 mg and 16 mg NE daily for women and men 14 years of age or older, respectively. [14] Average Western diets provide 16 to 24 NE/d. Nicotinic acid is present in most foods, except fats and oils. Meat, fish, and grain products are good dietary sources. Much is lost during grain processing, but it is added back. Niacin is well absorbed in the small intestine.

Pyridoxine (B_6). The term *vitamin B_6* refers to three naturally occurring pyridines: pyridoxine, pyridoxal, and pyridoxamine. All forms function similarly. Vitamin B_6 is essential for the function of many transaminases and amino acid decarboxylases. It is involved in the metabolism of all amino acids and in the synthesis of acetylcholine, porphyrin, arachidonic acid, dopamine, serotonin, and bile acids. Requirements are increased with a higher protein intake. The RDA for adults ages 19 to 50 years is 1.3 mg/d for average protein intake. Low levels of all three forms are present in all foods, with meats, fish, and grains good sources. The vitamin B_6 allowance has been estimated by using a ratio of 0.016 mg of vitamin per grams of protein ingested. Because energy and protein intake is lower in the older population, RDAs are increased for persons older than 50 years, and the estimates for women (i.e., 1.5 mg) are lower than those for men (i.e., 1.7 mg). [14] Vitamin B_6 is synthesized by microorganisms in the intestine, primarily in the colon, where the vitamin is not absorbed. Vitamin B_6 is rapidly absorbed in the small intestine and excreted in the urine as the metabolized product, 4-pyridoxic acid. Certain drugs are pyridoxine antagonists (e.g., isoniazid, hydralazine, penicillamine). A deficiency of vitamin B_6 and other B vitamins can occur in chronic alcoholics.

Folate (folacin, folic acid). *Folacin* is a generic term for compounds that have a structure and function similar to that of folic acid (pteroylglutamic acid [PGA]). The many forms differ in the degree of reduction of the double bonds in the ring structure (e.g., tetrahydrofolate), the presence of 1-carbon groups (e.g., methyltetrahydrofolate), and the number of glutamyl residues in the peptide chain (e.g., folate pentaglutamate). Folate functions as a carrier of 1-carbon groups from donor to recipient molecules and is necessary for the synthesis of nucleic acids, the initiation of protein synthesis, and the synthesis of acetylcholine and methionine. Three other vitamins—cobalamin, ascorbic acid, and niacin—are involved in converting folate to its active coenzyme forms. [14], [142] PGA is the form of folate used commercially, and it is a relatively poor substrate for dihydrofolate reductase. As a result, tissue utilization is much poorer for PGA than for natural methylated or reduced folates found in food. However, folate requirements have been based on replacement with PGA. The RDA for folate has been modified dramatically from the 1989 estimate of 200 µg/d for adults [10] to the current level

of 400 µg. [14] This change was the result of recognition of the role of folate in reducing the incidence of neural defects, [143] and the role of elevated serum homocysteine concentrations as a cardiovascular risk factor. [144] Dietary folate is now reported in folate equivalents, in recognition of the greater bioavailability of synthetic folic acid compared with natural folate. The RDA for women ages 14 to 50 years is 400 µg/d and should comprise synthetic folic acid plus dietary folate. During pregnancy, the amount of synthetic folic acid is specified at 400 µg/d. [14] The vitamin is abundant in citrus juices, enriched cereals and breads, legumes, liver, nuts, and green leafy vegetables. It occurs in food largely in the polyglutamate form, and its bioavailability is generally high. However, boiling, steaming, or frying can lead to significant losses. Folate is absorbed in the proximal small intestine by active transport. It is converted in the liver and other tissues to the 5-methyltetrahydrofolate form and is stored as polyglutamate. [145] Total body stores are relatively small and can be depleted in a few months if dietary intake is negligible. It can enter the serum or the bile and be reabsorbed, undergoing an enterohepatic circulation amounting to about 100 µg/d. In diseases that cause malabsorption, body stores of vitamin B_6 are lost more rapidly than in simple dietary deficiency.

Cobalamin (vitamin B_{12}). Cobalamin contains a cobalt atom to which are bound active groups, including hydroxy-, methyl-, and nitrocobalamin. The vitamin functions as a carrier for methyl and hydrogen groups. It is required for two enzyme reactions, methionine synthase and methylmalonic acid mutase, and thus participates in methionine and succinyl-CoA synthesis. The total body content of cobalamin is 2 to 2.5 mg, most of which is in the liver, and the half-life is 1.5 to 3.5 years. Thus, daily losses average about 1.3 µg/d. The RDA was set at 2 µg/d for adults, based on 70% absorption efficiency. [10] However, because 10% to 30% of adults older than 51 years may have protein-bound cobalamin malabsorption, the new RDA has been set at 2.4 µg/d. [14] Although this malabsorption probably is caused by reduced pepsin and gastric acid secretion, most elderly persons have some intrinsic factor. Thus, it is recommended by some experts that most intake in older persons be in the form of a dietary supplement, to ensure its adequacy. [146] The vitamin is synthesized only by bacteria and enters animal tissues after the ingestion of contaminated foods or production in the lumen. It is found only in animal products, including meat, fish, eggs, and milk. The average Western diet contains 5 to 15 µg/d. Cobalamin is relatively stable during cooking and processing. The absorption of cobalamin is complex. [147] In food, it is bound to enzymes from which it is released by gastric proteases. It is bound to haptocorrin in the stomach, released from haptocorrin by the action of pancreatic enzymes, and then bound to intrinsic factor, with which it is absorbed in the ileum by the process of receptor-mediated endocytosis. The receptor for the intrinsic factor–cobalamin complex, cubilin, is a large, multifunctional protein that also binds apolipoproteins. [148] In the enterocyte, the vitamin is released from intrinsic factor, bound to transcobalamin II, and delivered to the tissues complexed to that protein. It is released into the bile bound again to haptocorrin, and 5 to 10 µg/d undergoes an enterohepatic circulation. As with folate, body stores are lost more rapidly if malabsorption is present because endogenous as well as dietary cobalamin is lost.

Ascorbic acid (vitamin C). Ascorbic acid is an essential cofactor for several hydroxylation reactions and plays a key role in the synthesis of collagen. It may also function as an antioxidant for vitamins A and E, and it is involved in the formation of norepinephrine and serotonin. This role in neurotransmitter synthesis may explain the fatigue and weakness seen in scurvy. [149] A daily intake of 10 mg of ascorbic acid per day cures clinical signs of scurvy but does not maintain body stores. The previous RDA of 60 mg/d [10] produced wide fluctuations in plasma levels. The ascorbic acid requirement is also compounded by its possible chemoprotective value in some disorders (e.g., colon cancer, heart diseases, cataracts), at doses far in excess of those needed to prevent scurvy. Intake of 200 mg of ascorbic acid per day is needed to begin to saturate tissues, an intake that approximates the vitamin C content of diets (~225 mg) that allow maximal protective effects of the vitamin. [150] The new DRI values represent a compromise between the old RDA value and those needed for chemoprevention and are set at 75 mg/d and 90 mg/d for adult women and men, respectively. [14] During pregnancy and lactation, the RDA should be increased by 10 mg/d and 45 mg/d, respectively. The vitamin is especially concentrated in green vegetables and citrus fruits, although it is widespread among all foods. The food content depends on the state of ripeness and on the method of preparation because ascorbic acid is very sensitive to heating and oxidation. It is well absorbed in the small intestine by two sodium-dependent cotransporters (SVCT1 and SVCT2) at intakes of up to 180 mg/d. [151] Over that amount, the proportion appearing in the stool increases, and at high doses (>3–4 g/d), diarrhea can result.

Biotin. Biotin is a coenzyme for various carboxylases and is important in the metabolism of carbohydrate, protein, and fat. [152] It is produced by colonic bacteria and absorbed in the small bowel and colon by facilitated diffusion. Because of this endogenous production, an RDA has not been determined, but the AI for adults has been estimated at a DRI of 30 µg/d. [14]

Pantothenic acid. Pantothenic acid is a precursor of CoA, which is essential for the metabolism of fats, carbohydrates, and proteins and for the synthesis of steroids and porphyrins. [14, 153] It is widely distributed in foods, especially animal tissues, whole grain cereals, and legumes. Microflora may produce some pantothenic acid, but the data in humans are not clear. Although an RDA has not been established, the estimated AI for older adolescents and for adults is 5 mg/d. Pantothenic acid is well absorbed in the intestine and is excreted unchanged in the urine.

Vitamin A. *Vitamin A* is the collective term for vitamin A alcohol (retinol) and its related biologically active forms. It is essential for growth and development, the maintenance of epithelial cells, the stability of cell membranes, reproduction, and vision in dim light. [16, 154] The ß-carotenes are precursors of vitamin A and appear to have additional beneficial functions, probably as antioxidants. [155] The DRI allowance for vitamin A is based on many nutritional studies and amounts to 900 µg of retinol per day for men and 700 µg/d for women. [16] The recommendations for ß-carotene are even more complex because no reproducible biologic activities are available to establish adequate intake. Some epidemiologic studies show correlations between low serum levels (still in normal range), but no positive results in intervention studies. [156] Moreover, some carotenoids (e.g., lutein) are accumulated in the retina preferentially, whereas others (e.g., lycopene) lack provitamin A function but exhibit other biologic activity. The data were judged by the DRI Committee to be insufficient to make a recommendation on the required percentage of dietary vitamin A that must be derived from provitamin A carotenoids. [15] Vitamin A activity in foods usually is expressed in international units (IUs) and an equivalence established with retinol activity, accounting for both vitamin A and provitamin compounds in the diet. The previously accepted 6:1 equivalence of ß-carotene to vitamin A [10] has been questioned because of inefficient bioconversion of plant carotenoids. Thus, the new conversions are 1 retinol equivalent (RE) = 1 µg of all-*trans*-retinal, or 12 µg of ß-carotene, or 24 µg of mixed carotenes. One RE is also equivalent to 3.3 IU of retinol activity or 10 IU of ß-carotene activity. This means that older food tables have overestimated the vitamin A activity in foods. This change may be of especial importance in underdeveloped countries that rely mostly on vegetable products for their vitamin A. Animal products are rich sources, including liver, kidney, dairy products, and eggs. Carotenoids, especially ß-carotene, are found in green and yellow vegetables. There are more than 400 carotenoids in foods, only about 60 of which have provitamin A activity. In the United States, dairy products and margarines are supplemented with retinyl esters, and these products are the major dietary source of the vitamin. Vitamin A, ingested in the form of long-chain retinyl esters, is hydrolyzed to retinol by lipases and esterases in bile and pancreatic secretions or in milk. More than 80% of the vitamin is absorbed passively, reincorporated into retinyl esters, packaged into chylomicrons, transported in the lymphatic circulation, and stored in the liver, which controls its release. [16, 157] Carotene is absorbed passively, but less well than vitamin A (40%–60%). Most is hydrolyzed to retinol inside the enterocyte, and a small amount is absorbed intact. After vitamin A is released from the liver, it is transported in the plasma as a trimolecular complex with retinol-binding protein and transthyretin. [157, 158] If stores are adequate, any excess vitamin A is excreted in bile. A very small amount is excreted in urine along with other metabolites. About 10% of hepatic retinol is converted to retinoic acid, which in turn is conjugated with glucuronide and undergoes enterohepatic circulation. As in the case of folate, cobalamin, and 1,25-dihydroxyvitamin D, this enterohepatic circulation leads to the loss of endogenous as well as dietary vitamin A if malabsorption occurs.

Vitamin D. *Vitamin D* is the designation for a group of sterols and their metabolites that have antirachitic activity. [13] Cholecalciferol (vitamin D_3) is formed in the skin from 7-dehydrocholesterol by the action of ultraviolet light, and about 100 IU/d (10 µg = 400 IU) is produced in persons living in the temperate zone. [159] Ergocalciferol (vitamin D_2) is present in plants. Vitamin D is a provitamin, with the active metabolite being 1,25-dihydroxyvitamin D. The active vitamin promotes the intestinal absorption of calcium and phosphorus, in conjunction with parathyroid hormone. The vitamin is necessary for normal bone formation and regulates calcium and phosphorus metabolism in bone and kidney. [160] Because more than 90% of circulating 25-hydroxyvitamin D_3 is derived from skin and is endogenously produced, requirements have not been established for daily need. The current DRIs are based on AIs. Because vitamin D deficiency is more prevalent in older adults, the recommended AI for adults older than 50 years is twice that of younger adults (10 versus 5 µg/d, or 400 versus 200 IU), and for adults older than 70 years it is tripled (15 µg/d). [13] Vitamin D occurs naturally in foods of animal origin, such as fish liver oils, eggs, liver, and dairy products. Fortified foods now supply the major dietary sources, although most vitamin D is made endogenously. Vitamin D is absorbed in the small intestine along with other lipids, but it requires bile salt micelle formation for efficient absorption. It is transported in the lymph with chylomicrons and other lipoproteins. The serum content of vitamin D is not limited by the content of the specific vitamin D–binding protein, and the ingestion of excessive doses can produce toxic levels of vitamin D or its metabolites in the serum. Vitamin D is stored in fat depots (e.g., liver, adipose tissue) and muscle, and it is released slowly. The 25-hydroxyl group is added in the liver, and the 1-hydroxyl group in the kidney. 1,25-Dihydroxyvitamin D and other polar metabolites are excreted in the bile and undergo an enterohepatic circulation. Malabsorption disorders produce earlier deficiency because endogenous as well as exogenous vitamin is lost. Small amounts of the vitamin are excreted in the urine.

Vitamin E. The term *vitamin E* refers to two groups of lipid-soluble compounds, tocopherols and tocotrienes, that are found in plants. a-Tocopherol is the most active and abundant of these compounds. These compounds function as fat-soluble antioxidants and free-radical scavengers, in conjunction with the selenium/glutathione peroxidase system. [161] The RDA previously was based on the assumptions that the diet had no more than 0.1 ppm of selenium, average amounts of sulfur amino acids, a ratio of vitamin E to PUFAs of 0.4, and less than 1.5% linoleic acid in a diet containing 1800 to 3000 kcal. [10] Current recommendations also consider the possible role of vitamin E as an antioxidant in preventing disease, the increased intake of PUFAs in the United States, and the serum vitamin E values from NHANES III (Third National Health and Nutrition Examination Survey, 1998–1994). [15] Thus, the new DRIs are set about 50% higher than the 1989 levels (15 mg/d for adults). The vitamin is abundant in the lipids of green leafy plants, in vegetable oils, and in seeds. Foods high in PUFAs are also excellent sources of vitamin E. [15, 161] Vitamin E is absorbed passively from the small intestine with other lipids, and like that of other fat-soluble vitamins, its absorption requires bile salt micelles. Only about 40% of an oral dose is absorbed. The natural form is an acetate ester; bile salt–dependent pancreatic esterase is also required for absorption. There is no specific serum carrier for vitamin E. Because it is bound to LDL and other lipoproteins, serum levels are proportional to total lipids. The vitamin is delivered to the liver after the action of lipoprotein lipase, and from the liver it is delivered in lipoproteins to adipose tissue, where it is stored. Vitamin E destroys tissue peroxides that promote the oxidation of LDL [162] and prevents platelet adhesion by an antioxidant-independent mechanism. [163] These effects are the basis for the potential effect of the vitamin in preventing ischemic damage.

Vitamin K. The term *vitamin K* designates naphthoquinone compounds with antihemorrhagic activity. They are critical for the production of plasma clotting factors II (prothrombin), VII, IX, and X. Two

forms occur naturally: vitamin K_1 (phylloquinones) in green plants and vitamin K_2 (menaquinones) in bacteria. Colonic bacterial synthesis provides an estimated 2 µg/kg of body weight, and absorption of that source presumably occurs by backwash into the terminal ileum. The RDAs of 1989 were based on the function of the vitamin for clotting proteins, but the requirement may be greater for the nonhepatic vitamin K–dependent proteins, especially those in bone. [164] Because of the lack of data on which to estimate an average requirement, the current DRIs are based on AIs, set at 90 µg/d and 120 µg/d for adult women and men, respectively. [16] Therapeutic sources of vitamin K are synthetic compounds. The best food sources are green leafy vegetables, and they are considered to be the major source of the vitamin despite some endogenous production. Vitamin K is passively absorbed in the small intestine, a process that requires bile salt micelles and pancreatic enzymes. Unlike the other fat-soluble vitamins, vitamin K is not stored in large amounts in adipose tissue. The plasma form is carried on lipoproteins, but the storage form is primarily long-chain menaquinones. The vitamin is concentrated in the liver and is excreted in bile, stool, and urine. [16, 160] Vitamin K acts by carboxylating selected glutamic acid residues of proteins to form a-carboxyglutamic acid (Gla), which binds calcium. [165] The coagulation function of the vitamin K–dependent hepatic proteins (e.g., prothrombin and factors VII, IX, and X) and the function of the bone proteins (e.g., osteocalcin, matrix Gla protein) are proportional to the degree of carboxylation. Other vitamin K–dependent proteins of unknown function are present in other tissues.

ALTERED NUTRITIONAL STATES

Starvation

The metabolic response to starvation enhances survival by increasing the use of adipose tissue triglycerides as a source of fuel, preventing severe hypoglycemia, conserving lean tissue, and decreasing the metabolic rate. The duration of survival during starvation depends on the amount of body fat and lean body mass. In lean men, death occurs after approximately 60 days of starvation, [166] whereas obese persons can survive complete energy deprivation for more than 1 year without obvious adverse consequences. [167]

Marked metabolic adaptations occur within the first 24 hours of fasting. The mobilization of adipose tissue triglycerides, ketone body production, and the oxidation of plasma fatty acids increase, whereas hepatic glucose production and plasma glucose oxidation decrease. [168]

The rate of lipolysis of adipose tissue triglycerides increases because of a decrease in circulating insulin, an increase in plasma epinephrine concentration, and an increase in the lipolytic response to catecholamines. [169, 170] and [171] After 3 days of fasting, lipolysis of adipose tissue triglycerides increases to more than double the values observed after an overnight (i.e., 12-hour) fast. The increase in lipolysis and plasma fatty acid concentrations increases fatty acid oxidation. The increased delivery of free fatty acids to the liver in conjunction with a decrease in the plasma ratio of insulin to glucagon stimulates hepatic ketone body production. [172] The rate of ketogenesis is maximal by 3 days of starvation; plasma ketone body concentration increases 75-fold by 7 days. [173] Ketone bodies are water soluble and able to cross the blood-brain barrier. As plasma ketone body concentrations increase, ketone body oxidation by the brain increases; by 7 days of starvation, ketone bodies provide 70% of the brain's energy needs. [174] The shift in fuel use by the brain helps spare the limited supply of plasma glucose for glucose-requiring tissues.

Whole-body glucose production decreases by more than half during the first few days of fasting because of a marked reduction in hepatic glucose output. [175] Only 15% of hepatic glycogen stores remain after 24 hours of fasting. [176] Therefore, the contribution of gluconeogenesis from plasma precursors to total hepatic glucose output increases as the rate of hepatic glycogenolysis declines. As fasting continues, the conversion of glutamine to glucose in the kidney represents almost 50% of total glucose production.

Normally, about 70 g of amino acids are mobilized from protein stores and about 10 g of nitrogen is excreted in the urine. [177] During starvation, it is critical to slow down the rate of protein breakdown to prevent clinically significant protein losses. If protein breakdown proceeded at a normal rate throughout starvation, a potentially lethal amount of muscle protein would be catabolized in less than 3 weeks. The increase in ketone bodies [178] and starvation-induced inactivation of thyroid hormone (conversion of triiodothyronine [T_3] to reverse T_3) [179] directly inhibit muscle protein breakdown.

Energy expenditure is conserved during fasting because of a decrease in physical activity caused by fatigue and a decrease in the resting metabolic rate, which decreases by 10% to 15% at 7 days because of diminished size and function of metabolically active tissues, [180] increased conversion of active thyroid hormone to its inactive form, [181] and suppressed sympathetic nervous system activity. [182]

Maximum adaptation occurs as starvation continues. After 14 days of fasting, lipid, carbohydrate, and protein metabolism plateaus. Adipose tissue provides more than 90% of daily energy requirements. Muscle protein breakdown decreases to less than 30 g/d, causing a marked decrease in urea nitrogen production and excretion. Fluid requirements decrease because the diminished osmotic load from urea causes a decline in urine volume to 200 mL/d. Total glucose production decreases to about 75 g/d, providing fuel for glycolytic tissues (40 g/d) and the brain (35 g/d) while maintaining a constant plasma glucose concentration. Energy expenditure decreases by 20% to 25% after 30 days of fasting [183] and remains relatively constant thereafter despite continued starvation.

During the terminal phase of starvation, body fat mass, muscle protein, and the size of most organs are markedly decreased. The weight and protein content of the brain remains relatively stable throughout starvation. In rodent models, when fat stores are depleted, the energy derived from body fat decreases and muscle protein catabolism increases. Death occurs when 30% of muscle protein is lost. [184]

Metabolic Response to Illness and Injury

The metabolic response to illness and injury is characterized by hypermetabolism, negative nitrogen balance, insulin resistance and hyperglycemia, and increased mobilization and oxidation of adipose tissue triglycerides. These events are mediated by a complex cascade of endogenous mediators that cause a predictable physiological response. Increased production and secretion of the counterregulatory hormones (e.g., catecholamines, glucagon, and glucocorticoids) and cytokines are probably responsible for most of the observed responses to illness and injury.

In the 1930s, the classical work of Cutherbertson [185] on long-bone fractures provided the basis of our understanding of the metabolic response to injury. Cuthbertson demonstrated that the response to injury could be divided into two phases: the early ebb phase (12–24 hours after trauma) and the subsequent flow phase. The ebb phase is characterized by decreased blood pressure, oxygen consumption, cardiac output, and body temperature. The flow phase is characterized by hypermetabolism and increases in oxygen consumption, cardiac output, body temperature, and the urinary excretion of nitrogen, potassium, and phosphorus. Subsequently, Moore [186] divided the flow phase into the catabolic and anabolic phases. The restoration of tissue perfusion marks the beginning of the catabolic phase and lasts for days to weeks, depending on the severity of injury, medical intervention, and the premorbid health of the patient. This phase is characterized by catabolism, heat production, negative nitrogen balance, and hyperglycemia. [185, 186] It ends after volume deficits are corrected, infection is controlled, pain is eliminated, and oxygenation is restored. At this point, net anabolism may occur, resulting in a slow reaccumulation of protein and body fat.

Hormone and Cytokine Mediators During the flow phase, the secretion of several hormones is increased, and they act synergistically to generate alterations in intermediary metabolism. Catecholamines increase lipolysis and hepatic glucose production. Glucagon increases hepatic gluconeogenesis and glycogenolysis. Cortisol enhances protein breakdown and increases hepatic gluconeogenesis. Cytokines, produced by macrophages, lymphocytes, Kupffer cells, and endothelial cells, are also critical mediators of the metabolic response. TNF is believed to be the primary cytokine mediating many of the responses to infection and trauma, including fever, increased acute phase protein synthesis, protein catabolism, hypotension, decreased lipoprotein lipase activity, and metabolic acidosis. [187, 188, 189, 190] and [191] IL-1 and TNF act synergistically in promoting tissue injury and stimulating the release of counterregulatory hormones. [192] IL-1 causes fever, hypotension, and increased insulin and glucagon secretion, and it affects the concentrations of plasma divalent cations. IL-1 stimulates the liver to synthesize metallothioneins, which sequester zinc, and mediates the sequestration of iron in hemosiderin and ferritin, depriving invading organisms of these trace elements. [189, 190, 191, 192, 193, 194, 195, 196, 197, 198] and [199] IL-1 stimulates other portions of the acute phase response, such as fibrinogen and C-reactive protein production by hepatocytes and the release of lactoferrin by neutrophils. [193, 194] and [195] IL-1 enhances immunoglobulin production by B lymphocytes and is a potent stimulus for the synthesis and release of IL-2 by T lymphocytes. [193, 195, 200] IL-6 is also inducible by TNF and functions primarily as a stimulator of the hepatic acute phase protein response and lymphocyte proliferation. [192, 200] IL-8 is inducible by TNF and IL-1 and is a potent neutrophil chemoattractant. [200]

Energy Metabolism Increases in metabolic rate correlate directly with the severity of illness and injury. [201] For example, the REE increases after uncomplicated surgery by about 10%, after long-bone fractures by 20%, and after multiple trauma by 50%. The REE rarely exceeds twice the normal rate regardless of the extent of injury. [184] In fact, even patients with severe burns usually do not experience an increase in REE by more than 50% for any prolonged period. [202] In certain types of injury, a temporary resetting of the hypothalamic thermoregulatory set point is responsible for a 1° to 2°C elevation of body temperature known as *posttraumatic fever*. [187, 203] The REE increases about 12% for each 1°C increase in core body temperature. Because the central temperature set point is higher, the comfort temperature for an injured patient is elevated, and elevating the ambient temperature decreases the energy requirement. [184]

Protein Metabolism Illness or injury increases protein synthesis and protein breakdown. The increase in protein breakdown is greater than the increase in protein synthesis, resulting in negative nitrogen balance. Skeletal muscle is the major site of protein catabolism, but increased catabolism of extracellular proteins, including acute phase reactants, coagulation system proteins, and complement system proteins, also occurs. [193, 204, 205] and [206] Considerable protein synthesis is directed toward host defense, including phagocyte activity, hormones, cytokines, intracellular proteins,

immunoglobulins, complement, coagulation system proteins, and acute phase reactant glycoproteins. [193] The composition of amino acids released by muscle does not reflect the composition of muscle proteins. The branched-chain amino acids of skeletal muscle are metabolized within the muscle cell for energy, and transamination generates glutamine and alanine. As a result, alanine and glutamine, which constitute only 12% of muscle protein, make up 50% to 60% of the amino acids released into the plasma by muscle. Conversely, branched-chain amino acids make up 15% of the muscle protein but only 6% of the amino acids released. [193], [201] Glutamine is taken up and metabolized by the kidney at an accelerated rate, providing additional ammonium for excretion to help maintain acid-base balance in the face of the acidosis that frequently accompanies critical illness. [201] In addition to carrying amino groups from the periphery to the liver and kidney, glutamine serves as a major energy source for the lymphocytes, fibroblasts, and the gastrointestinal tract. [207] Alanine is captured by the liver for gluconeogenesis, and its nitrogen contributes to the increase in ureagenesis. [208] During severe illness, nitrogen losses may reach 20 to 40 g/d. This represents catabolism of 600 to 1200 g of lean body mass per day. Providing exogenous nitrogen and energy may [209] or may not [210] decrease the rate of catabolism, but it enhances protein synthesis and thereby decreases negative nitrogen balance. [207], [211]

Carbohydrate Metabolism The stress response is marked by hyperglycemia, in large part related to hepatic gluconeogenesis fueled by lactate, pyruvate, glycerol, alanine, and other glucogenic amino acids. Hepatic glucose production may exceed 500 g/d and is resistant to suppression by insulin. [212] Peripheral insulin resistance decreases skeletal muscle glucose uptake, which also contributes to hyperglycemia. [187] Glucose consumption by wounds and injured extremities is increased to provide fuel for inflammatory cells, such as fibroblasts, macrophages, and leukocytes. These cells metabolize glucose anaerobically and can release large quantities of lactate into the bloodstream, which is subsequently recycled to glucose by the liver.

Lipid Metabolism Fat is a major oxidative fuel in critically ill patients, even when exogenous carbohydrates are administered. The rate of lipolysis correlates directly with the severity of illness. [213] The increased delivery of fatty acids to the liver stimulates very-low-density lipoprotein (VLDL) production. However, the rate of VLDL secretion is not adequate to remove the excessive supply of fatty acids and thus contributes to hepatic fat accumulation. Hypertriglyceridemia can occur because of both increased VLDL production and decreased peripheral lipoprotein lipase activity and VLDL clearance.

CHAPTER 22

Karen D. Crissinger and D. Neil Granger

GASTROINTESTINAL BLOOD FLOW

The ultimate function of the gastrointestinal tract is to assimilate nutrients and water from the external environment and make them available to cells throughout the body. Although the mucosal epithelium is largely responsible for extracting nutrients from the external environment, the blood and lymph circulations provide the conduits for transferring absorbed nutrients and water to the entire body. The vascular supply to the gastrointestinal mucosa is particularly well suited for the absorptive and secretory functions of this tissue in that it can accommodate a high rate of blood flow, has a large exchange surface area, and permits easy permeation of nutrients and water, yet largely retains proteins within the plasma compartment. This chapter summarizes current concepts regarding circulatory control and function in the gastrointestinal tract during normal physiological conditions, and it reviews current knowledge about pathophysiological mechanisms of intestinal injury resulting from periods of inadequate perfusion (i.e., ischemia).

ANATOMY OF THE GASTROINTESTINAL CIRCULATION

Extramural Vessels

Arteries In humans, the major arteries supplying the stomach and intestines are the celiac, superior mesenteric, and inferior mesenteric arteries. The celiac artery supplies the stomach, the first portion of the duodenum, a portion of the pancreas, and the liver. The superior mesenteric artery supplies the remainder of the pancreas and duodenum, the jejunum, the ileum, and the colon through two thirds of the transverse segment. The inferior mesenteric artery supplies the remainder of the colon and rectum, except the distal rectum, which is supplied by rectal arteries arising from the internal iliac arteries. Along the mesenteric border of the intestine, arterial and venous branches form multiple arcades, anastomose with one another, and provide a pathway for collateral blood flow. The arcades give rise to vasa recta, which branch to encircle the intestine and ultimately pierce the circular muscle. [1], [2] and [3]

Veins Blood from the stomach, pancreas, and intestines drains into the portal vein, except for that of the distal rectum, which drains into the internal iliac veins. The vessels that drain the intestines course within the mesentery, except those vessels supplying retroperitoneal portions. [1], [2] and [3]

Lymph Lymph vessels are closely associated with the arteries supplying the stomach and intestines, ultimately draining into the intestinal lymph trunk to the cisterna chyli, and then into the systemic circulation through the thoracic duct into the left subclavian vein. In humans, the lymphatic drainage of the distal portion of the intestines occurs by way of the left lumbar lymph trunk, which empties into the cisterna chyli separate from the drainage of the proximal gut. [1], [2] and [3]

Intramural Vessels and Microcirculation

Stomach In the human stomach, submucosal arterioles branch into capillaries at the base of the gastric glands, pass perpendicularly through the mucosa, form a lumenal capillary network, and drain into mucosal venules only at the most lumenal level of the lamina propria (Fig. 22-1). These venular branches converge on infrequent mucosal collecting venules, which then pass directly to the submucous venous plexus without receiving any direct capillary tributaries within the mucosa. [4]

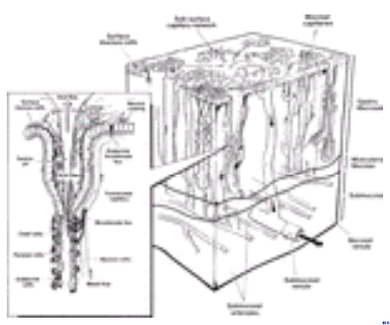

FIGURE 22-1. The vascular organization in gastric mucosa (**right**). The proposed mechanism for the vascular transport of HCO_3^- is toward the surface mucous cells from deeper within the mucosa (**inset left**). (From ref. [4].)

Small Intestine The major intramural arterial vessels are located in the deep submucosal plexus. Both arteries and veins in the deep submucosal plexus undergo extensive self-anastomosis. The capillaries of the muscular, submucosal, and mucosal layers are supplied by branches from the submucosal vascular network. [1], [2]

Villus microvascular architecture varies considerably among species (Fig. 22-2). [5] Human villi contain single, eccentrically located arterioles that pass to the villus tip, break up in a fountain-like pattern, and anastomose with eccentrically located venules that start at about 15% of the villus height below the villus tip. A tufted pattern of capillaries, derived from the tubular capillary plexus surrounding the epithelium of the crypts, supplies the basal 70% to 80% of the villus and also drains into the venule high in the villus (Fig. 22-3). [2], [6]

FIGURE 22-2. Models of mucosal microcirculation of the intestine. **A:** Fountain. **B:** Tuft. **C:** Stepladder patterns of villus blood supply. **D:** The dual pattern comprises both fountain and tuft components. *a*, arteriole; *v*, venule; *arrows*, principal direction of capillary blood flow in each pattern. (From ref. [5].)

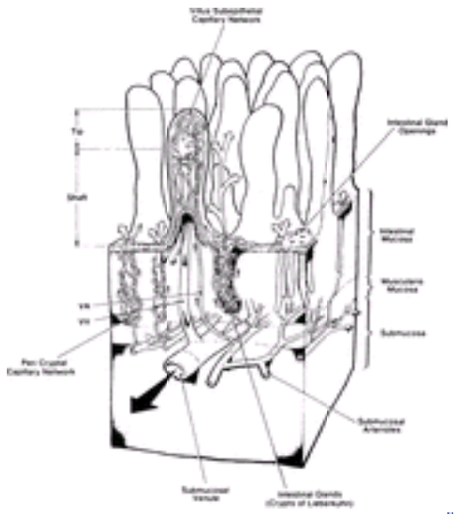

FIGURE 22-3. Mucosal microcirculatory patterns typical of human and rabbit small intestine. *VA*, villus arteriole; *VV*, villus venule. (Adapted from ref. [6].)

Anatomic requirements for countercurrent exchange include the presence of a countercurrent flow of blood and a short arteriolar-capillary distance. Although the existence of countercurrent exchange within the villi has been proposed, [7] controversy continues about whether these requirements are met in human villi. [5]
Colon The colonic mucosa is devoid of villi; therefore, the arterioles and their capillary branches pass to the epithelial surface between the crypts to form a network of capillary plexuses around the crypts. The colonic capillaries are much closer to the epithelial cells than are the villus capillaries in the small intestine. [8]

Intramural Lymphatic Circulation

The gastric lymphatics normally begin as a plexus of vessels immediately superficial to, within, and below the muscularis mucosae. The upper two thirds of the gastric lamina propria is normally devoid of lymphatics. [9]

Small intestine lymphatic vessels begin as centrally located, blind-ending vessels (i.e., lacteals) in the villi and are emptied when smooth muscle in the villus core contracts. These initial lacteals—similar in size to venous capillaries but with open endothelial intercellular junctions, few pericytes, and tenuous basement membranes—drain into a submucosal plexus connected to the collecting lymphatics. The lymphatics leave the intestine at the mesenteric border and pass through the mesentery in association with blood vessels. [2], [10]

Colonic lymphatics begin at the level of the muscularis mucosae, are smaller and more sparsely distributed than those in the small intestine, and do not penetrate higher than the bases of the crypts in humans. [11]

BLOOD FLOW REGULATION

Intrinsic Control

It is well recognized that blood flow in the gastrointestinal tract is normally maintained within narrow limits and changes in response to various functional stimuli. This ability to modulate blood perfusion in accordance with the moment-to-moment demands of the tissue has been attributed to intrinsic vasoregulatory systems. Several regulatory mechanisms have been proposed to explain vascular phenomena such as pressure-flow autoregulation and functional hyperemia in the gastrointestinal tract. Of these, metabolic, myogenic, and hormonal mechanisms are considered to be of the greatest physiological significance. The following section summarizes the available data implicating intrinsic factors in the regulation of gastrointestinal blood flow and the specific mechanisms that have been invoked to explain these vascular phenomena.

Pressure-Flow Autoregulation Pressure-flow autoregulation has been demonstrated in stomach, [29], [30] small intestine, [22], [31], [32], [33], [34], [35], [36], [37], [38] and [39] and colon. [12], [13], [40], [41] and [42] Autoregulation of blood flow in the gastrointestinal tract during fasting is not the intense phenomenon observed in kidney and brain; however, the results of several studies indicate that the intensity of autoregulation increases during periods of enhanced functional activity (Fig. 22-4). [14] Furthermore, it appears that the autoregulatory ability of the more metabolically active mucosal region of the intestine exceeds that of the whole organ. [43]

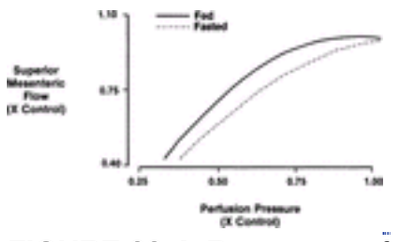

FIGURE 22-4. Responses of intestinal blood flow to step reductions in perfusion pressure in fed (*solid line*) versus fasted (*dashed line*) dogs demonstrate an increased intensity of autoregulation during enhanced functional activity. (From ref. [14].)

The correlation between metabolic rate and autoregulatory ability does not appear to apply to the neonate because autoregulation of blood flow is less intense or absent in neonatal intestine, which is more metabolically active than adult intestine. [44] Additionally, autoregulation is enhanced by hypoxia or ischemia [45] or by increasing intestinal oxidative metabolism in 1-month-old, but not in 3-day-old, piglet intestine. [46] One study suggests that autoregulation in the intestine is an endothelium-dependent phenomenon. [47] Although blood flow is not perfectly regulated with an arterial pressure of 100 to 50 mm Hg, oxygen uptake remains within normal limits over the same range of pressures. [12], [13] This autoregulation of gastrointestinal oxygen uptake is often cited as evidence that tissue oxygenation, rather than blood flow, is the controlled variable. As arterial pressure is reduced, vascular resistance falls, whereas perfused capillary density rises. These changes enhance both the convective and diffusive exchange of oxygen during the reduced pressure state. As a result, tissue oxygen tension tends to remain above the level at which oxygen availability limits mitochondrial oxygen consumption. Mathematical models of intestinal oxygen exchange predict that the contribution of capillary recruitment exceeds that of vasodilation in maintaining normal tissue oxygenation during acute hypotension. [48]
Reactive Hyperemia The term *reactive hyperemia* is used to describe the overshoot in blood flow that occurs after the release of arterial occlusion. All regions of the gastrointestinal tract exhibit a reactive hyperemia after brief (<5 minutes) periods of arterial occlusion. [49] The magnitude and duration of the hyperemic response are related to the extent and duration of the arterial occlusion, suggesting that the vascular response is caused by metabolite accumulation, oxygen deficiency, or both. The ability of the intestine to repay the oxygen debt incurred during vascular occlusion is largely determined by which vessel is occluded—that is, artery or vein. With arterial occlusion, repayment of the oxygen debt is inadequate, and the magnitude of the deficit is proportional to the duration of the arterial occlusion. [50], [51] Venous occlusions are associated with overpayment of oxygen in the postocclusion period, the magnitude of which is related to the duration of occlusion. It is suggested that arterial occlusions depress intestinal oxygen utilization, whereas venous occlusions enhance it. Increasing basal intestinal oxygen consumption by intraenteric placement of nutrients prolongs the reactive hyperemic response and increases the oxygen payback-to-debt ratio. [100] Laser Doppler studies indicate that mucosal and total blood flow consistently show reactive hyperemia in response to a 60-second occlusion, but the muscularis externa does not.
Alterations in Arterial Blood Gases and Hematocrit Alterations in arterial blood gases and hematocrit also affect gastrointestinal blood flow. Arterial hypoxemia increases blood flow and elicits capillary recruitment in denervated intestinal preparations. [52], [53] The vasodilation and increased perfused capillary density tend to minimize the reduction in oxygen uptake induced by the limited oxygen delivery. When blood flow is held constant, the intestine maintains oxygen consumption within 48% of control during arterial hypoxemia. When both blood flow and capillary density are free to increase, however, oxygen uptake remains within 26% of control despite the hypoxia. Similar to hypoxia, hypercapnia induces a marked relaxation of resistance vessels. [53] In contrast to hypoxia, hypercapnia causes the precapillary sphincters to constrict and the capillary density to decrease. Alterations in arterial hematocrit also influence gastrointestinal blood flow and oxygenation. [15], [16] and [17] An inverse linear correlation exists between the intestinal blood flow and the hematocrit, and a direct linear correlation between the arteriovenous oxygen difference and the hematocrit in both the intestine and stomach. The relation between intestinal oxygen uptake and hematocrit is parabolic (Fig. 22-5), [15] showing a maximal uptake at a hematocrit of 48.7%—that is, the optimal hematocrit. Intraenteric placement of nutrients increases the optimal hematocrit to 57.1%. In the stomach, the

optimal hematocrit is 38.2% during resting conditions, and it increases to 45.7% during pentagastrin stimulation. In the neonate, intestinal blood flow and oxygen uptake are not changed by alterations in hematocrit over a range between 10% and 54%, indicating that increases in oxygen extraction play a major role in maintaining a normal rate of oxygen utilization when intestinal oxygen delivery is reduced by lowering the hematocrit. [54]

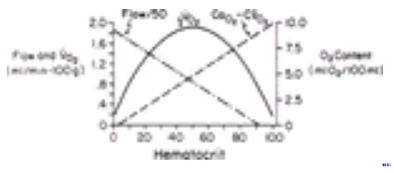

FIGURE 22-5. Effect of hematocrit on canine intestinal blood flow, oxygen consumption ($\dot{V}_{O_2}$), arterial oxygen content, and arteriovenous oxygen difference ($Ca_{O_2} - Cv_{O_2}$). (From ref. [15].)

Venous Pressure Elevation Venous pressure elevation has proved to be a useful perturbation for determining whether metabolic or myogenic mechanisms are involved in local vasoregulation. The metabolic hypothesis predicts that acute venous hypertension causes vasodilation and increased capillary density as a result of reduced blood flow and vasodilator accumulation. According to the myogenic hypothesis, vascular resistance increases and capillary density decreases during venous pressure elevation because of a rise in intravascular (intramural) pressure at the arteriolar and precapillary sphincter levels (Fig. 22-6). [49]

FIGURE 22-6. Metabolic and myogenic theories of intestinal blood flow regulation. (From ref. [49].)

Studies of the stomach, small intestine, and colon in adult animals indicate that vascular resistance rises in response to venous pressure elevation, [12], [13], [19], [25], [40], [41] and [42], [54], [55], [56], [57], [58], [59] and [60] findings consistent with a myogenic mechanism. In newborn animals, the intestinal vasculature dilates, rather than constricts, in response to venous hypertension, suggesting that metabolic factors are dominant in the hypermetabolic neonatal intestine. [24] Acute venous hypertension in the adult intestine elicits vasoconstriction as a result of rising in precapillary (arteriolar) resistance while postcapillary resistance falls. [61] Capillary exchange capacity increases in the stomach and the colon but decreases in the small intestine during venous hypertension. [49] These observations are consistent with the view that metabolic factors exert a greater influence on precapillary sphincters in the stomach and colon, whereas myogenic factors dominate in the small intestine. Despite the intense capillary derecruitment initiated by venous hypertension in the small intestine, oxygen extraction increases disproportionately to the reduced blood flow, and consequently, oxygen consumption rises. [56] The elevated intestinal oxygen utilization during venous hypertension has been attributed to increased villus motility. [62] There are conflicting reports regarding the influence of enhanced oxidative metabolism on the vascular responses to elevations in venous pressure. Some investigators have observed that increased oxygen demand significantly reduces or abolishes the rise in vascular resistance, [14], [42] whereas others have noted an exaggerated resistance response to venous pressure elevation. [63] Researchers uniformly agree that acute venous hypertension alters the distribution of blood flow within the bowel wall. [19], [64] As venous pressure is elevated, the percentage of total blood flow directed to the mucosa and submucosa is reduced, whereas the muscularis receives a larger fraction of the total blood flow. These observations indicate that the constriction of arteriolar and precapillary sphincter smooth muscles elicited by venous hypertension takes place in the mucosal and submucosal layers, and that the vasculature of the muscularis dilates in response to venous hypertension. Whereas exposure of the splanchnic circulation to an acute elevation in portal venous pressure is likely to elicit a myogenically mediated constriction of splanchnic arterioles, chronic portal hypertension tends to dilate the splanchnic vasculature. Furthermore, chronic portal hypertension has a significant impact on other regional vascular beds and on systemic hemodynamics. Blood flow to the gastrointestinal tract, kidneys, and skeletal muscle is significantly elevated. This presumably results from an increase in circulating vasodilators (e.g., glucagon) and a decrease in vascular sensitivity to vasoconstrictors (e.g., norepinephrine). The widespread dilation of arterioles results in a reduction of peripheral vascular resistance and a corresponding reduction of arterial blood pressure. In addition, cardiac output is elevated as a consequence of the increased venous return associated with the splanchnic and peripheral vasodilation. The elevated portal pressure results in the opening of portosystemic shunts to divert portal blood from the liver and reduce portal pressure. These shunts generally run along the esophagus (i.e., esophageal varices). The increase in portal pressure impairs venous drainage from the spleen into the portal vein, resulting in the accumulation of blood within, and distention of, the spleen (i.e., splenomegaly). [65], [66] and [67] Organ blood flow is determined by the arterial-venous pressure gradient and vascular resistance. It follows then that portal pressure is determined by portal venous inflow and portal venous resistance. The relationship between portal venous flow and portal pressure at a normal portal vascular resistance is depicted in Figure 22.7 as a solid line. In this instance, an increase in portal venous flow will produce a proportional increase in portal pressure (point A to point B; flow-induced portal hypertension). When portal vascular resistance is increased, the relationship between portal pressure and portal venous flow is shifted upward and to the left, as depicted by the dashed line. At any given portal venous inflow, an increased portal vascular resistance will result in an increase in portal pressure (point A to point C; resistance-induced portal hypertension). Portal pressure can be further increased by a concomitant increase in portal venous flow and portal vascular resistance (point A to point D; flow- and resistance-induced portal hypertension). Indeed, the latter situation appears to reflect the vascular changes that account for the elevated portal pressure observed in some experimental models of chronic portal hypertension, and it is likely to account for the portal hypertension associated with some forms of liver disease. With a portal vascular resistance that is 40% higher in the portal hypertensive than in the control state, it is predicted that increased portal inflow and increased portal vascular resistance account for 40% and 60% of the increase in portal pressure, respectively. [68]

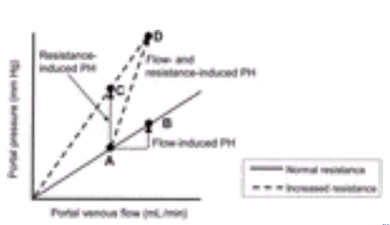

FIGURE 22-7. Hypothetical relationship between portal pressure and portal venous flow in the presence of a normal (*solid line*) or elevated (*broken line*) portal vascular resistance. Even when portal vascular resistance is normal, an increased portal blood flow (from point A to point B) can result in an increased portal pressure—that is, portal hypertension. An elevation in portal vascular resistance in the absence of increased portal blood flow (point A to point C) can also lead to portal hypertension. When both portal blood flow and vascular resistance are increased (point A to point D), the increase in portal pressure is more substantial. (From ref. [68].)

The portal hypertensive state leads to the development of collaterals (mostly along the esophagus; esophageal varices) to shunt blood from the congested portal vein, around the liver, to the systemic circulation (i.e., portosystemic shunting). Because a large proportion of portal venous blood bypasses the liver as a result portosystemic shunting, the hepatic degradation of different compounds, including circulating vasodilators, such as glucagon, is reduced. The diminished catabolism of circulating vasodilators increases their concentration in the plasma, allowing these agents to relax arteriolar vascular smooth muscle and reduce splanchnic vascular resistance. Another important action of some of the vasodilators that accumulate in chronic portal hypertension (e.g., glucagon) is to reduce the sensitivity of the splanchnic arterioles to vasoconstrictors such as norepinephrine, vasopressin, and angiotensin. The net result of the direct and indirect actions of the accumulated circulating vasodilators is increased splanchnic blood flow, which serves to perpetuate the portal hypertensive state. [65], [66] and [67]

Postprandial Hyperemia The term *postprandial hyperemia* is used to describe the increase in blood flow that occurs in response to a meal. The anticipatory-ingestion phase of digestion is characterized by transient increases in heart rate, cardiac output, and aortic pressure; however, gastrointestinal blood flow is either unchanged or slightly increased. [69], [70], [71], [72] and [73] These transient hemodynamic responses appear to be mediated by activation of the sympathetic nervous system, because they can be attenuated by adrenergic blocking agents. [71] In conscious animals, blood flow to the stomach and proximal bowel increases 30 to 90

minutes after ingestion of a meal. [69], [70], [71] and [72] Blood flow to the ileum increases 45 to 120 minutes postprandially, whereas colonic blood flow generally does not increase. [74], [75] and [76] Transient decreases in distal colon blood flow have been observed 30 minutes after a meal, a response attributed to tonic contractions produced by the gastrocolic reflex. [76] Blood flow in the superior mesenteric artery of conscious animals typically increases by 25% to 130% after ingestion of a meal. [69], [70] and [71], [77] The splanchnic vasodilation may last for 4 to 7 hours, depending on the nature and quantity of the meal. [78], [79] A smaller increase (10%–60%) in blood flow is observed in isolated bowel segments in adult animals after intralumenal placement of digested food or nutrient solutions. In similar preparations of isolated bowel segments in developing piglets, the response after placement of intralumenal nutrients is age-dependent. Total intestinal blood flow to the distal jejunoileum of 6- to 8-hour-old piglets that have never nursed does not increase after placement of lumenal nutrients, whereas that of all older age groups does increase with feeding. [80] Mucosal and submucosal blood flow does increase postprandially, but at the expense of flow to the muscularis and serosa. It remains unclear whether postprandial hyperemia is confined to those bowel segments that are exposed to chyme. In general, placement of nutrient solutions into one of two isolated segments in anesthetized animals increases blood flow to the segment containing the nutrient while not affecting blood flow to the adjacent segment. [81], [82], [83], [84] and [85] In conscious animals, however, ingestion of a meal produces hyperemia in distal bowel segments that are not yet exposed to chyme, suggesting that the hyperemia is a diffuse phenomenon. [23] The intramural responses to nutrient absorption are generally confined to the mucosal layer. [76], [84], [85] and [86] In some instances, blood flow to the external muscle layer decreases after intralumenal placement of nutrients. [80], [87] Studies in the rat small intestine suggest that postprandial hyperemia in this species occurs uniformly in all layers of the bowel wall. [88] Considerable effort has been devoted to defining the lumenal stimuli responsible for postprandial hyperemia. Although mechanical stimulation of the mucosa elicits hyperemia, chyme per se does not appear to produce the degree of mechanical stimulation necessary to increase intestinal blood flow. Similarly, lumenal placement of undigested food does not elicit hyperemia, whereas digested food significantly increases blood flow. [82] The latter observation indicates that hydrolytic products of food digestion initiate the hyperemia. The rise in lumenal osmolality that often accompanies a meal has received some attention, particularly in view of the fact that the intestinal vasculature dilates significantly in response to an increase in plasma osmolality. [89] Normally, the osmolality of intestinal chyme varies between 220 and 320 mOsm/kg, yet lumenal osmolalities in excess of 1500 mOsm/kg are needed to increase gut blood flow. [81], [90] A similar argument has been advanced to negate the theory of a role for pH changes in postprandial hyperemia in the jejunum and ileum; gut blood flow increases only when lumenal pH falls below 2.5. [91] Bile appears to play an important role in postprandial intestinal hyperemia. Ten percent gallbladder bile, the steady-state concentration in proximal bowel in the early postprandial period, does not increase jejunal blood flow, yet it appears to render glucose and long-chain fatty acids vasoactive. [92] Thirty-three percent gallbladder bile renders both short-chain fatty acids (e.g., caproic acid) and amino acids vasoactive and further enhances glucose-induced hyperemia. Although intralumenal placement of endogenous or synthetic bile does not have a direct vasoactive effect in the jejunum, bile more than doubles blood flow in the ileum. [82], [93] Bile acids are largely responsible for bile-induced hyperemia, an assertion supported by the observation that cholestyramine abolishes the vasodilator effects of endogenous bile on ileal blood flow. [93] Ingestion of protein-rich meals in humans and gastric placement of protein in conscious rats produces marked increases in splanchnic blood flow. In isolated loops of proximal small bowel, a protein-rich diet (64%) increases blood flow by the same extent as a carbohydrate-rich diet (68%). [94] Although hydrolyzed proteins are well-known to induce postprandial hyperemia, the specific hydrolytic products of protein digestion that mediate the response remain unknown. When postprandial concentrations of 16 different amino acids and three peptides are placed in the bowel lumen, blood flow fails to increase. [82] It has been suggested that fragments cleaved off protein molecules during hydrolysis may possess amino acid sequences similar to those found in vasoactive regulatory peptides normally produced in the intestinal mucosa. [95] After a meal, the lumenal concentration of glucose fluctuates between 28 and 222 mM. At these concentrations, glucose usually produces only a slight hyperemia (5%–10%) in dog and cat small intestine. [81], [82], [96], [97] An 18% to 21% increase in blood flow is produced by glucose in rat small bowel. [98] Glucose analogs have been used to define the contribution of absorptive and oxidative processes in carbohydrate-induced hyperemia. [99] Analogs of glucose that are neither transported nor metabolized (e.g., 2-deoxyglucose) do not increase blood flow, but 3-0 methylglucose, which is transported but not metabolized, produces a hyperemia that is about one-third that produced by glucose. Solubilized long-chain fatty acids appear to be the most potent lumenal stimulus of postprandial intestinal hyperemia. Oleic acid (10–20 mM) solubilized in 10% gallbladder bile produces a 20% to 60% increase in intestinal blood flow. [81], [92], [100] Recent evidence suggests that this increase in blood flow may be a response to epithelial cell injury. [101] Relatively little is known about the vascular response of the gut to the lumenal placement or ingestion of other dietary lipids. Short-chain fatty acids (e.g., caproic acid) do not alter blood flow, even in the presence of 10% gallbladder bile. Although lipids produce the greatest degree of intestinal hyperemia, the vascular responses elicited by protein and carbohydrate are not insignificant in that the three major dietary components of food—that is, fats, proteins, and carbohydrates–appear to act synergistically on blood flow when placed in the bowel lumen (Fig. 22-8). [102]

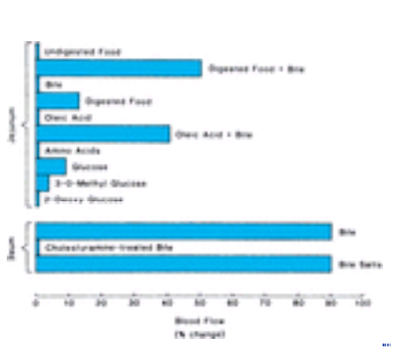

FIGURE 22-8. Effects of intralumenal placement of various constituents of chyme on intestinal blood flow. (From ref. [102].)

Modulators of Intrinsic Vasoregulation A number of chemical and physical factors have been proposed to explain intrinsic vasoregulatory phenomena in the gastrointestinal tract. These factors generally fall into one of three major categories: myogenic factors; chemicals directly linked to oxidative metabolism; and vasoactive peptides, hormones, and autocoids. The myogenic theory has been invoked to explain both pressure-flow autoregulation and the responses to venous pressure elevation in the intestine and stomach. The myogenic theory is based on the assumption that vascular wall tension is a controlled variable. According to this concept, arteriolar tension receptors modulate vascular smooth muscle tone in response to changes in microvascular transmural pressure. In accordance with the Laplace law, resistance vessels should dilate when vascular transmural pressure is decreased and constrict when it is increased; therefore, the myogenic theory predicts that vascular resistance should fall when arterial pressure is reduced. Similarly, this mechanism predicts the rise in intestinal vascular resistance that occurs during acute venous pressure elevation (Fig. 22-9). [19]

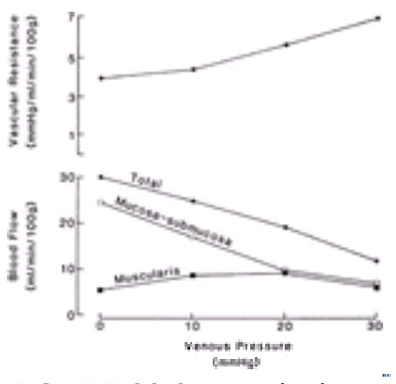

FIGURE 22-9. Intestinal vascular responses to acute venous hypertension in cats. The increase in vascular resistance and decrease in blood flow during acute venous pressure elevation are consistent with the myogenic theory of intrinsic vasoregulation. (Data from ref. [19].)

Because the intensity of all intrinsic vasoregulatory phenomena described in the gastrointestinal tract is significantly influenced by the oxidative requirements of the tissue, metabolic factors have received much attention. According to the metabolic theory of blood flow regulation, vascular resistance and precapillary sphincter tone are linked to the metabolic status of the tissue. Any condition that reduces oxygen delivery, increases oxygen demand, or both, will lead to a reduction in tissue oxygen tension and an accumulation of vasodilator metabolites in the immediate perivascular space. These changes cause relaxation of arteriolar and precapillary sphincter smooth muscle. The resulting increase in blood flow and capillary recruitment stabilize capillary oxygen tension (PO_2), increase the surface area for oxygen exchange, and decrease the capillary-to-cell diffusion distance. The ultimate effect of these changes is to maintain cell PO_2 above the critical level at which oxygen availability limits energy metabolism. The metabolic theory has been invoked to explain the vascular responses during pressure-flow autoregulation, reactive hyperemia, arterial hypoxemia, postprandial hyperemia, and venous pressure elevation. Both adenosine and tissue PO_2 have been proposed as mediators of metabolic vasoregulatory responses in the gastrointestinal tract. Adenosine is a powerful vasodilator when infused into the splanchnic circulation. [103] Adenosine accumulation in venous blood has been demonstrated during reactive and postprandial hyperemia in the small bowel. The role of adenosine in local vasoregulation

has been assessed with the use of substances such as theophylline, a competitive antagonist; the enzyme adenosine deaminase, which converts adenosine to inosine; and dipyridamole, an inhibitor of adenosine reuptake. These agents have been shown to attenuate or completely abolish the vasodilation associated with reductions in arterial pressure, release of an arterial occlusion, reactive hyperemia, acute and chronic hypoxia, and absorption of nutrients. [104], [105], [106], [107] and [108] For example, adenosine deaminase completely prevents absorptive hyperemia in rat and dog small intestine. [104], [107] Similarly, 8-phenyltheophylline abolishes pressure-flow autoregulation and reduces the reactive hyperemic response by 50% in the superior mesenteric artery of anesthetized cats. [109] Considerably less information is available regarding the role of tissue PO_2 in intrinsic vasoregulation. Mucosal PO_2 falls by about 50% during the absorption of glucose in the proximal small bowel, and the hyperemic response is quantitatively and temporally related to the decrease in mucosal PO_2. [88] Taurocholic acid produces a similar decrease (58%) in mucosal PO_2 and a 65% increase in blood flow in the ileum. Cholic acid does not affect either mucosal PO_2 or blood flow when placed in the ileal lumen. A large body of indirect evidence also suggests that the degree of tissue oxygenation influences intestinal vasoregulation. For example, it is well established that at any given oxygen uptake, the magnitude of the postprandial hyperemia is greater if the resting oxygen extraction (i.e., arteriovenous oxygen difference) is high; this indicates that the vascular response is influenced by the prevailing tissue PO_2. [36] Most of the hormones and peptides produced in the gastrointestinal mucosa act as vasodilators when infused into the splanchnic circulation. Because many of these substances are also released into the mucosal interstitium in response to a meal, it has been proposed that peptides and hormones mediate postprandial hyperemia. This hypothesis has received less attention because of studies demonstrating that gastrointestinal peptides and hormones are not vasoactive when infused into arterial blood to reproduce postprandial concentrations. Cholecystokinin, secretin, gastrin, and neurotensin do not produce vasodilation when infused, either alone or in combination, into the arterial supply of the proximal bowel at rates that reproduce postprandial hormone levels. [110], [111] In the distal ileum, however, neurotensin significantly increases blood flow at postprandial concentrations. [108] Although vascular infusion studies tend to argue against a role for gastrointestinal hormones and peptides in postprandial hyperemia, these experiments do not exclude the possibility that the peptides induce vasodilation by a paracrine action. Immunoneutralization techniques have been used to evaluate this concept. [112] Intravenous administration of antiserum directed against vasoactive intestinal polypeptide (VIP) produces a dose-related suppression of the absorptive hyperemia induced by the lumenal placement of bile-oleic acid. Antisera against cholecystokinin or substance P have no effect on absorptive hyperemia. These results indicate that VIP, which is released from mucosal neurons, mediates at least a fraction of postprandial hyperemia by acting as a paracrine agent. A variety of endogenous autocoids also have been implicated as local paracrine mediators in the regulation of intestinal blood flow. These substances are diverse in regard to structure and overall biologic activity, but they appear to have at least one property in common: they cause vasodilation of the gastrointestinal vasculature. Three members of this diversified group have been studied in relation to mediation of postprandial hyperemia: serotonin, histamine, and prostaglandins. Feeding or acid perfusion of the duodenum elevates serotonin levels in portal blood. [113] However, a serotonin antagonist, methysergide, does not reduce the magnitude of postprandial hyperemia. Intrajejunal placement of a mixed meal increases blood flow by 30%, a response that is attenuated by pretreatment with a histamine H_1 receptor antagonist, tripelennamine, but not with metiamide, a histamine H_2 receptor antagonist. [114] Because tripelennamine also blocks the food-induced increase in oxygen uptake, it remains unclear whether histamine directly dilates the vasculature during postprandial hyperemia or whether the blunted response to histamine H_1 receptor blockade reflects a reduction in oxidative metabolism. Studies of rat and dog jejunum suggest that endogenous prostaglandins may also play a role in postprandial hyperemia. [115], [116], [117] and [118] The cyclooxygenase inhibitors indomethacin and mefenamic acid greatly enhance food-mediated increases in blood flow and oxygen uptake, whereas arachidonic acid attenuates these responses. [115], [116] and [117] Jejunal production of prostaglandins I_2, E_2, and F_2 and thromboxane A_2 increases during nutrient absorption. Addition of arachidonate to food attenuates the release of the former two and enhances the release of the latter two substances, thereby attenuating food-induced jejunal hyperemia. [118] The available data suggest that prostaglandins are produced during the postprandial state, and these cyclooxygenase products tend to limit the increase in blood flow, either by inhibiting oxidative metabolism or by a direct vasoconstrictor action. Attention has been devoted to the potential role of endothelial cell–derived factors in the regulation of gastrointestinal blood flow. Vascular endothelial cells are known to produce agents that act on the underlying smooth muscle to promote protein phosphorylation, leading in turn to a decrease in smooth muscle tone. [119] Nitric oxide (NO) is a potent endothelial cell–derived vasodilator that is synthesized from L-arginine by the enzyme NO synthase. [120], [121] NO produced by endothelial cells diffuses to adjacent vascular smooth muscle, where it binds to soluble guanylate cyclase, which in turn increases the production of cGMP, with subsequent relaxation of smooth muscle (Fig. 22-10). [122] Endothelial cells contain both a constitutive and an inducible form of NO synthase. The constitutive form of the enzyme is Ca^{2+}/calmodulin– and NADPH-dependent, [123] and it produces NO in response to receptor (e.g., acetylcholine) or physical (e.g., shear stress) stimulation. [124], [125] The inducible form of NO synthase is increased in response to certain stimuli that act directly on endothelial cells (e.g., cytokines). The inducible form of the enzyme can produce larger quantities and a more sustained release of NO. The requirement of NO synthase for L-arginine appears to be absolute, in as much as L-arginine or analogs of L-arginine (N^G-monomethyl-L-arginine [L-NMMA], N^G-nitro-L-arginine-methyl ester [L-NAME]) do not act as substrates. Consequently, L-arginine analogs have been used in experimental animals to inhibit NO synthase. [123], [126] Inhibition of NO synthase has been used to demonstrate that endogenous NO mediates the intestinal hyperemic response to intralumenal bile-oleate, because NO synthase inhibition reduces the magnitude of the hyperemic response. [127]

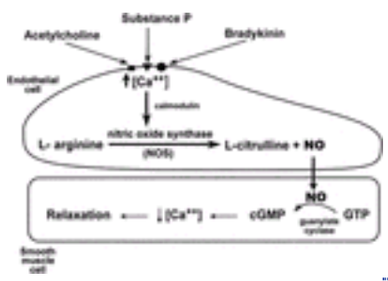

FIGURE 22-10. Mechanism of nitric oxide (NO)–mediated relaxation of vascular smooth muscle. NO generation by the endothelial cell enzyme NO synthase is induced by certain stimuli, such as acetylcholine, substance P, and shear stress. The endothelial cell–derived NO produced by these stimuli readily diffuses into the underlying smooth muscle cells, where it binds to and consequently activates soluble guanylate cyclase (sGC). The cGMP produced by sGC promotes smooth muscle relaxation by lowering intracellular calcium.

The mechanism for NO mediation of intrinsic regulation of gastrointestinal blood flow has not been well defined. In vitro studies using monolayers of cultured endothelial cells indicate that the rate of production of NO is influenced by physical forces such as shear rate and transmural pressure. [124], [125] The production of NO by endothelial cells appears to be directly coupled to shear rate, yet it is inversely related to transmural pressure. The relation between NO production and shear rate does not favor a role for NO in the gastrointestinal vasodilation associated with reductions in local arterial pressure (i.e., pressure-flow autoregulation); however, the increased NO production that would be elicited by a decline in endothelial cell transmural pressure may provide a chemical basis for the phenomenon of pressure-flow autoregulation. Nonetheless, it has been demonstrated that the autoregulatory capacity in the superior mesenteric artery is attenuated by NO, favoring a more profound influence of shear rate than transmural pressure on NO production in the vasculature of the superior mesenteric artery. [128] The contribution of NO to basal vascular tone in the gastrointestinal tract has been demonstrated with analogs of L-arginine. Inhibition of NO synthase reduces resting blood flow in the gastrointestinal tract. [129] The endothelium-dependent relaxation of gastric vascular smooth muscle by agents such as acetylcholine and bradykinin is also attenuated by inhibitors of NO synthesis. [126] In fetal [130] and developing [131] intestine, inhibition of NO synthase demonstrates that NO is an important regulator of basal intestinal vascular tone. The NO-cGMP axis in the regulation of intestinal vascular resistance is more important in 3-day-old than in 35-day-old swine. [131] A growing body of evidence indicates that NO mediates the gastrointestinal hyperemia associated with conditions as diverse as portal hypertension and central vagal stimulation. [132], [133] and [134] Inactivation of the NO that is basally produced by endothelial cells may also explain the increased vascular resistance that is observed after reperfusion of ischemic tissues. Superoxide rapidly and efficiently inactivates NO [135]; consequently, conditions associated with an accelerated production of superoxide [136] (e.g., ischemia and reperfusion) may abolish endothelium-dependent vascular tone and reduce blood flow. Interpretation of the blood flow responses to NO synthase inhibitors is complicated by the actions of these agents on circulating blood cells. The NO produced by endothelial cells appears to play an important role in preventing the intravascular adhesion and aggregation of platelets and leukocytes. [137], [138] and [139] Inhibitors of NO synthesis promote the adhesion and aggregation of platelets and leukocytes within the microcirculation. [139] A potential consequence of these events is increased vascular resistance secondary to obstruction of microvessels with platelet-leukocyte aggregates.

Extrinsic Control

Blood flow within the gastrointestinal tract is also influenced by extrinsic neurohumoral factors. Because the splanchnic organs receive about 25% of the cardiac output and contain about 25% of the total blood volume at rest, neurohumoral control of the splanchnic vascular bed can be an important component in the overall reflex control of the circulation, especially during periods of stress, such as exercise and shock. [140]

Neural Control Neural control of intestinal blood flow occurs predominantly by way of sympathetic noradrenergic nerves. [141] Extrinsic cholinergic nerves from the vagus do not supply the intestinal vasculature, [142], [143] but the myriad extravascular actions of parasympathetic stimulation in the gastrointestinal tract may indirectly affect blood flow. A local, intramural vasodilator nervous pathway also appears to exist within the intestine and causes an increase in intestinal blood flow after local electrical or mechanical stimulation of the mucosa. [144], [145] This response is blocked by tetrodotoxin or lidocaine, but not by autonomic denervation.

Autoregulatory Escape Autoregulatory escape (Fig. 22-11) [28] is a phenomenon in which stimulation of sympathetic nerves or intraarterial infusion of norepinephrine produces an initial intense vasoconstriction and decrease in blood flow, followed by a return (i.e., escape) of blood flow toward baseline levels despite continued nerve stimulation or norepinephrine infusion. Discontinuation of stimulation or infusion results in poststimulatory hyperemia.

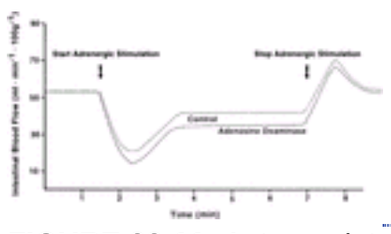

FIGURE 22-11. Autoregulatory escape from adrenergic stimulation in autoperfused piglet small intestine. Adenosine de-aminase pretreatment reduced the steady-state escape response to norepinephrine infusion, whereas pretreatment with chlorpheniramine, a histamine H_1 blocker, had no effect. (Data from ref. [28].)

Autoregulatory escape in the intestine was first described by Folkow and colleagues in 1964, [146] but the mechanism of the phenomenon is still not completely understood. Autoregulatory escape occurs only in arteriolar smooth muscle, not in venous smooth muscle. [146] It is unaltered by ß-receptor blockade [147] and administration of atropine. [148] In growing animals, there are conflicting reports regarding the ability of the intestine to escape from nerve stimulation. In one study, [149] the intestine of swine younger than 2 weeks of age did not undergo autoregulatory escape, whereas in another study, no difference in intestinal autoregulatory escape was observed between 3-day-old and 35-day-old piglets. [150] Three mechanisms commonly invoked to explain autoregulatory escape are redistribution of blood flow from the mucosa to the submucosa, adaptation of adrenergic receptors to continued nerve stimulation, and accumulation of vasodilator metabolites. The first possibility of blood flow redistribution has not been substantiated, as demonstrated by in vivo microscopic studies in which the vessels that initially constrict subsequently relax during the steady-state escape phase. [151] Adaptation of adrenergic receptors is also unlikely, because infusion of norepinephrine during the steady-state escape phase of sympathetic erve stimulation leads to further vasoconstriction and a second escape. [147] The most popular theory used to explain autoregulatory escape is that vasodilator metabolites accumulate during the initial vasoconstrictor phase, leading to arteriolar dilation and consequent restoration of blood flow toward normal. [147], [152], [153] and [154] The metabolic theory of intestinal vasoregulation states that tissue metabolism and arteriolar smooth muscle constitute a local control system that provides the necessary coupling between blood flow and tissue nutritional requirements. Any condition causing an imbalance between oxygen supply and demand will produce an outpouring of metabolites into the interstitial fluid. The metabolites then diffuse to the arterioles and precapillary sphincters to cause vasodilation and capillary recruitment. The increased blood flow or oxygen extraction restores oxygen supply to a level compatible with tissue oxygen demand. [155] Consistent with this theory is experimental evidence that the propensity for blood flow to escape from sympathetic vasoconstriction is significantly greater in the metabolically active mucosa than in the muscularis. [156] Adenosine appears to play at least a partial role in autoregulatory escape (see Fig. 22-11) [28]; however, a role for histamine [28], [148] and prostaglandins [148] has not been substantiated. Evidence also implicates a role for vasodilator peptidergic neurons in effecting autoregulatory escape after sympathetic nerve stimulation but not during infusion of norepinephrine. [157], [158] One neurotransmitter substance produced by these fibers is VIP. [112]

Circulating Vasoactive Substances Circulating vasoactive substances that affect gastrointestinal blood flow include adrenergic agents, vasopressin, and angiotensin. Norepinephrine, a predominantly a-adrenergic receptor stimulant, causes intestinal vasoconstriction, a decrease in capillary density, and a reduction in oxygen uptake. [154], [159], [160] With continuous intraarterial infusion, the intense initial vasoconstriction is followed by the return of blood flow toward control levels despite continued norepinephrine infusion (see previous section " Autoregulatory Escape"). Epinephrine can cause either a-receptor–mediated vasoconstriction at high doses or ß-receptor–mediated vasodilation at low doses, as well as a variable response in oxygen uptake. [154], [161], [162] Both vasopressin and angiotensin II are potent physiological vasoconstrictors that reduce blood flow and increase vascular resistance in all gastrointestinal organs. These agents cause generalized vasoconstriction, with a disproportionate selective reduction in mesenteric blood flow at doses that have been measured in pathophysiological states of hypotension. [163] Vasopressin causes a decrease in capillary density and a reduction in intestinal oxygen uptake, whereas angiotensin II reduces or does not affect [164] splanchnic oxygen uptake. In normal rat intestine, a-adrenergic and vasopressin activity account for most extrinsic vasoconstrictor tone, whereas vasopressin and angiotensin II account for most extrinsic vasoconstrictor tone in portal hypertensive rat intestine. [165] Renin-angiotensin and vasopressin systems are also involved in the intestinal vasoconstrictor response to hemorrhage and hypovolemia, and significant attenuation of this increase in vascular resistance occurs only when both systems are blocked simultaneously, [166], [167] even in the presence of an intact sympathetic system. Furthermore, angiotensin does not affect the mesenteric circulation indirectly through activation of the sympathetic nervous system or by promoting vasopressin release; it plays a physiologically important, direct role in the control of mesenteric blood flow after volume depletion. [168]

Oxygen Uptake–Blood Flow Relation: Functional Implications

Considerable attention has been devoted to the interaction between gastrointestinal blood flow and oxygen uptake, and the relevance of this interaction to mucosal function and integrity. Figure 22-12 depicts the observed relation between intestinal blood flow and oxygen uptake when blood flow is altered with a pump or by graded reductions in perfusion pressure. [20] Oxygen uptake remains virtually constant over a wide range of blood flow levels (i.e., it is independent of blood flow), and it is compromised only when blood flow reaches a critically low level. Below this level, oxygen uptake is dependent on blood flow. Resting blood flow in the small intestine, stomach, and colon is usually greater than the critical blood flow at which oxygen uptake is dependent on blood flow. [13], [18], [169], [210]

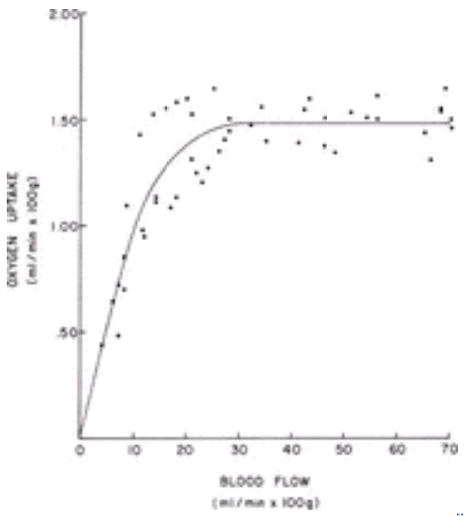

FIGURE 22-12. Relation between intestinal blood flow and oxygen uptake in feline jejunoileum when blood flow is altered with a pump or by graded reductions in perfusion pressure. (From ref. [20].)

The reduction in oxygen uptake that occurs when blood flow falls below a critical level can be explained in terms of the normal relation between mitochondrial oxygen consumption and cell PO_2. This relation predicts that oxygen uptake remains constant over a wide range of cell PO_2 levels, and uptake is reduced only when cell PO_2 falls to a low level, the critical PO_2. The resting cell PO_2 is normally well above the critical PO_2. Evidence indicates that graded reductions in blood flow produce concomitant reductions in cell PO_2 without altering oxygen uptake in the stomach. [164] At very low rates of blood flow, however, the rate of oxygen diffusion to the cells is so low that the intracellular PO_2 falls below the level required to maintain normal oxidative metabolism. The reduction in oxygen uptake observed at low blood flow

may simply reflect a depression in oxidative metabolism caused by the limited oxygen availability.

Many conditions alter the relation between oxygen uptake and blood flow such that oxygen uptake is dependent on blood flow even when it is increased above normal. These include lumenal distention, [170] alterations in hematocrit, [171] and devascularization. [40] All these conditions are thought to reduce tissue oxygenation severely in discrete or generalized regions of the stomach or gut. Lumenal distention and devascularization reduce tissue oxygenation by compromising blood flow, whereas a low hematocrit limits oxygen delivery, even at high blood flows. Normal physiological conditions can also influence the relation between oxygen uptake and blood flow. Stimulation or inhibition of oxidative metabolism will shift the plateau of the blood flow–oxygen uptake curve upward or downward, respectively (Fig. 22-13). [164] Stimulation of intestinal motility or enhancement of active transport raises the plateau of the blood flow–oxygen uptake curve. [172] Conversely, decreasing the temperature of isolated bowel segments lowers the plateau.

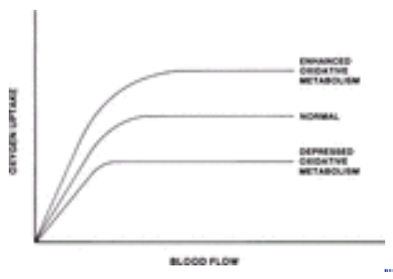

FIGURE 22-13. Relation between blood flow and oxygen uptake during stimulation or inhibition of oxidative metabolism. (From ref. [164].)

Another important aspect of the blood flow–oxygen uptake relation in the small bowel is that it will predict the influence of blood flow reductions on oxygen-requiring processes, such as absorption and secretion. For example, it has been shown that the reductions in glucose absorption produced by graded decrements in blood flow parallel the decline in oxygen uptake, [173] suggesting that oxygen availability limits solute transport when cell PO_2 falls.

Many vasodilators tend to increase intestinal oxygen uptake, irrespective of their effects on oxidative metabolism. These observations have been attributed to the use of preparations in which oxygen uptake is dependent on blood flow. If vasodilators are infused into these preparations, the increase in oxygen uptake would be expected to parallel the increase in blood flow. Vasodilators will not alter oxygen uptake in preparations in which oxygen uptake is independent of blood flow unless an effect is exerted on the oxidative metabolism. In general, vasoconstrictors decrease oxygen uptake in preparations exhibiting either a normal or abnormal relation between blood flow and oxygen uptake, unless the agent enhances oxidative metabolism. Vasoconstrictors that do not affect oxidative metabolism would be expected to decrease oxygen uptake by simply moving down the normal blood flow–oxygen uptake curve.

Another important determinant of the rate of oxygen exchange across capillaries is the effective capillary density. The number of capillaries perfused at any given time determines the flux of oxygen out of the capillary and into the tissue through an effect on diffusion parameters (i.e., surface area available for exchange and capillary-to-cell diffusion distances). The expected influence of capillary density on the relation between blood flow and oxygen uptake is shown in Figure 22-14. If capillary density within an organ is increased, the minimum blood flow required to attain the plateau of the blood flow–oxygen uptake curve will be lower (i.e., the curve will be shifted to the left) as a result of an increased capillary surface area and a reduced capillary-to-cell diffusion distance. [164]

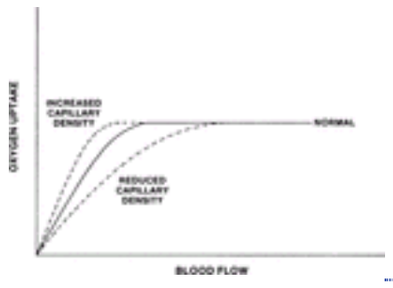

FIGURE 22-14. Relation between oxygen uptake and blood flow under conditions of increased or reduced perfused capillary density. (From ref. [164].)

The relation between blood flow and oxygen uptake has also been useful in explaining some of the reported observations regarding the influence of blood flow on gastric acid secretion. [174] The production of gastric acid is an energy-consuming process that results in an increase in gastric oxygen uptake. The consistent finding that acid secretion and oxygen consumption are highly correlated raises the question of whether acid secretion in the stomach is dependent on blood flow. The answer to this question largely depends on the surgical preparation used. In some preparations, a number of vessels supplying the stomach are occluded, and the end result is flow-dependent oxygen uptake. In this situation, an increase or decrease in blood flow is associated with a corresponding change in acid secretion. In normally perfused preparations, however, acid secretion and blood flow exhibit a relation similar to that observed between oxygen consumption and blood flow; acid secretion is dependent on blood flow at low blood flow rates and is independent at higher flow rates. This explains why vasoconstrictors tend to reduce gastric acid output and why some vasodilators (i.e., acid secretagogues) increase acid output whereas others (i.e., nonsecretagogues) do not. The controversy regarding the relation between gastric acid output and blood flow cannot be resolved entirely on the basis of tissue oxygenation. Most of the reports that demonstrate a relation between blood flow and acid secretion have relied on the aminopyrine clearance technique for measurement of blood flow. It is now well recognized that aminopyrine clearance reflects acid output by the stomach more accurately than it does blood flow to the stomach.

Recognition is increasing of the importance of determining both intestinal blood flow and oxygen uptake in developmental studies. Evaluation of age-related differences in intestinal blood flow has received significant attention because of a disease, neonatal necrotizing enterocolitis (NEC), and the belief that mesenteric ischemia plays a role in its pathogenesis. The capacity for regulation of blood flow does not provide information about the ability of the intestine for oxygen extraction when blood flow falls; therefore, conclusions based on blood flow data alone regarding the susceptibility of developing intestine to tissue hypoxia and subsequent mucosal injury may be erroneous. This concept is illustrated in Figure 22-15, in a study of the developmental cardiovascular and oxygenation responses to lumenal nutrients. [80] Blood flow does not increase with feeding in 1-day-old piglet intestine, but oxygen extraction increases so dramatically that oxygen uptake is not different among age groups (1 day–1 month) 30 minutes postprandially.

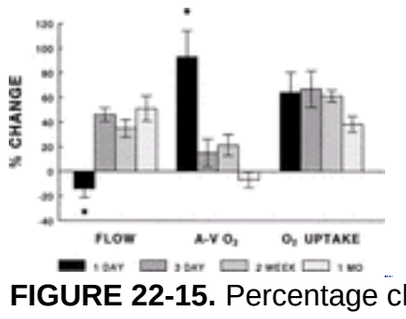

FIGURE 22-15. Percentage change from zero time in intestinal blood flow, arteriovenous oxygen ($A\text{-}V\,O_2$) content difference, and oxygen (O_2) uptake at 30 minutes after lumenal instillation of a predigested and bile acid–solubilized cows' milk–based artificial pig formula. * P <.05 for 1-day-old piglets versus older age groups. (From ref. [80].)

PHYSIOLOGY AND BIOCHEMISTRY OF ISCHEMIA

Ischemic damage to the intestine occurs when splanchnic blood flow falls to a level at which delivery of oxygen and other nutrients is insufficient to maintain oxidative metabolism and hence cell integrity. Blood flow to the gastrointestinal tract may be reduced during generalized nonocclusive ischemia (e.g., circulatory shock and congestive heart failure, especially in patients treated with cardiac glycosides) and in occlusive disorders (e.g., embolism, atherosclerosis, thrombosis) that primarily involve the mesenteric circulation. The mortality of acute mesenteric ischemia in adults has been reported at 70% to 90%, [175] primarily because of the difficulty of making an early diagnosis before bowel infarction occurs. Surgical intervention (e.g., embolectomy, intestinal resection) [176] and local intraarterial infusion of vasodilators (e.g., papaverine) [177] are used to treat acute mesenteric ischemia, but the mortality of this disease continues to be significant. Experimental nonocclusive mesenteric ischemia in dogs has been treated successfully with intravenously administered selective mesenteric vasodilators (e.g., urotensin I, sauvagine, and corticotropin-releasing factor), [178] thereby potentially obviating the risk of an indwelling angiographic catheter, but the use of these drugs in humans remains to be investigated.

Mesenteric ischemia also appears to play a role in NEC, a disease that predominantly affects the ileum and colon of premature infants, with an average 40% mortality, and can result in short-bowel syndrome and intestinal strictures. The pathogenesis of NEC is unknown, but enteral alimentation, infectious agents and immune factors, and mesenteric ischemia and tissue hypoxia have been rumored to be primary initiators of the disease. [179], [180]

Alterations of Intestinal Morphology with Ischemia

The response of the intestine to decreased blood flow can range from no damage to transmural necrosis, [181] and a gradient of sensitivity to ischemic injury has been demonstrated from the villus tips to the muscularis. [181], [182] and [183] Mesenteric ischemia is associated with characteristic mucosal lesions that progress from subepithelial edema within 30 minutes after total vascular occlusion, to loss of epithelial cells along the villus after 1 hour of total occlusion, to total loss of villi after 2 hours of occlusion. [181], [182] Within 30 to 60 minutes after total mesenteric artery occlusion, changes indicative of cellular failure appear, such as mitochondrial vacuolization and decreased oxygen uptake, loss of adenosine triphosphate, and release of lysosomal enzymes. [183]

Changes in Vascular and Mucosal Permeability with Ischemia

Increases in the capillary filtration coefficient and microvascular permeability in the small intestine have been observed after ischemia. [184] The osmotic reflection coefficient of ileal capillaries to plasma proteins decreases after 1 hour of ischemia and reperfusion; this is indicative of increased vascular permeability. Furthermore, the increase in permeability is derived from an increase in the number of large (200 Å) pores; the small-pore (50 Å) population is unaffected. In the intestine, the increase in the capillary filtration coefficient observed after ischemia and reperfusion is not solely a result of increased capillary surface area.

Increases in mucosal permeability induced by ischemia and reperfusion have been estimated based on the clearance of solutes ranging from 700 to 70,000 d. [26], [185] The ischemia/reperfusion–induced increases in mucosal permeability are dependent on both the duration and severity of the ischemic insult (Fig. 22-16). [186] Mucosal permeability increases significantly after 1 to 2 hours of mesenteric artery occlusion in adult animals.

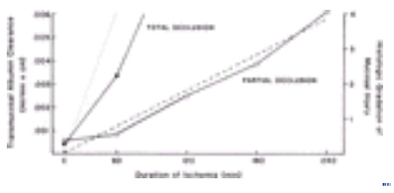

FIGURE 22-16. Comparison of quantitative morphologic data (*dotted* and *broken lines*) and mucosal albumin clearance results (*solid lines*). (From ref. [186] .)

In growing intestine, a similar correlation is observed between the duration of ischemia and the magnitude of the increase in clearance of 358-d ^{51}Cr-EDTA during reperfusion. [187] The extent of reperfusion-induced injury in the absence of lumenal nutrients is similar among groups of young swine ranging in age from 1 day to 1 month, but perfusion of the ileal lumen with cows' milk–based formula causes a significantly larger increase in mucosal permeability in 1-day-old swine than in all older age groups. [187] This increased permeability can be attributed to the lipid component of formula (Fig. 22-17). [188] Furthermore, lumenal perfusion with predigested and bile acid–solubilized premature human infant formula, combined with ischemia and reperfusion of the superior mesenteric artery, leads to an animal model of NEC in 1-day-old piglet intestine. The necrotic injury does not occur unless the lipid fraction of the formula is present, nor does it occur in 1-month-old animals. [189] The chemical composition of fatty acids appears to be the most important determinant of this lipid-associated mucosal injury. [190]

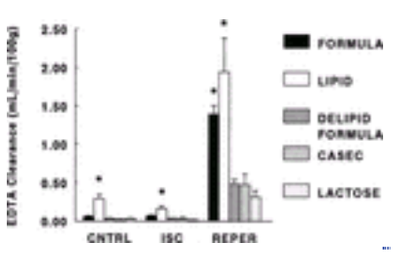

FIGURE 22-17. Comparison of ^{51}Cr-labeled EDTA clearance among nutrient solutions groups in 1-day-old piglet distal jejunoileum during 1 hour each of control (*CNTRL*), ischemia (*ISC*), and reperfusion (*REPER*). The nutrient solutions were all predigested and bile acid–solubilized and included cows' milk–based artificial pig formula, 5% corn oil, delipidated pig formula, 2.3% Casec (Mead Johnson Nutritionals), and 7% lactose. * P <.05 versus other nutrients within a time period. (From ref. [188] .)

Blood Flow, Oxygenation, and Ischemic Injury

Ischemic injury to the intestine occurs when blood flow is reduced to a level at which delivery of oxygen and other nutrients to the tissue is compromised. Although the correlation of tissue PO_2, mucosal blood flow, and mucosal injury has not been investigated, reduction of blood flow to levels that do not affect oxygen uptake are not associated with any evidence of mucosal damage in adult animals. [27] Furthermore, substantial increases in mucosal albumin clearance are not seen until the blood flow falls to levels at which oxygen consumption is reduced by approximately 50% (Fig. 22-18). [27]

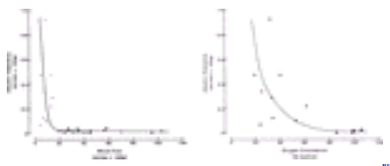

FIGURE 22-18. Relation between blood flow during control (*closed circles*) and ischemia (*open circles*) and mucosal albumin clearance during reperfusion of canine jejunum (**left**). Relation between intestinal oxygen consumption during control and ischemia and mucosal albumin clearance during reperfusion of canine jejunum (**right**). Substantial increases in albumin clearance were not seen unless blood flow was reduced to below 20 mL·min $^{-1}$·100 g $^{-1}$ or oxygen consumption was reduced to approximately one-half that of the control values. (From Bulkley GB, Kvietys PR, Parks DA, et al. Relationship of blood flow and oxygen consumption to ischemic injury in the canine small intestine. Gastroenterology 1985;89:852.)

Neonatal intestine, which has a limited capacity to maintain oxygen uptake during reductions in perfusion pressure, arterial hypoxia, and hemorrhage, and during the combined stresses of hypoxemia and feeding, ischemia/reperfusion, and reductions in perfusion pressure, has been shown to be more vulnerable to mucosal injury induced by ischemic cardiovascular stress than the intestine of older animals. [187], [188] and [189], [191], [192] This suggests, but does not prove, a relation between tissue hypoxia and mucosal injury.

The importance of collateral blood flow in the prevention of intestinal ischemia is well recognized in humans [193], [194] and [195] and adult animals. [21], [196], [197] Intestinal collateral blood flow may occur through anastomotic connections at several levels of vessel branching, including the main arterial trunks (i.e., celiac, superior, and inferior mesenteric arteries), [21], [193] extramural vessels (i.e., arterial arcades, marginal arteries), [197], [198] and intramural vascular plexuses located within the intestinal wall itself. [193], [198] Quantitative studies in adult animals have demonstrated that collateral channels among the major arterial trunks and between adjacent bowel segments both play a role in the prevention of intestinal ischemia. In the adult cat, perfusion through collateral vessels after occlusion of the superior mesenteric artery maintained flow to the small intestine and proximal colon to within 30% to 65% of preocclusion flow. [21] However, the efficiency of collateral perfusion by way of the celiac and inferior mesenteric arteries is substantially lower in dogs after superior mesenteric artery occlusion. [196] In adjacent segments of canine small bowel, collateral vessels maintain blood flow in one segment at approximately 55% of its control level when the artery to that segment is totally occluded. The percentage of collateral flow attributed to extramural vessels is 67%, whereas that attributed to intramural vessels is 33%. [197] In developing piglet intestine, after occlusion of a distal branch of the superior mesenteric artery, total wall and mucosal and submucosal blood flow is reduced by 70% in 1-day-old animals, compared to a 25% decrease in 1-month-old animals. This finding suggests that newborn rather than adult intestine may be at greater risk for ischemic injury because of poorly developed or inefficient collateral blood vessels.

Possible Mechanisms of Injury or Villous Necrosis

Ischemic injury in the intestine appears to be related, either primarily or secondarily, to the effects of tissue hypoxia. In some species, the hypoxic stress induced by ischemia is exacerbated by the presence of a countercurrent exchange mechanism. [7] A role for hypoxia is supported by the observation that intralumenal perfusion with oxygenated saline solution markedly attenuates mucosal injury during ischemia induced by hypotension, [199] whereas perfusion with nitrogenated saline solution does not attenuate injury. Possible mechanisms of mucosal injury induced by tissue hypoxia include depletion of high-energy phosphates necessary to produce protective substances, such as mucus, leading to increased susceptibility to the action of intralumenal proteases [200]; accumulation of histamine, leading to increased microvascular permeability [201]; production of metabolic acidosis, leading to release of lysosomal enzymes and cellular digestion [202]; conversion of xanthine dehydrogenase to xanthine oxidase, an enzyme that can produce cytotoxic oxygen-derived free radicals during reoxygenation [203]; and attraction of circulating granulocytes into the mucosa, or activation of resident leukocytes within the mucosa, with release of neutrophilic proteases and oxidants to initiate or propagate mucosal injury. [204]

It has been demonstrated that changes in the intestinal mucosa induced by circulatory shock lead to an increased vulnerability to the digestive action of trypsin and chymotrypsin. Inhibition of pancreatic proteases by aprotinin [205] or previous ligation of the pancreatic ducts [206] significantly attenuates ischemic mucosal injury. In addition, an intralumenal injection of trypsin exacerbates mucosal injury. [205] The digestive action is caused by enzymes already present along the intestinal wall before shock, because removal of the pancreas has no effect if the animal is subjected to shock immediately after pancreatectomy. [207] Inhibition of pancreatic elastase and bile salts, both of which contribute to the loss of protective brush border glycoproteins, [208], [209] decreases mucosal injury. It has been proposed that if impairment of mesenteric blood flow prevents the steady regeneration of these brush border glycoproteins, then the mucosa becomes accessible to the digestive action of the pancreatic endopeptidases present along the intestinal wall and lumen. [200] It is generally believed, however, that pancreatic proteases are not the primary mediators of ischemic injury in the small bowel.

A possible role for histamine in the pathogenesis of mucosal injury during intestinal ischemia arises from its known capability to increase microvascular permeability to macro-molecules [51], [201], [210] and the finding that the plasma histamine concentration is elevated after reperfusion of ischemic intestine. [211] Furthermore, inhibition of diamine oxidase, a histamine-catabolizing enzyme present in large quantities in the superficial epithelial cells of the intestinal mucosa, reduces survival in dogs [212] and rabbits [213] subjected to intestinal ischemia. It appears unlikely, however, that histamine is a mediator of ischemic injury in the small intestine, based on the failure of histamine H_1 and H_2 receptor antagonists to attenuate the increased vascular permeability resulting from ischemia and reperfusion of the intestine. [214] Histamine is also a potent vasodilator, and this effect should decrease, rather than increase, mucosal injury resulting from mesenteric ischemia. [161]

Because most lysosomal enzymes have an acid optimal pH, it has been postulated that ischemia-induced metabolic acidosis may stimulate the release of hydrolytic enzymes from lysosomes. Elevated plasma levels of lysosomal enzymes have been reported in association with acute mesenteric ischemia. [202] Although it has also been postulated that massive doses of corticosteroids administered to patients in a state of shock attenuate the hypoxia-induced lability of lysosomal membranes, [202] no well-controlled studies have demonstrated a beneficial effect of corticosteroid treatment of shock. The reperfusion-induced increase in microvascular permeability after mesenteric ischemia also is not attenuated by pretreatment with methylprednisolone. [214]

A role for reactive oxygen metabolites in the pathogenesis of injury associated with reperfusion of the ischemic bowel has received considerable attention during the past 20 years. Reactive oxygen metabolites play an important role in normal cellular metabolism, most notably as intermediates in mitochondrial and microsomal electron transport systems. [215] More than 90% of the molecular oxygen consumed by most cells is reduced by the mitochondrial electron transport chain to form water, and the remaining oxygen is metabolized to reactive oxygen species. Under normal conditions, tissues are protected from these oxygen-derived free radicals by the action of certain antioxidant enzymes and scavengers.

In adult animals, the digestive system is particularly well endowed with the enzymatic machinery capable of generating significant quantities of reactive oxygen metabolites. For example, the intestine and liver are the richest sources of xanthine oxidase, [216] an enzyme that catalyzes the production of both superoxide and hydrogen peroxide. Xanthine oxidase activity in the small intestine is located primarily within the mucosa, with a gradient of activity from villus tip to base. [217] In addition, the intestine contains a large, resident population of phagocytic cells (i.e., neutrophils, eosinophils, macrophages), which, when activated, produce considerable quantities of superoxide, hydrogen peroxide, and hypochlorous acid. [218] Oxidants generated by either xanthine oxidase or activated phagocytes can injure cells by a variety of mechanisms, including lipid peroxidation, degradation of the extracellular matrix, protein and carbohydrate decomposition, and DNA strand breakage. [215] Cellular enzymatic defense mechanisms against these oxidants include superoxide dismutase, which converts the superoxide anion to hydrogen peroxide and oxygen, and catalase and glutathione peroxidase, which detoxify hydrogen peroxide. [219] Another important oxidant defense is reduced glutathione, which serves both as a cosubstrate for the glutathione peroxidase–catalyzed decomposition of hydrogen peroxide and as a free radical scavenger. [215]

A large body of experimental data supports the hypothesis that reactive oxygen metabolites mediate the microvascular and mucosal permeability changes after reperfusion of the ischemic intestine and stomach in adult animals. [204], [220], [221], [222], [223] and [224] Increased intestinal vascular permeability produced by ischemia and reperfusion injury is not attenuated by antihistamines, indomethacin, or methylprednisolone, arguing against a role for histamine, prostaglandins, and lysosomal enzymes in this injury. [219] In contrast, superoxide dismutase (which scavenges superoxide anions), catalase (which detoxifies hydrogen peroxide), and dimethylsulfoxide (which scavenges hydroxyl radicals and decomposes hypochlorous acid) attenuate the vascular permeability changes observed after reperfusion of the ischemic intestine. [220]

A role for xanthine oxidase in the increased vascular permeability and morphologic changes induced by reperfusion has been proposed based on the following observations: attenuation of injury by pretreatment with allopurinol or pterin aldehyde, which are inhibitors of xanthine oxidase [221], [225], [226]; increased vascular and mucosal permeability during intraarterial infusion of hypoxanthine-xanthine oxidase, a superoxide anion–generating system [227]; attenuation of injury by soybean trypsin inhibitor, a substance that prevents the conversion of xanthine dehydrogenase to xanthine oxidase [222]; and attenuation of reperfusion injury by administration of a tungsten-supplemented, molybdenum-deficient diet, which inactivates xanthine oxidase. [228] In the intestine of developing piglets, however, the total absence of xanthine dehydrogenase/oxidase activity precludes its role in intestinal ischemia and reperfusion injury. [229]

Evidence to support a role for granulocyte-mediated injury after ischemia and reperfusion is also accumulating. Ischemia may lead to neutrophil activation, release or production of neutrophilic oxidants (e.g., superoxide, hydrogen peroxide, hypochlorous acid, *N*-chloramines) and proteases, and subsequent tissue injury. [218], [230], [231] and [232] A five- to sevenfold increase in myeloperoxidase activity, which is an index of granulocyte number, occurs during ischemia, whereas reperfusion induces an 18-fold increase in myeloperoxidase activity in feline intestine. [223] Both neutrophil depletion and prevention of neutrophil adherence significantly attenuate the increased intestinal microvascular permeability induced by ischemia and reperfusion in cat intestine, [204] suggesting that neutrophils, which migrate into the mucosa, mediate the injury produced by reperfusion of the ischemic bowel.

It has also been proposed that xanthine oxidase–derived oxidants may serve as chemoattractants for granulocytes in postischemic adult intestine. Allopurinol (an inhibitor of xanthine oxidase), [218] superoxide dismutase (a superoxide scavenger and inhibitor of neutrophil adherence), [218] catalase (a scavenger of hydrogen peroxide), [233] deferoxamine (an iron chelator), [233] dimethylthiourea (a hydroxyl radical scavenger), [233] and IB $_4$ (a CD18-specific monoclonal antibody inhibitor of neutrophil adherence) [234] all inhibit reperfusion-induced granulocyte accumulation in the small intestine.

Neonatal swine intestine contains significantly fewer resident granulocytes than does that of older piglets, a fact that does not support the theory that neonatal intestine is more vulnerable to oxidant-induced injury than that of older animals. [229] This lower number of resident granulocytes in the mucosa does not preclude the possibility of injury induced by resident granulocytes or granulocytes recruited into the tissue during ischemia or other stresses.

The view that leukocyte–endothelial cell adhesion plays an important role in the pathogenesis of ischemia and reperfusion injury, as well as in other inflammatory conditions of the gastrointestinal tract, [235], [236] has led to an increased interest in defining the factors that modulate leukocyte adherence and emigration in postcapillary venules. Intravital microscopic techniques have been used to monitor and quantify leukocyte–endothelial cell adhesion in mesenteric venules exposed to 60 minutes of ischemia and 60 minutes of reperfusion. [237] During the final 10 minutes of a 60-minute 80% reduction in mesenteric blood flow, the numbers of adherent and emigrated leukocytes increase by fourfold and threefold, respectively. At 60 minutes after reperfusion, sevenfold and eightfold increases in adherence and emigration are noted. Electron microscopic analyses of postischemic mesenteric venules reveal that more than 85% of the leukocytes that emigrate into the adjacent interstitial compartment are neutrophils. [238]

Several chemical mediators produced by endothelial or parenchymal cells have been implicated in the leukocyte–endothelial cell adhesion elicited by mesenteric ischemia and reperfusion. A growing body of evidence implicates xanthine oxidase–derived superoxide as a major mediator in this process. A role for superoxide is supported by reports that superoxide dismutase, whether administered before ischemia or after reperfusion, effectively reduces the number of adherent and emigrated leukocytes in mesenteric venules exposed to ischemia and reperfusion. [237], [239] Superoxide dismutase is also effective in attenuating the adherence of neutrophils to endothelial cell monolayers exposed to anoxia and reoxygenation. [239] However, superoxide dismutase is ineffective in altering neutrophil adhesion to biologically inert surfaces (e.g., plastic), indicating that endothelial cells are required for the enzyme's antiadhesive action. A similar antiadhesive action has been reported to occur with allopurinol, [237], [240] suggesting that xanthine oxidase is a likely source of the superoxide produced after reperfusion. Xanthine oxidase, rather than neutrophils, also appears to be responsible for generating the oxidants that mediate reperfusion-induced lipid peroxidation in intestinal mucosa. This contention is based on reports demonstrating that although both allopurinol and CD18-specific monoclonal antibodies prevent the reperfusion-induced increase in mucosal myeloperoxidase activity, only allopurinol prevents the rise in tissue conjugated dienes, an index of membrane lipid peroxidation. [241], [242]

The mechanism by which superoxide mediates reperfusion-induced leukocyte adherence and emigration within the mesenteric microcirculation has received much attention. The generation of superoxide on the surface of postcapillary venules of hamster cheek pouch by hypoxanthine-xanthine oxidase leads to leukocyte adherence, which can be prevented by superoxide dismutase. [243] Superoxide may promote leukocyte adherence by interacting with extracellular fluid to form a superoxide-dependent chemoattractant [244]; however, this possibility is not supported by studies demonstrating that exposure of intestinal interstitial fluid to superoxide does not generate a chemoattractant for neutrophils. [245] A more likely explanation for the proadhesive action of superoxide is that it inactivates an antiadhesion molecule that is normally produced by endothelial cells. NO, a product of L-arginine metabolism in endothelium that is rapidly inactivated by superoxide, may be such an endogenous antiadhesion molecule. NO donors are very effective in preventing the recruitment of leukocytes, platelet-leukocyte aggregation, and tissue injury associated with ischemia/reperfusion. [246] Inhibitors of NO production lead to a dramatic increase in the number of leukocytes adhering to and emigrating from mesenteric venules. [139] This adhesion response can be prevented or reversed by simultaneous exposure of venules to an NO synthase inhibitor and either L-arginine (but not D-arginine) or nitroprusside, which spontaneously generates NO. The observations that NO synthase inhibitors promote leukocyte adherence while superoxide dismutase reduces reperfusion-induced adherence are consistent with the view that the enhanced formation of superoxide by postischemic endothelial cells leads to NO inactivation and consequently results in enhanced leukocyte adhesion. Such a mechanism would explain why superoxide dismutase exerts an antiadhesive effect in postischemic tissues, because the enzyme would prevent inactivation of NO. NO also stabilizes mast cells through a mechanism that involves superoxide. [247]

Growing evidence indicates that in addition to protecting the microvasculature, endogenous NO regulates mucosal barrier integrity. [248] Inhibition of endogenous NO leads to increases in reperfusion-induced mucosal permeability, whereas exogenous sources of NO can reduce reperfusion-induced mucosal barrier dysfunction independently of alterations in intestinal blood flow. [249] Mucosal injury after hypothermic ischemia and reperfusion is also attenuated by exogenous sources of NO and therefore may be beneficial in intestinal allografts subjected to prolonged hypothermic ischemia. [250]

Catalase also has been shown to attenuate reperfusion-induced leukocyte adherence in mesenteric venules. [240] This observation is consistent with reports that demonstrate that hydrogen peroxide is produced by endothelial cell monolayers exposed to anoxia and reoxygenation, [251] and hydrogen peroxide promotes neutrophil adherence to cultured endothelial cells and in mesenteric venules. [252], [253] The levels of hydrogen peroxide required to promote adherence are well within the range of the hydrogen peroxide concentration produced by activated neutrophils. Both in vivo and in vitro studies indicate that hydrogen peroxide–induced neutrophil adherence is mediated by platelet-activating factor (PAF). [252], [253] PAF-receptor antagonists effectively attenuate the neutrophil adherence induced by hydrogen peroxide in feline mesenteric venules [234] and isolated canine carotid arteries. [254] The hydrogen peroxide–induced, PAF-mediated leukocyte adherence is prevented mostly by monoclonal antibodies directed against the common ß subunit of CD11/CD18.

The proposed role of reactive oxygen (hydrogen peroxide, superoxide) and nitrogen (NO) species in mediating the endothelium-dependent inflammatory responses observed in the gastrointestinal microcirculation after ischemia/reperfusion is summarized in Figure 22-19. Ischemia/reperfusion leads to an increased production of superoxide and hydrogen peroxide by the enzyme xanthine oxidase, with a corresponding reduced production of NO by endothelial NO synthase. The enhanced generation of oxidants results in the activation and deposition of complement, and phospholipase A $_2$–mediated production of leukotriene B $_4$ and PAF. Oxidants also mediate the initial expression of P-selectin by mobilizing the leukocyte rolling receptor from its preformed pool (Weibel-Palade bodies) in endothelial cells. Firm adhesion of leukocytes, which is mediated by ß $_2$-integrins (CD11/CD18), is induced by the engagement of activated complement, leukotriene B $_4$, and PAF with their receptors on rolling leukocytes. Sustained rolling and adhesion of leukocytes on endothelial cells is ensured by an oxidant-dependent synthesis of endothelial cell adhesion molecules, such as E-selectin and intracellular adhesion molecule-1 (ICAM-1). Oxidants, derived from either endothelial cells or leukocytes, elicit this biosynthetic response by activating specific nuclear transcription factors (e.g., nuclear factor-?B) that bind to the genes for these adhesion molecules. The inflammatory responses to ischemia/reperfusion are amplified by mediators released from mast cells and macrophages that normally reside near postcapillary venules. [255]

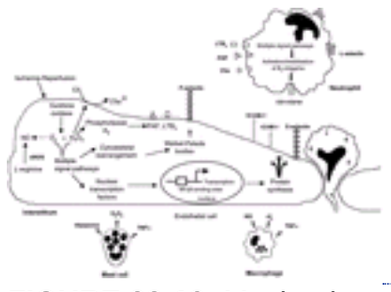

FIGURE 22-19. Mechanism proposed to explain the endothelium-dependent inflammatory responses observed in the postischemic microvasculature. *C5a*, complement 5a; *CD11/CD18*, leukocyte adhesion glycoprotein; *eNOS*, endothelial nitric oxide synthase; H_2O_2, hydrogen peroxide; *I/R*, ischemia/reperfusion; *ICAM*, intracellular adhesion molecule; LTB_4, leukotriene B_4; *NF-?B*, nuclear factor-?B; *NO*, nitric oxide; O^-_2, superoxide; *PAF*, platelet-activating factor; *TNF-a*, tumor necrosis factor-a; *VCAM*, vascular cell adhesion molecule. CHAPTER 23

Mark W. Babyatsky and Daniel K. Podolsky

GROWTH AND DEVELOPMENT OF THE GASTROINTESTINAL TRACT

Structural and functional integrity of the mature gastrointestinal (GI) tract results from a developmental program that derives from many levels of regulation and interactions. During embryonic and fetal life, the GI tract and its accessory organs evolve from a single, nondescript tubular structure into constituent organs that exhibit unique structural, cellular, and functional specificities by the time of parturition. Final functional maturation, however, is completed only after birth. Recent gene targeting and deletion studies in mice and advances in understanding of the transcriptional control of growth and development have further defined the complex interactions that determine the cellular differentiation and growth patterns that result in the mature GI tract.

Although important characteristics in architectural organization are similar along the length of the GI tract, regional specialization is inherent to its development. Disruption of the normal sequence of developmental evolution in utero leads to a wide spectrum of anatomic disorders usually manifest during infancy. The GI tract undergoes dynamic renewal throughout life, with a continuing, if regionally variable, cycle of cellular proliferation, differentiation, and senescence. An appreciation of the mechanisms of ongoing self-renewal, apoptosis, and maturation is integral to an understanding of the pathogenesis of a number of neoplastic and inflammatory disorders.

This chapter first considers the structural development of the GI tract and pancreas; a discussion of functional maturation and its regulation follows. The latter also includes an overview of the processes controlling homeostasis of the epithelium in the adult, with an analysis of the transcriptional regulation of GI tract development, highlighting discoveries made through gene deletion or overexpression of specific genes in transgenic mice. Although much of our understanding of development has been achieved through the study of rodents, which demonstrate altricial development (i.e., maturational events concurrent with weaning), processes critical to human GI tract development are similar, even though human gastrointestinal development is precocious (i.e., functionally mature at birth). These processes, which unfold over the course of the normal 40-week gestation in humans, occur during the 21-day gestation of mice and rats. The relatively short period of gestation in these species makes them especially suitable for studies of developmental processes.

EMBRYOLOGY AND HISTOGENESIS

The human embryonic GI tract can first be recognized in the 4th week of gestation, when infolding creates an endoderm-lined tubular structure extending from the esophagus to the cloaca. The nascent GI tract is joined at its ventral region to the yolk stalk and allantois, which initially expand outside the embryo. During development, the GI tract is comprised of foregut (esophagus, stomach, and duodenum to the level of the ampulla of Vater), liver, pancreas, biliary tract, midgut (second portion of the duodenum to the proximal transverse colon), and hindgut (distal transverse colon to the proximal anal canal).

Esophagus

The foregut and respiratory tract are initially formed by a single tube at the proximal end of the primitive GI tract. [1] Subsequent development includes longitudinal division, resulting in the separation of respiratory and foregut structures, with the esophagus occupying a dorsal position by the 2nd month of gestation. The intimate relationship between the developing esophagus and tracheobronchial structures contributes to the potential for developmental anomalies (e.g., fistulae) involving connections between the esophagus and trachea. The esophagus can be distinguished from the stomach as early as the 4th week of gestation. [2] Rapid cephalad extension of the esophageal anlage leads to an elongated structure, which achieves its mature length relative to other structures by the 7th week of gestation. At the same time, rapid proliferation of the endodermal lining leads to near or actual occlusion of the lumen. Recanalization occurs through vacuolization of the endodermal cells, reestablishing the esophageal lumen by the 8th week of gestation. A similar sequence of proliferation, lumenal obliteration, and reestablishment of the lumen through vacuolization is found throughout the GI tract. In esophageal development, failure of recanalization may be a factor in the development of esophageal stenosis or atresia and may be associated with tracheoesophageal fistulae.

The esophagus is initially covered with a simple, cuboidal epithelium. By the 5th week of gestation, two layers of cuboidal cells and some neuroblasts dispersed in a developing layer of circular smooth muscle have developed. By 8 weeks of gestation, synaptic protein and glial supporting tissue can be demonstrated. [3] The external longitudinal layer of muscle develops later in gestation than the inner layer of circular muscle and is first appreciated during the 8th week. The epithelium becomes vacuolated during the 7th week of gestation, leading to the formation of a longitudinal channel, which forms the lumen when the vacuolization process is complete in the 8th week. In the 10th week of gestation, the esophageal epithelium is ciliated; subsequent proliferation and maturation lead to a stratified squamous epithelium typical of the adult esophagus by 22 weeks of gestation. Superficial glands may be found as early as 18 weeks of gestation, but the deep mucosal glands characteristically found in the mature esophagus are rare before birth and appear to develop during postnatal life.

The myenteric plexus can be demonstrated by gestational week 10, and mature ganglion cells by 13 weeks. [3] Extensive innervation of the esophagus is established before the onset of motor activity at 16 to 17 weeks of gestation, but maturation, reflected by an increase in neuron diameter and reduction of cell and fiber density, continues throughout gestation and into the 1st year of life. The cells that ultimately form the enteric nervous system migrate from the neural crest during the 1st trimester. [4] By the 8th week of gestation, neuroblasts have matured and become more numerous; synaptic protein and glial supporting tissue can be demonstrated asymmetrically penetrating the outer layers of the poorly differentiated muscular layer. [5] Neuropeptide immunoreactivity appears during the 11th week of gestation, when bombesin and neuropeptide Y can first be detected in the myenteric plexus. [6] Other neuropeptides are first expressed between the 13th and 18th weeks of gestation and, in order of appearance, include vasoactive intestinal polypeptide (VIP), galanin, substance P, somatostatin, metenkephalin, and calcitonin gene–related peptide (CGRP). Neuronal density peaks at 16 to 20 weeks of gestation, decreasing to adult levels in the 3rd trimester. In neonates and adults, the muscle of the proximal esophagus is striated, derived from the caudal branchial arches, and innervated by branches of the vagi. In the midesophagus, an intermediate zone exists after birth where neuropeptides are found in the smooth muscle circular layer but not in the longitudinal layer of striated muscle. Neuropeptide immunoreactivity can be detected in both muscle layers in the distal esophagus. The submucous plexus, absent in the adult human esophagus, is present by 13 to 19 fetal weeks, when protein gene peptide 9.5, a generalized neuronal marker, and VIP immunoreactivity can be detected.

The mature esophagus is a muscular organ throughout its length. The smooth muscle in the distal two thirds of the esophagus derives its innervation from the

splanchnic plexus. In mice, the entire esophagus is lined by smooth muscle until birth; skeletal muscle appears to be derived from differentiated smooth muscle cells by transdifferentiation during late fetal and early postnatal development, [7] commencing in the proximal esophagus at murine gestational day 16 and reaching the mature pattern of striated and smooth muscle on postnatal day 8. [8] However, the basic helix-loop-helix transcription factors that regulate skeletal muscle development (myogenic regulatory factor [Myf5]) are present at 12 to 13 days of mouse gestation, suggesting that endodermal cells of the foregut are committed to skeletal muscle differentiation even before smooth or skeletal cells become recognizable at 14 to 15 days of gestation. [9] However, gene disruption of Myf5 does not affect the development of smooth muscle, but it markedly delays the appearance of skeletal muscle by presumed transdifferentiation. [10] Cholinergic neurons are present before transdifferentiation occurs, but nicotinic receptor clusters do not appear until striated muscle is recognizable. Whereas targeted deletion of c-Ret or glial cell line–derived neurotrophic factor (GDNF) genes in mice leads to a lack of enteric neurons of the small intestine and colon with a phenotype similar to that of Hirschsprung disease (see section " Functional Maturation—Colon"), mice lacking Mash1, a transcription factor necessary for the development of enteric neurons of the esophagus, have no milk in their stomach and cannot relax their lower esophageal sphincter. However, transdifferentiation progresses normally; extrinsic neurons and extrinsic muscle development of the esophagus are normal in Mash1 null mice. [11]

Stomach and Duodenum

In the 4-week old human embryo, the stomach develops as a fusiform dilation of the foregut in the neck (Fig. 23-1A). [12] As it grows, the stomach descends into the abdomen by the 7th week of gestation. The gastric walls grow at disparate rates, creating the characteristic asymmetric shape as the dorsal border (which becomes the greater curvature) grows more rapidly than the ventral border (Fig. 23-1B). During the 6th week of gestation, the stomach undergoes a 90° clockwise rotation along its longitudinal axis so that the dorsal border lies to the left and the ventral border (which become the lesser curvature) moves to the right (Fig. 23-1C). As a result of this rotation, the left and right vagi largely supply the anterior and posterior areas of the stomach, respectively. The pyloric region of the stomach can be identified by the 3rd month of gestation. Although the shape of the stomach is suggestive of the adult gastric configuration by the end of the 7th gestational week, the cardia is still moving to the left of midline and the antrum is still moving to the right, so that the ultimate stomach contours are not reached until 8 to 9 weeks of gestation. [13] The greater curvature, lesser curvature, corpus, antrum, and pylorus can be clearly distinguished by 14 weeks. The duodenum forms from the distal foregut and cephalad midgut, which meet and fuse just distal to the area that becomes the ampulla of Vater. The duodenum grows rapidly, rotating to the right at the time of gastric rotation, creating a C-shaped loop in its retroperitoneal position by the 6th week of gestation. During this period of rapid growth, the duodenal lumen is temporarily obliterated by proliferation of the epithelium, but it is reestablished through vacuolization by the 8th week. Apoptosis of developing duodenal cells does not increase during duodenal recanalization and thus is not responsible for this process. [14] Failure of recanalization results in duodenal stenosis or atresia.

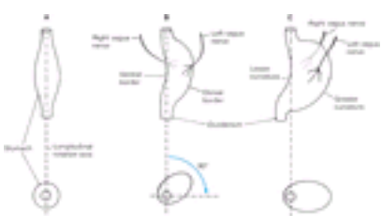

FIGURE 23-1. Schematic representation of the positional changes of the stomach. **A:** The stomach at 4 weeks. **B:** Rapid growth of the dorsal border, resulting in asymmetry. **C:** After a 90° clockwise rotation along the longitudinal axis, the left and right vagus nerves supply the anterior and posterior stomach, respectively. (Adapted from ref. [12].)

In gastric histogenesis, the stomach is lined by a stratified columnar epithelium composed of two to three cell layers in the 7th week of gestation. [15] Gastric pits, although rare at 7 weeks, begin to increase in number initially in the region of the lesser curvature, then in the greater curvature in the 8th week and the antral and cardiac regions by weeks 10 and 11. The glands first develop mucous neck cells, followed by parietal and chief cells. Ablation of parietal cells by the administration of ganciclovir to transgenic mice that express herpes simplex virus 1 thymidine kinase, driven by the H^+,K^+-ATPase promoter, is accompanied by ablation of the chief and mucous cells. [16] With cessation of ganciclovir, however, all cell types return, supporting the existence of pluripotent stem cells in the gastric mucosa. Targeted disruption of the H^+,K^+-ATPase gene a subunit in mice leads to complete inhibition of acid secretion, but parietal and chief cells and the H^+,K^+-ATPase ß subunit are preserved; gastric metaplasia with poorly differentiated ciliated cuboidal cells is seen. [17] In contrast, ablation of the ß subunit results in gastric mucosal hypertrophy, fewer parietal and chief cells, and a failure of delivery of the a subunit to the plasma membrane, in addition to achlorhydria and hypergastrinemia. [18] Omeprazole-induced hypochlorhydria, which blocks both H^+,K^+-ATPase subunits equally, results in a decreased parietal cell mass. [19]

Enteroendocrine cells can be detected by the 8th week of human gestation, and the fully differentiated spectrum of endocrine cell types can be detected by week 10, [20] suggesting a possible role in fetal development of the stomach. Substance P, neurokinin A, and CGRP appear first, followed by peptide YY cells, which are frequently colocalized with gastrin G cells after birth. During the first postnatal week, gastrin G cells appear in the gastric antrum while those in the pancreas disappear. Similarly, somatostatin D cells appear throughout the gastric mucosa, although they are detectable in the pancreas and duodenum in midgestation. Mice rendered deficient in Pdx1, a transcription factor that regulates multiple pancreatic and enteroendocrine genes, demonstrate a lack of G cells, but D cell expression is preserved. [21] Although earlier studies failed to demonstrate enterochromaffin-like (ECL) cells in the gastric mucosa before birth, histamine-containing cells appear by midgestation. [22] ECL cell proliferation does not accelerate until 1 to 3 weeks postnatally. Targeted disruption of the gastrin or gastrin/CCK-B receptor gene in mice does not affect ECL development, suggesting that gastrin, which stimulates ECL proliferation in mature animals and humans, does not play a role in early ECL development. [23], [24] and [25]

In the rat, primitive chief cells, which resemble mature chief cells in ultrastructure but, analogous to mucous neck cells, are capable of binding various lectins, are detectable from the 16th day of gestation until postnatal day 14. Gastric stem cells, although not yet clearly defined, appear to be located in the mucous neck region, producing the differentiated cell types that migrate toward the surface or base of the pits. [26] Ablation of parietal cells in transgenic mice by diphtheria toxin alters the balance between all the cell types, suggesting important developmental interactions between the cell lineages. [27]

Muc1, an epithelial mucin expressed in the mature upper GI tract, is also expressed at high levels early in rat gestation. [28] Muc1 mRNA is detected in the stomach by the 10th day of gestation, and protein is found by day 12. Initially, Muc1 lines the lumenal border of the gastric mucosa immediately after branching and differentiation of the gastric epithelial buds begin, suggesting a role for Muc1 in gastric epithelial development. In humans, Muc1-,-4, -5AC, -5B, and -6 mRNAs appear by 8 weeks of gestation. [29] Muc3 mRNA appears by 10.5 weeks, Muc2 not until 26 weeks of gestation. In adults, Muc1, -5AC, and -6 predominate; gastric carcinoma is associated with a fetal pattern of MUC gene expression. Spasmolytic polypeptide, a mucin-associated member of the trefoil family of peptides, [30] is abundantly expressed in fetal stomach before gastrin or somatostatin is expressed, [31] suggesting a role in gastric functional maturation.

Tyrosine kinases and phosphatases have been shown to play key roles in gastric development. Two families of receptor type tyrosine kinase genes, *elk/erk* and *esk/TTK,* are expressed at high levels in rat stomach from days 14 to 16 days of gestation, [32] decreasing after day 18, and are undetectable in adult rats. Protein tyrosine phosphatases may also be important in that PRL1 phosphatase expression correlates with the terminal differentiation of gastric zymogen cells and may play roles in the development of the esophagus, liver, and small intestine. [33] Both kinase and phosphatase genes are expressed early in development and reexpressed in a variety of gastric cancers.

Pancreas

The liver, biliary tract, and pancreas share a developmental origin in the ventral outpouching of the foregut. The pancreas emerges from the distal foregut as two buds at 9.5 days of gestation in the mouse and 10.5 days in the rat. In humans, the pancreas emerges from the hepatic diverticulum, which appears between the 3rd and 4th weeks of gestation and consists of the liver primordia and biliary system as well as the ventral pancreas. The dorsal bud is recognized first; shortly afterward, the ventral bud separates from the caudal-most region of the hepatic diverticulum (Fig. 23-2A,B). As the duodenum grows and rotates, the ventral bud migrates around the duodenum to fuse with the dorsal bud on the 11th day of mouse gestation and 5th week of human gestation, forming the uncinate process and inferior portion of the pancreatic head (Fig. 23-2C,D). Malrotation of the ventral bud results in an annular pancreas. The ventral duct also fuses with the distal portion of the dorsal duct

to form the duct of Wirsung, which becomes the main pancreatic duct emptying into the ampulla of Vater; the accessory duct of Santorini reflects the residual proximal dorsal duct (see Fig. 23-2C,D). Incomplete fusion of the two ductal systems results in pancreas divisum, which may be associated with later development of recurrent pancreatitis.

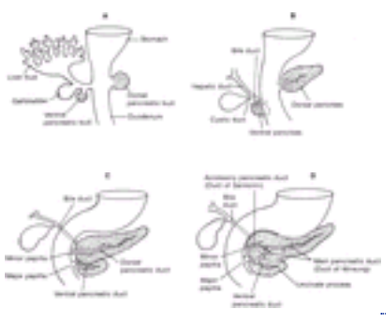

FIGURE 23-2. Successive stages in the maturation of the pancreas. **A:** The pancreas at 4 weeks. Note the location of the ventral bud arising from the primitive hepatobiliary system (i.e., hepatic diverticulum). **B:** The pancreas at 5 weeks. Note the rapid growth and elongation of the dorsal bud. **C:** The pancreas at 6 weeks. Note the migration of the ventral pancreatic bud to join the inferior portion of the dorsal bud. **D:** The pancreatic ductal system at 6 weeks. The main pancreatic duct joins the bile duct to enter the duodenum at the minor papilla. (Adapted from ref. [12].)

Early pancreatic development requires the interplay between endodermal and mesenchymal tissue. [34] Pancreatic fetal development appears to occur in three main stages. Initially, histological differentiation leads to recognition of distinctive pancreatic tissue on day 9.5 of gestation in mice and day 10.5 in rats, during which the ventral wall of the primitive gut endoderm begins to bulge into the surrounding mesoderm as part of the hepatic diverticulum (Fig. 23-3A). [35] During the subsequent 3 to 4 days of gestation, cytodifferentiation progresses, and low but significant levels of both exocrine and endocrine pancreas-specific gene products can be detected. [36] Beginning about day 15 of rat gestation, further differentiation leads to a rapid increase in rough endoplasmic reticulum, specific acinar enzymes, and islet cell hormones, as well as the appearance of zymogen and hormone granules. [37] After birth, the introduction of nutrients and weaning result in changes in the relative expression of pancreas-specific gene products, leading to the mature, terminally differentiated state. [38]

FIGURE 23-3. Schematic representation of pancreatic development. **A:** Mouse and rat development. **B:** Human development.

By the 8th day of mouse gestation, endodermal tissue in the regions of future pancreatic development is committed to pancreatic epithelial differentiation. Initially, morphogenesis of the pancreatic anlage occurs at two separate anatomic sites. The dorsal pancreatic bud appears first as a broad-based swelling immediately dorsal to the rudimentary stomach; the ventral pancreas appears 12 hours later on the opposite side of the gut, where the common biliary duct meets the ventral wall of the gut. [39] ^{3}H-thymidine incorporation studies have demonstrated that the appearance of the pancreatic buds occurs through a process of evagination and folding, as opposed to differential cell division and growth. By day 11 of mouse gestation, the pancreatic rudiment appears as a hollow epithelial bulb surrounded by condensed mesenchyme; single layers of cells face the lumen, linked together by junctional complexes. [40] At about the same time, the two primitive glands merge. During the next few days, rapid multiplication of these differentiated cells results in thickening of the pancreatic bud, which fills with tubular ductlike structures. At this stage, endocrine cells also appear scattered throughout the branching epithelium. By gestational day 15 in the mouse and days 16 to 17 in the rat, typical acini are evident. The endocrine cells pinch off from the pancreatic ductules, forming the islets of Langerhans.

In human development, the pancreas emerges histologically at the end of the 8th week of gestation as a collection of primitive epithelial tubules (Fig. 23-3B). [41] These structures subsequently branch, and their termini become surrounded by cell buds from which mature acini develop. During the 3rd month of gestation, secretory acini and islets of Langerhans are recognizable. At the beginning of the 2nd trimester, a lobular arrangement of the pancreas becomes visible, leading to the compact structure of the mature pancreas. Morphologic and functional development of ductal and acinar cells has been reported at 19 weeks of gestation. [42] Also at 19 weeks, the pancreatic mucin gene *MUC1* appears [43]; *MUC5B* appears at 12 weeks, and *MUC5* at 26 weeks. [44] *MUC3,* strongly expressed in adult pancreas, is not expressed during fetal life.

The acinar cell of the mature pancreas is normally a quiescent cell with a low mitotic rate. In fetal development, however, newly formed acinar cells maintain active cell division even after cytodifferentiation. [45] Antibodies specific for lumenal plasma membranes of acinar or duct cells of the mature exocrine pancreas demonstrate that fetal acinar cells undergoing rapid mitosis still express duct cell antigen. [46] Further, during regeneration after experimental pancreatitis, acinar cells transiently express ductal antigen, indicating a less differentiated state, until active cell division decreases.

Small Intestine and Colon

During the 5th week of gestation, the tubular midgut portion of the intestinal tract, joined to the yolk sac by the vitelline duct, rapidly elongates, extending ventrally into the body stalk. The vitelline duct, normally obliterated before birth, occasionally persists as a Meckel diverticulum. Between weeks 5 and 10, the small intestine extends through the umbilicus as the result of further elongation. During this period of rapid elongation, the midgut rotates 90° around the superior mesenteric artery in the dorsal mesentery. This rotation brings the proximal midgut to the right and the distal midgut to the left (Fig. 23-4A). As the midgut reenters the abdominal cavity in the 10th week of gestation, it undergoes a further 180° rotation (Fig. 23-4B). The proximal jejunum enters first and occupies the left side of the abdomen, and the ileum settles into the right side. The cecal swelling enters last, locating temporarily in the right upper quadrant just caudal to the right lobe of the liver (Fig. 23-4C). Between the 3rd and 5th months of gestation, the cecum descends into the right iliac fossa and becomes fixed to the posterior wall of the abdomen (Fig. 23-4D). As the liver increases in size, the ascending colon and the hepatic flexure become distinct from the transverse colon. The descending colon loses its mesentery and becomes anchored to the abdominal wall, leaving the sigmoid colon in its more caudal position on mesentery. The rectum arises independently from the remaining large intestine as a subdivision of the cloaca, separated from the urogenital sinus by the urorectal septum. The urorectal septum reaches the cloacal membrane during the 7th week of gestation, forming the perineum. During the 8th week, the rectum fuses with the colon, and the cloacal membrane forms the anal membrane, lost during the 9th week to establish communication with the amniotic space.

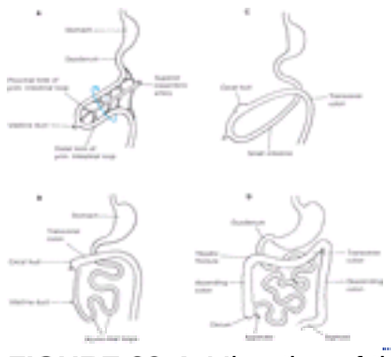

FIGURE 23-4. Migration of the intestinal loops. **A:** The intestine after a 90° rotation around the axis of the superior mesenteric artery, the proximal loop on the right and the distal loop on the left. **B:** The intestinal loop after a further 180° rotation. The transverse colon passes in front of the duodenum. **C:** Position of the intestinal loops after reentry into the abdominal cavity. Note the elongation of the small intestine, with formation of the small intestine loops. **D:** Final position of the intestines after descent of the cecum into the right iliac fossa. (Adapted from ref. [12].)

Histologically, the small and large intestines are lined initially by a simple cuboidal epithelium. As in the duodenum, epithelial proliferation during weeks 6 and 7 may lead to occlusion of the lumen. At 8 weeks, the epithelium is stratified; heparin sulfate, type IV collagen, and laminin, produced by epithelial cells, are detectable at the base of the undifferentiated epithelium, forming a basement membrane before further differentiation. [47] The lumen is reestablished during weeks 9 and 10, and a simple columnar epithelium reappears by the 12th week of gestation.

Villi form first in the proximal intestine during week 9 (Fig. 23-5), emerging in successively more distal regions over the ensuing days and completely formed by the end of week 13. In the stratified epithelium of the near-term fetal rat small intestine and colon, secondary lumina are thought to play a crucial role in villi formation. These lumina surround the main lumen and are joined by continuous tight junctions. The secondary lumina enlarge and eventually fuse with the main lumen, leaving a villus outpouching. Crypt formation begins in the 10th to 12th weeks of gestation, also progressing in a proximal-to-distal sequence. Postnatal development of absorptive enterocytes is associated with marked lengthening of the microvilli. [48]

FIGURE 23-5. Schematic representation of small intestine development. **A:** Mouse and rat development. **B:** Human development.

The four cell types found within the intestinal epithelium—absorptive columnar, goblet, enteroendocrine, and Paneth cells—appear to arise from a common progenitor cell. [49] Studies in chimeric and transgenic mice in which several cellular markers were used have demonstrated that the crypts in mature animals are clonal products of single progenitor cells. [50] However, crypts initially appear to be polyclonal; a single stem cell must become entrenched during development through undefined competitive mechanisms. Ablation of Paneth cells in transgenic mice with use of the cryptdin-2 gene promoter to drive the expression of diptheria toxin A or SV40 T antigen does not affect the expression or maturation of the other three cell types. Thus, Paneth cells, despite close anatomic association, are not critical for crypt stem cell function. [51]

The intestinal tube is initially surrounded by a layer of mesoderm that ultimately forms connective tissue, muscle, and serosa. As in gastric mucosa, enteroendocrine cells can be detected by the 8th week of gestation. Transgenic studies demonstrate that enteroendocrine cells share a developmental origin with endocrine cells of the pancreas. [52] Furthermore, secretin, peptide YY, and gastrin can de detected in fetal pancreatic islet cells. [53], [54] Mice with targeted disruption of the BETA2/NeuroD transcription factors, which normally bind an E-box motif crucial for enteroendocrine and pancreatic endocrine expression, fail to develop mature pancreatic islets and secretin- and CCK-producing cells in the small intestine, [55] and mice lacking the Pdx1 transcription factor demonstrate agenesis of the pancreas and a dramatic reduction in the number of small intestinal endocrine cells. [56] The circular muscle layer can be discerned by week 8; its appearance is followed closely by the emergence of the longitudinal muscle layer. The muscularis mucosae develops later but is present throughout the bowel by 20 weeks of gestation. The Auerbach plexus can be found by week 9 and the Meissner plexus by week 13, and Peyer patches emerge by about week 20.

Regional histogenetic differences during colon development have been observed. During late gestation in the rat (i.e., 18 days), the architecture of the proximal and distal colon is similar. However, the proximal but not the distal colon subsequently forms villuslike structures, although those disappear by 22 to 26 days after birth (Fig. 23-6). [57]

FIGURE 23-6. Schematic representation of colon development. **A:** Mouse and rat development. **B:** Human development.

FUNCTIONAL MATURATION

The structural features of the GI tract are well developed by the end of the 2nd trimester. In general, human GI tract functional development is precocious, with a wide spectrum of capabilities appearing well in advance of the time they are needed (Fig. 23-7), whereas many other species demonstrate altricial development, in which the development of many absorptive and enzymatic activities coincides with weaning, a process that begins in the 3rd week of life.

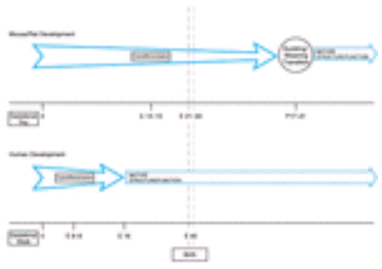

FIGURE 23-7. Comparative time course of major events in gastrointestinal development in rodents and humans. The digestive tract is structurally and functionally mature by the end of the first half of gestation in humans but reaches maturity in rodents only during the third postnatal week, following the suckling-weaning transition. *E,* embryonic day postconception; *P,* postnatal day.

Esophagus

Tagged erythrocyte isotope studies [58] and ultrasonography demonstrate that fetal swallowing occurs as early as the 11th week of gestation. The rate of fetal swallowing of amniotic fluid increases from 13 mL/d at 20 weeks' gestation to 450 mL/d in the presence of a mean amniotic fluid volume of 850 mL at term. [59] The role of swallowing in the regulation of amniotic fluid volume remains unclear, but fetal swallowing is important in GI tract development; fetal sheep [60] and rabbits [61] treated with esophageal ligation in the 2nd trimester demonstrate altered enterocyte morphology (including absence of microvilli), glycogen accumulation, and altered lysosomal morphology, changes similar to those observed in malnourished infants. Absorption of infused intraamniotic nutrients has been demonstrated in fetal rabbits, indicating that nutrient delivery via the fetal GI tract may be a potential treatment for intrauterine growth retardation. Sucking can be detected as early as 18 to 20 weeks' gestation, [62] although in preterm infants, sucking movements are generally feeble. By 34 to 35 weeks' gestation, a mature nutritive sucking pattern develops. The esophageal motility of preterm infants is characterized by poorly propagated, low-pressure biphasic contractions. After birth, swallowing in the full-term infant remains poorly coordinated for the first 12 hours, with both a high peristaltic rate and frequent nonperistaltic, simultaneous contractions throughout the length of the esophagus.

Ultrasonographic studies demonstrate the development of a functional lower esophageal sphincter during the 32nd week of human gestation, causing gastric enlargement by reduction of gastroesophageal reflux. [63] Lower esophageal sphincter pressures increase dramatically during the last trimester and again postnatally, [64] achieving adult levels by 3 to 6 weeks of age. Free gastroesophageal reflux is common postnatally and persists in up to 10% of infants for the 1st year. [65]

Stomach

Structural features of the stomach are also well developed by the end of the 2nd trimester, while functional maturation continues. Neither gastric secretory capacity nor gastric motility is fully developed at birth in either humans or rats. By the 27th to 28th week of gestation in humans, the gastric antrum exhibits only 20% to 25% of the motility reached by the term infant. [66] The gastric mucosa of most animals, including humans, is capable of secreting some acid before birth. [67] As noted, parietal cells are present before the end of gestation. In the rat, basal gastric acid secretion increases from the 19th to the 21st day of gestation, with maximal stimulation by pentagastrin at day 21. [68] However, acid secretion in the neonatal rat is very low and is insensitive to gastrin. [69] The pH of the gastric contents is nearly neutral in the term rat, remaining between pH 5 and 6 on day 10 after birth, falling to pH 4 on day 15, and reaching adult levels after weaning. [70] In humans, acid production, which is less than 50% of adult values during the first 3 months of life, reaches mature levels at 2 years of age.

Neonates are relatively insensitive to gastrin, evidenced by neonatal hypergastrinemia in humans, [71] dogs, [72] and rats. [73] Studies have revealed that the CCK-B receptor that binds gastrin is present before birth, [74] suggesting that the receptor is functionally immature. Compared to the acid response to gastrin, an early normal gastric acid response to cholinergic stimulation is present at birth, [75] whereas the gastric secretory response to histamine [76] does not mature until weaning. Produced by the parietal cell along with hydrochloric acid, intrinsic factor is detectable in human gastric mucosa by the 14th week of gestation; it increases rapidly after birth and achieves mature levels by postnatal day 10. The intrinsic factor receptor is expressed coordinately with its ligand and becomes restricted to the ileum at about 25 weeks' gestation. [77] Gastric lipase is expressed as early as 11 weeks of gestation, reaching adult levels by the 3rd postnatal month. [57]

Pepsinogen 1 immunoreactivity can be demonstrated in secretory granules of primitive chief cells of the murine fundic mucosa by the 16th day of gestation. [78] By postnatal day 13, pepsinogens 1 and 3 are present in almost equal amounts in rat fundic mucosa; pepsinogen 1 levels rise to adult levels after weaning. In humans, pepsinogen secretion is half of adult levels during the first 3 months after birth, rising to adult levels by 2 years of age. The mucous neck cell is the primary source of pepsinogen in the neonate; mature chief cells, which appear after birth, soon become the major source.

In the rat, concentrations of free cortisone rise immediately before the onset of weaning and peak during weaning. [59] In the neonate, injection of adrenocorticotropic hormone (ACTH) or glucocorticoids causes a precocious rise in gastric pepsinogen levels [79] and the number of functional gastrin receptors, [80] an early rise in antral gastrin concentrations, and an earlier induction of the acid secretion response to histamine, carbachol, and gastrin stimulation. Furthermore, cortisone induces a precocious rise in pepsinogen mRNA and a decrease in methylation of the pepsinogen genes, reflecting induction of chief cell differentiation. [81] Maturational glucocorticoid sensitivity disappears after weaning. Thyroxine also induces a precocious rise in pepsinogen activity, an effect that is additive with that of corticosterone. Estrogens reduce food intake, acid secretion, serum gastrin levels, and the number of gastrin receptors in the female or castrated male rat. [82]

Pancreas

Functional Development—Exocrine In contrast to the differentiation of endocrine cells (see next section), pancreatic exocrine cell differentiation follows morphogenesis. Exocrine gene transcription begins 24 hours after the pancreatic diverticulum is apparent. About 85% of the mature gland is comprised of the acinar cells of the exocrine pancreas, which synthesize and secrete large amounts of digestive enzymes, including amylase, lipase, trypsins, carboxypeptidases, and elastases. Although reverse transcriptase–polymerase chain reaction (RT-PCR) first detects carboxypeptidase A mRNA on day 10.5 of gestation in the mouse and amylase on day 12 (in the rat, carboxypeptidase A and elastase I are detected on days 12 to 13), immunostaining cannot detect amylase before visible differentiation of the acini and ducts at day 14.5. [83] The secretion of amylase and chymotrypsin is detected on day 15 of rat gestation, and that of trypsin, ribonuclease, elastase and lipase on day 18. The secretion of digestive enzymes is insensitive to known secretagogues until after birth, and fetal acini do not respond to intracellular messengers such as phorbol dibutyrate and calcium. Throughout the remainder of rat gestation, the levels of all digestive enzymes rise. After birth, lipase, ribonuclease, and elastase levels fall initially, rising to adult levels after weaning. [84] Trypsin and chymotrypsin mRNA levels rise at parturition, although chymotrypsin levels fall after weaning. Amylase mRNA concentrations do not change appreciably at birth but rise steadily after weaning. Enzymatic activity correlates well with the appearance of the various enzymes, with trypsin activity lagging behind the activities of the other digestive enzymes. [85] Acinar and ductular tissues have been assumed to derive from endodermal precursors. Destruction of exocrine cells with use of the elastase I promoter to drive diphtheria A toxin expression in transgenic mice also results in a decrease in ductular and islet mass. [86]

Functional Development—Endocrine Endocrine cells and specific endocrine gene products can be recognized even before pancreatic morphogenesis or before the appearance of exocrine-specific gene products, suggesting a possible role for these factors in pancreatic development. Somatostatin mRNA can be detected as early as day 7.5 of mouse gestation; insulin and glucagon mRNAs can be found at about day 9, gastrin on day 10, and pancreatic polypeptide on day 10.5. [87] Studies assessing the presence of the corresponding peptides have yielded conflicting results, probably because of the epitope variance in specificity of the antibodies used. However, it appears that the first mature peptides present are insulin and glucagon on day 9.5 of mouse gestation. A pancreatic polypeptide family member, probably peptide YY, is also expressed on day 9.5 and appears to be transiently coexpressed by all four differentiating endocrine cell types as they appear. Glucagon and insulin are frequently coexpressed in the same scattered individual cells from days 9.5 to 12.5 of mouse gestation. After a transient decrease in expression, insulin reappears at much higher concentrations in mature ß-cells around day 18.5 of gestation; glucagon expression reaches adult levels early in gestation, before the appearance of mature a-cells in typical islets. Gastrin is maximally expressed in late gestation and is switched off in the pancreas shortly after birth. [88] Somatostatin is first detected by immunocytochemistry on day 15.5 of mouse gestation; pancreatic polypeptide does not appear until after birth. As mature islets form toward the end of gestation, a sharp spatial segregation of their component cells occurs in rodents. In humans, the segregation of cell types is more subtle. Islet formation begins at gestational week 12; the islets initially derive from pancreatic ducts but lose their contact with the ducts by 17 to 20 weeks. The heterogeneity of endocrine cells in different segments of the mature mammalian pancreas may be secondary to the dual origin of the pancreas from ventral and dorsal buds. [89] The observation that cells expressing pancreatic polypeptide predominate in the lower head region of the mature pancreas suggests an embryological origin from the ventral pancreatic bud. [90] Although the pancreatic endocrine cell had long been thought to derive from the neural crest, [91] more recent data demonstrated that the endocrine cell arises from the

ductular cell, which also gives rise to the acinar cell. Tyrosine hydroxylase, an endocrine marker, is transiently expressed along with insulin and glucagon or both in the pancreatic duct on day 10 of mouse gestation. [92] The embryonic pancreatic duct retains the ability, when grown in vitro, to regenerate into a complete pancreas containing ductular, endocrine, and exocrine cells. [93] Quail-chick marker studies demonstrate that quail ectoderm and chick mesoderm explants grown in culture always produce pancreatic endocrine cells of chick type. [94] Mouse aggregation chimeras demonstrate that ß-cells of a single islet are derived from both chimeric components, suggesting that islets arise by the aggregation of individual cells rather than by the monoclonal expansion of cells. [95] Finally, the Pdx1 transcription factor, which transactivates the insulin and the somatostatin promoters, is expressed in endocrine cells of the pancreas and the duodenum, implying a common precursor for both types of endocrine cells. [96]

Regulation of Pancreatic Endocrine and Exocrine Development

Hormones and growth factors. The control of early development of all three structural components of the pancreas (i.e., acini, ducts, and islets) has long been thought to be dependent on mesenchymal factors. Although efforts in the 1970s to identify specific factors were unsuccessful, [97] more recent studies revealed that pancreatic epithelial rudiments isolated on day 11.5 of mouse gestation develop normal ductular, acinar, and endocrine structures when cultured in the presence of mesenchyme. [98] If the rudiments are placed in vivo under the renal capsule of a syngeneic mouse, no ducts or acini appear, but mature islets with the orientation of central insulin-expressing cells and peripheral glucagon-expressing cells develop. These studies demonstrate that at day 11.5 of mouse gestation, the developmental program for islet development is fully in place. Moreover, islets, as previously described, thought to derive from pancreatic ducts and ductules, can form in the complete absence of pancreatic ductal or mesenchymal tissue. Basement membrane components such as laminin and collagen type IV are important for pancreatic ductal development, whereas mesenchyme, previously thought to be necessary for the differentiation of all pancreatic constituents, is required only for acinar development. In further attempts to identify specific mesenchymal factors that may influence pancreatic differentiation, it was shown that pancreatic epithelial rudiments isolated at 12.5 days of mouse gestation and grown on rat tail collagen gels develop acini and small clusters of endocrine cells. [99] Epidermal growth factor (EGF) increases the ductular portion of the pancreas but decreases acinar tissue and leaves the relative amount of endocrine clusters intact. [100] EGF and its homolog, transforming growth factor-a (TGF-a), are expressed in developing rodent mesenchyme and in acinar and ductular cells; EGF receptors, which bind both factors, are also found on acinar cells and the apical surface of ductal cells. [101] Transgenic overexpression of TGF-a in the mouse pancreas results in ductular hyperplasia and interstitial fibrosis without an increase in acinar cell mass; acinar metaplastic changes of the ductules also occurs, evidenced by amylase expression and the appearance of zymogen and mucin granules. [102], [103] and [104] In contrast, TGF-ß $_1$ inhibits acinar development, enhances islet development, and has no effect on ductular tissue. [105] CCK and gastrin are two structurally and functionally related peptides that bind with different affinities to receptors; CCK has a higher affinity for the CCK-A receptor, gastrin for the CCK-B receptor. They exhibit distinct patterns of tissue localization and play important roles in the regulation of pancreatic growth. Pancreatic hypertrophy can be observed in animals fed a diet rich in soybeans, because the soybean trypsin inhibitor contained within is thought to abolish the usual inhibition of CCK by trypsin. Infusion of CCK or its analog, cerulein, increases pancreatic size, weight, DNA content, and acinar cell mass. [106] The use of specific CCK-A receptor antagonists confirms that CCK stimulates pancreatic growth in a dose-dependent manner, but it is not essential for pancreatic development. [107], [108] A strain of rats congenitally lacking the CCK-A receptor have a smaller pancreas than control rats. [109] As observed with CCK, gastrin induces a rapid rise in pancreatic RNA, DNA, and protein in healthy and in hypophysectomized rats. [110] However, neither endogenous hypergastrinemia nor hypogastrinemia induced by various mechanisms has any affect on rat pancreatic growth [111]; blockade with specific CCK-B antagonists similarly has no observable effect on growth of the rodent pancreas. [112] Gastrin plays more of a role in fetal pancreatic development, because fully processed CCK is expressed only at negligible levels during fetal life, whereas gastrin is exclusively expressed in the fetal pancreas. Hypergastrinemia or the persistence of pancreatic gastrin expression in the neonatal period is associated with nesidioblastosis. [113] Gastrin-overexpressing transgenic mice demonstrate no significant change in pancreatic morphology, but when they are cross-bred with TGF-a–overexpressing mice, their progeny demonstrate an increased islet cell mass and a dramatic reduction in TGF-a–induced ductular metaplasia. [114] Thus, the two peptides appear to modulate pancreatic development coordinately. The pancreatic regenerating (*reg*) gene may play a role in pancreatic growth, particularly in the development of ß-cells. Two nonallelic *reg* genes have been identified in humans, [115] rats, [116] and mice, [117] initially cloned from a cDNA library obtained after partial pancreatectomy. Expression of *reg* is noted after day 9 (*reg* I) or day 12 (*reg* II) in mouse gestation [118] and after 17 weeks of human gestation. Although *reg* expression rises dramatically after partial pancreatectomy, levels also rise with sham laparotomies. Similarly, despite correlation of *reg* expression with ß-cell mass, chronic glucose infusion, which induces ß-cell growth, is not associated with an increase in *reg* expression, [119] and fetal *reg* expression does not correlate well with ß-cell development. Other factors contribute to the regulation of pancreatic growth and development, but more studies are needed to define their precise roles. Secretin, expressed in fetal pancreas, stimulates pancreatic growth and may potentiate the stimulation of pancreatic growth by CCK. [120] The insulin-like growth factors (IGFs) types I and II are also expressed during fetal pancreatic development. [121] They stimulate fetal islet cell growth and are reactivated during pancreatic regeneration. [122] Targeted disruption of one of the alleles for mouse IGF-II results in a global growth-deficient phenotype without a specific pancreatic phenotype. [123] Although glucocorticoids inhibit overall pancreatic growth in adult rats, they increase pancreatic growth in fetal and suckling rats, [124] increase amylase activity in fetal rat pancreas, increase the accumulation of pancreatic enzymes in fetal rat explants, and enhance differentiation of the AR42J pancreatic acinar cell line. [125]

Small Intestine

The small intestine performs highly specialized functions responsible for most digestive and absorptive processes. As such, maturation of these complex functions can be arbitrarily analyzed according to specific nutrient groups.

Carbohydrate Digestion and Absorption Lactase–phlorizin hydrolase (LPH) activity can be detected early in the human fetus and is measurable by 12 weeks of gestation. [126] A significant increase in this activity occurs after the 24th week, and a late gestational surge is observed throughout the 3rd trimester. In rodents, this burst of activity is observed immediately before birth; it declines at weaning in association with a change in the primary carbohydrate sources, as a diet rich in maternal milk lactose is exchanged for a laboratory diet rich in sucrose and starch. Humans demonstrate a high level of LPH activity at birth, but the decline in activity does not correlate well temporally with weaning; humans are the only known species in which LPH activity does not fall in the postweaning period. Paradoxically, disaccharidase activities, such as those of sucrase-isomaltase, maltase, and trehalase, which should be physiologically unnecessary before weaning, are already present after 10 weeks of gestation at 60% to 70% of human adult levels, reaching adult levels by term. [127] In contrast, adult levels of disaccharidase activities in rodents are observed only during postnatal weaning. Sucrase-isomaltase and trehalase activities are undetectable before weaning but rise to adult levels by the 4th week of life. Glucoamylase, a microvillus enzyme, is also detected as early as the 10th week of gestation. Seventy percent of adult levels are achieved by 26 to 34 weeks of gestation. Salivary amylase can be detected after 20 weeks of gestation, and the level increases with fetal age. Proximal-to-distal gradients for LPH and other glucosidase activities can be demonstrated after 17 weeks of gestation, with maximal activities in the proximal jejunum and progressively less of these enzymatic activities along the more distal portions of the small intestine. [128] In all species studied, glucose transporters are present before birth, but fructose transporters appear only in the postnatal period. Uptake of glucose against a concentration gradient is demonstrable in the jejunum and ileum at 11 to 19 weeks of gestation in humans. [129] The longitudinal gradient in the level of glucose transport activity, well-documented in the mature intestine, occurs by 17 to 20 weeks of gestation. Active Na^+-dependent transport can be demonstrated after 19 days of gestation in fetal rat ileum. In the rodent, expression of SGLT1, a Na^+-dependent glucose transporter, remains unchanged after birth. Mutation of the SGLT1 gene results in severe glucose/galactose malabsorption and can result in overwhelming diarrhea in the newborn. [130] The facilitative transporter for glucose, GLUT2, and that for fructose, GLUT5, appear in rat fetal intestine before villus formation. [131] After birth, GLUT1 expression disappears and carbohydrate transporter levels are genetically programmed to match the species' natural diet. [132] The aldohexose transporters, which take up galactose and glucose with various affinities, demonstrate a shift to glucose transport corresponding to a decrease in dietary galactose in the suckling animal. [133] After weaning, fructose transport capacity rises sharply in rats and rabbits but not in cats; their adult diet continues to contain little fructose. Rats prevented from weaning still undergo the same steep rise in fructose uptake capacity, despite continued low fructose intake. [134] It is unclear whether the increase in absorptive capacity for hexose transport after birth reflects an increase in the number of transporters or an increased transporter efficiency.

Protein Digestion and Absorption Pancreatic trypsin and chymotrypsin activities depend on activation by enterokinase, and thus, enterokinase plays an important role in the early developmental stages of protein digestion. Enterokinase activity is only 6% of adult levels at 26 to 30 weeks of gestation and remains at 20% of adult levels even at the time of parturition. [135] Although trypsin can be detected at 20 weeks' gestation, its activity becomes measurable only at 28 weeks, reflecting its activation by enterokinase. Microvillar dipeptidase enzymes, which complete peptide digestion, are detected throughout the length of the small intestine in the 11-week-old fetus. Adult levels of dipeptidase activity have been demonstrated in the 14- to 16-week-old fetus. Concentrations of other microvillar dipeptidases are generally found in a longitudinal gradient, with the highest levels in the proximal intestine. Leucine aminopeptidase is an exception to this general organization, with distal activity twice that of proximal activity in the 16th week of gestation. Brush border and cytosolic peptidases reach adult levels in the neonate. Rat microvillar peptidase activity rises dramatically at weaning. Amino acid transporters also develop prenatally. [136] At birth, levels appear to be essentially equivalent to adult levels. Six different transporters for neutral and charged amino acids have been demonstrated during the 2nd trimester in the human fetus, [137] although the developmental pattern of uptake is not identical for all amino acids. In the fetus and neonate, macromolecular transport plays an important role in the digestion of proteins and lipids. In experimental animals, the small intestine epithelium appears to be more permeable to amino acids and peptides in the immediate postnatal period than in the mature intestine. Macromolecular tracers infused into the amniotic fluid or the intestinal lumen late in gestation are absorbed into enterocytes of humans, monkeys,

guinea pigs, and rats, reflecting a high rate of pinocytosis. [138] This process is extremely active in the first 2 weeks postnatally and decreases dramatically with weaning. The sites of absorption of different proteins vary in the rat. Intact immunoglobulins are transported in the jejunum but not in the ileum. [139] Nutritional proteins undergo pinocytosis in the ileum in a nonspecific manner. Pinocytosis of nutritional proteins and immunoglobulins decreases at weaning, although the adult rat can still absorb small amounts of intact protein. [140] In parallel with pinocytosis, enterocytes exhibit high levels of lysosomal proteases, such as cathepsins and other peptidases, during the first 2 weeks postnatally, but these levels fall thereafter. These intracellular enzymes provide a mechanism for protein digestion before the appearance of pancreatic proteolytic enzymes. Intact proteins also are absorbed in premature and term human infants during the first few months of life. Macromolecules may continue to cross the healthy adult small intestine, but the amounts are low compared to those in the newborn. Imperfect barrier function during the first months of life may play an important role in conferring a tolerance of or sensitivity to dietary proteins.

Lipid Digestion and Absorption The higher rate of fecal fat loss in neonates than in adults correlates with lower lipase and lower intralumenal bile acid concentrations. Lipase has long been detected in pancreatic extracts of 16-week-old human fetuses. Although levels rise significantly during the 3rd trimester, lipase activity in week 32 of gestation remains at only 50% of term levels, which are themselves only 10% of adult levels. The human neonate also has lingual lipase activity, which rises to adult levels by 2 years of age. The relatively low levels of lipase may explain the presence of unhydrolyzed triglycerides in neonate feces. In humans and rats, lingual lipase and maternal milk lipase aid in neonatal fat digestion. [141] Gastric lipase appears as early as 10 to 13 weeks of gestation. [142] Adult distribution of gastric lipase is established by 16 weeks' gestation and appears to be the major determinant of lipolytic activity in gastric aspirates of premature infants. Lingual lipase is produced in the serous glands of the tongue and appears to aid in the digestion of milk triglycerides in neonatal rats, mainly through hydrolysis in the stomach. In the rat, lingual lipase exists in small amounts at birth and increases markedly at weaning. Maternal milk lipase also plays a role in fat digestion. Synthesis of bile acids from cholesterol and conjugation with taurine and glycine can be demonstrated in organ culture in vitro with human liver tissue obtained from fetuses after 15 weeks of gestation. [143] Biliary secretion can be demonstrated as early as the 22nd week of gestation. Bile acid reabsorption occurs in the neonate by passive diffusion throughout the small intestine, but active Na^+-dependent ileal transport of bile acids does not occur until weaning in rats, rabbits, and humans. [144] Both secretion and reabsorption of bile acids are lower in suckling rats than in adults. Bile acid concentrations are initially too low to facilitate the formation of micelles. In the neonatal period, before the maturation of bile acid secretion and reabsorption and the mature production of pancreatic lipase, the suckling rats' small intestine exhibits increased permeability to both triglycerides and cholesterol. [145] The lipoproteins required for chylomicron production are abundant in the small intestine of the suckling rat, and chylomicrons can be formed and presumably transported into lymphatic channels. [146] After weaning, the dietary fat content decreases, pancreatic lipase activity matures, and fewer large lipid particles are seen in the enterocyte. Ileal bile acid absorption also begins at this time, reaching adult capacity after 1 month in the rat. [147] In human neonates, bile acid synthesis occurs at relatively high levels. However, because ileal resorptive mechanisms are not yet mature, a reduction in the bile acid pool results. In premature infants, this reduction is even more severe, and 10% to 20% of fat intake in formula-fed premature infants may not be absorbed. During the first 4 to 6 weeks of human life, intralumenal bile acid levels increase as absorptive mechanisms mature, leading to improved lipid absorption.

Small Intestine Immune System The GI tract, particularly the small intestine, contains a highly complex mixture of immune cell populations. The gut-associated lymphoid tissue (GALT) encompasses organized aggregates dominated by lymphocytes (Peyer patches) and a diffuse heterogeneous population of lymphocytes, monocytes or macrophages, and other cells, such as eosinophils and mast cells in the lamina propria. Intraepithelial lymphocytes are also scattered throughout the surface epithelium. Structures resembling Peyer patches can be demonstrated as early as 11 weeks of human gestation; by 14 weeks, $CD4^+$ and $CD8^+$ lymphocytes can be seen. [148] By the end of the 2nd trimester, Peyer patches histologically resemble the adult structure, indicating that antigen exposure or bacterial colonization is not necessary for their development; however, germinal centers do not form until after birth. [149] In transgenic mice carrying a null mutation for tumor necrosis factor-a (TNF-a), Peyer patches or lymph nodes do not develop, and splenic organization is markedly abnormal; if the 55-kd receptor for TNF-a is disrupted, lymph nodes and splenic tissue develop normally, but Peyer patches are still absent, suggesting that the 55-kd receptor provides specificity for Peyer patch development. [150] Other targeted mutations that preclude Peyer patch development in mice include knock-out of the inhibitory helix-loop-helix transcription factor Id-2, [151] lymphotoxins, [152] and the lymphotoxin-ß receptor. [153] In mice lacking Peyer patches, oral tolerance does not develop. [154] $ß_7$-Integrin–deficient mice have severely impaired GALT formation, [155] affecting the development of Peyer patches, the homing of lymphocytes, and small intestinal immune responses to experimental parasitic infection. [156] Targeted disruption of the homeodomain-containing transcription factor NKX2.3 in mice results in significant defects in intestinal development, as well as smaller Peyer patches and lack of the mucosal addressin cell adhesion molecule-1 (MAdCAM-1), normally responsible for B- and T-cell homing to peripheral lymphoid organs. [157] Lamina propria lymphocytes are first detected after 11 weeks of gestation. During fetal life, they consist of increasing numbers of scattered T and B cells. In contrast to aß T cells, ?d T cells, which make up 5% to 15% of small intestinal and 40% of colonic intraepithelial lymphocytes, can develop extrathymically as well as in the thymus. [158] Soon after birth, ?d T cells undergo clonal expansion, but with further maturation, they become clonally restricted and unique in each individual. Targeted deletion of ?d T cells in mice results in a lack of mucosal IgA-producing T cells but has no effect on aß T-cell development, which is thought to occur intrathymically. [159] IgA- and IgM-producing plasma cells are not found in the lamina propria until after birth and antigenic exposure. Intraepithelial lymphocytes appear at 11 and 12 weeks of gestation. [160] Fetal lamina propria lymphocytes are mostly $CD4^+$, as in the adult lamina propria, whereas fetal intraepithelial lymphocytes are often $CD4^-/CD8^-$; $CD8^+$ cells become more predominant postnatally. [161] Macrophages are present at 12 weeks, but their numbers increase greatly after birth. [162] Unlike mature colonic and ileal villus epithelium, fetal intestinal epithelial cells do not express MHC class II antigen, suggesting that antigen exposure may be important for its induction. In rats, suckling and germ-free animals have fewer intestinal lymphocytes than adults, and weaning, associated with intestinal maturation and increasing bacterial colonization, is also characterized by marked development of the mucosal immune system. [163] Cyclosporine, an inhibitor of T-lymphocyte activation, retards normal lymphocyte development in the small intestine. [164] Natural killer activity of intraepithelial and lamina propria lymphocytes is absent before birth, rising dramatically after weaning. [165]

Vitamins and Minerals Both passive and carrier-mediated absorption is increased in neonatal small intestine. Copper, iron, magnesium, and zinc are absorbed by the suckling rat small intestine in increased amounts, but rates of absorption decline to normal at weaning. Highly specific lactoferrin receptors for milk are present in human fetal and suckling small intestine. [166] Lead, cadmium, radium, plutonium, barium, and other toxic heavy metals are also absorbed more easily in the suckling than in the adult rat. Active transport of calcium occurs throughout the rat small intestine and colon before weaning but depends on mechanisms distinct from those in the mature mucosa, uniform throughout the intestine and not requiring vitamin D, in contrast to vitamin D–dependent uptake mechanisms concentrated in the duodenum that appear after weaning. Human neonates absorb iron, copper, calcium, zinc, and lead more efficiently than do adults. Although the mechanisms remain uncertain, these processes can facilitate lead intoxication. Inadequate bone mineralization is a common problem in premature human infants. This is not thought to result from a lack of absorptive capacity but from an insufficient supply of calcium in maternal or formula milk. Simple calcium supplementation can correct the calcium imbalance. Impaired absorption of fat-soluble vitamins is present in neonates and likely reflects the same pattern of impaired absorption of all lipids. Vitamin B_{12} absorption has been demonstrated in the rat neonate. [167] Intrinsic factor receptor activity is detectable throughout the small intestine and colon of the human fetus after 10 to 19 weeks, but it is present only in the distal ileum at the end of fetal development. [168] Folate absorption is impaired in the human neonate and infant compared with the adult. Biotin transport was found to be higher in the ileum than in the jejunum of suckling rats, equal in both parts of the small intestine in weanlings, and higher in the jejunum than in the ileum of adult rats. [169]

Regulation of Intestinal Maturation

Role of diet. During weaning, the infant GI tract is exposed to a dramatic change in dietary composition. Maternal milk is high in fat and low in carbohydrate, whereas a "conventional" diet includes relatively high amounts of carbohydrate and has a low fat content. The dominant carbohydrate source changes from lactose to a more varied mixture, dominated by sucrose and starch. Many of the maturational changes of the small intestine occur at weaning, leading to the supposition that dietary composition is an important factor contributing to these ontogenic changes. Although this association may be important in the rodent, in humans, dietary factors are not essential to the expression of many functional activities that emerge. LPH exhibits an accelerated surge before parturition, which suggests that the birth process (and possibly hormonal factors related to it), rather than a dietary challenge, regulates expression of this activity. Even in rodents, the importance of dietary components in triggering changes in various activities during weaning may be limited, and similar changes occur at almost the same time in rats prevented from weaning. [170] Premature weaning also elevates glucocorticoid levels, which can result in precocious digestive tract maturation. Other observations suggesting that dietary factors do not play a major role in small intestine development have been obtained through studies of intestinal explants. Despite subsequent implantation into the kidney or a subcutaneous space, or if cultured in vitro, the normal pattern of functional maturation has been observed. [171] Rat ileum that is bypassed surgically at 12 to 14 days of age expresses sucrase and maltase activity in the normal temporal framework. [172] Intestinal explants from 6-day-old rats cultured in the absence of hormones cannot be induced to precocious expression of sucrase-isomaltase or maltase. Although dietary factors may not fundamentally regulate the temporal sequence of GI tract development, they may modulate the process. A high-carbohydrate diet enhances intestinal glucose transport by increasing the number of glucose transporters along the crypt-villus axis. [173] Humans or rats fed a diet high in maltose or sucrose exhibit increased maltase or sucrase-isomaltase activity, but not increased LPH activity. Similarly, feeding lactose increases the level of brush border membrane LPH in rats, and prolonged suckling delays the usual decrease in LPH expression at weaning. [174] However, high levels of LPH mRNA persist after premature weaning. Malnourished suckling rats display delayed patterns of mucosal enzyme development, which can be reversed by refeeding. [175] Experimental studies have shown that bypassed segments of intestine maintain high levels of LPH, whereas the shortened segments of intestine left in continuity exhibit decreased LPH activity. [172] Clinically, a high-protein diet can stimulate greater pancreatic secretion of trypsin and lipase in premature infants. Dietary constituents other than nutrients may also modulate functional maturation. Pig, rabbit, and dog neonates in their first 24 hours after birth exhibit greater increases in small intestine weight, size, and DNA or protein content when fed colostrum than when fed an artificial diet. 173a Rat neonates fed colostrum also have increased small intestine DNA content and synthesis, although their intestinal weight does not vary from that of neonatal rats fed mature milk. 174a High concentrations of EGF occur in human, mouse, and rat milk. 175a EGF is found throughout the lumen of the GI tract of the rat and at

higher levels in suckling than in adult rats, correlating with the milk intake, implicating milk as an important source of EGF in the suckling period. [176] EGF retains biologic activity in the small intestine of suckling rats after ingestion of milk. Milk-borne or orally administered EGF is absorbed and distributed throughout the digestive tract. IGF-I is also found in human milk and colostrum. The peptide is protein-bound but released after treatment with acid. [177] Insulin, too, is found in colostrum and milk, and induces precocious sucrase-isomaltase activity in neonatal mice. Small amounts of glucocorticoids and thyroxine also are present in milk. [178] Corticosterone induces precocious intestinal expression of sucrase-isomaltase and maltase activity in adrenalectomized rats, but at higher concentrations than are found in maternal milk, a level similar to that of 18- to 20-day-old control rats, in which sucrase-isomaltase and maltase activities are normally expressed.

Hormones and peptide growth factors. Although nutrients in the diet may modify some ontogenic changes of the GI tract, lumenal or systemic hormones and peptide growth factors may play a more direct role. Among these factors, glucocorticoids have the best-documented impact on intestinal development. Tissue concentrations of free corticosterone rise 48 hours before the appearance of the enzymatic changes associated with weaning, suggesting that weaning may promote development indirectly by inducing changes in corticosteroid concentration. The administration of glucocorticoids to rats and mice during the suckling period prematurely decreases pinocytosis and levels of lactase and lysosomal hydrolases, and prematurely increases sucrase-isomaltase, maltase, trehalase, peptidase, pancreatic and salivary amylase, pepsinogen, and gastrin receptor levels. Glucocorticoids increase sucrase-isomaltase and LPH mRNA levels in rats, although enzyme activities appear also to be regulated by posttranscriptional events. [179] Age appears to be an important determinant of the response to glucocorticoids because glucocorticoids accelerate the rate of cellular proliferation of the suckling rat but not of the adult rat. In mice, dexamethasone induces maturation during the days immediately preceding weaning. [180] The concentration of glucocorticoid receptors in the intestinal mucosa peaks at the time of weaning in the rat, and hypophysectomy is associated with decreased intestinal sucrase-isomaltase activity in suckling rats; this can be normalized by the administration of cortisone. [181] Thus, during a limited period, glucocorticoids can influence maturation of the small intestine. Enzyme levels are not stimulated by glucocorticoids in rats adrenalectomized after 17 to 18 days of age. [182] Although adrenalectomy slows the rate of enzymatic changes at weaning in the rat, the changes commence at the same time and eventually reach the same levels as in sham-operated controls. [183] These studies suggest that the changes may be genetically programmed and are not glucocorticoid-dependent. Genetic programming would explain the preserved temporal development of sucrase-isomaltase, LPH, maltase, and ß-galactosidase activity in fetal rat and mouse intestine after transplantation into an adult. In humans, prenatal administration of glucocorticoids decreases the incidence of necrotizing enterocolitis in the neonate, presumably by promoting intestinal maturation, including the intestinal mucosal barrier. [184] Glucocorticoids also influence the differentiation of human fetal intestine in organ culture. [185] The neonates of mothers who received glucocorticoids in late pregnancy have a larger bile salt pool than do neonates of the same age whose mothers were not treated. [186] Thyroxine affects intestinal maturation, but interpretation of the mechanism is difficult because thyroxine also increases glucocorticoid levels. [187] Although hypothyroidism prevents or delays intestinal maturation, it also abolishes the developmental rise of corticosterone. The maturational delay in the expected rise in sucrase-isomaltase activity in hypothyroid fetuses can be reversed by the administration of glucocorticoids without thyroxine. Thyroxine and corticosteroids produce a synergistic response in the rat, enhancing the expression of small intestine enzymes before weaning. [188] However, the administration of cortisone results in only partial restoration of reduced jejunal lactase activity after hypophysectomy, whereas thyroxine alone fully restores this decline. Thyroxine administration alone also decreases LPH mRNA levels and increases intestinal alkaline phosphatase, but it has no effect on sucrase-isomaltase mRNA levels in rat small intestine. [189] Colostrum and maternal milk in many animal species, including humans, contain EGF. At weaning, EGF levels in mouse maternal milk decrease, and endogenous sources of EGF increase markedly. [190] EGF may have important trophic effects throughout the GI tract, but the lack of a precise temporal relation of declining maternal milk EGF concentrations to the augmented production from endogenous sources indicates that EGF is unlikely to play an essential role in the regulation of developmental changes. EGF administered orally increases cell growth in the intestine and pancreas of neonatal rats, even though EGF is largely degraded by proteolytic enzymes. [191] EGF in amniotic fluid is taken up in the small intestine by endocytosis in the 20-day-old rat fetus and may play a role in fetal intestinal development. [192] TGF-a appears to be the major ligand for the EGF receptor in fetal development and thus may contribute greatly to fetal GI tract development, until EGF expression increases at the end of gestation. [193] EGF receptors are most abundant at 8 to 12 weeks of gestation in the human fetus. [194] Gastrin also may play a role in GI tract development; it is found in detectable concentrations in fetal plasma and at high levels in neonatal plasma. Antrectomy performed on midgestation fetal sheep induces a 70% decrease in plasma gastrin levels, leading to reduced crypt and villus density, a lower crypt-to-villus ratio in the distal small intestine, and shorter gastric glands. Furthermore, mice bearing deletions of the gastrin [195] or the CCK-B/gastrin receptor genes have decreased numbers of parietal and ECL cells, resulting in atrophy of the corpus mucosa, particularly in the pit and basal regions. Bombesin, also known as *gastrin-releasing peptide (GRP),* stimulates gastric, colonic, and pancreatic cell growth in suckling rats. [196] Parenteral administration of bombesin during the suckling period of rabbits results in hypertrophy of the stomach, small intestine, and colon. A bombesin-like compound has been found in the breast milk of some mammals. [197] However, a physiological role for bombesin in intestinal maturation has not been proved. Insulin administered to suckling mice causes premature maturation of the small intestine. [198] These effects include precocious cessation of the intestinal macromolecular transport and induction of sucrase-isomaltase and other brush border enzyme activity in adrenalectomized suckling rats. Endogenous insulin levels rise during the weaning period in the rat, although no clear role has been established for insulin in the maturation of the GI tract. Prostacyclin prematurely increases sucrase-isomaltase and maltase activity in suckling rats, and these effects occur in the absence of glucocorticoids in adrenalectomized rats. Proglucagon-immunoreactive cells are first detected in the rat gut by day 14 of gestation. Proglucagon is processed to form glucagon or glicentin, oxyntomodulin, and glucagon-like peptide 1 (GLP-1) or GLP-2 in the small intestine and colon. GLP-2 stimulates cell proliferation and inhibits apoptosis in the small intestine and colon. [199] GLP-2 and its receptor are both expressed by day 18 of gestation in the rat, suggesting roles in gut maturation. Other gut peptides present during fetal development include galanin (day 15 of rat gestation), substance P and CGRP (day 18 of rat gestation), and VIP (week 9 of human gestation).

Effect of bacterial colonization. Bacterial colonization of the GI tract of human neonates occurs within a few days of delivery. Gut bacteria have no role in fetal development but may play a role in postnatal development. Disaccharidase activity of germ-free rats is greater than that of control rats after weaning. Introducing the cecal contents of control rats into the small intestine of germ-free rats causes disaccharidase levels to decrease to normal levels. [200] The intestine of the germ-free rat is also considerably thinner, with shallower crypts and a smaller mucosal surface area than those of control rats. The importance of bacterial colonization on intestinal development has been highlighted by the demonstration that colonization of germ-free mice with *Bacteroides thetaiotamicron,* an important constituent of both mouse and human intestinal microflora, induces many transcriptional changes associated with postnatal development— for example, adenosine deaminase, ornithine decarboxylase, the Na^+/glucose cotransporter SGLT1, colipase, and liver fatty acid–binding protein gene expression. [201] Other normal components of intestinal commensal bacteria, including *Bifidobacterium infantis, Escherichia coli* K12, or a “complete” complement of murine microflora, led to distinct transcriptional changes, suggesting that specific bacteria that colonize the intestine after birth play unique roles in postnatal intestinal maturation. After birth, Paneth cells play an important role in intestinal host defense against bacteria. Of interest, cryptdins 4, 5, and 6, lysozyme, and matrilysin, all implicated in mature Paneth cell antimicrobial properties, are expressed on the first postnatal day in mice, before crypt formation or Paneth cell differentiation. [202]

Colon

The functional maturation of the colon has not been studied as extensively as that of the small intestine. LPH is expressed transiently in newborn rat colon. Sucrase-isomaltase activity is found in the colon during fetal life, but disappears before birth. The fetal rat colon is capable of actively transporting glucose and alanine. However, Na^+,K^+-ATPase a and ß subunit mRNA levels are low in the rat colon before birth, increasing to adult levels by postnatal day 25. [203] Dexamethasone, but not aldosterone, induces a dose-dependent increase in Na^+,K^+-ATPase subunit mRNA levels. [204] Administration of glucocorticoids to the fetal rat colon enhances sodium absorption, an effect not seen in the rat small intestine. [205] Calcium, strontium, and magnesium are also absorbed in the colon at much higher rates in suckling than in adult rats.

Human colonic fetal tissue maintained in serum-free organ culture demonstrates no morphologic or enzymatic changes after the administration of hydrocortisone. EGF, however, causes a precocious drop in sucrase-isomaltase, maltase, and alkaline phosphatase activities. [191] TGF-a appears at 18 days of gestation in the distal fetal rat colon, before crypt formation, and by day 20 of gestation at the crypt bases. The proximal colon undergoes more complex structural changes at 20 days, including villi formation and expression of brush border hydrolases. [206] TGF-a is detectable in the lower half of the villi in the proximal colon from days 10 to 24 of postnatal development, during the establishment of adult proximal colonic architecture, and may play a role in the maturation of he distal and proximal colon to adultlike structures. Gastrin may also play a role in fetal colonic development, because the mature amidated peptide is expressed in fetal rat colon. Posttranslational maturation of colonic gastrin ceases in the postnatal period. [207]

Motility The enteric nervous system and muscle layers form early in gestation, but mature patterns of contractile activity and motility are not found until near term, leading to difficulties in enteral feeding of premature infants. The enteric nervous system, developing from neural crest precursors that migrate in a craniocaudal direction, can be detected in the stomach by week 7 of gestation and in the rectum by week 12. [208] In mice, transgenic studies with use of the dopamine ß-hydrolase promoter confirm neural colonization of the ileocecal junction at day 11.5 of gestation, and of the rectum the following day. [209] Studies of quail-chicken chimera reveal that vagal neural crest cells migrate toward the cranial end of the primitive gut and populate the entire bowel to the rectum, while sacral neural crest cells migrate from the caudal end to colonize the distal intestine to the level of the umbilicus. [210] Retroviral tracing methods show that sacral crest cells colonize the distal intestine only after the arrival of the vagal crest cells. [211] Mesenchyme is critical for maturation of the enteric nervous system. For example, laminin binding directs the migration of

neural crest cells to form neuronal processes and ganglia. [212] Axonal and dendritic process formation from crest-derived, colonized neuroblasts continues throughout gestation and postnatally through poorly defined interactions with local microenvironmental factors. Neuroblasts commit to the expression of specific neuropeptides along a specific ontogenic timetable. Cholinergic and serotonergic neurons develop first, followed by adrenergic and finally peptidergic neurons. [213] Hirschsprung disease, a relatively common familial and sporadic disorder occurring in 1 of 5000 live births, is defined by a lack of myenteric and submucosal ganglia affecting a variable length of colon extending proximally from the anus. This disease has become an important model for defining a complex multigenic disorder in which distinct and specific transcriptional and receptor-ligand pathways and interactions important in development result in a single phenotype—megacolon. Two major models of pathogenesis have emerged, accounting for the megacolon phenotype in both mouse models and human disease, although further genetic alterations continue to be elucidated. The first mutation associated with Hirschsprung disease was of the tyrosine kinase c-Ret. [214] Ret gene activation in transgenic mice leads to a loss of enteric neurons and megacolon. [215] GDNF and its other family members, neurturin, persephin, and artemin, bind to one of four glycosyl-phosphatidylinositol–linked receptors, GFRa1 to GFRa4, that activate Ret transduction. [216] Murine and human mutations of GDNF result in a colonic phenotype identical to c-Ret mutations. Furthermore, alterations of Pax3 or Sox10, transcriptional regulators of c-Ret, also demonstrate Hirschsprung-like megacolon. [217] In the Ret/GDNF/GFRa1 mutations, neural crest progenitors do not divide and thus cannot migrate to populate the enteric nervous system, although in humans, some residual Ret activity persists, and aganglionosis is limited to the distal bowel. [218] A second model involves disruption of endothelin-3 and its receptor, endothelin-B or endothelin-converting enzyme, which results from premature differentiation of migrating neural crest cells in fetal development with depletion of these progenitors before colonization of the distal colon, which occurs in a proximal-to-distal distribution. [219] In the latter model, proliferation of the progenitor cells is intact, but later stages of migration and differentiation cause a phenotype similar to the Ret mutation phenotype. Of note, GDNF-deficient mice demonstrate intact development of the interstitial cells of Cajal, which are responsible for normal slow wave activity of the GI tract, suggesting that the presence of enteric neurons or GDNF is not required for the ontogeny of the interstitial cells of Cajal. [220] However, the Kit receptor and its ligand, stem cell factor, are required for development of these pacemaker cells. [221] Most patients with Hirschsprung disease do not demonstrate mutations of the Ret or endothelin-3 pathways, suggesting that other factors play a role in the phenotype of this disorder. Alterations of enteric nervous system development at many different stages may account for the development of Hirschsprung disease, as exemplified by transgenic mice that overexpress *Hoxl-4* [222] or *Hoxa-4* [223] and exhibit aganglionic megacolon. Null mutation of *Hox11L.1* results in hypoganglionosis or neuronal intestinal dysplasia with a similar clinical phenotype. [224] Other genetic alterations may lead to megacolon, further enlightening our understanding of the development of the enteric nervous system. Like enteric nerves, enteric smooth muscle develops in a proximal-to-distal direction. Development of the outer circular muscle layer is detectable within the mesenchymal layer by week 8 of human gestation; the inner longitudinal layer is recognizable 2 to 3 weeks later. [225] However, contraction after electrical stimulation does not occur until the 3rd trimester. In premature infants, contraction pressures achieved at 25 weeks of gestation only approached only 60% of the levels reached at term. The mechanisms required for colonic defecation, including the coordinated contraction of colonic smooth muscle and the appropriate internal and external sphincter responses, are poorly developed until birth. Although 99% of term infants pass their first meconium stool within 48 hours after birth, infants born at 36 weeks' gestation may not pass their first stool until more than 1 week after birth. [226] Disorders of smooth muscle development affecting colonic motility, such as hollow visceral myopathy syndrome and megacystis microcolon hypoperistalsis, are quite rare compared to Hirschsprung disease, and factors important in their pathogenesis remain unknown. [227]

TRANSCRIPTIONAL REGULATION OF DEVELOPMENT

The application of powerful molecular biologic techniques has provided insights into the transcriptional control of development. An understanding of the mechanisms that regulate the transcription of tissue-specific genes allows a clearer understanding of development at its most fundamental level. Patterns of morphologic and functional development reflect the activation or suppression of expression of specific genes. Gene transcription, in turn, is determined by the presence of regulatory proteins (i.e., transcription factors). Transcriptional hierarchies provide a code of messages controlling crucial events in development, from the earliest stages to the terminal differentiation of maturing tissues. *Hox* genes are the most extensively studied class of genes in vertebrate development. In mice and humans, these genes are found in four clusters on different chromosomes and are similar to the Antennapedia/Bithorax cluster of genes in *Drosophila*. The latter are known to play homologous roles in differentiation and segmentation along the anteroposterior embryonal axis in insects. [228] More than 20 *Hox* genes are thought to play a role in GI tract development. [229] Targeted deletions of the *Hox* genes and other developmental genes in mice have shown that these genes are critical for many developmental programs. Some of these mutations are lethal in mice, and thus may not reveal multiple roles for specific transcription factors that may occur at later stages of development.

Within the GI tract and its appendages, a paradigm for transcriptional control of development was elucidated first for the liver, where a transcriptional hierarchy is essential for hepatic organogenesis and differentiation. [230] The hepatocyte nuclear factor 1 (HNF-1) family, C/EBP (CCAAT/enhancer-binding protein), the HNF-3 family, and HNF-4 have all been shown to be crucial for the expression of liver-specific genes and the development of the hepatocyte phenotype. Many of these factors are also expressed in the pancreas and intestine and appear to play similar roles in the development of these organs. For example, the a-amylase promoter contains binding sites for HNF-3ß or HNF-3? required for efficient expression of this pancreas-specific gene. In a null mutation of murine HNF-3ß, initial endoderm differentiation occurs, but no foregut structures form, and specific pancreatic transcription factors are underexpressed (Pax6) or undetectable (Isl1) (see section "Pancreas"). In contrast, hindgut formation is relatively normal in many mutant embryos. [231], [232] Although new data continuously provide a more integrated view of transcriptional control, the findings summarized in the following text demonstrate the power of available techniques to define the genetic control of gastrointestinal development.

Pancreas

The significance of transcription factors in the initiation of pancreatic differentiation and further commitment to endocrine, exocrine, and ductular epithelium has been appreciated. In addition, different factors signal dorsal compared to ventral pancreatic bud development. Sonic hedgehog (Shh) and Indian hedgehog (Ihh) are expressed early in both mouse and human intestinal and stomach development, in the lateral prospective intestinal part of the epithelium, not in prospective pancreatic tissue. When Shh is overexpressed in transgenic mice, pancreatic differentiation is impaired and intestinal development is enhanced. [233] Although, as previously discussed, pancreatic endocrine cells arise independently of neural crest cells, the two cell types share many developmental similarities, including expression of similar peptides and transcription factors. Furthermore, the region of the intestine fated to form the dorsal pancreatic bud is initially in direct contact with the notochord; notochord-derived fibroblast growth factor 2 (FGF-2) and activin-ß repress Shh and Ihh expression in this primitive region of the intestine, an essential event for early pancreatic differentiation. [234] The ventral pancreatic bud is never in contact with the notochord, and thus its early differentiation appears to be notochord-independent. Targeted deletion of the homeobox gene *Hlxb9* selectively blocks dorsal, but not ventral, pancreatic development. [235] Isl1, expressed in all adult islet cells, [236] first appears at 9 days of mouse gestation, immediately before the appearance of insulin- and glucagon-expressing endocrine cells. Isl1 is also expressed later in somatostatin and pancreatic polypeptide–expressing cells, immediately before expression of these peptides. Mesenchyme adjacent to the dorsal, but not ventral, bud of the primitive pancreas also expresses Isl1. In mice with targeted disruption of the Isl1 gene, ventral pancreatic epithelium and adjacent mesenchyme appear normal at 9.5 days of gestation. [237] In the dorsal bud, however, there is a complete lack of adjacent mesenchyme, and dorsal endocrine cells fail to appear, suggesting that Isl1 is required for dorsal mesenchyme and endocrine cell development. Isl1 is important for maximal expression of Pdx1. In turn, BETA2 (ß-cell E-box transactivator 2), a basic helix-loop-helix transcription factor, activates Isl1 expression. [238] BETA2 dimerizes with the ubiquitous E47 basic helix-loop-helix factor to transactivate the insulin promoter. [239] BETA3, homologous to BETA2, inhibits binding of BETA2 to the insulin E-box enhancer. [240]

Pdx1, or Ipf1, is a homolog of *Xenopus* XlHbox 8, a homeobox gene that plays a key role in *Xenopus* pancreatic and duodenal development. [241] Initially cloned as an activator of the insulin and somatostatin promoters, murine Pdx1 is first expressed in the dorsal endoderm of the primitive gut while it is still an open tube at 8.5 days of gestation. By day 9.5, Pdx1 expression is associated with the emerging dorsal and ventral pancreatic buds as well as with the duodenal endoderm between them. [242] Pdx1 expression is subsequently down-regulated but reappears in differentiating ß-cells during later gestation. Expression is maintained in adult mouse duodenal epithelial cells and islet ß-cells, where it transactivates the insulin gene. Mice with targeted deletion of *Pdx1,* as well as humans not expressing *Pdx1,* lack a pancreas and die soon after birth with elevated urinary glucose levels. [243] Closer examination of the *Pdx1*-deficient mice reveals that the initial stages of dorsal bud formation occur along with the appearance of insulin- and glucagon-expressing cells at the appropriate time. [244] The adjacent mesenchyme develops normally and is capable of directing normal development of pancreatic rudiments at the same stage of arrested development of the mutated mice, suggesting that development of the pancreatic mesenchyme is independent of Pdx1 expression and development of adjacent pancreatic epithelium. Pdx1 acts downstream of the initial specification of gut endoderm to a pancreatic fate. Following these initial changes, Pdx1 is required for the expression of genes that allow the pancreatic epithelial cells to grow, branch, and differentiate. The lack of Pdx1 in insulin- and glucagon-expressing cells indicates that the endocrine cell phenotype is not dependent on Pdx1, although late terminal differentiation of ß-cells and the maintenance of insulin gene expression in adulthood is Pdx1-dependent.

Following Pdx1-mediated stages of differentiation, Isl1, NeuroD/ß2, Pax4, Pax6, and NKX2.2 are expressed in both developing pancreatic and neuronal tissues, and are important for pancreatic endocrine commitment. [245] Parallel to neuronal development, pancreatic endocrine differentiation occurs through the notch signaling

pathway. Mice deficient for Dll1(delta-like 1), the intracellular mediator RBP-J?, or Hes (hairy and enhancer of split), as well as mice overexpressing ngn3 (neurogenin3) or Notch3, which repress notch signaling, demonstrate premature differentiation of pancreatic endocrine cells and depletion of pancreatic precursor cells. [246], [247] and [248] Moreover, targeted deletion of *ngn3* results in a pancreas without any endocrine cells, [249] further implicating the notch signaling pathway in pancreatic endocrine differentiation.

Exocrine cell differentiation is also controlled at the transcriptional level. Analysis of the elastase I promoter has identified a complex enhancer region and unique transcriptional controls in both exocrine and endocrine differentiation. In transgenic mice, the transcriptional enhancer of the rat elastase I gene lies proximal (-72 to -205) to the transcriptional start site and consists of three principal *cis*-regulatory elements. The A element, common to many exocrine pancreatic gene promoters, binds an acinar-specific transcription factor, pancreas transcription factor 1 (PTF1), and is itself sufficient to direct acinar-specific transcription of the elastase I gene. [250] PTF1, first expressed at 15 days of mouse gestation, may be responsible for the high level of acinar transcription of multiple genes at this stage of development. The B element of the elastase I promoter enhances the level of elastase I gene transcription in concert with the A element, but it is insufficient to activate transcription by itself through the binding of an unknown B element binding factor. The C element is required for optimal transcription of elastase I in acinar cells, but like the B element, it cannot activate transcription alone. [251] Future analyses of exocrine cell–specific genes will further elaborate the mechanisms of transcriptional control of pancreatic exocrine development.

Small Intestine and Colon

Transcriptional hierarchies responsible for tissue- and cell-specific expression exist along the length of the entire GI tract. As described above, normal gut tube formation is dependent on reciprocal interactions between the endoderm and the mesoderm. [252] HNF-3ß, which plays an important role in early gut endoderm formation, is capable of inducing transcription of *Shh,* a segment polarity gene, expressed in the earliest stages of chick gut formation in the primitive endoderm. [253] *Shh,* in turn, induces expression of members of the Abd-B class of *Hox* genes during early hindgut formation, perhaps through the induction of mesodermal *Bmp4,* a member of the TGF-ß superfamily. [254] *Hox* gene expression then plays a critical role in the formation of gastrointestinal morphologic boundaries. This is illustrated by mice carrying the null mutation for *Hoxd12* or *Hoxd13,* both of which demonstrate disorganization of the anorectal region, manifest by decreased rectal smooth muscle formation and defective morphogenesis of the internal anal sphincter. Transgenic mice overexpressing *Hoxl4* exhibit altered formation of hindgut structures, leading to the appearance of megacolon. [255] Mice with disruption of the *Hoxc4* gene die soon after birth secondary to complete blockage of the esophageal lumen and disorganization of the esophageal musculature. [256] Deletion of *Hoxa5* results in normal morphogenesis but delayed functional maturation of the small intestine, exhibited by lower brush border hydrolase expression at the time of weaning. [257] Gene deletions of other *Hox* family members should provide more insights into the role of these factors in gastrointestinal regionalization and morphogenesis.

Homeobox genes lying outside the *Hox* gene clusters also appear to be important in the regulation of differentiation of the digestive tract. Homologs of the *Drosophila* caudal gene likely play important roles in intestinal development. These genes, designated *Cdx1* and *Cdx2* in the mouse, are expressed early in development when endoderm differentiates into columnar epithelium within nascent villi. [258] *Cdx2* expression is observed proximally by day 9.5 of gestation in the mouse, *Cdx1* not until day 12.5 in the distal hindgut. [259] Postnatally, *Cdx2* is strongly expressed at the crypt-villus junction and into the villus, whereas *Cdx1* becomes more restricted to the proliferative area of the crypt, suggesting roles for these transcription factors in the patterning of the vertical intestinal axis. Inactivation of *Cdx2* in mice is embryonically lethal in homozygotes; heterozygotes demonstrate polypoid lesions predominantly in the proximal colon, which is the region of peak overlap between *Cdx1* and *Cdx2* expression. These lesions are predominantly hamartomas [260] or lesions composed of heterotopic stomach and small intestinal mucosa, [261] suggesting important roles for *Cdx2* in regional cellular differentiation. *Cdx1* homozygous null mice have grossly normal GI tracts, although the intestinal phenotype has not yet been studied in detail. [262]

Examination of the regulation of cell-specific gene products should elucidate the molecular mechanisms controlling development in the intestine. Of the multiple cell types found in the intestine, study of enterocyte-specific gene products, including sucrase-isomaltase, LPH, and the fatty acid–binding proteins, has yielded the first insights into transcriptional control. The *cis*-regulatory elements required for intestine-specific transcription are often found proximal to the transcriptional start site, in a manner similar to that for the elastase I gene. For example, the nucleotide sequence -103 to +28 of the rat intestinal fatty acid–binding protein is sufficient to limit expression to the enterocyte, [263] although elements outside this region do further modulate expression.

The sucrase-isomaltase gene is expressed along a vertical and horizontal gradient. [264] Studies using transgenic mice in which various regions of the sucrase-isomaltase promoter direct the growth hormone reporter gene have revealed that the sequence -8500 to +54 of the promoter directs transcription to all four intestinal cell types. Using -3524 to +54 limits transcription to enterocytes and endocrine cells, whereas using only -201 to +54 limits transcription almost exclusively to enterocytes. [265] Further analysis of the sucrase-isomaltase promoter in transient transfection assays revealed specific regulatory elements. [266] The SIF2 (sucrase-isomaltase footprint 1) and SIF3 elements are positive regulatory elements and bind HNF-1a and HNF-1ß with different affinities. [267] An increase in HNF-1a binding to the SIF3 element compared to HNF-1ß coincides with a marked induction of sucrase-isomaltase at weaning in mice. [268] The SIF1 element, a 22-nucleotide element located just upstream of the transcriptional start site, binds Cdx2. [269] Cdx2 transactivates sucrase-isomaltase and LPH transcription, [270] binds to multiple intestine-specific genes, [271] and induces enterocyte and goblet cell differentiation of undifferentiated small intestine epithelial IEC-6 cells, suggesting that Cdx2 plays a role in the initiation of intestinal differentiation in addition to maintaining the enterocyte phenotype. Cdx2 and HNF-1a act synergistically through direct protein-protein interaction to activate expression of the LPH gene by binding to their closely linked regulatory elements in the LPH promoter in the intestinal Caco-2 cell line. [272]

Laminin-1 stimulates small intestine villus differentiation through induction of Cdx2 expression. [273] Careful examination of the promoters of other intestine-specific genes, such as the trefoil peptides for mucus-expressing cells, cryptdin for the Paneth cells, and the various peptides expressed by enteroendocrine cells, should similarly provide new insight into gastrointestinal development. For example, keratinocyte growth factor (KGF) promotes goblet cell differentiation in a colonic cell line through the induction of a novel transcription factor, the goblet cell silencer inhibitor–binding protein (GCSI-BP), which may play an important role in intestinal goblet cell differentiation. [274]

As discussed previously, Pdx1 is important in islet cell development of the pancreas and enteroendocrine cell development of the upper small intestine. When Pdx1 is transfected into the rat small intestine cell line IEC-6, the cells become capable of producing multiple enteroendocrine peptides, including serotonin, CCK, gastrin, and somatostatin. Thus, the homeobox Pdx1 gene promotes enteroendocrine differentiation in enterocytes. [275]

The complexity of the transcriptional regulation of intestinal development has been further underscored through the analysis of factors controlling the expression of genes encoding regulatory factors such as Cdx1 and Cdx2. For example, the Wnt/ß-catenin signaling pathway induces expression of Cdx1 in rodent embryonic stem cells and endoderm. [276] TCF-4, a member of the TCF/LEF-1 (T-cell factor/lymphocyte enhancer factor 1) family of transcription factors, mediates the ß-catenin transactivation of the Cdx1 gene through several TCF-binding motifs located in the Cdx1 promoter. Mice homozygous for a targeted deletion of *Tcf4* reveal a decreased number of villi, a lower number of intervillus proliferating epithelial cells from which postnatal crypts derive, and a complete lack of enteroendocrine cells. [277]

The forkhead family of transcription factors is also expressed in the developing intestine in both the epithelium and surrounding mesenchyme. Mice with targeted deletions of the *Fkh6* mesenchymal gene demonstrate precocious fetal crypt development, particularly in the proximal small intestine. [278] Postnatally, crypts are enlarged, disorganized, and branched and form cell-lined cysts, suggesting that Fkh6 inhibits crypt cell proliferation. Although all four cell lineages are present in *Fkh6* mutant mice, there is a selective increase in the goblet cell population in the duodenum and jejunum. Other members of the forkhead family that are expressed in developing intestine include *HFH1* and *HNF3ß,* expressed in both the mesenchyme and epithelium of the fetus but restricted to proliferating crypt cells in the adult mouse, suggesting roles in intestinal development and proliferation. [279] *Nkx2-3* is similarly expressed in proliferating crypts, and targeted deletion resembles the *Fkh6* knock-out except that goblet cell numbers are not increased. [280] Bone morphogenetic proteins (BMPs) also have been implicated in intestinal development [281]; *Nkx2-3* knock-out mice are associated with markedly reduced expression of antimitotic *BMP2* and *BMP4*. [280]

The inhibitory transcription factors, Ids, are dominant-negative basic helix-loop-helix proteins that antagonize other helix-loop-helix transcription factors. Ectopic expression of Id-1 in transgenic mice with use of the fatty acid–binding protein promoter results in a subset of transgenic mice that manifest intestinal adenomas and Paneth cell loss. [282] Interestingly, transgenic mice heterozygous for a mutant allele of the adenomatous polyposis coli gene, Apc^{min}, develop multiple intestinal adenomas that may be secondary to altered phospholipase A_2 expression from Paneth cells. [283] However, diphtheria toxin A–mediated Paneth cell ablation in mice does not lead to the development of intestinal adenomas, suggesting complex interactions between Paneth cells and growth control in intestinal crypts. Mice

homozygous for targeted disruption of *Id1* demonstrate no obvious intestinal phenotype. [284]

GROWTH AND DIFFERENTIATION IN THE MATURE GASTROINTESTINAL TRACT

Cellular Components

Undifferentiated stem cells are present throughout the GI tract. In the small intestine, they give rise first to committed stem cells [285] and then to four distinct cell lineages: the Paneth cell, which migrates downward; the goblet; the enteroendocrine; and the most abundant columnar absorptive cell. The latter three migrate up the villus. The committed stem cells retain proliferative activity and reside in the middle zone of the crypt. By the 2nd postnatal week in rats, each crypt appears to be a monoclonal population derived from a single stem cell anchored three to five cell positions from the base of the crypt. Although there are no markers for stem cells, indirect evidence and mathematical modeling suggest that in the small intestine, stem cells are located at the third to fifth cell positions, whereas in the colon they are located at the first to second cell positions. Transplanted isolated crypts in immunocompromised mice develop all four cell lineages; however, these experiments have not yet led to purification of the elusive stem cell. [286]

An analogous organization may be present at other sites along the length of the GI tract. In the stomach, neck cells located in the middle third of the gastric glands serve as stem cells for the mucus-secreting cells in the pit, pepsinogen-secreting chief cells at the base of the gland, and parietal, enteroendocrine, and caveolated cells throughout the pit-gland gastric unit. The esophageal epithelium forms three successive layers—the basal layer (cuboidal cells and the putative stem cell), the intermediate layer (prickle cells), and the functional layer (stratified squamous cells). [287] In the small intestine, the adult villus columnar cell undergoes significantly greater differentiation than its fetal counterpart. In early fetal life, columnar cells contain short microvilli and large glycogen deposits. During later fetal life, the organelles of the columnar cells differentiate, with the appearance and subsequent disappearance of the meconium corpuscle system and the apical tubular system. Columnar cells exhibit still further morphologic evolution during continued gestation, including a reduction in glycogen content, the appearance of smooth endoplasmic reticulum, and the development of tall, uniform microvilli. [288] The mature villus cell is a highly polarized cell with a well-organized complex of endosomal compartments and markedly different apical and basolateral surface membranes. A gradient of functional differentiation is present in enterocytes along the vertical axis of the villus.

In the adult GI tract, the presence of certain secretory products has led to the identification of more than ten distinct enteroendocrine cell types. In the stomach, the mucous neck cell is thought to be the stem cell for the enteroendocrine cell. The primary enteroendocrine cells in the gastric antrum are the gastrin (G) cell, which secretes gastrin, and the D cell, which secretes somatostatin. The gastric fundus also contains the A cell, which secretes enteroglucagon, and the ECL cell, which secretes serotonin and histamine. The small intestine contains enteroendocrine cells that migrate toward the villus tip, differentiating during this migration, as evidenced by an increase in the number of cytoplasmic granules and a progressive loss of the ability to divide. Studies using transgenic mice that express intestine-specific transgene products because of the presence of villus-specific intestinal fatty acid–binding protein promoters have demonstrated the fundamental heterogeneity of enteroendocrine cell populations. [289] Transgenic mice containing the 5' flanking region of the rat liver fatty acid–binding protein ligated to growth hormone reporter gene demonstrate expression in most CCK-, GIP-, secretin-, and glucagon-producing small intestine cells, as well as 30% of serotonin- and substance P–expressing cells. [290] These mice demonstrate two populations of colonic enteroendocrine cells: one group expressing peptide YY, neurotensin, glucagon, and CCK, and another group expressing serotonin/substance P. A 1.6-kilobase region of the rat secretin promoter directing the growth hormone reporter reveals a close association between secretin- and CCK-expressing cells in the small intestine and secretin/neurotensin and glucagon/peptide YY cells in the colon.

Goblet cells express specific *MUC2* and *MUC3* genes in the small and large intestines, [291] and provide the structural backbone for the unstirred, continuous layer of mucus that lines the intestine. These cells also express intestinal trefoil factor (ITF/TFF3), [292] a lumenally stable peptide that protects against gastrointestinal injury. [293] , [294] The number of goblet cells increases from the duodenum to the ileum; they respectively constitute 4%, 6%, and 12% of all epithelial cells. [295]

Paneth cells, which play a role in host defense, are the only cell lineage deriving from the crypt stem cells that migrate downward toward the crypt base. Each mouse crypt contains 30 to 50 mature Paneth cells, the longest-lived lineage, surviving for 18 to 23 days before being phagocytosed by neighboring cells. Products of Paneth cells include lysozyme, phospholipase A_2, [296] TNF-a, guanylin, and cryptdins, homologs of leukocyte defensins that possess antibacterial activity. [297] Although morphologically indistinguishable, Paneth cells are heterogeneous along the longitudinal axis of the intestinal tract, based on the specific cryptdins they express. [298]

Tuft cells, first described in mouse gastric mucosa in 1955, are widely distributed in the GI tract. [299] Recognized by distinctive caveolae invaginating the apical surface between individual long microvilli, they appear to be highly differentiated cells that, in the small intestine, arise from stem cells in the lower portion of the crypts. They migrate upward and are extruded from the villus tip. In mouse colon, tuft cells have an estimated turnover time of 8.2 days. Although their function is unclear, tuft cells contain an extensive vesicular network, consistent with a role in absorption.

The intestinal mucosa also contains the distinctive M cell, which is restricted to the dome epithelium overlying the lymphoid follicles of Peyer patches in the ileum and other lymphoid follicles in the more distal gut. [300] These cells appear to be important in sampling the antigen milieu in the lumen. Ironically, they also appear to be the avenue of infection for several viral agents (e.g., reoviruses) that can breach the mucosal barrier. Cells resembling adult M cells are first identified overlying lymphocyte aggregates in the distal small intestine in the 17th week of gestation, and their appearance is temporally related to the emergence of these lymphoid aggregates. The surface membrane of the M cell is characterized by microfolds instead of microvilli, and by abundant vesicles, which may facilitate the transport of lumenal antigens, microorganisms, and other macromolecules to the underlying lymphoid tissue. [301] M cells appear flattened because of the underlying accumulation of lymphoid cells in the connective tissue. [302]

Cell Kinetics

The epithelium of the GI tract undergoes rapid turnover in which cell production in zones of proliferation is usually balanced by apoptosis and cell extrusion, creating a steady state under normal conditions. True growth occurs when the rate of cell proliferation is greater than the rate of cell loss. Only selective populations of cells in the GI tract retain proliferative capability. The compartmentalization of proliferating populations and the zonal concentration of the nonproliferating cells committed to terminal differentiation are features shared by all regions of the lumenal GI tract.

The kinetics of cell proliferation has been largely defined through analysis of labeled mitotic frequencies after the administration of ^{3}H-thymidine to identify the fractional mitotic index. This analysis allows a determination of the duration of the constituent component phases of the cell cycle: S phase, or DNA synthesis; G_1, a premitotic latent period; M, a period of mitosis; and G_2, a pre-DNA synthesis latent period (Table 23-1). Pulse labeling of mucosal explants further permits an estimation of mucosal turnover rates as cohorts of labeled cells complete mitosis and emerge from the zone of proliferation to traverse the vertical distance to the surface mucosa before subsequent loss.

TABLE 23-1 Summary of Kinetic Parameters in Human Gastrointestinal Mucosa

Esophagus As stratified squamous epithelium, the esophageal mucosa differs from that of the rest of the intestinal tract. However, as elsewhere in the GI tract, proliferation in the esophagus occurs in the basal layer. Turnover of the esophageal squamous epithelium takes 4 to 5 days in rodents and longer in humans. [303] After cell division, one daughter cell may remain in the basal layer, one may migrate toward the esophageal lumen, or both may migrate. The life span of the basal cell in the esophagus is 80 hours in rats and mice and approaches 8 days in humans. [304] The rate of cellular proliferation in the esophagus is about one-third that in the jejunum. [305] This squamous epithelium is penetrated at irregular intervals by papillae of the lamina propria. Mucous glands similar to those found in the cardia of the stomach are found at the level of the cricoid cartilage beneath the epithelium. Having no secretory or absorptive functions, the esophageal mucosa serves mainly in a

protective capacity and has no specialized cells.

Stomach The stomach serves mostly as a secretory organ and contains many more specialized cell types than the esophagus. The body and fundus are lined by an epithelium that includes mucus-secreting cells extending into gastric pits, with long glands extending deep into the gastric mucosa. These glands are also lined by parietal cells, which secrete acid and intrinsic factor, and chief cells, which secrete pepsinogen. The mucous neck cells lie in the middle third of the gastric glands. The gastric antrum contains deeper gastric pits than the rest of the stomach, and these are lined in part by cells that secrete an alkaline mucus. Enteroendocrine cells are predominantly found in the middle portion of the gastric glands among the mucus-secreting cells in the antrum, body, and fundus. The pattern of expression of a transgene containing promoter sequences of the fatty acid–binding protein gene (*FABP*), a gene used as a marker of gastrointestinal differentiation, in the stomach suggests that mixed surface mucous cell populations exist in the gastric pits, unlike the coherent vertical bands found in small intestine villi. [306] These findings imply that a single isthmus contains more than one stem cell or that migration and differentiation are not as rigorously coupled as they are in the small intestine. The mucous neck cells, the principal proliferating cells of the stomach, migrate to the lumenal surface, where most differentiate into mucus-secreting cells. The cell population above the zone of proliferation for the gastric mucous–epithelial cell is replaced every 2 to 3 days in humans. Migration rates from the proliferative zone in the glandular neck to the surface are comparable to those in the small intestine and colon. [307] During development in the first 4 postpartum weeks, rates of DNA synthesis are markedly higher while fractional cell loss is lower, leading to significant mucosal growth. Parietal cells are incapable of dividing and are replaced by migrating cells that differentiate. [308] They appear to have a long life span (e.g., 90 days in the mouse). Most G cells located in the antrum are derived from mitosis of other G cells, although some may arise from the differentiation of other gastric cells. [309] G-cell turnover varies widely among animal species but is as long as 2 to 4 months in mice.

Small Intestine The small intestine mucosa is composed of villi, which project into the lumen, and the surrounding crypts of Lieberkuhn, which project away from the lumenal surface. A single layer of columnar cells lines the crypts and villi. [310] As they migrate, the columnar cells differentiate into the other small intestine cell types. Enteroendocrine cells also migrate toward the villus tip. Mature goblet cells are located in the upper crypts and villi, and immature oligomucous cells are limited to the crypts. Paneth cells are located at the base of the crypts. Transitional cells with features common to columnar and goblet cells are also found in the crypts. At birth, the progeny of several uncommitted stem cells populate the crypts. However, by the end of second postnatal week in mice, a selection process of unknown mechanism, termed *purification,* enables a single stem cell to dominate, and the cell population in a single crypt is clonal in origin. [311] Progeny from that crypt migrate up adjacent villi (Fig. 23-8). Because four to ten crypts surround most villi, villi are composed of linear stripes of cells of different lineage. This may be especially true in the context of X-linked genes in females, which undergo random X inactivation, creating mosaicism for those gene products.

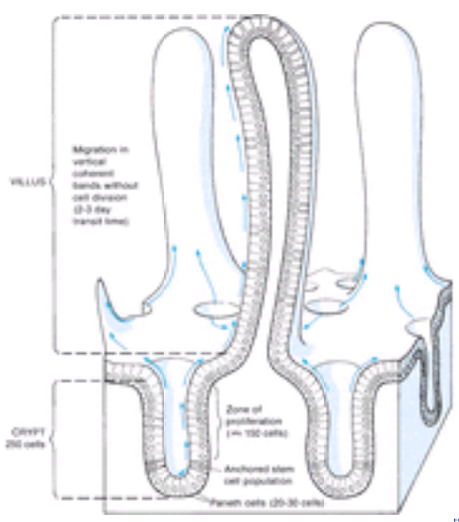

FIGURE 23-8. Schematic representation of the crypt-villus relation in the adult mouse small intestine. Each villus base is surrounded by 6 to 14 crypts, fewer proximally and more distally in the ileum (i.e., a horizontal gradient). The lower five cell positions contain a total of 40 to 50 cells that have an average cycle time of 26 hours and contain 20 to 30 nonproliferative Paneth cells. Anchored stem cells exist at the fifth position, with maximal rates of proliferation. The Paneth cells migrate from this position toward the villus tip and the crypt base. The upper portion of the crypt contains proliferating cells that undergo upward migration; 275 cells are delivered to the villus base from each crypt. This migration occurs in strict vertical, coherent bands toward the villus tip, where the cells are extruded.

In the organization of the intestinal crypt, true stem cells are present at a fixed position in the middle-to-lower region of the crypt cell, and a zone of clustered, actively proliferating progeny is just above in the midzone of the crypt. Clonal analysis reveals intermediate committed stem cells of two types: short-lived stem cells giving rise to one or two cell types and long-lived cells giving rise to all four cell types. [312] Columnar cell migration from the crypt base to the villus tip takes 5 to 6 days in the human proximal small intestine and 3 days in the human ileum. On average, these cells migrate one to two cell positions per hour. [313] As cells exit the crypt and enter the villus, they stop cycling and become trapped in the G_1 phase of the cell cycle as a result of down-regulation of cyclin D_1 and cyclin-dependent kinase 2. [314] After 2 to 3 days, they reach the villus tip, where, at least in the mouse, they shed at a rate of 1400 cells per villus per day. However, as ^{3}H-thymidine labeling has shown, a few scattered cells may remain for weeks. The shorter migration time in the distal than in the proximal small intestine may be secondary to the proximal-to-distal villus height–crypt depth gradient (i.e., the progressive decline in crypt depth and villus size through the length of the small intestine). Apoptosis, or programmed cell death, plays an important role in determining the architecture of intestinal epithelia. Two major apoptotic pathways have been identified. In the crypt, at the level of the stem and early committed stem cells, spontaneous apoptosis occurs at a low rate and regulates the number of cells entering the crypt-villus axis. [315] Mice bearing targeted deletion of *Bcl2* demonstrate increased levels of this spontaneous apoptosis in the crypt base of the colon, but not the small intestine. [316] In contrast, *Bax*-deficient and *p53*-deficient mice have normal levels of spontaneous crypt apoptosis. [317], [318] The trefoil peptide, ITF, inhibits crypt cell apoptosis through transactivation of the EGF receptor and phosphatidylinosotol 3-kinase (PI_3-K)-AKT pathways. [319], [320] Another pathway for spontaneous apoptosis in intestinal epithelia takes place at the villus tip, although apoptotic morphology is only rarely seen during the extrusion process. [321] This pathway is induced by activation of capsase 3, [322] but less is known about the role of specific apoptotic factors in the extrusion process. The cell cycle of the human small intestine basal crypt cell takes about 10 hours. Great variability exists, however; those cells that survive for weeks remain in a prolonged G_2 or G_0 (i.e., resting) phase. Neuroendocrine cells have cell cycles that last for several days, and Paneth cells turn over every 23.3 days, apparently being cleared from the crypt base by phagocytosis.

Colon The colon has a flat surface without villi, and cells appear to be extruded directly from the flat surface onto the bowel lumen. The proliferative zone is found in the basal half of the colonic crypts. Overall, the proliferative capacity of colonic crypts is comparable to that of the small intestine. However, proliferative activity appears to be greater in the distal colon than in the more proximal bowel. Crypts in the ascending colon have been estimated to contain 100 proliferating cells and produce six cells per hour, and the distal colonic crypts to contain 200 cells, producing 21 cells per hour. [323] Less is known about the organization of the stem cells and the zones of proliferation and differentiation in the colon than in the small intestine. However, observations of mice and colon tumors support a similar arrangement for colon and small intestine: an anchored stem cell giving rise to clonal populations of cells in a single crypt and the presence of a larger number of committed but proliferatively competent cells in the midportion of the crypt. The latter are presumed to give rise to the several cell types found in the normal colonic epithelium, most notably columnar absorptive cells and goblet cells. This suggestion is supported by the demonstration of clonality in colonic crypts and colonic tumors with the use of techniques to identify mosaicism of expression of X-linked markers in females and restriction fragment length polymorphism analysis. [324] The validity of the analogy is also supported circumstantially by the close ontogenetic similarity between colonic and intestinal epithelia with the identification of several colon cancer–derived cell lines (e.g., Caco-2, HT-29) that recapitulate the entire spectrum of small intestine epithelial cellular constituents when their growth conditions are properly manipulated. The proliferative zone is located in the bottom of the colonic crypt, with migration to the lumenal surface taking 3 to 8 days in humans and 2 to 3 days in rodents. [325] Great variability exists in the size and shape of the colon crypts along the length of the colon, and in the duration of the cell cycles of the proliferating crypt cell. [326] About 15% to 20% of cells in the crypt appear to be involved in DNA synthesis at any one time. In humans, the cell cycle duration varies from 58 hours in the descending colon to 25 hours in the cecum, with this variability a consequence of variability in the G_1 phase of the cell cycle. Cells migrate at somewhat less than one cell position per hour. Enteroendocrine cells undergo cell renewal more slowly, and populations appear to turn over in 35- to 100-day intervals. [327]

Cell Kinetics in Gastrointestinal Disorders Alterations of cell kinetics in a selected spectrum of gastrointestinal disorders provide insights into the mechanisms regulating cell growth. Inflammatory or destructive lesions of the intestinal tract induce proliferation or atrophy of the mucosa. In the esophagus, injury resulting from reflux esophagitis is characterized by a thickened basal layer in the involved portion of the esophagus, as demonstrated by increased ^{3}H-thymidine incorporation in the proliferative basal layer. In the stomach, stress-induced gastric erosions are associated with a decrease in gastric epithelial mitosis and thymidine labeling, and pernicious anemia is linked with a decrease in thymidine labeling, migration, and proliferation of gastric epithelial cells, and an increase in endocrine cell proliferation and gastric carcinoids secondary to hypergastrinemia. [328] Ethanol decreases the depth of gastric pits within 4 hours in the dog stomach, but mitotic activity increases at 20 to 24 hours with a prompt renewal of normal gastric mucosa. In the small intestine, ethanol decreases crypt and villus cell number and is associated with shorter villi in the jejunum. Ileal crypts reveal increased mitotic and thymidine kinase activity and an increased cell number in response to injury induced by alcohol. [329] In the

mucosa of patients with duodenal ulcer disease, a fall in thymidine incorporation and mitosis occurs, and this decrease in proliferation has been implicated in the pathogenesis of peptic ulcerations. Infection with *Helicobacter pylori,* a bacterium that colonizes gastric epithelium with great specificity, can result in either gastric atrophy or hypertrophy. Furthermore, the *Helicobacter* species can induce apoptosis of gastric epithelial cells by the stress-activated protein kinase SAPK/JNK pathway. [330] In the colon, repeated radiation injury leads to cell death. In mice with surviving cells, crypts are larger and have higher labeling indices than those in control mice. [331] Irradiation also alters epithelial cell morphology, and in humans results in the appearance of cuboidal epithelial cells and a decreased mitotic rate. After irradiation, early cell proliferative activity is seen at the bottom of the crypt, suggesting that this is where the putative stem cell resides. [332] Mice deficient in p53 demonstrate an absence of stress-induced apoptosis that would normally be observed 3 to 4 hours after ?-radiation. [333] Thus, acute apoptosis after radiation is p53-dependent. BCL2 also plays an important role in the apoptotic response to radiation in the colon, but not in the small intestine. Disorders of the GI tract that are precursors to malignancy are associated with various degrees of altered cell proliferation. In Barrett epithelium, for example, the number of proliferating cells is increased and some proliferative cells are present on the mucosal surface. Intestinal metaplasia is found and an increase in ^{3}H-thymidine incorporation occurs at the base of the villus-like columnar epithelium. [334] A similar pattern is observed in atrophic gastric mucosa with a selective increase in mitotic activity found in those glands demonstrating intestinal metaplasia. [335] Aberrant crypt foci, which on staining appear darker, larger, and thicker than normal crypts, cluster in aggregates and increase in size over time. [336] These foci grow by crypt fission and branching; they contain hyperproliferative epithelial cells and have a higher labeling index. [337] Although only a minor fraction of aberrant crypt foci undergo malignant transformation, these foci are recognized as an intermediate precursor of colorectal carcinogenesis. [338] In colonic adenomas, progressive expansion of the proliferative zone to the lumenal surface has been demonstrated. Abnormal retrograde migration from the mucosal surface also occurs, a pattern that is accentuated in colonic carcinoma. In the mucosa of patients with Gardner syndrome or familial polyposis, progressive expansion of the proliferative compartment occurs to the extent that mitosis may be seen anywhere in the mucosa. [339] Cell proliferation of flat colorectal mucosa is increased in patients with sporadic colonic tumors. Expansion of the proliferative zone toward the lumen has also been observed in ulcerative colitis. Higher rates of proliferation of the colonic mucosa appear to persist during the remittent stages of ulcerative colitis. Alterations in the cell cycle and resistance to apoptosis may also contribute to the development of colorectal carcinogenesis. Whereas low-level apoptosis occurs in the stem cell region of small intestinal crypts, apoptosis does not occur in the stem cell zone of colonic crypts. [340] In colonic adenomas and carcinomas, apoptosis is reduced. [341] In the goblet cells of “normal” colorectal mucosa in patients with colon cancer, the levels of apoptosis are reduced. [342] The APC (adenomatous polyposis coli) gene, mutated in familial adenomatous polyposis and some sporadic colorectal cancers, appears to be an important mediator of apoptosis resistance in colorectal carcinoma. [343]

Regulation of Proliferation and Differentiation

The functional importance of the constant cycle of proliferation, differentiation, and senescence in the GI tract is not entirely clear but may reflect a necessary means of protection from the constant exposure of mucosal cells to potentially injurious factors present in the lumen. Rapid replacement of the mucosal cells could be especially important in the colon, where the lumenal contents often include potent mutagens and carcinogenic substances. The high rate of cell turnover requires exquisite regulatory mechanisms to maintain mucosal homeostasis. Apoptosis, cell proliferation, and cellular commitment to differentiation must be balanced precisely. Myriad factors modulate this balance, including nutrients and other factors in the lumen and the proteins and hormones produced within the mucosa and at more distant sites.

Unlike the needs of other tissues in the body, the nutritional requirements of the GI tract mucosa are usually obtained directly from dietary components in the lumen. Lumenal substances, including nutrients and other factors, regulate growth and differentiation in three ways: by inducing direct effects on the absorptive cells before entering the systemic circulation, by stimulating systemic factors (e.g., trophic hormones), and by modulating motor activity. It has been suggested that the villus height–crypt depth gradient in the small intestine reflects the important contribution of lumenal nutrient concentration to mucosal growth. The greater villus height and crypt depth in the proximal small intestine may result in part from exposure to higher concentrations of nutrients, local growth factors, and pancreaticobiliary secretory products than in the more distal intestine. Transposing the ileal and jejunal loops reverses the gradient; the transposed ileal segment exhibits increased villus size, and the distally placed jejunal segment contains smaller villi. [344]

The role of lumenal factors in the maintenance of mucosal growth has been examined through the use of Thiry-Vella loops, in which intestinal segments with intact neurovascular connections are disconnected from the remainder of the bowel and the two ends are brought to the abdominal wall. [345] These loops may be used to study local effects of a variety of factors and to assay directly the importance of lumenal substances on mucosal growth and proliferation. After Thiry-Vella loops are formed from jejunal or ileal segments, hypoplasia of the intestinal mucosa is observed. Administration of liquid elemental diets into the bypassed segments in the dog induces mucosal hyperplasia. [346] However, comparable nutrient effects were not observed in similar studies performed in rabbits. [347] Furthermore, systemic interleukin-11 prevents the mucosal atrophy observed in Thiry-Vella loops. [348]

Small intestine resection leads to hypertrophy and dilation of the remaining small bowel, with epithelial cell hyperplasia, villus growth, increased cell migration rates, and increased absorptive capacity. [349] Local nutrition may be important in the development of hyperplasia after resection; dogs fed intravenously after jejunal resection do not show the same adaptive proliferation response observed in dogs fed orally. Intravenous feeding was also associated with decreased pancreatic secretion and reduced levels of several gastrointestinal hormones. The latter observations suggest that lumenal nutrients may exert their trophic actions directly or indirectly through the stimulation of hormones and other peptides, and through neural mediators, which modulate mucosal growth (i.e., neurocrine regulation). This concept is supported by the observation of gastric hypersecretion after small intestine resection in the dog, rat, and human, indicating that trophic factors such as gastrin could play a role in the adaptive response to small intestine resection by way of local (i.e., paracrine regulation) or systemic (i.e., hormonal regulation) action.

Other observations suggest that the importance of lumenal nutrients and other lumenal factors may be limited. Hyperplasia has been observed in ileal mucosa after resection of the colon. [350] Similarly, distal small bowel resection has been associated with hyperplasia of the more proximal small bowel, and resection of distal or proximal small bowel can result in hyperplasia of the gastric mucosa. [351] The mucosal hypoplasia observed in Thiry-Vella loops may be reversed by partial resection of any of the small intestine remaining in continuity. Additional evidence supporting the concept that systemic factors may be more important than the direct effect of the lumenal contents is derived from the study of paired rats in which cutaneous or vascular connections were established. In these studies, mucosal hyperplasia was observed in the small bowel of control (nonoperated) rats when connected to rats undergoing small bowel resection.

Glucose stimulates cell production and mucosal hyperplasia of the proximal small intestine when infused into surgically prepared sacs. [352] However, in the same system, galactose, methylglucoside, and NaCl, which are actively transported but not metabolized by the small bowel mucosa, have the same trophic effect as glucose. Mannose, which is not actively transported or metabolized by the small intestine, does not increase cell production or cause mucosal hyperplasia. These findings have led to the notion that the active transport workload itself may be the stimulus for growth in response to some lumenal factors; this is the functional workload hypothesis.

The importance of local nutrition in the regulation of intestinal growth is further discounted by the results of a series of experiments in which amino acid incorporation was studied. [353] Orally administered labeled amino acids were found to be incorporated into nonproliferating surface villus absorptive cells of the small bowel mucosa. However, amino acid incorporation in the proliferative zone of the crypt is slight unless the amino acids are provided by an intravenous route. These observations demonstrate a differential economy between the functionally active but mitotically inert differentiated villus cells and the actively proliferating crypt compartment. These results are consistent with the observation that lumenal nutrients can lead to villus hypertrophy but not true mucosal hyperplasia.

Fiber within the diet may have an important effect on mucosal proliferation. When cellulose is added to a low-fiber synthetic diet, an increase in DNA synthesis and content in gastric and colonic mucosa ensues, regardless of the protein or carbohydrate content of the diet. [354] Guar and pectin, two fibers that are poor bulking agents, are stimulants of growth in the colon, indicating that the effect of fiber on growth is not simply through bulk. [355] Kaolin, an excellent bulking agent, does not appear to have any effect on mucosal growth. Fibers that cause fermentation appear to stimulate colonic mucosal growth more than those that are inert, an effect possibly mediated through a decrease in lumenal pH in the colon. The proliferative effect of refeeding fermentable dietary fiber to starved rats is not seen in germ-free rats, indicating that the products of intestinal fermentation, and not fiber itself, stimulate intestinal growth. [356] Specifically, dietary fiber acts as the main substrate for the fermentation of short-chain fatty acids—butyrate, propionate, and acetate. [357] Of these, butyrate serves as the principal energy source for colonic epithelial cells. Further, butyrate stimulates cell proliferation of normal colonic crypts; reduction of lumenal butyrate levels leads to mucosal atrophy, which is reversible by the administration of butyrate. [358] In contrast, butyrate inhibits proliferation of neoplastic colonic epithelial cells by inhibiting DNA synthesis and arresting colonocytes in the G_1 cell cycle phase and induces differentiation and apoptosis in neoplastic, but not in normal, colonocytes. [359]

The polyamines spermidine and spermine, and their precursor putrescine, are present in the diet and synthesized in the gut lumen. After ligation of the small intestine in the rat, the concentrations of lumenal polyamines increase markedly in the proximal bowel, where a large increase in mucosal growth also occurs. [360] Polyamines

may contribute to the longitudinal gradient of growth observed in the small intestine. Moreover, infusion of dietary polyamines prevents the decrease in gastric and small intestine weight and in DNA, RNA, and protein content normally observed after antrectomy. [361] The trophic effect of polyamines on the gastric mucosa is independent of their ability to stimulate gastrin release, because comparable trophic effects are found after antrectomy.

Ornithine decarboxylase is the enzyme controlling the rate-limiting step in the formation of the polyamines spermine and spermidine. The activity of this enzyme is increased by many gastrointestinal proteins, by food, after partial resection, and during lactation. Difluoromethylornithine, an inhibitor of ornithine decarboxylase activity, decreases the proliferative response to lactation, intestinal obstruction, and feeding. [362] In response to feeding or refeeding, an increase in ornithine decarboxylase has been observed, predominantly in nondividing villus cells near the lumenal surface. In contrast, EGF leads to increased ornithine decarboxylase activity throughout the entire length of the crypt-villus unit. [363] Certain growth factors may increase ornithine decarboxylase activity in stem cells and influence intestinal growth through this mechanism. Polyamine synthesis and subsequent cellular proliferation after refeeding of cultured gastrointestinal crypt cells appears to be regulated by a calcium-activated, calmodulin-dependent process. [364]

Several gastrointestinal proteins with potential growth-modulating properties are present in the intestinal lumen and may exert growth regulation effects through interaction with the lumenal mucosal surface. EGF and EGF-related peptides, including TGF-a, interact with the intestinal lumenal surface. EGF is synthesized in the salivary glands and Brunner glands of the duodenum, a distribution consistent with the notion that this protein could contribute to the proximal-to-distal horizontal gradient of villus height–crypt depth found in the small intestine. [365] EGF is not present in serum in physiologically important amounts.

Gastrin is found in the intestinal lumen in large amounts. It is synthesized in the proximal GI tract, with the highest rates of production in the gastric antrum and smaller quantities in the duodenum and pancreas. When gastrin was infused into the ileum through a catheter, mucosal hyperplasia was observed downstream from the catheter in the absence of a demonstrable elevation of serum gastrin levels. However, when the same amount of gastrin was infused into the stomach, the peptide was degraded, and no trophic effect was observed in the gastric or small intestine mucosa. [366] These findings suggest that lumenal gastrin may not be present in sufficient quantities in the lumen under physiological conditions to play an important role in regulating mucosal growth and proliferation. However, gastrin exerts systemic trophic effects on the gastrointestinal mucosa (see section “ Gastrointestinal Peptides ”).

Prostaglandins appear to promote small intestine and gastric proliferation and growth, but some studies indicate that they may inhibit growth in the colon. Nonetheless, rats treated for 48 hours with 16,16-dimethylprostaglandin E_2 exhibit an increase in gastric and small intestine weight and an increase in ^{3}H-thymidine incorporation into the mucosa of the duodenum and colon. [367] Prostaglandins delivered by a gastric feeding tube produce an increase in antral weight and in small intestine weight and length. A similar study shows increased mucosal thickness throughout the digestive tract, most marked in the antrum, after administration of exogenous prostaglandins. [368] Prostaglandins are gastroprotective against alcohol, acid, hypertonic saline, and alkali at doses below those required to inhibit acid secretions. Furthermore, they prevent ethanol-induced decreases in gastric mucosal DNA, RNA, and protein content.

Pancreatic and Biliary Secretions Several proteins synthesized by the endocrine pancreas that are capable of trophic effects on the intestinal mucosa are also found in exocrine pancreatic secretions. These include gastrin, insulin, and glucagon. The concentration of these proteins from pancreatic secretions decreases along the length of the small intestine in parallel with a proximal-to-distal gradient of growth in the small intestine. Diversion of pancreatic and biliary secretions into the ileum causes ileal mucosal hyperplasia in the rat. [369] However, displacement of these secretions into the distal ileum does not result in hypoplasia or decreased growth of crypts or villi in those areas of the proximal intestine removed from exposure. [370]

Systemic Factors Several nongastrointestinal hormones are thought to play a role in the maintenance of intestinal growth. Hypophysectomy results in decreased weight, mitotic activity, villus height, and diameter of the small intestine in experimental animals. [371] Hypophysectomy also decreases the incorporation of thymidine and orotic acid into DNA and RNA in the intestinal mucosa and leads to reduced rates of protein synthesis. Hypophysectomy results in atrophy of parietal and chief cells in the gastric mucosa. However, hypophysectomy also markedly decreases appetite and food intake and may exert some of its effects through its impact on some of the lumenal factors discussed previously. Moreover, the various pituitary hormones removed by hypophysectomy may affect intestinal growth indirectly by undefined influences on various gastrointestinal proteins. Serum gastrin levels decrease by 60%, in parallel with decreases in antral gastrin content after hypophysectomy. Small intestine secretin content is also iminished in this setting. Adrenalectomy results in gastric and intestinal atrophy to a lesser degree than hypophysectomy. ACTH and glucocorticoids inhibit cell proliferation in the stomach and, to a lesser extent, in the duodenum. In other regions of the small intestine, glucocorticoids increase digestive and absorptive functions but decrease cell proliferation. [372] Glucocorticoids increase antral gastrin levels in the rat and prevent the decrease in antral gastrin content that occurs in hypophysectomized rats. It appears that corticosteroids promote the manifestations of functional differentiation while inhibiting proliferative activity. Growth hormone stimulates the growth of most tissues during development. Growth hormone stimulates mitosis in the duodenal crypts of hypophysectomized or thyroidectomized rats, and it leads to increased pancreatic DNA and RNA content and increased pancreatic weight in hypophysectomized rats. [373] However, growth hormone also leads to increased food intake, small intestine secretin content, and serum and antral gastrin levels in hypophysectomized rats. Antral G-cell proliferation and an increase in antral gastrin content have occurred in patients with acromegaly. Overexpression of bovine growth hormone in transgenic mice leads to an increase in villus height and small intestine mass. [374] This effect is not secondary to increased food intake, because diet-restricted mice and mice fed ad libitum demonstrate the same increases. In humans, growth hormone improves clinical parameters in Crohn’s disease, [375] perhaps through a trophic effect produced by intermediate modulation of several other growth factors. IGF-I, also known as *somatomedin C,* is expressed throughout the intestine and may mediate many of the actions of growth hormone on the GI tract. Thyroxine causes an increase in pancreatic weight and RNA content, but it does not increase DNA content. [373] Thyroxine does not increase the mitotic activity of duodenal crypts in hypophysectomized rats unless growth hormone is also administered.

Gastrointestinal Peptides Gastrin, the most potent stimulant of gastric secretion, is thought to have important trophic effects on the GI tract. Exogenous gastrin stimulates the growth of mucosa throughout the entire GI tract except in the esophagus and, possibly, the gastric antrum, where most of the peptide is produced. Gastrin has no trophic effects outside the intestinal tract, and within the intestinal tract, its effects appear to be limited to the mucosa. [376] In the stomach, gastrin increases the parietal cell population by shortening the time it takes fundic stem cells to differentiate into parietal cells. Pentagastrin also increases thymidine kinase activity in the rat gastric mucosa. The number of enteroendocrine cells, but not chief cells, is increased by gastrin in the stomach. Gastrin stimulates the production of its own receptors, as evidenced by a direct correlation between serum gastrin levels and gastrin binding capacity. [377] Proglumide, a competitive inhibitor of gastrin binding to its receptor, inhibits the trophic actions of gastrin on the stomach, duodenum, and colon. CCK also competes for binding to the gastrin receptor, and secretin blocks the gastrin receptor in a noncompetitive manner. Intravenous infusions of gastrin that maintain serum gastrin concentrations similar to those expected after a meat meal lead to increased DNA synthesis. Gastrin 17 and gastrin 34, the two most abundant forms of endogenous gastrin, are equal to pentagastrin in increasing DNA synthesis and content in duodenal and gastric mucosa. [378] Serum gastrin levels also parallel gastrointestinal growth responses after antrectomy or dietary manipulations. Marked increases in serum and antral gastrin levels caused by H^+,K^+-ATPase blockers are associated with a 25% to 30% increase in parietal, chief, and mucous cell numbers and a fivefold increase in ECL cells and thymidine incorporation. [379] Gastrin has also been postulated to promote growth of colorectal carcinoma through an autocrine mechanism. Gastrin mRNA has been detected in colon cancer cell lines, and serum gastrin levels are elevated in a subset of patients with colonic adenomas and carcinomas. [380] Gastrin receptors are present in colon cancer cell lines and tumors. [381] Studies using highly specific monoclonal antibodies reported that gastrin precursors that had not undergone full posttranslational modification were the predominant form of gastrin peptide in colorectal carcinoma. [382] Colonic cells may possess a distinct class of gastrin receptors that bind nonamidated gastrin instead of the classical amidated hormone. Amidated gastrin appears to stimulate cell proliferation by inducing c-Fos and c-Jun, whereas glycine-extended intermediates of gastrin stimulate transcription through early gene activation mediated by a distinct receptor. [383] Transgenic mice that selectively express elevated levels of incompletely processed gastrin demonstrate evidence of increased colonic mucosal proliferation in vivo. [384] The IGFs (types I and II) and their receptors are expressed throughout the GI tract. Administration of IGF-I to normal cats, growth hormone–deficient mice, rats after partial small bowel resection, or dexamethasone-treated rats increases gastrointestinal mass. [385] The trophic effect on IGF-I on the intestine is polyamine-dependent and can be blocked by difluoromethylornithine. IGF-II appears to play the dominant role in fetal growth and development, although adult intestinal epithelial cells express both IGF-II and its receptor. [386] VIP is structurally related to secretin. VIP similarly inhibits the effect of pentagastrin on the markers of gastrin and colonic mucosal proliferation but does not appear to have any significant intrinsic trophic effects. VIP also has no effect on the growth of pancreatic acinar cells in vitro. [387] GRP is homologous to the amphibian peptide bombesin. In the GI tract, GRP stimulates antral G-cell proliferation and increases gastric and colonic mucosal DNA content. [388] Its effects may be partly or completely mediated through the stimulation of gastrin release from the G cell. GRP reduces small intestine atrophy that results from ingestion of an elemental diet and improves the survival of patients with chemotherapy-induced enterocolitis. [389] Neurotensin, a tridecapeptide widely distributed throughout the GI tract, is a member of the pancreatic polypeptide family secreted by the N cell, the most abundant cell in the ileum. Neurotensin increases small intestine mucosal weight, DNA, and protein content in the rat, but it did not appear to have any effect on mucosal growth in the colon. [390] Neurotensin stimulates mucosal growth throughout the small intestine and increases levels of sucrase, maltase, and alkaline phosphatase in the small intestine. Infusion of peptide YY, a peptide synthesized in the pancreas and by enteroendocrine cells, inhibits CCK-stimulated pancreatic growth and may serve as a physiological inhibitor of pancreatic growth. [391] Peptide YY infusion also stimulates enterocyte proliferation in vitro, and when the effect of EGF on plasma levels of gastrin, enteroglucagon, and peptide YY was correlated with gut proliferation, only peptide YY levels were significantly elevated by EGF, indicating a possible role for peptide YY as a mediator of the trophic effects of EGF. Plasma levels of peptide YY are elevated after massive small bowel resection, and administration of peptide

YY is trophic for mouse small intestine and colon. [392] Neurotensin appears to bind the same receptor site as peptide YY in small intestine epithelial cells, but these receptors have a greater affinity for peptide YY than neurotensin. Neurotensin and peptide YY decrease VIP- or prostaglandin-stimulated cAMP levels in rat jejunal epithelial cells. Serum levels of EGF are very low, but intravenous EGF stimulates epithelial cell proliferation in humans, chickens, and mice. [393] Exogenous EGF stimulates DNA, RNA, and protein content of the gastric mucosa but may not stimulate growth of duodenal and colonic mucosa. After small bowel resection, EGF increases residual small intestine thickness and weight. [394] Within 1 week after surgical excision of submandibular glands, rats demonstrate lower jejunal and ileal but not colonic RNA and DNA content than sham-operated controls. Specific receptors exist for EGF in intestinal epithelial cells at the microvillar and basolateral surfaces. The detection of receptors in microvillus membrane preparations through binding of the labeled ligand has lent support to the notion that lumenal EGF may regulate intestinal epithelial growth, although the significance of this discovery is uncertain. The mitogenic activity of EGF in most responsive cells may be mediated through the regulation of extracellular matrix and ornithine decarboxylase. Some members of the EGF family of peptides, including amphiregulin and cripto, which are expressed in the colon, and heregulin, which is expressed in the stomach, pancreas, and small intestine, may also have mitogenic activity in the intestinal tract. [395] TGF-a, a structural homolog of EGF that binds to the same receptor, stimulates thymidine incorporation in many cell types. TGF-a, mRNA, and bioactive protein are demonstrable in human and rodent stomach and in small intestinal and colonic epithelium, and they may be the dominant physiological factor interacting with the EGF receptor in the distal GI tract. [396] Transgenic mice overexpressing TGF-a in the gastric mucosa demonstrate hyperplasia and hypertrophy similar to that seen in Ménétrier disease. [397] TGF-a also promotes restitution of gastric mucosa and of intestinal epithelial cell lines. TGF-a is expressed in a variety of esophageal and gastric carcinomas and colon cancer cell lines, leading to the supposition that TGF-a may contribute to autocrine neoplastic growth. The TGF-ß family of peptides plays key regulatory functions in a wide spectrum of biologic processes, including stimulation or inhibition of cell proliferation, cellular differentiation, embryological development, and formation of extracellular matrix. TGF-ß inhibits proliferation of all epithelial cell populations, including the intestinal epithelium, and overrides the effects of direct mitogens (e.g., EGF, TGF-a). [398] In the small intestine, the highest concentrations of TGF-ß mRNA are found in the crypts rather than in the villi, although the peptide may be more generally distributed. TGF-ß and its receptors are found in many colon cancer cell lines and appear to inhibit their growth. [399] Targeted disruption of the TGF-ß $_1$ gene in mice results in diffuse inflammation and ulceration of the stomach and intestine. [400] The ability of TGF-ß to promote collagen synthesis may be important in the formation of strictures in inflammatory bowel disease. In patients with inflammatory bowel disease, an increase in TGF-ß $_1$ mRNA levels secondary to increased TGF-ß expression in the lamina propria may contribute to stricture formation. [401] The fibroblast growth factor (FGF) family of peptides has not been examined extensively in the context of the GI tract, but it may play an important role in neovascularization, proliferation, and modulation of the functional phenotype of fibroblasts after gastrointestinal injury. Immunoreactive basic FGF has been detected in the small intestine and colon within the extracellular matrix adjacent to epithelial cells and blood vessels. [402] FGF receptors are also present in the GI tract. FGF that has been chemically modified for lumenal stability enhances ulcer healing, and immunoneutralized anti-FGF aggravates ulceration after injury in rodents. [403] Basic FGF demonstrates mitogenic activity in several human colon cancer cell lines, overriding the growth inhibitory effects of TGF-ß. [404] Keratinocyte growth factor (KGF), a member of the FGF family, increases intestinal crypt cell mitosis and protects against radiation-induced intestinal injury. [405] Hepatocyte growth factor (HGF) and its receptor, the c-Met protooncogene product, are expressed throughout the GI tract; HGF expression is greatest in the intestinal crypts. [406] HGF has been shown to be mitogenic for the liver, and it may also play a role in intestinal epithelial proliferation. [407] Somatostatin, which is found throughout the intestinal tract and pancreas, inhibits the release of many gut peptides, including gastrin. It also inhibits the action of gastrin and other gut peptides at their target cell. In addition to inhibiting gastrin release, somatostatin inhibits the stimulation of gastric mucosal growth by endogenous and exogenous gastrin. [408] It remains unclear whether somatostatin exerts its inhibitory effects on gastrointestinal growth solely through its inhibition of gastrointestinal peptides or whether it has direct effects on mucosal growth of its own, inducing apoptosis in intestinal crypts and villi. [409] High serum levels of enteroglucagon have been measured in several conditions associated with growth of the small bowel: adaptation after intestinal resection, celiac sprue, and tropical sprue. [410] After massive small bowel resection, ileal glucagon mRNA levels increase and intestinal L cells synthesize increased amounts of enteroglucagon. [411] Serum enteroglucagon levels correlate with the rate of crypt cell production in the distal small bowel but not in the colon. [412] Despite the correlation of enteroglucagon levels with mucosal growth, no evidence exists that enteroglucagon directly stimulates growth. The effects of pancreatic glucagon on intestinal growth are not well understood. Although glucagon has been shown to increase DNA synthesis and content in gastric and colonic mucosa, another study found that exogenous pancreatic glucagon decreases villus height along the rat small intestine. [413] Overexpression of GLP-2, one of the peptides derived from enteroglucagon, demonstrates a marked trophic effect on the intestine in transgenic mice. [414] The GI tract represents a dynamic model for the study of cell and tissue development, growth, and differentiation. Although insights into newly described growth factors and mechanisms of cell-to-cell communications and interactions have increased our understanding of the regulation of intestinal growth and development, the precise signals controlling these processes and the specific pathways of events, such as cell migration, adhesion, renewal, extrusion, and transformation, require further definition.

CHAPTER 24

John M. Carethers and C. Richard Boland

NEOPLASIA OF THE GASTROINTESTINAL TRACT

The gastrointestinal tract, including the hollow organs of the gut, pancreas, liver, and biliary tree, is the site of more cancers and the source of more cancer mortality than any other organ system in the body. However, no simple etiologic explanation can unify all gut tumors.

The most notable feature of international cancer epidemiology is the wide variability of tumor incidence from country to country by organ site. For example, an esophageal cancer belt extends from northeastern China through central Asia into northern Iran. [1] In portions of these regions, the incidence of squamous cell carcinoma of the esophagus is more than 100-fold higher than that in adjacent low-incidence regions. In the United States, three- to fourfold differences in the incidence of esophageal cancer occur between the sexes and among races. [2] In Japan, the incidence of gastric carcinoma is about ten times higher than it is in the United States. Colorectal cancer occurs less commonly in Japan, but it is the most common gastrointestinal malignancy in North America, western Europe, and much of the industrialized world. Over the past decade, the incidence of colorectal cancer in Japan has risen to almost the same level as in the West. [3] These marked differences in cancer risk are not based on racial or genetic factors. When people migrate from a high-incidence region to a low-incidence region, the organ-specific rates of some cancers change to match that of the new region, usually within two generations. Collectively, the epidemiologic observations strongly indicate the importance of environmental factors in gastrointestinal carcinogenesis; however, individual genetic differences may influence the effects of these factors.

Worldwide, people are exposed to different types of foods, the gastrointestinal flora differs as a result of dietary and host factors, and certain mucosal infections occur in different frequencies. Gastrointestinal carcinogenesis, therefore, is a complex problem to understand and to modify. For example, tobacco smoke causes cancers of the oral and respiratory tracts, and by eliminating smoke from the environment, the risks of tumor development can be controlled. However, everyone consumes some kind of diet, and the elimination of specific items results in the introduction of replacement nutrients. Moreover, the diet consists of a complex combination of macronutrients (i.e., fat, carbohydrate, protein, fiber) and micronutrients (i.e., vitamins, minerals, other agents present in tiny concentrations) that affect cancer risk. Directly acting carcinogens or indirectly acting procarcinogens also are part of each person's diet. Mucosal infections with human papillomavirus and *Helicobacter pylori* probably contribute to the genesis of cancers of specific gastrointestinal organs.

Ultimately, changes at the genetic level can alter the growth characteristics of healthy gastrointestinal cells. Although many deleterious genetic events must occur for a normal cell to become malignant, inactivation of a gatekeeper gene or pathway specific to each tissue may be required to initiate the neoplastic process. [4] This concept is evident in familial syndromes such as familial adenomatous polyposis (FAP), in which thousands of benign colonic adenomas develop at a young age; it can also be applied to the development of sporadic colorectal cancer. After the initial gatekeeper alteration, successive genetic events propel the cell toward the malignant phenotype. The loss of the gatekeeper's function and the successive genetic events lead to an uncoupling of cellular growth control mechanisms that typically regulate a normal gastrointestinal cell. These include loss of cell cycle control checkpoints, abrogation of programmed cell death, and dysregulation of intracellular signaling pathways. Some genetic perturbations have been identified as markers for the presence of neoplasia as well as prognostic factors for malignancy, but their clinical use has not been fully evaluated.

Because our understanding of carcinogenesis in the gut is far from complete, it is necessary to understand the principles of regulation of normal, nonneoplastic gastrointestinal cell growth before considering the abnormal events. The mechanisms of tumor development appear to be distinct among the gastrointestinal organs, but general pathogenetic principles apply at the cellular and molecular level for most tumors.

NORMAL CELLULAR CONTROL MECHANISMS

Cell Cycle Checkpoints

The cell replication cycle consists of five phases. [5] Resting diploid cells not involved in active replication may be in the G_0 or G_1 phase. G_1 represents the postmitotic period before the initiation of new DNA synthesis as the cell prepares to divide. The cell may spend a variable period of time in G_1. Cells not involved in replication may be described arbitrarily as resting in the G_0 phase. After receiving the signal to divide, cells enter a phase of active DNA synthesis, the S phase. After duplication of the entire genome, the tetraploid cell pauses briefly in the G_2 phase before entering mitosis (M phase). After cell division into two identical daughter cells, the cell reenters the G_1 phase. As the genome becomes more complex with tumor progression, the S and M phases may be prolonged, altering the apparent fraction of cells involved in replication. This complicates a direct comparison of the proliferative activity of tumors with that of normal tissue.

Each transition from one phase of the cell cycle to the next is regulated by a family of cyclin-dependent kinases (CDKs) and their activating partners, the cyclins (Fig. 24-1). The CDK-cyclin complexes are positively and negatively regulated by phosphorylation. The formation and activation of a CDK-cyclin complex requires proper completion of the previous cell cycle phase before the subsequent phase is entered. [6], [7] If DNA is damaged by ultraviolet light in the G_1 phase of the cell cycle, passage into the S phase will not occur until the damage is repaired. Likewise, if DNA is not replicated with complete fidelity during the S phase, passage into G_2 and mitosis is prohibited until an exact copy of the DNA is duplicated. The CDK-cyclin complexes receive input from other cellular proteins that relay information regarding the integrity of each checkpoint. The product of the retinoblastoma tumor suppressor gene, *RB,* and p53 relay information to G_1 phase CDK-cyclins to regulate the initiation of DNA synthesis (S phase). [6] These cell cycle checkpoints are lost in oncogenesis. The CDK-cyclin complexes themselves may be altered in some tumors, and in the gastrointestinal tract, changes occur in the regulators that relay information to CDK-cyclin complexes. These genetic perturbations allow the neoplastic cell to cycle with disregard for mutations and chromosomal rearrangements, essentially establishing progeny that differ from the parent. This generation of genetic diversity is a form of genomic instability.

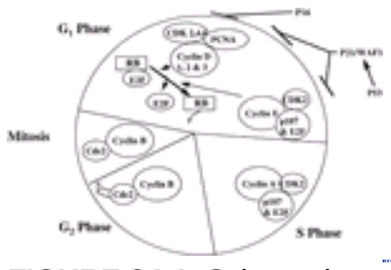

FIGURE 24-1. Schematic representation of the cell growth cycle. Transition through each phase of the cell cycle is regulated by cyclins and cyclin-dependent kinases (*CDK*s) to ensure completion of one phase before initiation of the subsequent phase. Each cyclin-CDK complex is positively and negatively regulated by phosphorylation. Inhibitors of CDKs include p21 and p16, both of which prevent transition to the S phase of the cell cycle. The transcriptional regulator E2F transactivates genes important for S phase entry. E2F is bound by the retinoblastoma protein (*RB*) until RB is phosphorylated, thus releasing E2F. Phosphorylation of RB is initiated and accelerated by cyclin D–dependent kinases and cyclin E–CDK2 complexes, respectively. *P,* phosphorylated; *PCNA,* proliferating cell nuclear antigen.

Programmed Cell Death

Deregulated proliferation is the sine qua non of the neoplastic process. An increase in the proliferation rate of cells can occur either by increased mitosis or by a decreased cell death rate. Programmed cell death is a physiological process that plays an essential role in normal tissue turnover and embryonic development. [8] This process has been shown to require energy, macromolecular synthesis, and de novo gene transcription. [8], [9] The morphologic changes of programmed cell death, first described in 1972 by Kerr and colleagues [10] and termed *apoptosis,* affect single scattered cells with characteristic changes in the nucleus (i.e., karyorrhexis), preservation of cytoplasmic organelles, cellular shrinkage, and the formation of apoptotic bodies. The initiation of programmed cell death may involve a sustained increase in intracellular calcium, which activates several calcium-dependent enzymes. [8] These enzymes, in turn, activate stored or newly synthesized transglutaminases (involved in the cross-linking of cytoplasmic proteins), proteases (e.g., caspases) that aid in disruption of the cytoskeleton and cell shrinkage, and endonucleases that cleave DNA into uniformly sized fragments. [8] Once activated, programmed cell death is irreversible. [9]

Activation of a cell death program is best illustrated by the normal turnover of the colonic epithelium. In healthy colonocytes, the surface epithelium is constantly renewed about every 6 days by cellular proliferation and differentiation of crypt cells. The proliferating compartment is in the lower third of the crypt, characterized by mitoses and upward migration from anchored stem cells. As cells move up the crypt, differentiation and maturation occur, and the cells lose their capacity to divide. Eventually, cells die and are shed. Programmed cell death of colonocytes thus maintains a uniform number of cells in the mucosa. Programmed cell death of colonocytes results, in part, from the activity of the adenomatous polyposis coli (APC) gene. [11] Other cellular proteins, such as those of the BCL2 gene family, may play a significant role in programmed cell death in the gastrointestinal tract.

Activation of programmed cell death is a mechanism involved in the treatment of gastrointestinal tumors. Both radiation and chemotherapy can induce apoptosis in tumors of the gastrointestinal tract, in addition to direct toxic tissue injury (i.e., necrosis). [8], [9] Apoptosis has been proposed to be the mechanism by which the nonsteroidal antiinflammatory agent sulindac and the cyclooxygenase-2 (COX-2) inhibitor celecoxib lead to the involution of colonic adenomas in patients with FAP. [12], [13] and [14] Interference with programmed cell death may be as important as deregulated cell proliferation in some gastrointestinal tumors, and its activation is the target of many therapeutic interventions.

Intercellular and Intracellular Growth Control Pathways

Cells that make up the tissues of the gastrointestinal tract are in contact with neighboring cells to form a tight epithelial barrier. In addition to functioning as a barrier, the epithelial junctions that interconnect neighboring cells distribute information about the cell's local environment, such as the presence of a contiguous cell (e.g., cell-cell adhesion and recognition at the zona adherens), and they may allow the direct passage of ions and small molecules through specialized pores called *gap junctions*. [15] Passage of ions and small molecules through gap junctions allows cells to be coupled and permits groups of cells to behave as a syncytium in regard to ion transfer. Cell-cell adhesion is primarily mediated through the intracellular adhesion molecule E (epithelial)-cadherin, which forms homeotypic interactions (i.e., with other E-cadherin molecules) and anchors the zona adherens to the actin cytoskeleton inside the cell. [16] Dysregulation of cell-cell adhesion disrupts normal intercellular communication and allows transformed cells to separate from each other and to spread locally, invading regional tissue. Proteins from the catenin family (a, ß, ?) bind to E-cadherin and to the actin cytoskeleton, but any signal relayed by the catenins for cellular adhesion is not currently known. Importantly, ß-catenin, a protooncogene that can transactivate genes associated with cellular proliferation, has its cytoplasmic levels regulated by the APC protein when its intercellular concentration rises (Fig. 24-2). [17], [18] and [19] APC targets ß-catenin for degradation; and if ß-catenin escapes this homeostatic regulation, it can move to the nucleus, where it associates with T-cell factor-4 (TCF-4) to transactivate genes that promote cell growth and prevent programmed cell death.

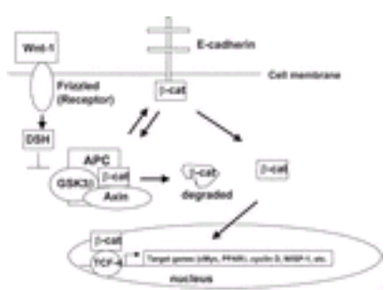

FIGURE 24-2. Adenomatous polyposis coli gene (*APC*) regulation of ß-catenin and its function as a tumor suppressor gene. Normal APC, in association with axin and glycogen synthase kinase-3ß (*GSK3ß*), binds, phosphorylates, and targets cytoplasmic ß-catenin (*ß-cat*) for degradation. Degradation of ß-catenin prevents its translocation into the nucleus, where it can initiate the transcription of genes by converting the transcriptional repressor T-cell factor-4 (*TCF-4*) to a transcriptional activator to promote cellular proliferation and prevent cell death. Cytoplasmic ß-catenin can bind to E-cadherin, usually in association with a-catenin. During embryogenesis, blockage of APC-mediated degradation can occur through the Wnt-1 signaling pathway (through the frizzled receptor and disheveled [*DSH*] signaling protein). Presumably, inactivation of APC would have the same consequences as Wnt-1 signaling.

Another mode of intercellular communication exists between epithelial cells and other cells that line the gastrointestinal tract. Growth factors are proteins that bind as a ligand to a receptor on the same (autocrine) cell or neighboring (paracrine) cell. Growth factors modulate growth characteristics of the cell. Once the growth factor is bound to its specific receptor, an intracellular signal is amplified and transmitted to the nucleus of the cell to induce or inhibit gene activation; this in turn modifies growth characteristics, metabolism, and ion transport. Although many growth factors use tyrosine phosphorylation at the start of their intracellular signaling pathway, other ligand-receptor complexes often use other pathways, such as serine/threonine phosphorylation, calcium and phosphoinositol formation, and the generation of cyclic nucleotides. Two important examples highlight the signal transduction process in normal and neoplastic growth in the gastrointestinal tract: the KRAS and transforming growth factor-ß $_1$ (TGFB1) signaling pathways.

The protooncogene Kirsten-RAS (*KRAS*) encodes an intracellular protein that binds the cyclic nucleotide guanosine tri- or diphosphate (GTP/GDP). On cell surface ligand-receptor activation (e.g., epithelial growth factor binding to its receptor), the KRAS protein is activated and exchanges the bound GDP for GTP (Fig. 24-3). Active KRAS molecules then interact with downstream intracellular effector molecules through an effector domain, conveying a growth response to the nucleus. To turn off this activity, KRAS is deactivated by hydrolysis of GTP to GDP, which returns KRAS to the inactive GDP-bound state. [20] This signal transduction process is perturbed with a mutant KRAS protein. Stabilization of mutant KRAS in its active state permits continuous signal transduction, allowing the cell to undergo unregulated proliferation. This process may be caused by mutations that inhibit the intrinsic GTPase activity of KRAS, allowing KRAS to stay in its active conformation, or by inducing an active conformation that does not require the binding of the guanine nucleotides. [20] Indeed, the most common mutations of *KRAS* in pancreatic and colon cancers involve codons 12, 13, and 61, corresponding to areas in the GTP/GDP binding domains of the KRAS protein. [20] In pancreatic cancers, mutant *KRAS* has

been reported in 95% of tumors, [21], [22] whereas it occurs in about half of colorectal cancers [23], [24] and [25] and is uncommon in gastric cancers. [26] It remains to be determined if other members of the RAS signaling pathway are involved in the pathogenesis of tumors with wild-type *RAS* alleles.

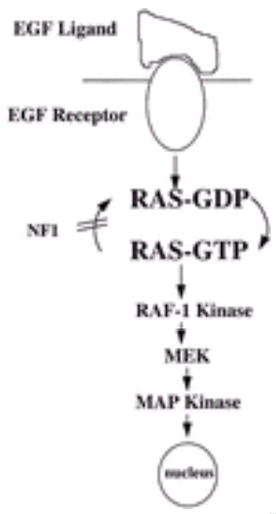

FIGURE 24-3. RAS intracellular signaling. Cell surface ligand binding to a receptor, such as epithelial growth factor (*EGF*) to the EGF receptor, triggers activation of GDP-bound RAS to GTP-bound RAS. RAS-GTP can activate subsequent steps in the intracellular signaling cascade (RAF-1 kinase, mitogen-activating protein [*MAP*] kinase kinase [*MEK*], and MAP kinase) to activate genes that promote cellular proliferation. The tumor suppressor protein neurofibromatosis 1 (*NF1*) is an activating protein for RAS, keeping RAS in the GTP-bound state. Activation of RAS by mutation allows continued signaling of this pathway.

TGFB1 is a ligand that inhibits the growth of gastrointestinal epithelial cells. [27] To exert its growth suppressive effect, TGFB1 in its latent form is activated by the insulin-like growth factor II receptor (IGF2R) present on the cell surface (Fig. 24-4). [28], [29] Activated TGFB1 then binds to TGFB1 type II receptor (TGFBR2), which subsequently phosphorylates (as a serine threonine kinase) the TGFB1 type I receptor (TGFBR1), forming a heteromeric complex of TGFB1, TGFBR2, and TGFBR1. [30], [31] The conjoined receptor complex then phosphorylates (as a serine threonine kinase) intracellular proteins that cascade to ultimately affect the transcription of growth-suppressing genes in the nucleus. In particular, SMAD2 and SMAD3 are phosphorylated by activated TGFBR1, which allows them to bind individually to SMAD4 and subsequently translocate to the nucleus. Inactivation of this pathway occurs in some gastrointestinal tumors. For example, many colonic and gastric tumors that exhibit microsatellite instability, a laboratory marker for the inactivation of the DNA mismatch repair (MMR) system, develop mutations in *TGFBR2*. [32], [33] and [34] Other tumors with microsatellite instability but with normal *TGFBR2* have mutations in *IGF2R*. [29] These mutations prevent expression of the receptor on the cell surface. The absence of TGFBR2 or IGF2R prevents activation and binding of the TGFB1 ligand and abrogates its growth-suppressive action. Some colon tumors without microsatellite instability have mutations in the kinase domain of TGFBR2. [35] Inactivation of the potential downstream signaling proteins SMAD4 and SMAD2 also has been found in gastrointestinal cancers. [36], [37] The key point is that essential growth-regulatory pathways may be deactivated at any one of several points in the cascade.

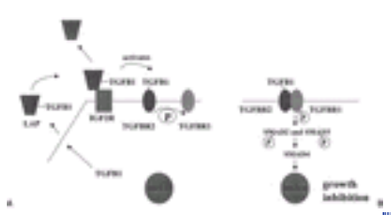

FIGURE 24-4. Transforming growth factor-ß $_1$ signaling. **A:** TGF-ß $_1$ (*TGFB1*) can be produced in an autocrine fashion by epithelial cells, and it is bound by a latency-associated peptide (*LAP*) once outside the cell. To activate TGFB1, LAP is cleaved by the insulin-like growth factor II receptor (*IGF2R*), leaving TGFB1 free to bind to the TGFB1 receptor type II (*TGFBR2*). This action, in turn, phosphorylates (P) the TGFB1 receptor type I (*TGFBR1*), which then forms a heteromeric complex with TGFBR2. **B:** Subsequent intracellular signaling to the nucleus occurs through the SMAD family of proteins, ultimately causing growth suppression. Mutations in *IGF2R, TGFBR2, SMAD2,* and *SMAD4* have been described that uncouple the growth-inhibitory effects of TGFB1 on the colonocyte.

Many of these growth-regulatory pathways are active simultaneously. They are often redundant and sometimes interconnected, but they typically provide a homeostatic balance for normal cellular growth. Alteration of one or more of these pathways may lead toward cellular proliferation and away from controlled growth and regulated cell turnover by programmed cell death, initiating and exacerbating transformation into neoplastic cells. The complexity of cellular growth mechanisms affords the neoplastic cell many opportunities for a pathway to become deregulated. It appears that more than one pathway is affected, which may be necessary for transformation. Specific pathway inactivations are more common in certain types or subtypes of tumors, creating opportunities for therapeutic intervention of gastrointestinal tumors as biotechnology advances.

MOLECULAR CARCINOGENESIS

Mechanisms by Which DNA Is Damaged

The current concept of carcinogenesis in the gastrointestinal tract begins with damage to normal cellular genes. This can occur through a variety of mechanisms. Mutations occur spontaneously because of predictable instability of the purine and pyrimidine bases themselves. The most common spontaneous mutation is depurination, which occurs after disruption of the *N*-glycosyl linkages between the purine base and the ribose chain. In another spontaneous event, deamination, cytosine is converted to uracil, or 5-methylcytosine to thymine. These single base mutations, if not repaired, lead to mispairing during the next round of replication. Both events are common and subject to revision by families of DNA repair enzymes.

Several environmental factors predictably damage DNA, including viral infections, chemical carcinogens, and radiation in the form of ultraviolet radiation, ionizing electromagnetic radiation such as x-rays and ?-rays, and particle radiation such as electrons, a particles, and heavy ions (Table 24-1). Radiation injury damages DNA by producing strand breaks. As an internal organ, the gastrointestinal tract is usually not exposed to sufficient radiation for it to be a major factor in gastrointestinal carcinogenesis. However, very high doses of x-rays administered under unusual circumstances have been implicated as a pathogenetic factor in some intestinal cancers. Viral oncogenesis has been documented in several nonhuman tumor models and in squamous cell carcinoma of the esophagus and anus in humans. [38], [39] JC virus, a DNA virus encoding a T antigen, is present in the gut and has been implicated in colorectal carcinogenesis. [40] There is evidence to suggest a role for viruses in the genesis of adenocarcinomas of the gastrointestinal tract, such as the role of hepatitis B and C viruses in causing hepatomas. Chemical carcinogens are thought to be most important in initiating adenocarcinoma in the gastrointestinal tract because of their access to the gut mucosa. This form of injury tends to produce mutations in single nucleotide bases.

Radiation Injury
Ultraviolet radiation
Especially important for skin
Most important wavelengths, 290–320 nm
Ionizing radiation
Electromagnetic radiation (e.g., x-rays, γ-rays)
Particulate radiation
Electrons, protons, neutrons, α particles, heavy ions
Viral Oncogenesis
Human papillomavirus
Squamous cell carcinoma of the esophagus
Anal carcinoma
Genital cancers
Epstein-Barr virus
Burkitt lymphoma
Nasopharyngeal carcinoma
Hepatitis B and C viruses
Hepatoma
Human T-cell leukemia viruses
Chemical Carcinogens
Important in a wide spectrum of cancers, including digestive, oral, pulmonary, urinary, cutaneous, and hematologic malignancies
Complex relation between host and environment involved
Numerous defensive or protective mechanisms at work

TABLE 24-1 Carcinogenic Agents

Single base pair mutations are characterized as *transitions* when they change one purine to another or change one pyrimidine to another. They are characterized as *transversions* when they produce a change between nucleotide classes. Losses of base pairs in the DNA sequence are called *deletions,* and gains are called *insertions*. Some single base pair changes are silent and do not result in amino acid changes. Mutations that change the amino acid in the protein product are called *missense mutations,* and they are characterized as conservative if the amino acid change occurs within the same class (i.e., from one neutral amino acid to another). Missense mutations can be serious if they result in the appearance or removal of charge, cysteines, phosphorylation or glycosylation sites, or other amino acids critical to the folding and function of the protein. Changes that create a stop codon within an open reading frame are called *nonsense mutations*. Nucleotide insertions and deletions (which do not occur in groups of three) create a frameshift, which commonly produces a series of missense and nonsense changes downstream on the DNA strand.

Chemical Carcinogenesis Chemical carcinogens are ubiquitous in the human diet but may not reach all the digestive organs in their active forms. [41], [42] Typically, proximate carcinogens are highly reactive, short-lived chemical compounds that bind nucleic acids, proteins, and other macromolecules near the site of their generation. Chemical carcinogens usually have a narrow range of host and tissue specificity. The microbial flora of the gastrointestinal tract and mucosal enzymes are important factors in the activation and inactivation of many carcinogens. For example, cycasin, an extract made from cycad nuts, produces intestinal tumors when administered to most rodents. [43] This compound is a glycoside that must be hydrolyzed by intestinal bacteria to produce methylazoxymethanol, which is unstable and spontaneously decomposes, giving rise to a reactive carbonium ion capable of methylating nucleic acids. Cycasin does not give rise to tumors in germ-free rodents because they lack the necessary glycosidases produced by the intestinal flora. The procarcinogen is never activated and is therefore unable to damage their DNA. For the same reason, cycasin is active only when administered orally and does not produce colon cancer after parenteral injection. Studies using derivatives of this compound have led to an understanding of the complexities involved in the metabolism of procarcinogens to the active, proximate mutagen. [44], [45], [46], [47] and [48]

Carcinogen Metabolism Although cancer is best characterized as an acquired disease based on environmental exposures, there are large individual differences in cancer susceptibility. [49] The best-known example of chemical carcinogenesis in humans is the relation between tobacco use and lung cancer. However, not all smokers are equally susceptible to cancer, even when differences in the number of cigarettes smoked are taken into account. The enzyme cytochrome P450 (CYP2EI) is responsible for the activation of many carcinogens, including many of those in tobacco smoke, and it is expressed heterogeneously throughout the population. One study indicated that the inheritance of specific alleles of the gene for this enzyme was associated with significantly different risks for lung cancer. [50] Although it was initially suggested that individuals who are rapid acetylators of potential carcinogenic compounds are at increased risk for colorectal cancer, there is little insight into this mechanism for increased risk for bowel cancer. [51], [52], [53] and [54] Nonetheless, it is reasonable to expect that differences exist in the ability to activate procarcinogens or inactivate proximate carcinogens that are important factors for cancer risk.

Mechanisms by Which Genes Are Damaged

Point Mutation The significance of point mutation in gene damage was first appreciated when it was found that animal tumor viruses carried mutated forms of cellular protooncogenes. Transfection of these mutated genes into NIH3T3 cells transformed the fibroblasts into cells that assumed a malignant morphology in vitro, no longer exhibited contact inhibition, and could form tumors when injected into nude mice. A transforming oncogene was first found in the Rous sarcoma virus, and later the *HRAS* gene was found to be oncogenic in this laboratory setting. [55], [56] *RAS* gene mutations have been demonstrated in about half of colorectal cancers and in most pancreatic cancers. [22], [24], [25] Point mutations may be produced in DNA by the administration of alkylating agents; for example, treatment of rats with the carcinogen 1,2-dimethylhydrazine (DMH) results in the alkylation of DNA throughout the genome. [57] After exposure to such an agent, the host attempts to repair damaged DNA, or in some instances, the cell responds to the damage by initiating programmed cell death. [8], [9] The action of a carcinogen triggers a dynamic response; the DNA is altered first, and the host then attempts to limit the impact of mutational damage, possibly sacrificing some damaged cells to prevent the replication of a damaged genome. Carcinogens may produce characteristic damage based on the chemistry of the interaction between the reactive compound and certain susceptible sites in purines and pyrimidines (Fig. 24-5). [58] A single genetic locus may be more likely to undergo a specific mutation, depending on the mutagen involved, as shown in Table 24-2. [59] The alkylator DMH preferentially methylates the O^6 position of guanine in DNA, although this is not the only site of damage. [60] Alkylation of guanine results in mispairing of DNA; the O^6-methylguanine acts like an adenine during replication, and the opposite strand pairs with a thymine (instead of cytosine) at replication. During the second round of replication, the newly inserted thymine pairs with an adenine, in place of the original guanine residue, resulting in an apparent guanine-to-adenine (G-to-A) mutation. Depending on the location of this mutation, it may have a trivial or profound effect on cell behavior. For example, when this change occurs in codons 12 or 13 of the *KRAS* gene, this signaling pathway is continuously activated, and a marked functional change occurs in the cell. Some mutations are silent, but the appearance of others results in a growth advantage for the cell, and the error is amplified through clonal expansion of the mutant cell.

TABLE 24-2 Mutagen-Specific DNA Damage in a Model Genetic Target

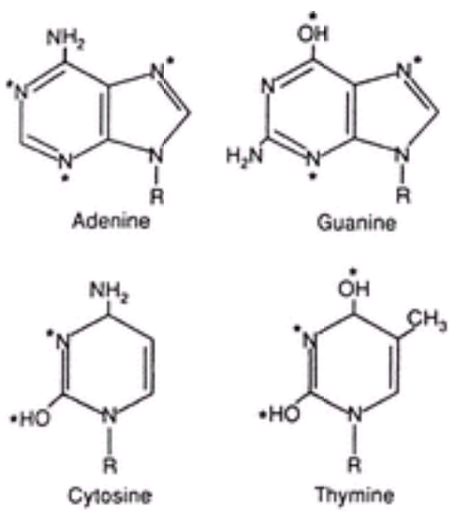

FIGURE 24-5. Alkylation sites in DNA bases. Specific sites on the purines adenine or guanine or the pyrimidines cytosine or thymine are targets for alkylation, as indicated by the asterisks. The adduct formation leads to mispairing during the next round of DNA replication. For example, O^6-methylguanine may mispair with

thymine instead of cytosine, and during the next cycle of DNA replication, the original guanine residue is replaced by adenine (i.e., a G-to-A transition mutation). Similarly, O^4-alkylated thymines lead to T-to-C transition mutations. Spontaneous deamination of cytosine results in uracil, which may mispair, and deamination of 5-methylcytosine creates a thymine residue (i.e., a one-step C-to-T transition mutation). Deamination of guanines and adenines creates xanthine and hypoxanthine, respectively. Thymine has no amino group to lose.

In rats treated with DMH, G-to-A mutations in *KRAS* develop in 66% of the colon cancers, indicating a strong selection for this mutation. [61] Other mutations may occur in locations that result in the inactivation of a gene essential for cell survival, and the cell is immediately eliminated. In the case of *KRAS,* mutations may occur anywhere in the gene. Mutational inactivation of the guanine nucleotide regulatory region of the *RAS* gene (at codons 12, 13, and 61) need occur in only one cell in the colon after carcinogen exposure because this cell will expand clonally, outgrow those around it, and create large numbers of progeny. Chronic inflammation is a common setting in which cancer develops in the gut, as in chronic esophagitis, chronic atrophic gastritis, and inflammatory bowel disease. Active forms of oxygen, such as hydroxyl and superoxide radicals, hydrogen peroxide, and singlet oxygen, arise as by-products of chronic inflammation and oxygen stress. These reactive species also mediate damage induced by ionizing and ultraviolet radiation. Reactive oxygen species create several forms of DNA damage, including strand breaks and single base changes. The two most common mutations induced by reactive oxygen molecules are the creation of 8-hydroxypurines, which result in misreading of those residues and adjacent pyrimidines. Because mispairing occurs in all four bases with almost equal frequency, it is not possible to predict what mutation this mechanism will induce.

DNA Rearrangement Gene expression may be modified by the gross rearrangement of DNA sequences. For example, in chronic myelogenous leukemia, a translocation occurs in which sequences from chromosome 22 are accidentally spliced in frame with the cellular oncogene *ABL* (i.e., the oncogene originally isolated from the Abelson murine leukemia virus and formerly designated v- *abl* or c- *abl*). The translocation creates a chimeric messenger RNA that translates into an abnormally large mutant ABL protein. [62] A similar rearrangement appears in Burkitt lymphoma, in which a reciprocal translation occurring between chromosomes 8 and 14 juxtaposes a portion of the immunoglobulin gene with the oncogene *MYC*. In this instance, *MYC* is not mutated, but the rearrangement causes an amplification of gene expression. [63] The protooncogene *BCL2* was first discovered in human B-cell follicular lymphoma as a t(14;18) chromosomal translocation, which placed *BCL2* under the control of the heavy immunoglobulin chain promoter. [64] Elevated levels of BCL2, a 26-kd protein, have since been found in adenocarcinomas of the colon and other tumors without this translocation. [65] BCL2 functions to inhibit programmed cell death and is often highly expressed in tumors resistant to chemotherapy. [66]

DNA Amplification DNA rearrangements can increase gene expression without the creation of additional copies of the gene. A normal cellular gene may also become a transforming gene through DNA amplification. This mechanism has attracted attention because resistance to methotrexate may be caused by amplification of the gene for dihydrofolate reductase. [67] Amplification of members of the *MYC* oncogene family are predictive of disease progression in neuroblastomas. [68] Some tumor cell lines have a large number of minichromosomes that exist independently as “double minutes” or are inserted into chromosomes (as homogeneously staining regions). Both represent examples of gene amplification. Amplification of *ERBB2* has been reported by several groups studying stomach cancers. [69], [70], [71] and [72] Other examples of amplified cellular oncogenes found in tumor cell lines include mutated *KRAS, MYB,* and *MYC*. [73], [74] and [75]

Altered Methylation of DNA Only a small percentage of the total genome is expressed in each tissue. One mechanism to control gene expression is to silence them through the stable, covalent methylation of the base cytosine at C-G sequences commonly found in promotors. DNA methylation is maintained by a specific methyltransferase, and the pattern of methylation is inherited in a stable way through successive generations of cells in a given tissue. A wide variety of genes are substantially hypomethylated in primary colorectal cancers in comparison with the adjacent normal mucosa. [76] These genes included the ?-globulin gene, which is normally hypomethylated only in blood precursor cells, and the ?-crystallin gene, which is normally hypomethylated only in embryonic lens tissue. [76], [77] Hypomethylation was found in even the smallest adenomas studied. The implications of hypomethylation are not clear. [78] Epigenetic alteration of DNA by methylation of promotor sequences of critical growth regulatory genes such as *p16* and *IGF2* have been described in microsatellite unstable tumors. [79], [80] The mechanism for promoter methylation is unknown, but there is evidence that the MMR system is not directly responsible for this activity. [80] The promotor of the MMR gene *hMLH1* has been shown to be methylated in about 10% of sporadic colorectal tumors (and is hypomethylated in surrounding normal tissue) with absence of *hMLH1* expression. [81] This indicates that DNA methylation is a mode of MMR gene inactivation in some sporadic tumors. The correlation between microsatellite instability and promoter methylation suggests that methylation abnormalities precede microsatellite instability in sporadic colorectal cancers, and that other genes with methylated promoters in microsatellite unstable tumors are additional targets of this poorly understood process.

DNA Deletion Cell proliferation is regulated by a family of genes known as *tumor suppressor genes*. These genes prevent inappropriate cell proliferation and regulate the number of cells in a tissue. Unlike oncogenes, these genes play a role in carcinogenesis through their inactivation. Even before the first tumor suppressor gene was identified, the presence of such genes was predicted by Knudson, [82] who proposed that some human cancers arise through a recessive mechanism in which both alleles of a tumor suppressor gene are independently inactivated. This concept was particularly important because it provided a framework for the inheritance of enhanced susceptibility to specific cancers. Loss of the first allele could occur as a dominantly inherited trait that is transmitted vertically in the germ line. Inactivation of the first allele can be phenotypically silent because the activity of the remaining second allele is sufficient to maintain the nonmalignant phenotype. However, such individuals are at extremely high risk for the development of cancer because only a single further inactivation mutation in a single cell may be required to trigger tumor development, usually at a young age. In contrast, the formation of sporadic tumors requires that two individual events occur independently, which decreases the likelihood of their occurrence in the same cell and increases the likelihood that they will occur later in life. Mutation of one allele followed by loss of DNA at the second allele (through chromosomal instability) is the “two-hit” mechanism for the complete inactivation of tumor suppressor genes.

Inactivation of DNA Repair

Nucleotide excision repair. DNA damaged by ultraviolet radiation, chemicals, and toxins is repaired by a complex of proteins that effectively excise the damaged DNA and religate the interrupted strand using the complementary DNA strand as a template. Collectively known as the *nucleotide excision repair complex,* the component proteins are designated *XP (xeroderma pigmentosum)* or *ERCC (excision repair cross-complementing)* in reference to the discovery of defective nucleotide excision repair in patients with xeroderma pigmentosum. [83] The XP and ERCC proteins are capable of recognizing and binding to damaged DNA, unwinding the DNA double helix by virtue of helicase activity, and excising 27 to 29 nucleotides containing the damaged DNA. [84], [85] and [86] The excision gap is then filled in by DNA polymerases. Some of the nucleotide excision proteins form an important transcription factor, TFIIH, which is involved in regulating the activity of all protein-encoding genes. [87], [88] Consequences of nucleotide excision repair defects include xeroderma pigmentosum, a disease characterized by sunlight-induced photodermatoses that result in skin cancers and neurological abnormalities. [84], [85] Cockayne syndrome and trichothiodystrophy, diseases characterized by neurological abnormalities and mental retardation without a major increase in skin cancers, are caused by mutations that impair the transcription function of nucleotide excision proteins. [84], [85] Malfunctioning nucleotide excision repair in cancers of the gastrointestinal tract has not been reported.

DNA mismatch repair. Unlike nucleotide excision repair, inactivation of the DNA MMR system is common in tumors of the gastrointestinal tract. Point mutations can occur in critical growth-regulatory genes and can accumulate in cells with a defective DNA MMR system (Fig. 24-6). The MMR system is responsible for maintaining replicative fidelity of DNA. Germ-line mutations in *hMSH2, hMLH1,* and *hMSH6* have been identified and clearly linked to hereditary nonpolyposis colorectal cancer (HNPCC), and somatic inactivation of *hMLH1* by promoter hypermethylation has been identified in sporadic tumors. [81], [89], [90], [91], [92] and [93] The contribution of *hPMS1* and *hPMS2* as a cause of HNPCC has not been proved, and no germ-line mutation in *hMSH3* has been identified in this syndrome. [94] The proteins that comprise the MMR system bind to nucleotide base-base mismatches of double-stranded DNA or loops of inaccurately replicated repetitive sequences (termed *microsatellite DNA*) and target the DNA area for excision, resynthesis, and ligation. [95], [96] The DNA sequences repaired by the MMR system have apparently escaped the normal editing function of DNA polymerase. Base mispairs, if not corrected by the MMR system, may cause nucleotide transitions or transversions, allowing a novel base to alter the authentic genetic sequence. [97] Such point mutations in genes that regulate cell growth may promote neoplastic growth.

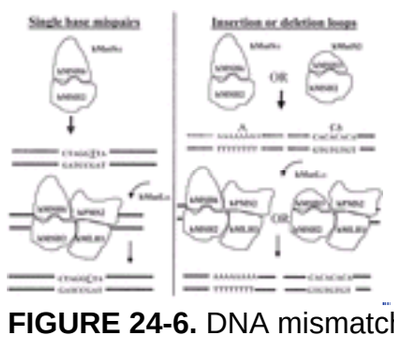

FIGURE 24-6. DNA mismatch repair (MMR). After DNA replication, mistakes that apparently have escaped the editing function of DNA polymerase are bound by the MMR proteins and targeted for repair. Single base mispairs and insertion or deletion loops of 1 base pair at microsatellite sequences can be recognized by hMutSa (heterodimer of hMSH2 and hMSH6), and insertion or deletion loops of greater than 1 base pair are recognized by hMutSß (heterodimer of hMSH2 and hMSH3). Subsequent recruitment of hMutLa (heterodimer of hMLH1 and hPMS2) to the altered DNA targets the area for excision, resynthesis, and ligation. Inactivation of the MMR proteins would permit these types of mutations to be passed to progeny cells.

Inherited Premutations Premutations may elevate familial cancer risk. [98] For example, a T-to-A mutation causing a substitution of lysine for isoleucine at codon 1307

in the *APC* gene is present in 6.1% of Ashkenazi Jews. [98] This missense mutation in itself is not thought to alter the function of the APC protein severely because most *APC* mutations are nonsense mutations, yielding a truncated protein. However, the T-to-A mutation converts the sequence AAATAAAA to $(A)_8$, a repetitive nucleotide tract that is relatively unstable during transcription and replication. In fact, the T-to-A premutation is associated with the acquisition of other nonsense mutations within and surrounding the $(A)_8$ tract, causing truncation of the APC protein. [98] This type of point mutation, which creates an intrinsically unstable repetitive DNA sequence, may lead to further mutations as a mechanism to inactivate gene function.

Genetic Mechanisms of Tumor Development

Gatekeeper, Caretaker, and Landscaper Genes Gatekeeper genes are cellular genes that directly regulate tumor growth by suppressing cell growth or promoting cell death. By definition, gatekeepers are tumor suppressor genes. It has been suggested that each human cell has only one or a few gatekeeper genes that are specific to that cell type. The esophagus, stomach, small intestine, colon, liver, and pancreas are different histologically, and the cells of these tissues express a different array of genes to perform their unique functions. The gastrointestinal organs probably do not share the same gatekeeper genes. Only the gatekeeper gene of the colon, *APC,* has been clearly identified. [99] Inactivation of a gatekeeper gene is the rate-limiting step for the initiation of tumor growth, and demonstrates a specific tissue distribution of that tumor. [4] As a tumor suppressor gene, inactivation requires alteration of the maternal and paternal alleles, fulfilling the Knudson two-hit hypothesis. [82] Restoration of the missing gatekeeper function in vitro leads to suppression of the neoplastic growth. Caretaker genes contribute to genomic stability, typically as part of a DNA repair process (e.g., *hMLH1* and *hMSH2*). Inactivation of a caretaker would lead to genomic instability by increasing the mutation rate of the cell, which may ultimately result in the mutation of a gatekeeper gene. This phenomenon might be likened to a constant and excessive exposure to mutagens. Therefore, caretakers indirectly promote neoplasia, and moreover they function as tumor suppressor genes. Restoration of caretaker function to a cancer cell will not affect its growth because these indirectly acting genes are not required for neoplasia. Defects in landscaper genes create an abnormal stromal environment for the epithelium, which contributes to neoplastic transformation. [100] For instance, chronic inflammation in ulcerative colitis affects the colonic epithelium, first with inflammation, but ultimately may cause neoplastic changes and progression to cancer. The regeneration that occurs to replace damaged epithelium may increase the probability of somatic mutations in an abnormal microenvironment. It has not yet been proved clearly that genetic defects in stromal cells are responsible for neoplastic changes in epithelial cells, but one could envisage alterations in intercellular signaling and cell-cell adhesion as mechanisms that influence surrounding cell behavior. Genetically, tumor initiation is caused by inactivation of both alleles of a gatekeeper gene. This may occur as the result of an inherited mutated allele (i.e., a germ-line mutation), coupled with somatic loss within a specific cell, or two somatic hits within a specific cell. For a caretaker gene to initiate neoplasia, both alleles must be inactivated; in addition, the resulting genomic instability must inactivate both alleles of the gatekeeper. It is believed that inherited susceptibility syndromes involving gatekeeper genes are associated with extremely high rates of cancer development, whereas inherited syndromes involving caretaker genes are associated with cancer rates lower than those of gatekeeper genes because some minimal number of additional mutations must occur. [4], [100] Inherited caretaker mutations would still be associated with cancer rates much higher than those in the general population.

Oncogenes The traditional concept of tumor initiation and promotion is inadequate to explain the full complexities of carcinogenesis. No single mutation or altered gene is sufficient to cause cancer in most cells. Multiple mutations, genetic deletions, and chromosomal rearrangements have been found in cancers that have been studied carefully. However, some single genes, when activated, can cause the phenotype of a cultured fibroblast cell line to become recognizably malignant. These initial cancer-causing genes were called *oncogenes,* and they were discovered by studying viruses that could transform chicken cells. [101] A number of oncogenes have been identified, and each can be activated by a point mutation that alters the activity of the gene product or by genetic rearrangement that results in an increase in gene expression (Table 24-3). [102]

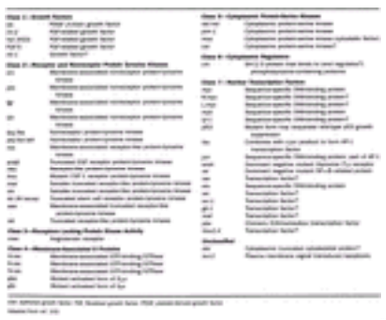

TABLE 24-3 Classification of Oncogenes and Gene Products According to Function

Some oncogenes produce growth factors (e.g., *SIS*), and when production is not regulated, the overproduced peptide ligand binds repeatedly and continuously to the receptor to cause unremitting stimulation. Other protooncogenes produce growth factor receptors (e.g., *ERBB2, FMS, KIT*). The most intensively studied protooncogenes are those involved in cellular signal transduction, including *SRC, RAS,* and *RAF*. These oncogenes are activated by point mutations that maintain the protein in a configuration such that signal transduction events are activated, regardless of whether the appropriate ligand or receptor is in place. Some of the protooncogenes, including *MYC, JUN,* and *FOS,* encode transcription factors, often nuclear phosphoproteins that interact with DNA and regulate gene transcription. Many of these genes were found because they had become incorporated into viral genomes, and because their expression had been deregulated by mutation or rearrangement, they created oncogenic viruses. In each case, these genes were capable of transforming cultured fibroblasts after infecting the cells. These oncogenes initially were designated v-oncogenes (e.g., v- *src*) because of their viral origin. Soon it was found that cellular protooncogenes could undergo activation in situ by point mutation or other genetic rearrangement and become oncogenic in the absence of a viral vector.

Tumor Suppressor Genes Boveri hypothesized as early as 1914 that the relentless growth of a malignant tumor was as likely to result from the inactivation or deletion of genes that inhibit proliferation as from enhanced activity of genes that promote growth. Tumors often have grossly abnormal karyotypes, and losses of chromosomal arms occur frequently. [103] Advances in molecular biology, specifically the use of restriction fragment length polymorphism and microsatellite analysis, have permitted the examination of specific chromosomal locations for genetic losses. Using such techniques, Vogelstein and colleagues [104] reported the widespread losses of genetic material in colorectal cancers and the deletion of specific genetic loci in most tumors. These investigators reasoned that identifiable hot spots for genetic loss would be the location of tumor suppressor genes relevant in the development of colorectal cancer. This hypothesis proved to be correct, and the concept has led to identification of a growing number of tumor suppressor genes in human cancer (Table 24-4). [105], [106] and [107] The mechanism of their activation may differ from gene to gene, but in all cases, it is the inactivation of the protein function that plays a role in carcinogenesis.

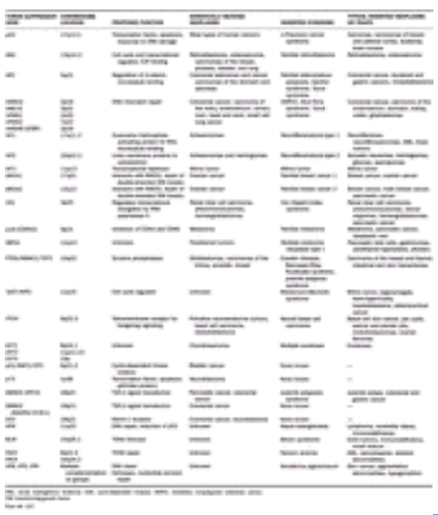

TABLE 24-4 Tumor Suppressor Genes Involved in Human Cancers

Perhaps the most important of these is the *p53* gene, which normally acts to prevent the cell from beginning new DNA synthesis or cell division. It serves as a critical regulatory gene to prevent inappropriate proliferation. [108] When DNA is damaged, the p53 protein becomes activated, which turns on the transcription of a variety of genes. These include activation of *WAF1/CIP1,* a gene encoding a 21-kd protein that inhibits cyclin-dependent kinase 2, thus arresting the cell in the G_1 phase of the cell cycle and preventing the replication of damaged DNA. [109], [110] and [111] p53 also stimulates the transcription of *GADD45,* and the protein gene product, in turn, complexes with proliferating cell nuclear antigen (PCNA), a necessary component for resynthesis of DNA after damaged DNA is removed. [112] By stimulating synthesis

of WAF1/CIP1 and GADD45, p53 effectively halts DNA replication and stimulates DNA repair. p53 protein also plays a critical role in programmed cell death, or apoptosis, when DNA is damaged, perhaps beyond repair. [109], [113], [114] and [115] Mutation of *p53,* therefore, would prevent cell death in the wake of DNA damage. Inactivation of *p53* in cancer involves two steps. First, one *p53* allele undergoes a missense point mutation, which typically occurs in a portion of the molecule involved in the binding to DNA. It is controversial how the presence of one wild-type together with one mutated copy of p53 protein alters the growth characteristics of a cell. However, most colon cancers have lost their wild-type *p53* gene, leaving a single mutated copy of the gene in the nucleus. [116] The peanut fungus *Aspergillus fumigatus* produces aflatoxin ß $_1$, which may cause hepatocellular carcinoma by mutating *p53* at a critical codon. [117] Other mechanisms have developed in certain cancers to inactivate p53 by interrupting its evolutionarily conserved regions (Fig. 24-7). These include the binding of viral proteins to p53 (i.e., JC virus or SV40 T antigen, human papillomavirus E6 protein, and adenovirus E1b protein), and binding of amplified cellular proteins to p53 (e.g., mdm2 oncoprotein in sarcomas). [40], [118] Mutant *p53* (with concomitant lack of normal *p53*) appears to be overexpressed in tumors, including colorectal tumors, and can be detected by immunohistochemical methods. [119] This overexpression is the result of enhanced stability of the mutant p53 protein, allowing its accumulation within the cell. [118], [119]

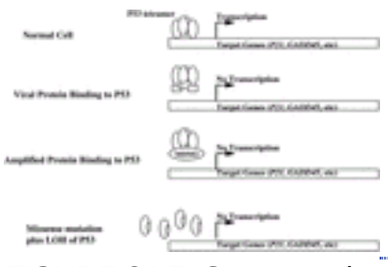

FIGURE 24-7. Some mechanisms for inactivating p53. The p53 protein binds as a tetramer to a p53-binding site in the promotor region of a target gene to activate genes involved in growth suppression and DNA repair. Viral proteins such as the SV40 T antigen, human papillomavirus E6, and adenovirus E1b can bind p53 protein to prevent its transactivating function. Similarly, amplified cellular proteins such as MDM2 can bind p53 protein to prevent promotor binding. In colon cancer, the typical p53 inactivation involves a missense mutation of one allele and loss of heterozygosity (*LOH*) of the second allele, leaving only mutated protein available. The mutated p53 protein may have limited or no binding to promotor sites to initiate transcription at target genes.

The tumor suppressor gene concept accommodates the notion of familial predisposition to cancer. The first example of this was found in familial retinoblastoma, in which there are germ-line mutations at the *RB1* locus. [105] The *RB1* gene has a tumor suppressor function in many tissues, including the gastrointestinal tract, but its inactivation is the limiting step (gatekeeper) only for the development of retinoblastoma. [120], [121] In familial retinoblastoma, every retinal epithelial cell contains one copy of a mutated *RB1* gene and one wild-type gene. The chance occurrence of a mutation in the wild-type *RB1* allele in any cell is sufficient to inactivate completely the tumor suppressive activity of the *RB1* gene. Because this event needs to occur in only a single cell to produce a tumor, the incidence of retinoblastoma is high in families with a mutated *RB1* allele. Essentially every child who inherits the mutated *RB1* allele is at risk for the development of bilateral tumors at an early age. In contrast, unaffected individuals require two inactivational hits in a single cell, one on each allele, for retinoblastoma to occur; accordingly, their sporadic occurrences are rare. Retinoblasts disappear from the eye after early infancy, so this disease is not seen later in life. Germ-line mutations at tumor suppressor gene loci may be associated with a normal phenotype at birth, but they are associated with very high risks for cancer. This is the outcome in Li-Fraumeni syndrome, in which there is a germ-line mutation in the *p53* gene; affected individuals are phenotypically normal at birth but develop breast cancers, sarcomas, and brain tumors at an early age. [105] An animal model for this disorder exists in mice made deficient for the *p53* gene by homologous recombination; these mice can survive with no copies of the *p53* gene, which underscores the redundancy and adaptability of the control over cell growth. [122] Two more recently discovered genes, *p63* and *p73,* have some functions similar to those of p53 protein, and perhaps redundant. [123], [124] and [125] Similar to p53, both p63 and p73 can form homooligomers, bind DNA, activate transcription from p53-responsive genes, and induce apoptosis. [125], [126] and [127] However, in contrast to p53, p63 and p73 give rise to multiple functionally distinct protein isoforms, some of which can function as “dominant negative” proteins, blocking the function of the corresponding full-length protein. [128] In addition, *p63* and *p73* are only rarely mutated in tumors and thus do not function as classical tumor suppressor genes. Furthermore, unlike *p53*-/- mice or patients with Li-Fraumeni syndrome, *p63*-/- and *p73*-/- mice are not tumor prone but instead manifest multiple developmental abnormalities. [129], [130] and [131] Germ-line *p63* mutations in humans cause ectrodactyly–ectodermal dysplasia–clefting (EEC) syndrome, an autosomal dominant disorder characterized by ectrodactyly, ectodermal dysplasia, and cleft lip with or without cleft palate. [132] Thus, although p63 and p73 have some overlapping functions and interactions with p53, they are not tumor suppressor genes like p53, and mutations do not pose the same high risk for cancer as p53 mutations.

Clonal Expansion A variety of genetic techniques have demonstrated that neoplasms are derived from a single cell, but most human cancers have multiple mutations, and it is unlikely that a single cell undergoes all these genetic changes at once. [133] The concept of multistage carcinogenesis assumes that gastrointestinal epithelium undergoes a constant barrage by factors that threaten to damage DNA, but the mutations occur one by one at critical locations in genes related to the control of cell growth or survival. Some of these mutations may inhibit the function of a gene essential for the life of the cell, which is lethal to that cell. Other mutations provide the cell with a slight growth or survival advantage over the rest of the cells in the tissue. In these instances, the mutated cells proliferate faster than the surrounding cells and gradually represent a larger proportion of the tissue. In other instances, a mutated cell may be less capable of repairing DNA damage, which facilitates the accumulation of mutations in succeeding generations. This expanded pool of cells continues to be susceptible to additional mutations. Because of the redundancy in the cellular mechanisms regulating proliferation, loss of any individual function is insufficient for the transformation of a normal cell. The accumulation of cooperating lesions is required to overcome the regulated cell growth. Periodically, an individual cell within an expanding clone experiences another mutation that adds to its growth or survival advantage, and the progeny of this cell then overgrow the population from which it originated. Successive waves of clonal expansion occur by the chance accumulation of new mutational events, which add to the survival advantage of the cell in an evolutionary manner. In early-stage neoplasms, there is evidence for only a small number of mutational events; later in neoplastic progression, however, the cell has a larger number of genetic lesions. [22], [134] Figure 24-8 demonstrates tumor progression as successive expansions of cellular clones with new growth characteristics.

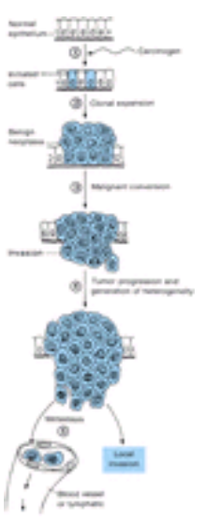

FIGURE 24-8. Tumor progression. This scheme illustrates the natural history of carcinogenesis. The first step represents a genotoxic event caused by a carcinogen. When a critical number of genes are mutated (the specific site and number remain speculative), a cell becomes neoplastic (step *1*). Clonal expansion gives rise to a benign neoplasm (step *2*). Unless additional events occur, a benign neoplasm may persist or grow indefinitely without becoming malignant. However, if additional genetic events occur, cells appear within a benign neoplasm that are capable of malignant behavior, such as invasion and metastasis (step *3*). A malignant neoplasm may invade locally and damage the host and surrounding organs. However, the genome of the malignant neoplasm is intrinsically unstable, and despite its monoclonal origin, the cancer becomes more heterogenous with time (steps *4* and *5*). Clinically, the generation of tumor cell heterogeneity increases the likelihood of metastasis to one or more distant sites.

Genomic Instability and Multistep Carcinogenesis Through the elegant work performed in the laboratories of Fearon and Vogelstein [134] and others, a conceptual interpretation of the genetic basis of colorectal cancer has been developed. This framework accommodates the growing evidence that most cancers develop slowly and that multiple genes are involved in the process. Certain types of genetic damage tend to occur early, and different types occur later. It is not yet clear how strictly the sequence of events is followed in most neoplasms, but not all cancers appear to accumulate every mutation or chromosomal deletion during their development. Some type of genomic instability is required to account for the mutations that occur in multistep carcinogenesis. In most colorectal cancers, the process could be called *chromosomal instability*. Chromosomal segments or entire chromosomes are deleted, duplicated, or rearranged, so that the normal diploid nucleus is changed

into an aneuploid one. A common finding in this pathogenic pathway is the allelic mutation of a tumor suppressor gene (e.g., *APC* or *p53*), followed by the loss of the remaining normal allele (termed *loss of heterozygosity,* or *LOH*). [104], [135] As an increasing fraction of allelic arms is lost, the prognosis for colorectal cancer worsens. Patients with tumors that have lost more than 20% of tested alleles are significantly more likely to die of their disease than those with tumors that have not, and this characteristic is a more powerful prognostic factor than the Dukes stage or the histological grade of the tumor. [135] It is not known what specific cellular function becomes disturbed, resulting in multiple LOH episodes throughout the genome. Chromosomal instability occurs in the smallest adenomas, suggesting that it occurs very early during colorectal neoplasia. [136] It has been hypothesized that structural changes to the chromosomes and abnormal mitoses are operative in the development of chromosomal instability. Mitotic checkpoint gene mutations, such as those found in *BUB1,* have been found, but only rarely in colorectal cancers. [137] A mutant APC protein, which is inactivated in the earliest stages of colonic neoplasia, is associated with defective chromosome segregation. [138], [139] Wild-type APC localizes to the kinetochore during mitosis and forms complexes with BUB1 and BUB3 mitotic checkpoint proteins. [139] Although mutant APC may contribute to ongoing chromosomal instability in a colonic cell, it is not clear how this causes the initial chromosomal instability responsible for APC inactivation. Other proteins, such as human securin, a protein necessary for completion of the anaphase portion of mitosis, may help maintain euploidy. [140] Telomerase dysfunction also has been implicated as a mechanism for chromosomal instability in mouse models. [141] Foreign proteins such as the T antigen from the polyomavirus JC Mad-1 strain have been found in colorectal cancers. [40], [142] T antigens are capable of inducing aneuploidy in cells and are known to inactivate important cell cycle proteins, such as p53 and RB. [40], [142] The mechanism for chromosomal instability remains under intense study. The early stages of carcinogenesis in the colon appear to occur slowly through the accumulation of mutations and LOH in a variety of loci. However, transition to the malignant stage is associated with widespread genomic instability and LOH throughout the genome, which accelerates the likelihood that tumor suppressor loci will be lost, including genes that may suppress metastatic behavior. Studies have shown that mutation of one *p53* allele coupled with LOH of the second allele coincides with the appearance of carcinoma within an adenomatous polyp, making *p53* the gatekeeper for malignant transformation in the colon. [143], [144] and [145] This model of multistep carcinogenesis reflects the consequences of gene dysfunction. A malignancy occurs when a sufficient combination of these mutated genes accumulates. In some instances, a sequential pattern for the occurrence of their metastasis may be required. The following sequence of events appears to be relevant to the chromosomal instability pathway of tumorigenesis in the human colon (Fig. 24-9). [134], [143] Hypomethylation of DNA occurs in the smallest adenomas and may be one of the early events in carcinogenesis, but the mechanism by which this occurs, the specific genes involved in the process, and its role in carcinogenesis are unknown. [76], [77] and [78] Mutations (and LOH) in the *APC* locus are also found in small adenomas, and these events have been linked to dysregulated proliferation on the basis of their role in FAP. [146] Mutations at the *APC* locus are typically nonsense mutations or insertions and deletions that produce frameshifts resulting in downstream stop codons. Mutations in the *KRAS* and *p53* genes are found in larger adenomatous polyps and are thought to play a mechanistic role in supporting neoplastic growth. Indeed, activation of KRAS seems to facilitate the exophytic growth of adenomatous polyps, as *KRAS* mutations are more rare in flat adenomas and cancers. [147]

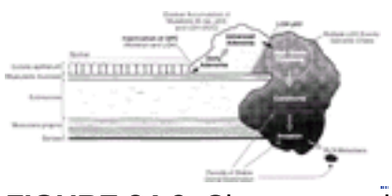

FIGURE 24-9. Chromosomal instability model of genetic events mediating neoplastic progression during colorectal tumorigenesis. This type of genomic instability is present in familial adenomatous polyposis and in about 85% of sporadic colorectal cancers in which segments or whole chromosomes are deleted, duplicated, or rearranged, forming aneuploid tumors. *APC* is inactivated by mutation and loss of heterozygosity (*LOH*) at the transition between normal colonic epithelium and adenomatous epithelium. Thereafter, successive rounds of clonal expansion occur, with accumulation of mutations (i.e., *KRAS, p53,* others) and LOH (i.e., chromosome 18q) that allow acceleration of growth and dominance over less-advantaged clones. *p53* inactivation by LOH of 17p13.1 first occurs in high-grade dysplasia, and defines the transition between benign and malignant neoplasia. Successive genetic events as well as prior genetic changes enable the colon cancer to invade and metastasize to regional lymph nodes (*RLN*s), and ultimately to distant organs such as the liver. (From ref. [143].)

Point mutations play a prominent role in the early stages of neoplastic progression, typically by inactivating the function of tumor suppressor genes. APC protein translation may actually halt after the creation of a nonsense mutation–induced gene. It has been hypothesized that mutant APC proteins may bind to the wild-type proteins and interfere with their function through a dominant negative mechanism. [148] In the case of *KRAS,* mutations inactivate the portion of the protein involved in halting signal transduction. [20], [149] In the case of *p53,* the mutations, which occur in a broad hot spot in the middle of the p53 protein, interfere with the ability of the protein to activate gene expression in the nucleus. [118] It is uncertain whether the mutant p53 protein can bind to and inactivate the wild-type protein and also act with a dominant negative mechanism, as suggested for APC. A second form of genomic instability that does not result in LOH events is involved in the genesis of about 12% to 15% of colon cancers. These tumors demonstrate multiple errors in DNA sequences throughout their genome, which results from a failure to edit errors made during DNA replication. [150], [151] and [152] This was first observed in microsatellite sequences, which are repetitive sequences that require the DNA mismatch repair system for proper replication because of an intrinsic tendency to be copied inaccurately. In certain tumors, minor changes occur in the DNA microsatellite length, termed *microsatellite instability*. Microsatellite sequences are ubiquitous and occur 100,000 times throughout the genome, and half or more may be mutated in tumors demonstrating microsatellite instability. Tumors with microsatellite instability demonstrate significantly less LOH than is commonly seen in colorectal cancers with chromosomal instability. Thus, either chromosomal instability or microsatellite instability develops as the type of instability within a tumor genome. [153] Microsatellite instability is more common in cancers of the proximal colon and is associated with diploid tumors and increased patient survival. [150], [154] This hypermutable phenotype appears to be the mechanism for rapid neoplastic progression in HNPCC and sporadic tumors that exhibit microsatellite instability. [152], [155] HNPCC and about 12% to 15% of sporadic colorectal tumors exhibit microsatellite instability. An analysis of repetitive sequences in tumor tissue led to the identification of other inactivated genes in these tumors, suggesting a second pathway for developing neoplasia. Each of these targeted genes contains a microsatellite within its (exonic) coding sequence, making it susceptible to mutation in the absence of DNA MMR activity. For example, a repeat of ten adenines in the *TGFBR2* gene has undergone frameshift mutation in 90% of colorectal tumors with microsatellite instability, inactivating this receptor, [27], [33] and the cell escapes growth suppression from the ligand TGFB1. In the remaining 10% of tumors with microsatellite instability, it is estimated that frameshift mutations of *IGF2R* at its polyguanine sequence uncouple TGFB1 growth suppression. [29] Another important target of microsatellite instability is *BAX,* a member of the BCL2 gene family. BAX heterodimerizes with BCL2 within the cell, and the mix of the heterodimer determines the cell's commitment to programmed cell death. *BAX* contains a polyguanine $(G)_8$ tract that is mutated in 50% of colorectal cancers with microsatellite instability, and in 64% of gastric adenocarcinomas with microsatellite instability. [156], [157] Mutation of *BAX* (by diminishing the ratio of BAX to BCL2) prevents programmed cell death. Other genetic targets identified include the MMR genes *hMSH3* and *hMSH6,* which may broaden and accelerate the accumulation of mutations. [158] A comprehensive search in which an online genetic database for coding microsatellites and subsequent colorectal tumor analysis were used revealed nine genes that were mutated in more than 20% of the tumors. [159] Aside from *TGFBR2, BAX,* and *hMSH3,* these included the activin type II receptor gene, *SEC63* (human homologue of a yeast DnaJ-like endoplasmic reticulum translocon component protein gene), *AIM2* (an interferon-inducible gene), NADH-ubiquinone oxidoreductase B14.5B subunit gene, *KIAA0977* (probable human homolog of the mouse embryonal protein *cordon-bleu*), and *PA2G4/EBP1* (homolog of the mouse cell cycle protein p38-2G4). [159] The role of these genes in the pathogenesis of tumors with microsatellite instability is not currently known. Several lines of evidence indicate that the Wnt signaling pathway, including the gatekeeper APC or other proteins in this signaling pathway, are affected in microsatellite-unstable tumors (see Fig. 24-2). Some *APC* mutations have been found in colorectal tumors with microsatellite instability. [160] In addition, ß-catenin, a protein that binds to and is normally degraded by the APC protein, undergoes a stabilizing mutation in microsatellite-unstable primary tumors and cell lines. [161] Activating mutations in ß-catenin signal the cell to proliferate incessantly, [162], [163] and the mutation prevents interaction with the APC protein and its subsequent targeting for degradation. TCF-4, to which ß-catenin binds as a partner in the nucleus for transcriptional activation, is mutated at its polyadenine site in 39% of primary colorectal cancers with microsatellite instability. [164] Simultaneous analysis of various components of the Wnt pathway in colorectal cancer indicates that there is frequently a perturbation in the Wnt signaling pathway, including mutations in APC, ß-catenin, TCF-4, or axin I (involved as a scaffold protein and negative regulator or Wnt signaling). [165], [166] Taken together, colorectal tumors exhibiting microsatellite instability appear to have initiated their growth through deregulation of Wnt signaling, which has the identical consequence as inactivating the gatekeeper APC. As described for the chromosomal instability pathway of tumorigenesis, inactivation of several genes likely promotes the progression of the neoplastic process in tumors with microsatellite instability, but a clear sequential pattern has not been elucidated. Mutations of *TGFBR2* and *BAX* appear to be late in the adenoma-carcinoma progression because these mutations occur in high-grade dysplasia at the interface between adenoma and carcinoma. [167], [168] A proposed scheme for the progression of microsatellite-unstable colorectal cancer is presented in Figure 24-10.

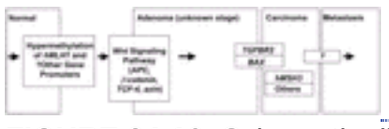

FIGURE 24-10. Schematic diagram of colorectal tumor progression in microsatellite unstable tumors. This type of genomic instability is present in hereditary nonpolyposis colorectal cancer (germ-line mutation of a DNA mismatch repair [MMR] gene) and in about 15% of sporadic colorectal tumors (hypermethylation of the *hMLH1* promoter). These tumors tend to be diploid because chromosomal arrangements typically do not occur. Biallelic inactivation of an MMR protein occurs to disrupt the DNA MMR system completely. The Wnt signaling pathway, including the gatekeeper protein APC and other proteins in this pathway, are deregulated. A number of genes with encoded microsatellites are targeted for mutation in microsatellite-unstable tumors, including *hMSH3, TGFBR2,* and *BAX*. *TGFBR2* and *BAX* mutations appear at the transition point during malignant conversion. Other mutated genes are likely to be involved in forming the final tumor and in mediating metastasis.

Much has been learned about multistep carcinogenesis through studies of colon cancer, and the principles may be applicable to cancers of many types. Multiple genetic events are required to overcome the redundancy in regulatory controls in the cell. These events accumulate during successive waves of clonal expansion and cooperate to produce tumor progression. The exact impact on growth regulation is not entirely known for any single genetic lesion. Because a small proportion of cancers lack the genetic events seen in most others, it is reasonable to speculate that there are additional mechanisms of tumor progression, and there is evidence for alternative pathways. [80], [147] One hypothesis involves widespread hypermethylation of gene promoters as a mechanism for epigenetic inactivation and gene silencing. [80] Indeed, sporadic colorectal cancers with microsatellite instability lose DNA MMR activity as a consequence of hypermethylation of *hMLH1*. [169], [170] Other genes commonly inactivated by hypermethylation at promoter CpG islands include the cell cycle regulator *p16,* the *THBS1* angiogenesis inhibitor, the estrogen receptor growth suppressor, the *TIMP3* metastasis suppressor, and the *O*[6]-methylguanine DNA methyltransferase DNA repair gene. [171] CpG islands are regions of DNA 0.5 to 2 kilobase pairs long, rich in cytosine-guanine dinucleotides, that are found in the 5' region of about half of all human genes. Methylation of cytosines within the CpG islands is associated with loss of gene expression and can be observed physiologically (as with X chromosome inactivation and aging), but also with neoplasia. A distinct pathway for colorectal cancer development, termed the *CpG island methylator phenotype (CIMP),* has been proposed. [172] In a study of colorectal cancers, the CIMP phenotype segregated with tumors that demonstrated microsatellite instability. [172] However, in a study of colonic adenomas, the CIMP and microsatellite instability pathways appeared to be distinct. [171] The CIMP phenotype seems to occur early in colorectal tumorigenesis, but the mechanism for its occurrence is not known.

TUMOR FORMATION AND BEHAVIOR

Molecular Histology

Much of the understanding of the genetics of gastrointestinal tract carcinogenesis has come from analyzing various histological stages of tumors. Neoplasia originates from a single cell that has developed a genetic alteration, and then grows at variable rates to larger sizes with differing histological morphology. In the colonic adenoma, there is continued mitosis and lack of cellular differentiation, so that the principal proliferative compartment moves from the base of the crypt to involve the entire crypt. Persistent replication of cells near the crypt surface, in concert with retarded cell maturation and extrusion, results in an increased number of replicating surface cells. Continued proliferation coupled with lack of cell death leads to a downward infolding of epithelial cells, which branch and interpose themselves between normal crypt elements. This process results in the characteristic branching glandular pattern of tubular adenomas. As the polyp continues to grow, the growth pattern of the underlying mesenchyme may be enhanced. [173], [174] If mesenchymal proliferation matches the rate of epithelial growth, resistance to continued epithelial proliferation is unimpeded, resulting in long, fingerlike projections of the glandular elements. This histological picture is characteristic of villous adenomas. Perhaps more commonly, an adenoma demonstrates a combination of these two histological types, a tubulovillous adenoma. Villous adenomas tend to be larger than tubular adenomas, consistent with the concept that the villous histology is associated with enhanced growth characteristics. Subsequently, some adenomas develop characteristics of carcinoma, giving rise to the malignant polyp. Malignant cells at some point develop the capacity to invade locally and the potential to spread to distant organs.

Each histological stage of neoplasia has been characterized genetically by analyzing the cells present in the specimen. Immunohistochemistry, RNA and DNA extraction, and in situ polymerase chain reaction are some of the techniques used to determine the genetic abnormalities of the cells. The sequential biologic process of tumor formation is now correlated to specific morphologic characteristics of tumors in their various stages. [143], [147]

The general features of the colorectal neoplastic model may be applicable to other gastrointestinal neoplasms. In esophageal, pancreatic, and hepatic neoplasms, it is difficult to obtain tissue samples at each stage of a multistep process. These tumors do not have a readily identifiable precursor lesion to obtain and study. Tumors of these organs, particularly of the esophagus and pancreas, often present in advanced stages, precluding an opportunity to obtain specimens at early stages of the disease.

Loss of Proliferative Control and Clonal Expansion

Proliferation is normally tightly regulated and confined to one compartment of the epithelial unit within the gastrointestinal tract. During periods of epithelial repair, this regulation is relaxed, and the rate of proliferation increases. When a sufficient number of cells has been produced, the rate of proliferation slows to match the rate of cell loss.

A chance genetic event may occur in one cell that has not yet been committed to programmed cell death, enabling it to undergo more cycles of replication than any neighboring cell. When this event affects the gatekeeper gene or pathway function, neoplasia is initiated. In the colon, the proliferative pool of cells migrates from its normally restricted site at the base of the crypt toward the apex of the crypt. The expanded pool of cells may be seen in magnified histological preparations of grossly normal-appearing colonic mucosa stained with methylene blue, termed *aberrant crypt foci*. [175] Aberrant crypt foci are collections of thickened epithelium with asteroid or oval-shaped glandular lumens. [176] The number of aberrant crypt foci appears to be higher in patients with a prior history of colon cancer, and highest in patients with FAP. [175] Most larger aberrant crypt foci do not appear to be neoplastic, although they contain mutations in the *KRAS* oncogene. [176], [177], [178], [179] and [180] However, dysplastic aberrant crypt foci have been reported to contain *APC* mutations. [177], [179] Dysplastic aberrant crypt foci may be the first histological counterparts that reflect loss of the gatekeeper gene function. The Wnt signaling pathway, of which APC is a part, appears to be critical for the initiation of colonic neoplasia and is the gatekeeper for colonocytes. [99], [146] Loss of the Wnt signaling pathway uncouples the cell from programmed cell death, the ability to regulate intracellular growth signaling, and recognition of cell-cell adhesion. [181], [182] Because these cells continue to proliferate but are incapable of invasion, they tend to expand locally and develop into an adenoma. Additional growth permits the formation of a polypoid lesion. This is a common stage in the development of colonic neoplasia but uncommon in the natural history of neoplasia of the esophagus, stomach, and pancreas.

The liberation from typical growth restraints allows the cell to grow at a faster rate than any surrounding cell. Subsequently, a new genetic event may occur in one of these cells, further accelerating growth. Each advantage gained in growth, beginning with the adenoma and subsequently progressing to carcinoma, occurs by successive waves of clonal expansion. Each clone gains its advantage by a genetic alteration within the cell that allows more successful proliferation than its predecessors. In the colon, it appears that mutations in the *KRAS* gene, and possibly the *p53* gene, participate in this process. Alterations in the KRAS signaling pathway may permit enlargement of the adenoma to an exophytic mass. [147] Flat cancers that have mostly been observed in Japan appear to lack *KRAS* mutations. [147], [183], [184] In microsatellite-unstable tumors, clonal expansion may be mediated in part by alterations in the Wnt signaling pathway and the TGFB1 signaling pathway, and by escape from BAX-mediated programmed cell death. [27], [33], [156], [157], [165], [166] In the gastrointestinal tract, the expanded pool of hyperproliferative cells undergoes new DNA synthesis in the hazardous environment of the gastrointestinal lumen. The unrestrained proliferation permits the clonal expansion of mutated cells, hastening the appearance of alterations that may provide a growth advantage.

The development of adenomas is a reversible biologic event in the colon, at least by gross appearance. Small, sporadic adenomatous polyps may spontaneously disappear, and small rectal adenomas often spontaneously disappear from patients with FAP after subtotal colectomy. [185] Patients who have hundreds of colonic adenomas may experience regression of these lesions after the administration of the nonsteroidal antiinflammatory drug sulindac or the COX-2 inhibitor celecoxib. [14], [186], [187] and [188] The mechanism underlying adenoma involution in response to sulindac or the COX-2 inhibitor celecoxib is the activation of programmed cell death. [12], [13] and [14] The incidence of gastrointestinal cancer is significantly reduced in patients taking aspirin and other nonsteroidal antiinflammatory drugs (see Chapter 91). Pharmacological therapies that may block neoplastic progression at this early stage are being evaluated.

Malignant Conversion

At least two genetic mechanisms permit destabilization of the cellular genome and the appearance of cancer. Both mechanisms involve the breakdown of a homeostatic mechanism by which the genome is faithfully reproduced.

Chromosome instability reflects a failure in the symmetric separation of sister chromosomes and results in LOH events throughout the genome. When LOH occurs at a tumor suppressor gene locus, additional clonal expansion is greatly favored. The inability to divide the tetraploid nucleus into two perfect diploid pairs at mitosis results in the random generation of aneuploid cells. Cells that accumulate extra chromosomal pieces become hyperploid, and those that lose chromosomal arms become hypoploid. Randomly occurring events that provide a growth advantage result in clonal expansion of the favored cell. Flow cytometry has been used to detect expanded clones with abnormal DNA contents. [189], [190] Highly aneuploid tumors exhibit increased virulence. [190], [191] The abnormal clones occur focally rather than diffusely throughout the tumor, and evidence suggests that metastatic lesions are derived from these aneuploid clones. [192] In the colon, the histological appearance of high-grade dysplasia coincides with the complete genetic inactivation of *p53* in chromosome-unstable tumors. [143]

A second type of genetic lesion capable of increasing the rate of mutation is inactivation of the DNA MMR system. This form of genomic instability leads to microsatellite instability, and allows an accumulation of mutations throughout the genome. Microsatellite instability leads to an increase in point mutations, as well as insertion/deletion mutations at simple repetitive DNA sequences (microsatellites). Cancer cells with microsatellite instability are typically diploid. [151] The polymerase chain reaction can detect the presence of the inaccurately copied microsatellite DNA. Because of the high mutation rate, it is probable that tumors with MMR defects may progress to carcinoma at a more rapid pace than other tumors. [152], [155] Malignant conversion in colorectal tumors with microsatellite instability involves mutation of *TGFBR2* and *BAX,* both of which appear in high-grade dysplasia at the interface of defining malignancy—the adenoma-to-carcinoma transition. [167], [168]

Malignant cells are capable of continued growth, invasion, and formation of distant metastases. The malignant phenotype is intrinsically unstable and gives rise to additional phenotypic diversity. Malignant tumors are dynamic by virtue of ongoing genomic instability. Some of the newly created cells lose proteins essential for survival and die. Other genetic events result in the generation of more virulent clones that overgrow and replace the parent tumor.

Metastasis

The metastasis of tumor cells is not a random or accidental process. For a tumor to metastasize, it must degrade the basement membrane and associated matrix components, migrate through the subtending connective tissue, enter into a lymphatic or blood vessel, migrate away from the parent tumor, avoid a gauntlet of naturally occurring defensive mechanisms, emigrate from the efferent vessel, lodge at a distant site favorable for its growth, and recruit a sufficient blood supply (Fig. 24-11). [193], [194] and [195] Metastasis occurs as a late event in the natural history of a tumor, because time is required for the gradual evolution of cells capable of all these behaviors.

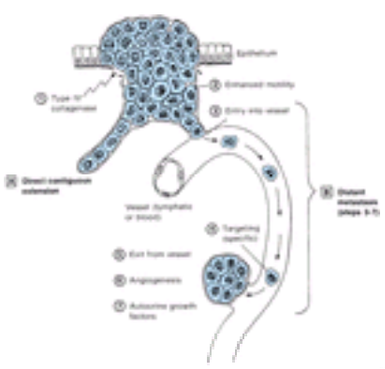

FIGURE 24-11. Tumor metastasis. Successful tumor metastasis requires several coordinated events. Specific collagenases are required to transgress the basement membrane (step *1*). The tumor may grow by direct contiguous extension into surrounding organs (**A**). Alternatively, tumor cells may enter a vascular structure for distant metastasis to occur (**B**). The spread of malignant cells is enhanced by the development of cellular motility (step *2*). Access to a vascular structure is permitted by the expansion of the growing tumor, the motile cells, and the ingrowth of blood vessels, which is stimulated by angiogenesis factors (steps *3* and *6*). Entry into the circulation is not sufficient to ensure distant metastasis. Specific targeting mechanisms and adaptations that would enhance survival at a distant site are required for distant metastatic spread.

The characteristics required for metastasis are quite specific. A malignant neoplasm, for example, may acquire the ability to digest the basement membrane and slowly expand into the submucosa, so that it is by definition malignant; however, it may not acquire other properties required for entry into the circulation or survival in a distant organ. Such a tumor is pathologically malignant and may become a bulky mass, but there may be a relatively long period during which it can be detected and successfully removed. Alternatively, a highly metastatic clone of cells emerging from a malignant tumor may give rise rapidly to a large number of metastatic units, and the host may suffer a brisk and relentless downhill clinical course.

Our insight into the metastatic process is insufficient to predict the clinical course of a malignancy by studying tumor cells in vitro. Tumor cells are frequently present in the portal and peripheral circulation at the time of colectomy for a colon cancer. [196], [197] However, the presence of cytologically identifiable tumor cells in the circulation has no prognostic significance because most of these cells are incapable of growing at a distant site and are susceptible to cytolysis by natural killer lymphocytes and other immunologic mechanisms. Clumps of cells appear to be more likely to survive as a metastasis, perhaps because individual cells in the clump have only some of the functions required for successful metastasis, but the entire “social unit” is capable of growing communally.

Tumor cells require a blood supply to survive. Oxygen can normally diffuse 100 to 200 µm from a blood vessel, which is roughly four to ten cell diameters, depending on the tumor. To facilitate their growth at metastatic sites, tumors stimulate the growth of capillaries. Tumor-associated angiogenesis appears to be mediated by a variety of different tumor growth factors, including angiogenesis factors. The presence of such growth factors can be demonstrated by the tumor’s ability to recruit endothelial cells to form capillaries in vitro. [198] Inhibition of vascular endothelial growth factor in mouse models of colon cancer blocks tumor growth and induces apoptosis by inhibiting angiogenesis and endothelial cell survival. [198] Evidence suggests that the expression of transcripts in the endothelium of tumor blood vessels differs from that in the endothelium of nontumor vessels. [199] Therapies to interfere with tumor angiogenesis are under development, including COX-2 inhibitors and other drugs. [200], [201]

The sites to which malignant cells metastasize may appear to be random, based purely on the blood supply of an organ, but the process is more complicated, and tumor cell targeting to distant organs may be mediated by specific cell membrane receptors. For example, although tumor cells may be present in the portal blood or peripheral circulation at the time of removal of a colon cancer, hepatic metastases occur only in some instances. Metastases may be present in the lung, bone, and other distant sites, such as the brain, even in the absence of hepatic metastases. Tumor cells can migrate through the hepatic sinusoids without establishing a malignant deposit in the liver.

Not all cells in a primary tumor have identical metastatic potential. [202] From a primary tumor, it is possible to clone cells with an enhanced capacity for metastasis and a propensity to metastasize to specific organs. For example, certain experimental tumor cells form lung metastases in rodents, but others do not. When these metastatic colonies are removed from the lungs, and their numbers are expanded in culture and reinjected by tail vein, each successive cycle produces a larger number of pulmonary metastases. The propensity of the highly metastatic cell line to grow in the lung appears to result from a specific interaction between the injected cells and the pulmonary capillary bed. Lung lesions are seen even after left ventricular injection of the cells, in which the lung is not the first capillary bed, or after transplantation of lung tissue to a subcutaneous location. By means of the same technique, other cell lines can be developed with an enhanced propensity to metastasize to the liver or to specific sites within the brain. [202], [203] and [204] Site-specific metastasis appears to be mediated by cell surface membrane glycoproteins. Removal of the glycoproteins from the tumor cell surface membranes interferes with the specificity of metastasis. By fusing membrane vesicles from metastatic cells to

those of nonmetastatic cells, it is possible to confer homing specificity to the recipient cells.

Primary colon cancer differs from metastatic colon cancer in that metastatic colon cells express sialylated mucin-associated carbohydrate structures that may play a role in adhesion to the target endothelial glycoproteins and the target cell basement membrane. [205] Other carbohydrate structures found on colon cancer cells appear to bind to molecules such as laminin, a normal component of the basement membrane.

Metastasis Genes

The genetic basis of metastasis is complex and incompletely understood. One gene has been identified that is associated with distant metastasis in colorectal carcinoma. The *NM23* gene (also designated *NME*) seems to function as a metastasis suppressor gene, inasmuch as it was deleted in distant metastases from colorectal cancer. [206] Patients without allelic deletions of this gene have a significantly better prognostic outlook. The cellular mechanism by which the *NM23* locus confers metastatic capability is uncertain, but transfection of the gene into certain tumor cell lines inhibits their ability to migrate in response to chemoattractants. [207] *NM23* gene mutation has been reported from human colorectal cancer metastases, suggesting that it may undergo a two-step inactivation, like other tumor suppressor genes. [208]

Other potential metastasis suppressor genes may be located on the long arm of chromosome 18. Chromosome 18q is lost in 80% of patients with stage IV colorectal cancer. [209] The deleted in colorectal cancer (DCC) gene, located on chromosome 18q21, was one such metastasis suppressor gene. *DCC* was identified after a study of commonly deleted regions on chromosome 18q in colorectal cancers. [210] *DCC* encodes a unique protein with homology to neural cell adhesion molecules and other related cell surface glycoproteins. This similarity has led to the hypothesis that the DCC gene product is involved in cell-to-cell adhesion and cell matrix interactions, which may be important in preventing tumor growth, invasion, and metastases. Expression of DCC was reportedly absent in most colorectal cancers metastatic to the liver, but it was lost in only a minority of nonmetastatic cancers. [211] However, germ-line inactivation of the murine homolog of *DCC* failed to support a tumor-suppressive function for its protein. [212]

Additional genes on chromosome 18q, such as the TGFB1 signaling molecules *SMAD2* and *SMAD4,* and other genes elsewhere may possess metastasis suppressor function, but further genetic and biochemical studies are required to resolve this issue. [213] Numerous genes participate in the metastatic phenotype, and their accumulation within malignant cells is responsible for the broad range of virulent behaviors seen in cancer.

CLINICAL MARKERS OF NEOPLASIA

Biologic Tumor Markers and Oncofetal Proteins

Some gastrointestinal cancers acquire and elaborate cell surface determinants that recapitulate structures transiently expressed during normal fetal development. These oncofetal proteins are typically glycoproteins and can often be detected in the plasma. Carcinoembryonic antigen (CEA) was first detected with antibodies developed after rabbits were immunized with colorectal cancer cells; these antibodies are largely directed to the carbohydrate moieties of the glycoprotein. [214], [215] Subsequently, elevated levels of CEA were demonstrated in patients with colorectal cancer and other cancers. However, the limitations of CEA measurements in the population as a whole have precluded the use of CEA as a screening or diagnostic marker. Poor sensitivity and specificity in asymptomatic populations render it less than useful for detecting early, potentially curable cancers. [216] Other conditions besides colorectal cancer are associated with elevated plasma levels of CEA, including cancers of the stomach, pancreas, and liver, nonmalignant diseases of the liver such as alcoholic hepatitis, inflammatory bowel disease, and tobacco use. [217] CEA levels measured at the time of diagnosis may be correlated to the prognosis of colorectal and other cancers (i.e., the higher the CEA elevation, the more advanced is the cancer stage at diagnosis). [218], [219] Nonetheless, this information cannot be used to predict outcome.

Other oncofetal proteins have been used to screen for the presence of gastrointestinal cancer. As with CEA, poor sensitivity and specificity and elevated levels in nonmalignant conditions have limited their usefulness in screening. The determinants for most markers reflect modifications of blood group antigens (e.g., Lewis blood group) and mucin glycoproteins. Table 24-5 shows some tumor markers and their associated cancers.

TABLE 24-5 Examples of Oncofetal Antigen Markers in the Gastrointestinal Tract

Genetic Tumor Markers

Cancer cells develop as a consequence of multiple genetic insults that affect normal growth regulatory mechanisms. Detection of mutations in tissue samples would therefore suggest the presence of cancer or precursor neoplasia. Techniques in molecular biology, largely through use of the polymerase chain reaction, allow the detection of minute amounts of tumor cells or free nucleic acid in biologic samples. For instance, *KRAS* mutations have been detected in DNA purified from feces, but benign and malignant colorectal tumors could not be differentiated. [220] In addition, *KRAS* mutations have been detected in the stool of patients with pancreatic adenocarcinoma as well as chronic pancreatitis. [221] The detection of *KRAS* mutations in feces as a means of differentiating neoplasia from inflammation is difficult, and differentiating between colonic and pancreatic neoplasia likewise is problematic. *KRAS* mutations also have been detected in the plasma of patients with colorectal cancer. [222] The detection of *KRAS* mutations in pancreatic juice may eliminate the colon as a source of the mutation, but still cannot distinguish benign from malignant disease. [223]

Mutation in *p53* has been associated with poor prognosis in several malignancies, including colon cancer, [224] and loss of normal *p53* signals the transition from benign to malignant colorectal neoplasia. [143] Tumors with mutations in *p53* tend to respond poorly to therapy, whereas malignancies that rarely have *p53* mutations (e.g., Wilms tumor, testicular cancer, acute lymphoblastic leukemia) often respond to therapy. [225] The finding of *p53* mutations in the urine of patients with bladder cancer and in the stool of patients with colorectal cancer suggests that detection may eventually be useful for screening. [226], [227] The presence of mutated *p53* suggests the presence of a neoplastic process; however, it may not indicate loss of the second, normal *p53* allele that is seen in malignant transformation. Thus, distinguishing a benign adenoma from colorectal cancer, as with *KRAS,* may be impossible. The costs and utility of advanced molecular diagnostics in colon cancer in comparison with those of conventional screening methods have not been addressed. Current oncology clinical practice guidelines do not recommend the routine use of tests for the *p53* tumor suppressor gene or the *KRAS* oncogene in screening for colorectal cancer. [228]

Detection of naked DNA by microsatellite analysis of the serum [229] and plasma [230] of patients with head and neck cancer and of patients with small cell lung cancer, respectively, indicates that these tumors release large amounts of DNA into the blood. For the most part, microsatellite alterations in the circulating tumor DNA were similar to those in the primary tumor. Enrichment of the tumor DNA in the blood may occur. Aberrantly methylated *hMLH1* promoter DNA has also been detected in the serum of patients with microsatellite-unstable tumors. [231] LOH can be detected in the serum, which requires higher concentrations of DNA than that needed for the detection of microsatellite instability. [232] However, plasma or serum microsatellite alterations in benign or nonneoplastic tumors have not been identified.

The status of chromosome 18q in a tumor may have prognostic significance for patients with colorectal cancer. Rates of survival associated with stage II (Dukes B2) colorectal cancer and LOH at chromosome 18q were similar to those associated with stage III cancer. [233] The survival rates of patients with stage II cancer and no LOH at chromosome 18q were similar to those of patients with stage I cancer. The status of chromosome 18q was determined from the resected tumor and suggested that patients with stage II disease and LOH at chromosome 18q should be offered chemotherapy because patients with stage III disease have been shown to derive survival benefit from chemotherapy. [234] It is not known what genes on chromosome 18q may be metastasis suppressor genes that, if lost from the tumor, may allow

spread to the regional lymph nodes (stage III) or distant organs. [213]

The test with the best specificity may be the detection of *APC* mutations in fecal DNA. [237] Mutations in *APC* generally initiate colorectal neoplasia, and detection of such mutations would be expected to segregate with neoplasia. In a feasibility study, *APC* mutations were detected in 57% of patients with polyps or cancer, but in none of the control patients without colorectal neoplasia. [235] A digital protein truncation test, in which multiple samplings of fecal DNA were amplified by the polymerase chain reaction and later subjected to an in vitro transcription translation assay, was used in the study. The test is based on the identification of abnormal proteins synthesized from mutant genes; future improvements in proteomics may increase the sensitivity of this assay. This approach will not detect defects in other proteins of the Wnt signaling pathway.

Assaying multiple genetic targets as part of one complete assay is another approach to detect neoplasia. There is some genetic heterogeneity in colorectal tumorigenesis that may extend to other cancers of the gastrointestinal tract. One group assayed mutations of *KRAS, p53,* and *APC* genes, *BAT-26* (a microsatellite instability marker), and highly amplifiable long-strand DNA from human fecal material. [236] *Long-strand DNA* refers to DNA that has not been degraded during apoptosis; it may be present in cells that have escaped programmed cell death. With use of the panel of multicomponent markers, the sensitivity for detecting neoplasia was 82% for adenomas and 91% for cancers. [236] When *KRAS* was excluded from the analysis, the specificity for detecting neoplasia increased from 93% to 100%, with a positive predictive value for colorectal neoplasia of 100% and a negative predictive value of 85%. [236]

The use of genetic tumor markers for screening and determining survival is currently limited. As our understanding of tumor biology progresses and the sophistication of biotechnology improves, genetic tumor markers will likely play a role in the management of cancer patients.

CHAPTER 25

Alex Novogrudsky and Andrew G. Plaut

THE BACTERIAL FLORA OF THE HEALTHY GASTROINTESTINAL TRACT

Interest in gastrointestinal bacteria can be traced back hundreds of years, but serious inquiry into the composition of the gut microflora and its impact on health began late in the 19th century. [1] Soon after bacteria were identified as agents of disease, bacterial masses living in the human intestine were looked on with suspicion. Why these bacteria were bad was hard to define for early clinician-scientists, but it was clear that the microflora was well worth changing, or abolishing altogether. The methods used included medications, physical devices such as high-volume enemas, and fermented foods such as yogurt. To this day, attempts to change the microflora persist, and well-controlled clinical studies on selected strains of *Lactobacillus* and *Saccharomyces* that are able to colonize the human intestine show some therapeutic benefit. Beyond the use of such probiotics, however, modifications of the enteric microflora by strategies such as enemas are useless and certainly risky reminders of the history of this discipline. Characterization of the gut microflora has encouraged the development of selective decontamination methods for the preparation of persons undergoing alimentary tract surgery and for patients receiving intensive care, but a recent review of ten studies indicates that this strategy is of limited utility. [2]

Serious study of the gut microflora first required reliable methods of culture, particularly for the study of the anaerobic bacteria that dominate the normal commensal gut microflora (*commensal:* “together at the table”). Anaerobes, which do not grow or are killed in the presence of oxygen, were first cultured in the laboratory of Louis Pasteur in 1877, and despite continued refinement of methods since that time, difficulties in handling these oxygen-sensitive species persist. Laboratory culture made it possible to carry out taxonomy of the dominant gut bacteria, an effort now on firmer footing with the use of methods of molecular biology to characterize chromosomal and plasmid DNA. These methods not only refine identification but also can establish the relationships among bacterial species and allow tracking of microorganisms as they are transmitted from one person to another. [3] The use of methods such as 16S ribosomal RNA-based molecular phylogeny as well as nucleic acid amplification technology can even identify microorganisms that until recently defied all attempts at in vitro culture—a good example being the identification of *Tropheryma whippelii* as the cause of Whipple disease. [4] The highly sensitive polymerase chain reaction and the availability of primers specific for highly conserved regions of bacterial 16S ribosomal DNA enable the detection of DNA derived from gut bacteria even in blood specimens from healthy individuals. [5] Such culture-independent methods may in time reveal that some illnesses of still uncertain etiology are caused by infectious microorganisms, some of which may originate in the bowel flora.

Beyond the significant advances already made in culture and taxonomy, the most recent chapter in the study of gut bacteria brings the surprising experimental finding that bacteria colonizing the small intestinal mucosa can signal the host mucosa epithelium to undergo surface modifications. In rodent models of bacterial colonization, bacteria not only have a high specificity for the cell or tissue they colonize but also may actually induce changes in host cell surfaces that improve the microbial nutritional microenvironment. These changes brought about by commensal bacteria may strengthen the resistance of the mucosa to infection, providing a rational basis for the use of probiotics as health supplements and therapy. Studies in experimental animals indicate that colonization is of mutual benefit for host and microbe; the host provides nutrients, a controlled temperature, and a favorable physical environment for bacterial replication, while the bacteria provide specific nutrients needed by the host and possibly protect against attachment and mucosal injury by pathogenic bacteria. As discussed later in this chapter, the very existence of a colonizing microflora is now regarded as essential for the development of key components of the mucosal immune system.

COLONIZATION OF THE HUMAN GUT

True colonization requires that entering bacteria bind to tissues, that they proliferate at the site of binding, that their progeny efficiently reattach, and that they withstand mechanical and other defensive mechanisms of the host. An alternative to direct binding to host cells is for incoming bacteria to bind to microbes already colonized, a process referred to as *coaggregation*. Few microorganisms meet the stringent criteria of colonization, including many strains currently used as probiotic agents. Anaerobes also depend on redox potentials in the gut that are low enough for their growth, conditions met in the colon through oxygen utilization by aerobic species. Successful colonization is independent of the number of microbes ingested, which is why early attempts to force colonization by large inocula were ineffective.

Microorganisms that colonize the normal gut are abundant, taxonomically complex, and markedly uneven in distribution, but the entire commensal microflora appears to consist solely of bacteria and a few yeasts. When collected by careful techniques, fluids or mucosal washes from the esophagus, stomach, and jejunum contain no more than 10^6 [6] bacteria per milliliter, and these relatively few microbes are likely to come from food or from the oral cavity, which itself has a rich bacterial population. Bacteria can proliferate in the upper gut if the gastric pH rises, if gut motility is abnormal, or if sluggishly emptying diverticula or fistulae offer a site for microbial persistence, the basis for bacterial overgrowth syndromes. Otherwise, the upper gut has no persuasive tissue-binding sites for commensal microbes. The same is not true for pathogens; *Helicobacter pylori* can attach and survive in the stomach, and *Vibrio cholerae* securely binds to G_{M1} ganglioside on jejunal epithelial cells, where it proliferates and produces cholera toxin. Why nonpathogens fail to find a niche in the upper reaches of the digestive tract is something of a puzzle, although the nutritional needs of a mass of microorganisms in the upper gut may leave the host at a competitive disadvantage.

The Gut of Nursing and Weaned Children

The gastrointestinal tract of a healthy newborn is not colonized, but a complex microflora is established within weeks after birth. Fecal enterobacteria, streptococci, and staphylococci appear within days, and by oxidative metabolism they reduce the redox potential to encourage rapid colonization by strict anaerobes. In breast-fed babies, about 90% of the fecal bacteria are *Bifidobacterium* species, the expansion of which is further encouraged by specific growth factors in human milk. Enterobacteriaceae and enterococci are present in low numbers, but *Bacteroides* species, staphylococci, and lactobacilli are absent. Within weeks of weaning an infant to food or cows’ milk–based formula, *Bacteroides* species, enterococci, lactobacilli, and clostridia appear, a change likely more a consequence of a profound reduction in the numbers of *Bifidobacteria* species (no longer promoted by milk growth factors) than of changes in the mucosa or growth conditions. This new

microflora dominates throughout adult life, and major changes do not occur without the use of antibiotic drugs.

The Gut of Healthy Adults

The lumenal contents of the distal ileum and colon and the feces of adults contain about 10^{11} to 10^{12} colony-forming units per gram, a value approaching the theoretical limits for packing of bacteria into a cubic centimeter. As indicated earlier, coliforms, enterococci, clostridia, and lactobacilli are all found in a normal fecal sample, but the most abundant species by far are the strictly anaerobic *Bacteroides* organisms and anaerobic lactic acid bacteria (Table 25-1). Although aerobic or facultative coliforms are easily cultured (hence the use of coliform counting to detect contaminated water), anaerobes, which are far more difficult to culture and recover, outnumber aerobes 1000- to 10,000-fold in the human colon.

BACTERIA	COMMENTS
GRAM-POSITIVE COCCI	
Peptostreptococcus	Formerly *Peptococcus*; anaerobic counterpart of the streptococci
Streptococcus	Colonic species are mainly serogroup D
Enterococcus	Formerly with serogroup D; species include *E faecalis* and *E faecium*
Gemella	Closely related to oral streptococci
GRAM-POSITIVE RODS	
Clostridium	Forms spores; more than 80 species
Actinomyces	No spores, filamentous; strongly prefer anaerobic growth
Bifidobacterium	No spores; dominate colonic microflora of nursing babies
Lactobacillus	No spores; native forms include *L acidophilus*, *L fermentum*, *L plantarum*
Eubacterium	
GRAM-NEGATIVE RODS	
Bacteroides	*B fragilis* strongly dominates the adult colonic microflora
Campylobacter	
Porphyromonas	Includes many organisms formerly classified with the *Bacteroides* (e.g., *P gingivalis*)
Prevotella	Includes many organisms formerly included with the *Bacteroids* (e.g., *P melaninogenica*)
Shigella	
Enterobacteriaceae	Includes *Escherichia coli*, *Citrobacter*, *Enterobacter*, *Shigella*, *Salmonella*, *Serratia*, *Proteus*, *Providencia*, *Klebsiella*, and *Yersinia* species
GRAM-NEGATIVE COCCI	
Veillonella	Closely related to aerobic Neisseriaceae

Note: Strict anaerobes are in **bold** type; others are microaerophilic or facultative.

TABLE 25-1 A Guide to the Facultative and Strictly Anaerobic Bacteria in the Human Colon

The nutritional requirements of *Bacteroides* species are easily met from dietary and host sources. *Bacteroides* organisms are saccharolytic, producing enzymes that cleave glycosidic linkages in the abundant complex polysaccharides such as dietary xylans, glucans, and pectins that reach the colon.[6,7] The same enzymes also attack *O*-linked oligosaccharides on mucin proteins produced by the gut epithelium; therefore, *Bacteroides* species cleave both endogenous and exogenous glycopolymer substrates, reducing all to mono- or disaccharides for efficient utilization as nutrients. The complex classification of *Bacteroides* organisms is reflected in recent changes in both genus and species designation (see Table 25-1). The predominant colonic *Bacteroides* species is *B fragilis;* the corresponding oral species have been reassigned to the genus *Prevotella* or *Porphyromonas*.[8] Species names can obscure close relationships; for example, *Bifidobacterium bifidum* in the infant colon is gram-positive, but a close relative of the gram-negative *Bacteroides* species that dominates the colonic flora in adult life. *Clostridium difficile* is a strict anaerobe that often colonizes infants, who are seemingly protected from its enterotoxin. A remarkable clinical observation is that most persons never have a serious anaerobic infection throughout life despite the great abundance of anaerobes in the oral cavity and colon. This cannot be attributed solely to inefficient transmissibility of these species from person to person, as shown by the highly efficient transmission of anaerobes such as *C difficile* in the hospital setting.

Fecal lactobacilli are facultative or strict anaerobes and produce very large amounts of lactic acid (and somewhat less acetic acid) from carbohydrate substrates. The feces contain 10^{4} to 10^{8} colony-forming units of lactobacilli per gram, levels somewhat below the 10^{7} to 10^{8} colony-forming units of Enterobacteriaceae, such as *Escherichia coli,* per gram. The introduction of lactobacilli as probiotics[9] to treat antibiotic-associated diarrhea and to maintain general health is an old idea that has been vigorously revived through the development of strains that colonize more efficiently.

Quorum Sensing: How Bacteria Count Their Numbers

Quorum sensing is a recently identified and well-characterized mechanism through which bacteria communicate with one another. Originally defined in *Vibrio* species living in marine environments, quorum sensing involves the microbial control of gene expression in response to cell density and is found among both gram-positive and gram-negative bacteria.[10] The sensing processes of gram-negative bacteria are based on the production of extrasignaling molecules. Termed *autoinducers,* these molecules are acylated homoserine lactones that communicate cell density via receptor-based signaling to which the same or similar species are capable of responding. It has been shown that the biosynthetic pathway of one of the autoinducers (termed *AI-2*) is identical in the gut bacteria *E coli* and *Enterococcus faecalis* and in the pathogens *Salmonella typhimurium* and *V cholerae,* suggesting that it may be a general signal for bacterial communication. Studies of enterohemorrhagic *E coli* (EHEC) O157:H7 show that several of its key virulence mechanisms and basic physiological functions involve genes regulated by quorum sensing through AI-2, a product of the *luxS* gene.[11] Interspecies communication based on quorum sensing has not been proved to occur in the human gut, but this mechanism could allow a given bacterium to know its cell density and relative numbers in a complex microbial environment, and to use this information to express, or suppress, genes controlling many metabolic processes.

THE MICROBIAL FLORA AND THE HOST EPITHELIUM

The Bacterial Microflora and the Mucosa

The precise physical relationships of commensal microbes to the mucosa of the healthy human colon are not known in detail, although the proximity of certain species such as *Bacteroides* to their preferred substrates has been studied in depth.[8] The study of similarly colonized sites, such as the oral cavity, which is more easily accessed for such research, shows it to be a complex interplay of bacterial species. For example, streptococci colonize the newly cleaned enamel surface of the tooth covered by the proteinaceous acquired pellicle within hours to days, but after several weeks, they are replaced by anaerobes that dominate the microbial flora. This sequential and predictable arrival of colonizing bacteria involves mutual dependency; electron microscopy of developing bacterial masses on the tooth surface shows that in-coming new species often bind not to host tissues but to a dissimilar but already adherent microbe. The study of similar microbial relationships in the ileum and colon is more challenging, not only because this part of the gastrointestinal tract is inaccessible but also because the underlying colonized epithelium undergoes continual renewal.

Microbial Attachment to Host Cells

Microbial adherence is a critical determinant of colonization and is host-, tissue-, and cell-specific. By definition, adherence easily overcomes mechanical factors such as fluid flow and motility, which is made vividly clear by the tight attachment of pathogens such as *V cholerae* to the epithelium of the self-cleaning upper gut. This raises the question of why the large surface area of the human small intestine is so free of colonizing bacteria, and suggests that innate defense mechanisms such as cationic defensin peptides[12] and adaptive mucosal immune mechanisms are truly protective. Evidence that bacteria cannot find enough nutrients in the small bowel to permit colonization is not persuasive, but unsuitable pH and oxidation-reduction potential at this site definitely limit the growth of anaerobic species.

Most detailed information on bacterial attachment derives from studies of enteric and urinary tract pathogens whose attachment to host epithelial cells involves either type I or type IV pili. Pili are assembled from pilin subunits into a rigid fibrillar rod that extends far enough from the bacterial surface to overcome what otherwise would be mutually repellent negative charges on the microbial and epithelial cell membranes. Pilus assembly involves multiple microbial proteins and transport systems, similar to those involved in bacterial entry into cells during infection.[13] Originally considered a largely passive process, bacterial adherence induces metabolic events in both host and bacterial cells. For example, both can sense when binding has occurred, as shown with *E coli* (of colonic origin) that expresses type I pili encoded by the gene fimA. Once bound to bladder epithelial cells, bacterial pilus assembly is quickly interrupted, a process dependent on the expression of a bacterial protease (DegP) that degrades unassembled pilus subunits in the periplasmic space.[14] Mouse models of bladder infection by enteric coliforms also show that host cells sense bacterial pilus attachment; adherence induces a signaling cascade in the epithelial cell that brings about DNA fragmentation, caspase production, cell apoptosis, and,

finally, shedding of the cell from the epithelium. This orchestrated cell death in response to pilus-based signaling is likely to be host protective, limiting proliferation of pathogenic microorganisms on mucosal surfaces. Whether binding of commensal bacteria to gut epithelial cells regulates colonization is not yet clear.

Changes Induced by Colonizing Microorganisms

Experimental models have been developed that explore changes in the host epithelial cells induced by colonizing bacteria. [15] This research began with the observation that ileal epithelial cells of conventionally reared (i.e., colonized) mice continue to produce surface fucosylated glycans after weaning, but the mucosa of germ-free animals does not. Also, fucosylated glycans reappear in germ-free animals if a normal mouse flora is introduced. To refine these observations, *Bacteroides thetaiotamicron,* an anaerobe that typically colonizes the mouse (and human) ileum and colon, was introduced into mice as the sole colonizing species, and when present at sufficient numbers, it was able to signal the host cell continually to produce fucosylated glycans. [16], [17] *B thetaiotamicron* accomplishes this through the combined function of its L-fucose operon and a transcriptional repressor (FucR) whose activity is determined according to the levels of fucose in the environment. If the fucose level is low, FucR is unbound, and transcription of a protein that stimulates the epithelial cell to synthesize flucosylated glycans proceeds. These glycans can then be used by the bacterium as a source of energy and may promote the entry of other commensals that can metabolize fucose.

Follow-up experiments have shown that such induced changes are not limited to glycan production. [16] In gnotobiotic animals, careful manipulation of colonizing species is possible. Laser-capture microdissection and real-time quantitative reverse transcriptase–polymerase chain reaction (qRT-PCR) have been used to probe the changes in epithelial cells after colonization with *B thetaiotamicron*. Colonization increased the ileal levels of Na^+/glucose cotransporter mRNA and induced changes in the proteins involved in lipid absorption, such as pancreatic lipase–related protein-2, colipase, fatty acid–binding proteins, and apo A-IV. Changes in proteins involved in gut defense also occurred under the influence of *B thetaiotamicron,* including a 2.6-fold increase in the polymeric immunoglobulin receptor, increases in decay accelerating factor (an apical epithelial inhibitor of complement-mediated cytolysis), and increases in other proteins postulated to be important in mucosal integrity. Somewhat more relevant to the human gut, *E coli* K12 and *Bifidobacterium* species also induced changes in the expression of colipase in the mouse model. These experimental results are remarkable because they show that commensal bacteria can directly modify epithelial cell function, opening a new chapter in understanding the biologic properties of the gastrointestinal microflora. Such host cell changes may have important implications in disease and may help explain the value of the normal flora in defense against enteric pathogens.

METABOLIC ACTIVITY OF COLONIZING BACTERIA

General Biochemical Properties

The biologic activities of the colonic microflora are as diverse as their number, and commensal bacteria are no less active in modifying ingested proteins, carbohydrates, lipids, and medications than are host enzymes themselves. Clinically relevant biochemical modifications are those of bile acids, mucins, drugs, and steroids, and the biochemical mechanisms involved are largely hydrolysis, dehydroxylation, and chemical reduction. [18] Hydrolysis involves attack on glycosidic bonds in diverse compounds such as conjugated bile acids, estriol-3-glucuronide, bilirubin glucuronide, and digoxin, to name only a few. Potential carcinogens such as diethylstilbestrol or 1-nitropyrene are detoxified in the liver by the addition of a glucuronide residue, but subsequent deconjugation by bacterial glucuronidase to the free form can restore carcinogenic activity, as occurs with carcinogenic substances that already occur as glycosides in nature. One well-characterized and clinically important deconjugation involves the bacterial removal of glycine and taurine residues from bile acids. These amino acids are ionized at physiological pH, increasing the amphipathic properties of the bile acids, which are essential for their role in the assimilation of dietary fat and fat-soluble vitamins in the small intestine. The principal deconjugating microbial enzyme is ß-glucuronidase, highly active in bacteria such as *E coli* and *Clostridium* species, although levels are relatively low in lactobacilli and bifidobacteria. [19] Colonic bacteria also remove and modify hydroxyl and keto groups on sterols, including those comprising steroidal drugs. [20]

Interaction among Microbial Species

Competition for essential nutrients, production of substances that inhibit bacterial growth, suppression of bacterial adherence, and quorum sensing are all examples of microbial interactions in the gut, some of which contribute to the ability of the normal flora to prevent enteropathogenic infections. Early investigators noted that coliforms in continuous or static flow cultures in a reducing environment inhibited the growth of *Shigella flexneri,* a finding attributable to successful competition by *E coli* for growth-limiting carbon sources, mainly glucose. [21] /SUP>The extremely high efficiency with which essential nutrients are taken up by all bacteria must be considered when low levels of essential nutrients are invoked as a control on colonization. [22] Toxic metabolic end products of normally colonizing bacteria, such as alcohols, short-chain fatty acids, H_2S, and H^+, probably also inhibit pathogens, [23], [24] as does lactic acid produced by resident *Lactobacillus* and *Bifidobacterium* species in the colon. A low pH inhibits the growth of many anaerobic and facultative pathogenic species, which possibly explains the efficacy of probiotic lactobacilli as a treatment for persistent colitis caused by *C difficile*. Conversely, short-chain fatty acids produced by anaerobic species in the colon are known to inhibit the growth of *S flexneri* and *S typhimurium*. [25] Specific antimicrobial substances known as *bacteriocins* are proteins produced by streptococci and gram-negative enteric bacteria, but a persuasive case for their role in defending against proliferation of pathogenic microorganisms has not been made. [26] Another proposed role for the colonizing microflora in preventing the entry of pathogens is adherence inhibition, which in principle suggests that occupation of the cell surface by a colonizing commensal microflora physically prevents access of pathogens to the mucosa. How this might occur is unclear [27] and again illustrates that relatively little is known about the physical interaction of the microorganisms in the colonic environment.

HEALTH BENEFITS OF THE NORMAL MICROFLORA

Production of Short-Chain Fatty Acids

Short-chain fatty acids have a vital role in nutrition of colonic epithelial cells. [28] They are derived from the fermentation of dietary carbohydrate and nonstarch polysaccharides by bacteria in the cecum and ascending colon. Most short-chain fatty acids arise from water-soluble polysaccharides (e.g., pectin, psyllium) rather than insoluble fibers (e.g., cellulose and lignin). The most important short-chain fatty acids for colonic cell energy consumption are acetate C2, propionate C3, and butyrate C4, with butyrate being the most abundant and most efficiently utilized. Short-chain fatty acids of bacterial origin vary in lipid solubility depending on their state of ionization, which is an important influence on their transport into colonocytes. Once in the colonocyte, short-chain fatty acids provide epithelial cell nutrition, regulate cellular proliferation, and play a role in regulating regional blood flow of the colonic mucosa. Propionate has been reported to inhibit cholesterol synthesis and may be responsible for the effects of dietary fiber on plasma cholesterol levels. In the small intestine, short-chain fatty acids have also been noted to increase the growth and differentiation of enterocytes. Given the many properties of short-chain fatty acids, their use in therapy for diseases such as diversion colitis, ulcerative colitis, radiation proctitis, and pouchitis has at times been strenuously advocated, but most controlled studies show modest therapeutic benefit at best.

?-Carboxylation of Glutamic Acid Residues

Vitamin K (the naphthoquinones) is found in leafy green vegetables as K_1 (phylloquinone), but the K_2 (menaquinone) form is synthesized by intestinal bacteria. Vitamin K_1 is required for the conversion of certain glutamic acid residues of coagulation factors and of prothrombin to the ?-carboxyglutamate form, essential modifications that promote calcium binding, which is required for the proper function of these proteins. Profound vitamin K deficiency increases the coagulation time, particularly in newborns before the intestinal microflora has been fully established. Less commonly, vitamin K deficiencies are seen in obstructive jaundice (vitamin K absorption is bile acid–dependent) and after the prolonged use of antibiotics that reduce the number of vitamin K–synthesizing bacteria in the bowel.

Mucosal Immunity

Mouse models of colonization and immunity show that colonizing bacteria promote the full development of the mucosal immune system. [29] T cell–deficient mice or mice that lack costimulatory factors for adaptive immunity have unexpectedly high immunoglobulin A (IgA) antibody levels in the gut, suggesting that a primitive T cell–independent mechanism is important in establishing the mucosal immune system. Experiments have shown that the B cells producing these IgA antibodies originate in the peritoneal cavity, [30] and the antibodies are directed against antigens of the commensal microflora. For example, pathogen-free mice colonized with 10^8 colony-forming units of the commensal *Enterobacter cloacae* have gut secretory IgA antibody specific for these bacteria, whereas completely germ-free animals do not. Furthermore, animals in which gut-associated lymphoid tissue (Peyer patches, dendritic cell network, or B-cell follicles) was rudimentary or absent were found to have nearly normal IgA-producing B cells in the lamina propria, whereas animals without lymphoblasts, which are incapable of establishing a B-cell lineage, did not. These results show that a primitive intestinal IgA-producing mechanism solely driven by antigens exists within the colonizing microflora, that its assembly is not dependent on organized lymphoid tissue, and that an IgA response to

bacterial proteins occurs only if the intestine is colonized, not germ-free. These results add to early observations showing that monocontamination of germ-free animals changes gut histology from that of the germ-free state (tall, thin villi; shallow crypts; few lamina propria lymphocytes; sparse Peyer patches) to that of the normal state, a condition that has been referred to as *controlled inflammation*.

Probiotics

The value of feeding capsules or solutions containing living yet safe bacteria to treat gastrointestinal illness is an old idea that now has regained a foothold in clinical medicine. [31] Interest has been renewed because of increasing concern about the overuse of antimicrobial drugs, the availability of safe microorganisms for use as probiotics, and the evidence that newer strains of these microorganisms successfully colonize the gastrointestinal tract, or at least persist for weeks after feeding stops. [32] The microorganisms in current use are *Lactobacillus acidophilus, Lactobacillus rhamnosus* (e.g., *Lactobacillus* GG), *Lactobacillus casei,* and various *Bifidobacterium* species. The criteria for use are safety, ability to survive and adhere to sites in the human gut, validated benefit, compatibility with food and food processing, and anticipated antagonism to recognized pathogens. Because of the unique colony morphology and metabolic properties of certain of these strains, such as *Lactobacillus* GG, they are readily identified in fecal culture, so that their ability to colonize is easily estimated. Aside from certain yeast probiotics that cause rare pediatric infections, these organisms are generally regarded as safe. Probiotic bacteria produce organic acids, peroxide, and antibacterial peptides in vitro, which helps explain their clinical benefits, but exactly how probiotics interrupt ongoing infectious and noninfectious diseases of the gut is uncertain. The hypothesis that "good bacteria drive out bad" has not been proved, and the induction of host epithelial cell change (discussed earlier) may be involved. Several controlled trials show that probiotics are useful in treating *C difficile* infection, gut infections related to human immunodeficiency virus, pouchitis, traveler's diarrhea, and inflammatory bowel disease.

INFLUENCE ON HORMONES AND DRUGS

The great variety of bacteria in the colonic microflora can modify many foreign compounds and medications that reach the colon. The most widely known beneficial action of bacteria on a drug involves sulfasalazine, which is used in the treatment of inflammatory bowel disease. This medication is formulated with an aminosalicylate moiety coupled to sulfapyridine by an azo bond, and cleavage of this bond by bacterial enzymes delivers the aminosalicylate directly to the inflamed colonic mucosa. Bacterial modifications of drugs can be troublesome, as an early and well-documented example demonstrates—the cardiac glycoside digoxin is metabolized to pharmacologically inactive metabolites such as dihydrodigoxin by the enteric bacterium *Eubacterium lentum*. [20] Another example is the dehydroxylation of 3,4-dihydroxyphenylalanine (DOPA) to *m*-hydroxyphenylacetic acid, which decreases the bioavailability of the drug. [33] Bacteria also modify many other drugs that enter the colon, but few such changes have had a demonstrable impact on drug bioavailability. Enzymes produced by the intestinal microflora can also aromatize, dehydroxylate, hydroxylate, deconjugate, reduce, or epimerize sterols in the gastrointestinal tract. Deconjugation modifies the gastrointestinal absorption (and subsequent renal excretion) of estrogens; the urinary levels of 12 estrogens in pregnant women were 33% to 38% lower in those treated with ampicillin, [34] presumably because a reduction in colonic bacteria resulted in less extensive deconjugation of these sterols. Patients depending on cyclic estrogen and progesterone oral contraceptives may experience higher failure rates and breakthrough bleeding when taking antibiotics. [35], [36]

The biochemical modifications of certain environmental compounds by gut bacteria can generate carcinogenic substances. Many procarcinogens in the environment and in products such as food preservatives, dyes, and dietary additives are subject to changes by bacterial ß-glycosidases, ß-galactosidases, nitroreductases, and azoreductases that generate mutagens and other tumor promoters. One of many examples is cycasin, a naturally occurring glycoside of methylazoxymethanol in the seeds and roots of cycad plants. Cycasin is decidedly carcinogenic and when fed to healthy rats can lead to the development of liver tumors, renal sarcomas, squamous cell carcinomas, and colonic adenocarcinoma; however, tumors do not develop in germ-free rats fed the same glycoside. [37] Because this aglycone methylazoxymethanol is tumorigenic irrespective of gut colonization, it is clear that the parent cycasin must be hydrolyzed (by ß-glycosidase) to the carcinogen. In addition to natural procarcinogens, other carcinogenic substances, such as *N*-hydroxyfluorenylacetamide [38] and 1-nitropyrene, [39] which are first detoxified in the liver by the addition of a glucuronide moiety, can be converted back to carcinogens when attacked by gut bacterial ß-glucuronidase. Textile dyes such as trypan blue, [40] methyl yellow, and methyl orange [41] and industrial pollutants such as *p*-nitrobenzoic acid [42] are not carcinogenic in their original form, but they are metabolized to mutagens by microbial nitro- and azoreductases.

THE NORMAL MICROFLORA IN CLINICAL ILLNESS

Bacterial Overgrowth Syndromes

The most compelling evidence of the vigorous metabolic activity of the bowel flora is the proliferation of colonic anaerobes in the upper gut as a result of motility disorders, autonomic neuropathy, diverticula of the jejunum, pancreatic insufficiency, partial bowel obstruction, fistulae, or achlorhydria. [43] The number of anaerobes in the upper gut of such patients exceeds 10^6/g (or mL) of lumenal content, and *Bacteroides* organisms and anaerobic lactobacilli and enterococci are the dominant species, as they are in the colon. These microorganisms are avid for dietary cobalamins (vitamin B_{12}), and their cleavage of trace-labeled bile acids, fatty acids, xylose, lactulose, and glucose forms the basis of breath tests for bacterial overgrowth. Anaerobes living in the upper gut have access to bile acids, and, as discussed earlier, deconjugation removes a major hydrophilic element from these polar compounds. In addition, bacterial 7-dehydroxylases remove hydroxyl groups from bile acid sterols to convert cholic to deoxycholic acid, and chenodeoxycholic to lithocholic acid. Modifications of bile acids impair their function because the loss of water-soluble components limits their capacity to form mixed micelles involved in absorption of dietary fat and fat-soluble vitamins. Although most of the metabolic consequences of stagnant loop syndromes can be treated by reducing the number of bacteria with antimicrobial drugs, recovery may be delayed because bacterial overgrowth induces mucosal injury that is only slowly repaired.

Hepatic Encephalopathy

The commensal gut microflora has a major role in perpetuating hepatic encephalopathy through the production of ammonia and unidentified compounds that are involved in brain dysfunction. About 40% of the urea produced by the liver is hydrolyzed by urease of the normal microbial flora in the digestive tract, [44] and this ammonia is the preferred source of nitrogen for most enteric microorganisms. Antibiotics were originally used to reduce colonic ammonia production in liver disease, but a more effective and certainly safer strategy is to use oral lactulose to acidify the colon contents, promoting conversion of ammonia (NH_3) to the ionized and less completely absorbed ammonium ion (NH_4^+). Acidification of the colon by lactulose is itself dependent on bacterial metabolism of lactulose to lactic acid.

Methylmalonic Acidemia

The normal bacterial microflora may participate in rare clinical problems associated with inborn errors of metabolism. An example is methylmalonic acidemia, an inherited metabolic defect that causes mental retardation, episodic vomiting, lethargy, and protein intolerance and results from mutations in the host enzyme propionyl-coenzyme A (CoA). [45] The enzyme deficiency prevents the conversion of methylmalonic acid to methylmalonyl-CoA, and the accumulated methylmalonic acid is shunted to the production of propionic acid, a toxic metabolite. Bacterial propionic acid production in the colon simply adds to the toxic load, which can be reduced by treatment with metronidazole.

INNATE AND IMMUNOLOGIC REACTIVITY

Tolerance—The Permissive Response

Although the intestinal immune system can launch a robust protective immune response to enteric pathogens, nonresponsiveness (tolerance) typifies the reaction of the gut to commensal microorganisms. [46] It is important to note that immune tolerance is not indifference, but rather an active immune response that does not produce mediators of protection. But how does the immune system distinguish between pathogenic and commensal microorganisms? Active research on this subject has relevance for several unexplained gastrointestinal diseases.

Mucosal defense involves a series of complex systems that include so-called innate immunity (mediated in part by a-defensins, phospholipases, lactoferrin, and lytic enzymes), [47] adaptive immunity (in the gut, largely IgA and to a lesser extent IgM antibodies), and cellular immunity. The innate immune system is primitive, coordinated through germ line–encoded receptors expressed on the surface of neutrophils, macrophages, and surface epithelial cells at the host-environment boundary. Phagocytes engulf and kill invading pathogens, present microbes in the context of major histocompatibility complex (MHC) class II molecules to T cells, and activate the synthesis of inflammatory cytokines. In contrast, the adaptive immune response is characterized by somatic gene rearrangements and diversification that ultimately lead to millions of antigen-recognizing receptors on the surface of B and T cells. Bacteria survive through their ability to evade these defensive mechanisms.

As is emphasized below, infection by pathogenic microorganisms results in the epithelial cell production of nuclear factor-?B (NF-?B), a proinflammatory cytokine that enters the cell nucleus to trigger transcription of the gene encoding interleukin-8 (IL-8) and other inflammatory cytokines. Nonpathogens do not elicit such a response; indeed, binding of commensal bacteria to epithelial cells can block the NF-?B response by increasing the cytoplasmic levels of I?B, a protein that binds cytoplasmic NF-?B, preventing its translocation to the nucleus. Cell binding of commensal microbes is thought to increase I?B levels by delaying addition of the polyubiquitination and phosphorylation markers that normally foster intracellular degradation of this protein. [48], [49] Despite recent insights into how commensal bacteria forestall inflammatory responses, many details are still lacking. It has been proposed that a specific subset of dendritic cells in the intestinal mucosa may phagocytose apoptotic enterocytes together with their bound commensal microflora, inducing a state of systemic tolerance to these microbes. [50] This tolerogenic potential of the gut points to a possible opportunity to treat or prevent autoimmune disease, a well-studied example being the prevention of experimental neurological diseases similar to multiple sclerosis by feeding myelin basic proteins. [51]

Toll Receptors

The innate immune system relies on the identification of distinct features unique to pathogenic bacteria known as *pathogen-associated molecular patterns (PAMPs),* and the receptors that recognize them are termed *pattern-recognition receptors (PRRs)*. PAMPs, which are produced by the pathogen and are essential for the survival of the organism (and are therefore conserved), signal the presence of a pathogen to the host cell. Examples of PAMPs are lipopolysaccharides, teichoic acids, and peptidoglycans in bacteria, and mannans in yeast. [52], [53]

On the mammalian side of this interaction are the Toll-like receptors (TLRs), proteins originally identified in *Drosophila* that trigger the production of defensive, antimicrobial peptides. Different TLRs are activated by different pathogens, allowing *Drosophila* to discriminate, for example, between fungal and bacterial pathogens. [54], [55] Production of the protective peptides in *Drosophila* involves transcription factors very similar to NF-?B that activate tumor necrosis factor-a and IL-12 in mammalian species. [56], [57] In mammals, a family of TLRs have an important role in the induction of the adaptive immune system. [58] TLR4, the first mammalian form to be identified, induces an NF-?B signaling pathway similar to its homolog in *Drosophila,* activating genes that trigger T-cell recruitment. The microbial ligands recognized by mammalian cells have not all been identified, but each activates a different TLR. [59], [60] However, unlike *Drosophila* TLRs, each of which can discriminate among microbial species, mammalian TLRs appear to recognize a range of PAMPs from numerous microorganisms.

Although the details of human TLR specificity are incomplete, binding of microbial products initiates signals in the host cell that activate intracellular receptors designated *NOD1* and *NOD2,* lipopolysaccharide-binding proteins that have important functions in innate immune defense. NOD2 has been implicated in inflammatory bowel disease, with the finding that mutations in the gene encoding human NOD2 (on chromosome 16) can be correlated with the presence of Crohn's disease. [61], [62] Because NOD2 activates NF-?B production in response to lipopolysaccharide, and mutations in the protein may result in under- or overproduction of inflammatory mediators, a role for NOD2 mutations in Crohn's disease is of major importance in helping to understand the sustained inflammation of this disorder. Active research in this area will help define patterns of responsiveness of the normal gut to its commensal microflora.

CHAPTER 26

Paul B. Watkins

DRUG METABOLISM IN THE LIVER AND INTESTINES

GENERAL PRINCIPLES

The absorption of drugs into the body most often involves passive diffusion through lipid membranes, usually via the digestive tract but occasionally through the skin or lungs. For this reason, drugs that enter the body typically are fat-soluble (lipophilic). Once inside the body, lipophilic drugs tend to sequester in the body's fat stores and bind in blood to plasma proteins. Drugs that are extensively bound to proteins are generally not readily eliminated in urine. If lipophilic drugs are excreted in bile, they tend to be reabsorbed from the digestive tract and thus undergo enterohepatic cycling. For these reasons, most drugs that gain entry into the body would remain there for a very long time if it were not for the body's ability to convert (metabolize) drugs into more water-soluble, and hence more readily excreted, metabolites. The liver is the major organ involved in drug metabolism. For some xenobiotics, the small intestine also plays a major role.

DISCOVERY OF DRUG-METABOLIZING ENZYMES

A major breakthrough promoting the study of drug metabolism was the development of techniques to isolate the endoplasmic reticulum from whole pieces of liver tissue. During this process, endoplasmic reticulum breaks up into small spheres called *microsomes*. It was discovered that under certain experimental conditions, liver microsomes produce most of the metabolites generated from drugs (and other xenobiotics) by the liver in vivo. The reactions characterized generally involved insertion of an oxygen atom into the drug (usually a hydroxylation) or covalent binding (conjugation) of the drug to a polar ligand such as glucuronic acid, sulfate, or glutathione. Many drugs first had to undergo hydroxylation to produce a reactive site on the molecule suitable for conjugation reactions. This typical sequence of events led to the division of xenobiotic metabolism into two categories: phase 1 (often hydroxylation reactions) and phase 2 (conjugation).

It is now appreciated that most (but not all) of what was described as phase 1 microsomal metabolism is the result of the activity of a large family of enzymes termed *cytochromes P450*. This somewhat awkward name derived from the fact that when first isolated, these enzymes appeared to be chemically similar to mitochondrial cytochromes. The *P* is an abbreviation for *pigment,* reflecting the fact that these enzymes are red in color (because of the presence of heme in the enzyme) and largely account for the reddish brown color characteristic of microsomes. Finally, it was noted that these enzymes intensely absorb light with a 450-nm wavelength (under certain experimental conditions). The cytochromes P450 are now usually referred to simply as *P450s* or *CYPs* (pronounced *sips*).

P450s AND DRUG METABOLISM

The vast majority of drugs in clinical use today are metabolized by liver P450s. A recent realization is that there are relatively few P450s important for drug metabolism. [1] Each P450 represents the product of a unique gene. The P450s involved in drug metabolism fall predominantly into three gene families, now termed *CYP1, CYP2,* and *CYP3*. [2] Within each P450 family, subfamilies are designated by capital letters. Each subfamily generally contains multiple members, designated by arabic numerals usually reflecting the order in which they were discovered. In general, orthologous P450s (the equivalent form in different species) are given a different final arabic numeral. For example, the term *CYP3A4* applies only to an enzyme present in human liver, whereas the related enzymes in other species have different numeric designations (e.g., CYP3A2, CYP3A6).

It is widely believed that the P450s involved in drug metabolism evolved as a mechanism to protect the body from potentially harmful chemicals, *xenobiotics,* present in the environment or in the diet. [3] According to this theory, plants produce potentially toxic xenobiotics to become inedible to insects and higher life forms. In addition, spoilage of food often involves bacteria and fungi capable of producing potentially toxic xenobiotics. The introduction into the environment of each new xenobiotic in turn created selection pressure for insects and animals to develop specific P450s capable of metabolizing and rapidly eliminating that xenobiotic (if the food source could not be easily avoided).

A list of the major P450s involved in human drug metabolism appears in Table 26-1. The most abundant single P450 in human liver is CYP3A4, and it has been estimated that this specific P450 may be involved in the metabolism more than 50% of drugs used clinically. [4] Only a few of the many substrates for CYP3A4 are listed in Table 26-1.

TABLE 26-1 Characteristics of Major Human Liver P450s

Some of the principles of P450 metabolism are shown in Figure 26-1 and Figure 26-2. Drugs either passively diffuse, or are actively transported, into the liver during passage through sinusoidal blood (illustrated by drug A in Fig. 26-1). Once inside the liver, drugs diffuse to the particular P450s capable of metabolizing them. With

some drugs, a single P450 is involved in most of the metabolism. The P450 inserts an oxygen atom onto the drug, usually in the form of a hydroxyl group. In some cases, however, the immediate product of P450 catalysis is unstable, and rearrangement of the molecule (such as *N*-dealkyation) then occurs, resulting in different end products. After the P450-catalyzed reaction, the resultant metabolite typically undergoes phase 2 conjugation. The conjugated metabolite is frequently secreted back into the space of Disse, now more water-soluble and less protein-bound, and hence more readily eliminated in urine by the kidneys. Alternatively, the metabolite can be secreted into the bile canaliculus to be excreted into the small intestine in bile, now less likely to undergo enterohepatic cycling because of its reduced lipophilicity. In many and probably most instances examined to date, P450-mediated metabolism is rate-limiting in the elimination of the drug. [5]

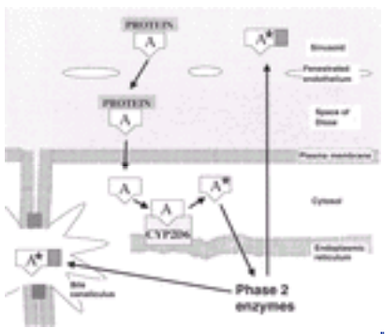

FIGURE 26-1. Metabolism of a drug in the hepatocyte. Lipophilic drugs, such as drug A, exist in sinusoidal blood largely bound to proteins. Drugs can diffuse through the endothelial cell fenestrations into the space of Disse while still protein bound. Drugs then enter the hepatocyte by active transport or passive diffusion. Once inside the cell, a drug typically encounters a specific P450 (CYP2D6 in this example) capable of binding to the drug and converting it to more water-soluble and chemically reactive metabolites. The resultant metabolite may be secreted from the hepatocyte without undergoing additional metabolism (not shown). In most instances, however, the P450-generated metabolite will undergo conjugation to a polar ligand in a reaction catalyzed by phase 2 enzymes. The resultant conjugated metabolite is then secreted into the biliary canaliculus for elimination in bile, or secreted back into sinusoidal blood to be excreted in urine.

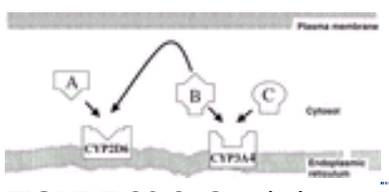

FIGURE 26-2. Catalytic specificity of P450s. Drugs are metabolized by a specific P450 only if they can fit appropriately into the substrate-binding site of the enzyme. In this example, drug A can be metabolized by CYP2D6, but not by CYP3A4. Drugs B and C can each be metabolized by CYP3A4, but only drug B can be metabolized by both CYP2D6 and CYP3A4. The principle of competitive inhibition between two substrates is illustrated by drugs B and C. If both are present in the hepatocyte, the metabolism of each may be reduced simply because both drugs cannot occupy the enzyme active site at the same time.

The concept of specificity of P450s is shown in Figure 26-2. In many instances, a single P450 represents the major pathway of metabolism of a drug. This is shown by drugs A and C, which can bind to, and be metabolized by, only CYP2D6 and CYP3A4, respectively. In many cases, however, a drug can be metabolized by more than one P450, and this is illustrated by drug B. Commercial vendors now supply recombinant expressed P450s that allow rapid identification of P450s capable of metabolizing a given drug. As will be discussed, knowing which P450(s) metabolizes a drug is useful information because it can often predict drug interactions and the extent of interpatient variability in disposition of the drug. For this reason, many pharmaceutical companies now use high-throughput technology to identify the P450s that metabolize compounds early in development and use this information to select lead candidates for further development. [6], [7]

The concept of specificity has allowed the use of some select drugs to quantify the activities of specific P450s in subjects in clinical trials. [8] Typically, the probe drug is administered intravenously or orally, and the concentration of the parent drug, or of a metabolite, is measured in urine, blood, breath, or saliva at a fixed time point. Some of the more commonly used probe-based tests are listed in Table 26-2.

P450	PROBE	ANALYTE
CYP1A2	Caffeine	Plasma, breath, urine, saliva
CYP2D6	Dextromethorphan	Urine, saliva
	Debrisoquine	Urine
CYP2C19	S-Mephenytoin	Urine
	Omeprazole	Urine
CYP2E1	Chlorzoxazone	Plasma
CYP3A4	Erythromycin	Breath
	Midazolam	Plasma

TABLE 26-2 Some Probe-Based Tests for P450s

The interindividual differences in the activity profile of the liver P450s are large, and in many instances, this variation appears to account for interpatient differences in the pharmacokinetics of medications. [4] In some cases, probe-based tests (see Table 26-2) have been shown to predict the clearance of specific drugs. For example, a caffeine-based test that measures CYP1A2 activity (caffeine breath test) has been shown to predict the clearance of tacrine. [9] In addition, an erythromycin-based test that measures CYP3A4 activity (the erythromycin breath test) has been shown to predict the clearance of cyclosporine [10] and docetaxel. [11] The variation among patients in the activities of specific liver P450s can reflect both genetic and nongenetic factors.

Genetic Factors Influencing P450 Activity

Genetic mutations in part explain why there are large interindividual differences in the activities of many of the P450s. [12], [13], [14] and [15] For example, both CYP2D6 and CYP2C19 are termed *polymorphic* enzymes because the population can be divided into distinct groups based on the relative activity of these enzymes. [16] About 5% of whites completely lack CYP2D6 activity and therefore are CYP2D6 “poor metabolizers.” Patients who are CYP2D6 poor metabolizers have been shown to have increased sensitivity to the effects of several drugs, including some medications commonly used to treat cardiac arrhythmias, psychosis, and depression. The poor metabolizer phenotype results from the simultaneous inheritance of two of multiple known functionally defective CYP2D6 alleles. [17] The incidence of CYP2D6 poor metabolizers varies substantially across different ethnic populations. [16] For example, fewer than 1% of Japanese are poor metabolizers.

The CYP2C19 poor metabolizer phenotype also occurs in approximately 5% of whites, but in up to 20% of Asians. [16] CYP2C19 poor metabolizers have been shown to have higher blood levels of omeprazole than others when treated with usual therapeutic doses. [18] This is expected because omeprazole relies on CYP2C19 for elimination (see Table 26-1). This appears to explain why CYP2C19 poor metabolizers have a higher cure rate for *Helicobacter pylori* infection when treated with omeprazole-containing regimens. [19] As is the case with CYP2D6, the poor metabolizer phenotype also results from the inheritance of two of several different functionally defective CYP2C19 alleles. In general, CYP2D6 and CYP2C19 poor metabolizer phenotypes behave as autosomal recessive traits, with heterozygotes having a metabolic capability that is intermediate between those of typical normal and poor metabolizers.

Allelic mutations resulting in diminished catalytic function have been described for other cytochromes P450, including CYP2C9 [20] and CYP2A6, [21] although individuals completely lacking these catalytically active enzymes have not yet been recognized. In addition, genetic mutations of unclear functional significance have been identified in CYP3A4 [22] and CYP2E1 [23] genes. Approximately 20% of whites and 50% of African Americans express a P450 closely related to CYP3A4, termed

CYP3A5. [24] It was originally believed that CYP3A5 was a minor liver P450 even in those who express the enzyme, but newer data suggest the liver content of CYP3A5 may be comparable to that of CYP3A4 in some individuals. [24] The functional significance of the CYP3A5 polymorphism is largely unexplored.

In one instance, genetic factors can cause an abnormally high level of activity of a P450. Approximately 2% of whites have gene duplication of CYP2D6, resulting in an “ultrarapid” metabolizer phenotype. [13] These individuals exhibit unusually rapid clearance of at least some CYP2D6 substrates, and this can account for therapeutic failure of some medications. The incidence of ultrarapid metabolizers in nonwhite populations is currently under investigation.

Nongenetic Factors Influencing P450 Activity

Inflammation and alterations in nutritional status can affect the activities of liver P450s. [25] In addition, many drugs can alter the activities of P450s, resulting in drug interactions. [26] Some drugs are known to inhibit the activity of specific P450s, reducing the elimination of drugs that require metabolism by that P450. Inhibition of P450 activity can occur by a variety of mechanisms, [27] but the most common form of inhibition reflects simple competition between two drugs for metabolism by the same P450. This is shown schematically in Figure 26-2, in which drugs B and C are each capable of binding to, and being metabolized by, CYP3A4. Hence, metabolism of drug B by CYP3A4 may be reduced in the presence of drug C, simply because drug C is physically interfering with the ability of drug B to bind to the active site on CYP3A4. Likewise, drug B could potentially inhibit the metabolism of drug C in an analogous fashion. Whether two drugs competing for metabolism by the same P450 will result in a clinically important interaction depends on a number of factors. These include the intrahepatocyte concentrations of each drug, the relative affinities of each drug for binding to the enzyme active site, and the importance of the P450 to the overall elimination of the drug. Additional important variables are the relative safety (therapeutic index) of the drugs involved and whether the metabolites generated by the P450 are pharmacologically active.

Some clinically important interactions involving inhibition can be inferred from Table 26-1. For example, patients treated with tricyclic antidepressants will have elevated tricyclic blood levels and possibly associated toxicity if certain selective serotonin reuptake inhibitors (SSRIs) are added to their treatment regimen (without lowering the dose of tricyclics). This results from the inhibition of CYP2D6 by SSRIs. [28] In addition, cyclosporine blood levels can rise to toxic levels in organ transplant recipients who receive concomitant treatment with erythromycin or ketoconazole, largely because of inhibition of CYP3A4. [29] Many interactions between drugs used in patients with human immunodeficiency virus (HIV) infection involve P450 inhibition. [30]

Some medications are such potent and selective inhibitors of specific P450s that they can be used in experimental settings to pharmacologically “knock out” the enzyme in a human subject. The drugs most frequently used to inhibit specific P450s are noted in Table 26-1. If elimination of a drug is not affected by the inhibitor, then it can be assumed that the target P450 does not represent a major pathway for elimination. In some cases, these inhibitors have very high affinity for the enzyme active site and largely prevent the enzyme from metabolizing other drugs on a competitive basis (illustrated in Fig. 26-2). For example, a single dose of quinidine or ketoconazole largely competitively inhibits the activities of CYP2D6 and CYP3A4, respectively. [31] Other selective inhibitors are not competitive inhibitors but rather “mechanism-based” inhibitors. [27] Mechanism-based inhibition is irreversible and occurs when the inhibitor is converted by the target P450 to a metabolite that noncompetitively inactivates the enzyme (often by covalently binding to the enzyme protein). This appears to be the mechanism by which a single therapeutic dose of disulfiram (Antabuse) results in greater than 90% inhibition of CYP2E1 activity that lasts for hours. [32] The effect of disulfiram is specific in that the catalytic activities of other major P450s are not affected (as measured by suitable probes). [32] Another example of a potent and selective mechanism-based inhibitor is the antibiotic troleandomycin, which, when administered in the usual therapeutic dose, produces greater than 90% reduction in liver CYP3A4 activity that also persists for hours. [33] Although it has been less well studied in vivo than disulfiram, data obtained in human liver microsomes suggest that the effect of troleandomycin is specific for CYP3A4 and that other major P450s are not inhibited. [34] Examples of other mechanism-based inhibitors include the CYP1A2 inhibitor furafylline [35] and the CYP2A6 inhibitor methoxsalen. [36]

In addition to inhibition, a medication can sometimes result in an increase in the activity of a particular P450. In most cases, this “induction” results from increased hepatocyte concentrations of a specific P450. Some medications that can induce P450s are listed in Table 26-1. Induction of P450 activity can occur by several mechanisms, but most commonly reflects an increase in the rate of transcription of the corresponding gene. In some instances, the cellular receptor involved in transcriptional activation has been identified. [37] For example, induction of CYP3A4 by rifampin and antiseizure medications appears to involve a nuclear receptor termed the *human pregnane X receptor (PXR),* [38] also termed *steroid xenobiotic receptor (SXR)* or *pregnane-activated receptor (PAR)*. The inducer binds the receptor, and after forming a heterodimer with another receptor (RXR), it binds to regulatory elements in the CYP3A4 gene. This results in increased transcription of the CYP3A4 gene, which in turn results in increases in the hepatocyte concentration of CYP3A4. [37] It appears that PXR also mediates induction of CYP2C9 (and probably CYP2B6) by rifampin and certain antiseizure drugs. [39] PXR has been proposed to be the major xenobiotic sensor present in humans, orchestrating a host response to rid the body of foreign substances. [40] PXR has also been shown to be activated by lithocholic acid, and activation of PXR results in up-regulation of genes involved in bile acid secretion. [41] It seems likely that phenobarbital and rifampin relieve pruritus in cholestasis by activating PXR. Polymorphisms in PXR have been identified, but their functional significance is not known. [42]

Induction of CYP1A2 also involves a receptor, termed the *aryl hydrocarbon (Ah) receptor*. [43] Aryl hydrocarbons in cigarette smoke and the drug omeprazole bind to the Ah receptor, mediating transcription of the CYP1A2 gene and increased production of the enzyme. Some P450s, such as CYP2D6 and CYP2A6, do not appear to be inducible.

Examples in which induction causes clinically significant drug interactions can also be deduced from Table 26-1. When transplant recipients are treated with rifampin or certain antiseizure medications, blood levels of cyclosporine can fall to subtherapeutic levels, largely because of induction of CYP3A4. [29] These patients are at risk for organ rejection unless their daily dose of cyclosporine is increased. Likewise, individuals treated with rifampin or antiseizure drugs are at risk for therapeutic failure of oral contraceptives (CYP3A4) and warfarin (CYP2C9). [26] Induction can also be used to assess the contribution of an inducible P450 to the disposition of a drug. For example, if treatment of subjects with rifampin does not increase clearance of a drug, it is unlikely that CYP3A4 or CYP2C9 are major pathways for metabolism.

Role of P450s in Drug-Induced Liver Injury

Most drugs that are capable of causing liver toxicity appear to do so through the generation of toxic metabolites. [44] As discussed above, P450s generally convert drugs to metabolites that are safely eliminated from the body. However, under certain circumstances, P450s can generate reactive and potentially toxic metabolites. Indeed, the identical enzymes (see Table 26-1) involved in the safe metabolism of drugs are those that have been most frequently implicated in the production of hepatotoxic metabolites. In general, P450s are expressed in highest concentration in zone 3 hepatocytes, and this in part accounts for the predominance of pericentral necrosis in some forms of drug-induced liver injury (such as that caused by acetaminophen). [45] Interspecies differences in P450 catalytic activities and regulation probably contribute to the imperfect ability of preclinical animal studies to identify human hepatotoxins. [46]

The most studied example of production of a hepatotoxic metabolite by P450s involves acetaminophen liver injury. Acetaminophen is believed to cause toxicity in the liver by production of the *N*-acetyl benzoquinone amine metabolite NAPQI. Studies with recombinant human liver enzymes suggested that NAPQI could be produced by several P450s, including CYP2E1, CYP3A4, CYP1A2, and CYP2A6. [47], [48] Investigators have addressed the relative importance of each of these enzymes in human studies by using inducers and inhibitors of specific P450s. NAPQI formed from acetaminophen in the liver is conjugated to glutathione and eliminated as various thiol metabolites in urine. Hence, the total production of NAPQI can be estimated from the production of thiol metabolites eliminated in urine. It has been shown that the urinary excretion of thiol metabolites is not increased in subjects pretreated with the CYP1A2 inducer omeprazole [49] or the CYP3A4 inducer rifampin, [50] so that a prominent role of these enzymes is unlikely (see Table 26-1). However, pretreatment of subjects with the CYP2E1-specific inhibitor disulfiram resulted in a 69% reduction in the production of NAPQI. [50] Hence, although in vitro studies indicate the potential involvement of multiple P450s, in vivo studies in humans indicate that a single P450, CYP2E1, accounts for most of the NAPQI formed after therapeutic doses of acetaminophen.

Some other observations have suggested a role for CYP3A4 in acetaminophen toxicity. There have been rare case reports of severe acetaminophen toxicity in patients treated with antiseizure medications, [51] which induce CYP3A4 but are not inducers of CYP2E1. In one series of patients with acute liver failure, [52] patients with acetaminophen liver injury who had been receiving treatment with antiseizure drugs appeared to have a worse outcome than other patients (although a more current report [53] from the same institution did not verify these findings). Studies in rodents have also suggested a role for CYP3A enzymes in the production of NAPQI. [54] However, marked differences between humans and rats in the catalytic activities of P450s involved in NAPQI production have been assessed in vitro. Moreover, in three separate studies, NAPQI production from acetaminophen did not increase in individuals treated with antiseizure medications known to induce CYP3A4. [55], [56] and [57] Of course, these human studies involved administration of relatively low (therapeutic) doses of acetaminophen, and it is therefore possible that CYP3A4

contributes to NAPQI production in an overdose situation.

Chronic consumption of ethanol appears to increase susceptibility to acetaminophen hepatotoxicity. [58] Ethanol is a recognized inducer of CYP2E1 (see Table 26-1), and ethanol induction of CYP2E1 therefore provides an attractive explanation for incremental risks in ethanol consumers. However, early animal [59] and human [60] studies did not show increases in NAPQI formation when acetaminophen was given during or immediately after the ingestion of ethanol. Indeed, these studies suggested that ethanol consumption actually reduces the rate of production of NAPQI, protecting the liver from toxicity. These observations have now been explained. [61] Ethanol is a substrate for CYP2E1 (see Table 26-1). When ethanol is present in the body in substantial concentrations, a large proportion of the CYP2E1 binding sites in the liver are occupied by ethanol. [62] Ethanol binds CYP2E1 with high affinity and is slowly metabolized by the enzyme. Hence, the rate of production of NAPQI from acetaminophen is reduced when ethanol is present. This is illustrated in Figure 26-3. An additional important finding is that when ethanol is bound to CYP2E1, the enzyme is stabilized against degradation, so that its intracellular half-life is increased. [63] Prolonged intoxication therefore results in an accumulation of (ethanol-inhibited) CYP2E1. With very high ethanol intake, induction of CYP2E1 may involve increased enzyme synthesis as well as stabilization. [64] When ingestion of ethanol is stopped and ethanol is cleared from the liver, the accumulated CYP2E1 is no longer inhibited, and the aggregate CYP2E1 activity is increased above normal levels. [61] However, the stabilization against degradation is also reversed, resulting is a relatively rapid fall of enzyme activity to the baseline value (before ethanol consumption). When acetaminophen was given to ethanol-treated subjects immediately after the ethanol had cleared from the body, increased production of NAPQI was demonstrated. [61] This effect of inhibition followed by transient induction is mimicked by some other substrates of CYP2E1, including isoniazid. [65] This may account for reports of enhanced susceptibility to acetaminophen toxicity in patients treated with isoniazid. [66], [67]

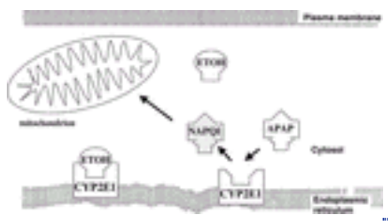

FIGURE 26-3. Effect of ethanol on the formation of the *N*-acetyl benzoquinone amine metabolite NAPQI from acetaminophen. The hepatotoxic metabolite is chiefly formed by CYP2E1. NAPQI appears to result in toxicity at least in part by causing mitochondrial toxicity. Ethanol binds to and is metabolized by CYP2E1. This is the presumed basis for inhibition of NAPQI formation while an individual is intoxicated. However, the ethanol-bound CYP2E1 is stabilized against intracellular degradation and therefore accumulates during prolonged periods of intoxication. When the individual stops drinking and ethanol leaves the liver, the accumulated CYP2E1 becomes catalytically active, causing an increase in NAPQI formation from acetaminophen. The effect is short-lived because the CYP2E1 is no longer stabilized against degradation once not bound to ethanol.

Techniques similar to those used in acetaminophen studies have been used to explore the role of P450s in liver injury produced by halothane. Halothane undergoes both reductive and oxidative metabolism in the liver. [68] The oxidative pathway of halothane metabolism has been implicated in producing a reactive metabolite (a trifluoroacetyl intermediate) that can bind covalently to proteins in the liver cell. These modified proteins are believed to stimulate an immunologic response, causing the severe form of liver injury associated with halothane. [69]

Pretreatment of patients with the CYP2E1 inhibitor disulfiram produced a 70% inhibition in the plasma and urine levels of trifluoroacetic acid, the stable product of the oxidative pathway. Methoxsalen pretreatment also produced a small reduction in trifluoroacetyl production, whereas troleandomycin pretreatment was without effect. [70] These studies indicate that the major enzyme involved in the oxidative metabolism of halothane is CYP2E1, followed by CYP2A6.

A variety of other studies have been performed to determine the role of specific P450s in liver disease produced by other drugs. [71], [72] and [73] In a few cases, positive results have been obtained. Five individuals who had completely recovered from liver toxicity caused by perhexiline (an antianginal medication used in Europe) were given debrisoquine to determine their CYP2D6 activity (see Table 26-2). [74] Four of the five individuals were characterized as CYP2D6 poor metabolizers. This frequency was significantly greater than anticipated (5% in whites). Perhexiline is believed to be metabolized by CYP2D6, and it is speculated that individuals deficient in CYP2D6 activity accumulate the drug in the liver. Toxicity could then be produced either by the parent drug, or might result from shunting metabolism to non-CYP2D6 pathways capable of generating reactive metabolites.

Patients who have recovered from chlorpromazine-induced liver injury have been reported to have both a reduced capacity for sulfoxidation of chlorpromazine [75] and an unusually high rate of hydroxylation of the drug. [75] The enzymes involved in sulfoxidation of chlorpromazine are not known, but the hydroxylation pathway appears to be catalyzed primarily by CYP2D6. A logical but as yet untested hypothesis is that individuals predisposed to chlorpromazine-induced liver injury are both ultrarapid metabolizers of CYP2D6 (because of gene duplication) and poor sulfoxidators (reflecting an as yet unidentified gene).

In most instances to date, however, attempts to link susceptibility to liver toxicity to variation in activity of specific P450s have failed. For example, there do not appear to be links between genetic deficiency in CYP2D6 activity and susceptibility to liver toxicity from several CYP2D6 substrates, including metoprolol, amitriptyline, and amodiaquine. [76] In addition, serum alanine aminotransferase elevations during treatment with the anti–Alzheimer disease drug tacrine are not associated with abnormal activity of CYP1A2, [77] even though this enzyme represents the major route of metabolism of tacrine and CYP1A2 has been implicated in the formation of a reactive metabolite from tacrine. [78] A final example is the nonsteroidal antiinflammatory drug diclofenac, which has been rarely associated with severe liver injury. [79] The major pathway of metabolism of diclofenac (and most nonsteroidal antiinflammatory drugs) is 4-hydroxylation catalyzed by CYP2C9. [80] However, attempts to link the risk for liver injury to functional mutations in CYP2C9 have been unsuccessful. [81]

Our limited success to date in using knowledge of P450s to predict those at risk for drug-induced liver injury probably reflects multiple factors. [44] Most of the hypotheses that have been tested involve examination of the major P450 involved in the overall metabolism of the drug in question. Toxic metabolites are often the result of minor pathways of metabolism that can be difficult to identify. Most importantly, the rate of production of a toxic metabolite by a given P450 is just one of many variables that are likely to determine whether toxicity actually occurs in a given patient.

Anti-P450 Antibodies and Drug-Induced Liver Injury

Liver disease caused by several different drugs is associated with circulating antibodies to P450s. [82], [83] Examples of anti-P450 antibodies are shown in Table 26-3. The current concept of the formation of these antibodies is that a P450 produces a metabolite so reactive that it binds directly to the P450, essentially immediately after the metabolite is formed. Antibodies are formed if this metabolite-drug adduct is antigenic and escapes from the cell to interact with immune cells. Controversy continues over whether anti-P450 antibodies actually mediate an immune attack on the liver, because no one has yet convincingly shown that they can cause liver injury in a living animal model. It remains possible that the antibodies are an epiphenomenon, appearing only after the antigens are released into circulation as hepatocytes are lysed by other mechanisms. However, cell lysis may not be necessary for antigen recognition because P450s appear to be present in low abundance on the outside of the liver plasma membrane. [83] Regardless of whether they mediate drug-induced liver injury, these antibodies can be used in immunochemical techniques to identify which specific human P450s are involved in generating the reactive metabolite, even if the structure of the reactive metabolite is unknown. The presence of anti-P450 antibodies can also be very helpful in establishing a drug as the cause of liver injury, although such tests are not widely available.

DRUG	MEAN FOLD INCREASE IN AUC*	REFERENCE
Simvastatin	13.5	96
Lovastatin	15.0	132
Midazolam	1.5	133
Triazolam	1.5	134
Saquinavir	2.0	135
Nifedipine	3.0	136
Carbamazepine	1.5	137
Buspirone	9.2	138
Cyclosporine	1.6	139

* Area under the blood concentration versus time curve divided by that observed when drug taken with water or orange juice.

TABLE 26-3 Some Drugs Affected by Grapefruit Juice

Intestinal P450s

P450 enzymes are detectable throughout the human digestive tract, including the esophagus, stomach, small bowel, and colon. [84] The concentration of total P450 enzymes is highest in the jejunum and gradually declines to lower levels in the ileum and colon. The major P450 in small bowel enterocytes is CYP3A4, accounting for at least 70% of the total P450s. [85], [86] and [87] CYP3A4 has been detected in the esophagus, stomach, and colon, but at much lower levels than in enterocytes. [85], [86] Other P450s detected in the digestive tract include CYP3A5, CYP2C9, CYP2C19, and CYP1A1. [88] Notably, CYP2C8, CYP2B6, and CYP1A2 have not generally been detected and appear to be liver-specific enzymes. In most cases studied, P450s are not found in the intestinal crypt cells, but they appear, probably as a result of transcriptional activation of the corresponding genes, as the epithelial cells migrate out of the crypt toward the villus tip (Fig. 26-4). This location is appropriate for the metabolism of xenobiotics in the gut because absorption is thought to occur chiefly in the upper part of the villus.

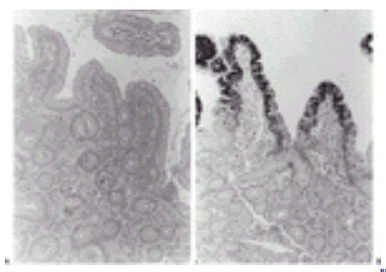

FIGURE 26-4. Induction of CYP3A4 in the small bowel of a patient treated with rifampin. This patient underwent duodenal biopsy (**A**) before and (**B**) after treatment with rifampin for 7 days. The biopsy specimens were fixed in formalin, sectioned, and subjected to immunoperoxidase staining after exposure to an antibody that specifically reacts with CYP3A4. CYP3A4 was detected only in mature enterocytes (*dark stain*) and was clearly induced by treatment with rifampin. In these sections, the antibody dilution was selected to maximally demonstrate induction. Lower dilutions of antibody revealed the presence of CYP3A4 in the mature enterocytes before treatment with rifampin (not shown). (From ref. [87].)

To date, the only intestinal P450 shown to catalyze significant drug metabolism is CYP3A4. This was originally demonstrated by intrajejunal administration of the CYP3A4 substrates cyclosporine [89] and midazolam [90] during the anhepatic phase of the liver transplant operation. In each case, up to 50% of the detectable drug absorbed into portal blood had been converted into metabolites characteristically produced by CYP3A4. Other studies have simultaneously administered unlabeled and stable labeled CYP3A4 substrates by intravenous and oral routes, respectively. If it is known that the drug is completely absorbed, it is possible to quantify intestinal metabolism. Such studies have shown that the intestine is a major site for metabolism of verapamil [91] and midazolam. [92]

The importance of intestinal CYP3A4 has also been highlighted by drug interactions produced by grapefruit juice. [93] A growing number of drugs have been shown to have enhanced oral availability when consumed with grapefruit juice (versus water or orange juice; see Table 26-3). This interaction has been shown to result from both competitive and mechanism-based inhibition of CYP3A4. In addition, the enterocyte content of CYP3A4 actually falls within hours after ingestion of a single glass of grapefruit juice, [94], [95] presumably because the inactivated enzyme undergoes rapid intracellular degradation. [95] The effect of grapefruit juice on the disposition of drugs is quite prolonged and is still detectable with some drugs up to 3 days after ingestion of a single glass of juice. [96] This presumably reflects the time required to replace the lost enzyme. The ingredients in grapefruit juice responsible for CYP3A4 inhibition appear to be compounds called *furanocoumarins* (also called *psoralens*). [95], [97] Furocoumarins are not present in most other types of fruit juice. Grapefruit juice does not appear to inhibit liver CYP3A4, at least when consumed in usual quantities. [93], [94] This presumably reflects insufficient concentrations of furanocoumarins reaching the liver after absorption. Grapefruit juice can therefore be used experimentally to “knock out” intestinal CYP3A4 (although it may affect some drug transporters as well). [98], [99] If grapefruit juice does not affect the oral availability of a drug, it can be assumed that intestinal CYP3A4 is not contributing much to the first-pass metabolism.

The aggregate CYP3A4 in the intestine is probably less than 10% of that in the liver. [100] For significant metabolism to occur in the intestine, it seems likely that a drug must be very rapidly metabolized by CYP3A4, be administered in relatively small amounts, or have a prolonged absorption phase (i.e., prolonged contact with the enzyme). It has been proposed that the physiological role of intestinal CYP3A4 may be primarily to limit entry into the body of potentially harmful dietary compounds. One study [101] suggested that CYP3A4 may convert aflatoxin ß $_1$ to reactive metabolites that bind to macromolecules within enterocytes. This, in effect, traps the metabolites within the cells. Because the enterocytes are normally sloughed into the digestive tract, the aflatoxin metabolites are eliminated in stool.

Intestinal CYP3A4 may also represent a significant pathway for the systemic clearance of some CYP3A4 substrates. This was suggested by the demonstration that an average of 8% of a dose of midazolam perfused through the mesenteric artery was metabolized in the intestine on a single pass. [90] In one patient, 25% of the systemically administered midazolam was metabolized in the intestine. [90]

In the general population, it appears that large differences in the activity of CYP3A4 are found in the intestine, just as in the liver. [102] There does not appear to be coordinate expression of the CYP3A4 gene in liver and intestine. [102] For example, a person can simultaneously have a relatively low level of CYP3A4 activity in the liver and relatively high levels of expression of the same gene in the enterocytes (and vice versa). Given the effects of grapefruit juice discussed above, it seems likely that as yet unidentified dietary factors may account, at least in part, for this discordance. In rats, for example, ethanol treatment and removal of iron or selenium from the diet results in the reduction in intestinal P450 activity but has little effect on P450 activity in the liver. [103], [104] and [105]

No natural dietary components have yet been reported to up-regulate the expression of CYP3A catalytic activity in the intestine of any species, including humans. However, in rats and humans, intestinal CYP3A enzymes have been shown to be inducible by at least some of the medications that also induce these enzymes in liver (see Fig. 26-4). [87] PXR is present in enterocytes and likely mediates this induction. It is likely that drug interactions involving CYP3A4 substrates that have previously been attributed to induction or inhibition of CYP3A4 in the liver may largely reflect these processes in the intestine.

The intestinal activity of CYP1A1 appears generally to be low but is greatly influenced by diet. When healthy volunteers are maintained on a semisynthetic diet, a significant fall in the catalytic activity characteristic of CYP1A1 is noted in biopsy specimens of intestinal mucosa. [106] In humans, polycyclic hydrocarbons that result from charcoal broiling can dramatically induce CYP1A1 in the intestine. [107], [108] In addition, CYP1A1 mRNA and catalytic activity are significantly induced in the intestine of volunteers treated with the ulcer medication omeprazole. [109] No studies have directly shown a significant contribution of intestinal CYP1A1 to first-pass metabolism of drugs. However, in one clinical study involving the consumption of charcoal-grilled hamburger, investigators found an inverse correlation between intestinal CYP1A1 expression and levels of polycyclic aromatic hydrocarbon protein adducts in circulating lymphocytes. [108] These investigators suggested that induction of CYP1A1 in the small intestine may be protective by reducing the absorption of polycyclic aromatic hydrocarbons.

PHASE 2 ENZYMES

In general, phase 2 enzymes have not been as well characterized as the P450s. This in part reflects the fact that phase 2 enzymes are generally colorless (so that purification is more difficult) and tend to lose catalytic activity during purification. The best-studied phase 2 enzymes are the uridine 5'-diphosphate (UDP)

glucuronosyltransferases (UGTs), the glutathione *S*-transferases (GSTs), and the sulfotransferases, which catalyze conjugation to glucuronic acid, glutathione, and sulfate, respectively.

UDP Glucuronosyltransferases

Conjugation to glucuronic acid results in enhanced water solubility; for this reason, glucuronide conjugates are usually readily excreted into urine. Glucuronide conjugates are also excreted into bile and, because of their water solubility, generally pass in the stool. In addition, glucuronidation generally results in reduced pharmacological activity. However, glucuronides can occasionally retain pharmacological activity. An unusual example of this is morphine glucuronide, which actually has roughly 50-fold greater opioid activity than morphine itself. [110] In addition, some glucuronides (particularly acylglucuronides) have been shown to be reactive molecules, capable of covalent binding to proteins. [111] For example, a glucuronide metabolite of diclofenac has been shown to covalently bind multiple proteins in the hepatocyte, and this covalent binding may contribute to the hepatotoxicity rarely associated with this drug.

Like the P450s, the UDP glucuronosyltransferases arise from a multigene family of microsomal enzymes, some of which are inducible. [112], [113] In humans, 15 UGT cDNAs have been identified comprising two gene families, UGT1 and UGT2. There are two gene subfamilies within the human UGT2 family (A and B) and one (A) within the human UGT1 family. The UGT1 family contains eight enzymes (designated by arabic numerals), and the UGT2 family contains seven enzymes. All UGT1A proteins have the identical 245 carboxyl-terminal amino acid sequence, and this reflects a process called *exon sharing*. There is considerable catalytic specificity of UGTs toward drugs, although such characterization is progressing relatively slowly. One problem has been that unlike the P450s, which exist on the outside of microsomes, the UGTs are located on the inside of microsomes. It is therefore often necessary to permeabilize microsomes to assess UGT activity, and this may introduce artifacts.

Multiple polymorphisms of the UGT1 family have been demonstrated. [114] The best studies of polymorphisms involve UGT1A1, which is the enzyme responsible for bilirubin conjugation. [112] Mutations in the UGT1A1 gene have been shown to account for Gilbert and Crigler-Najjar (types 1 and 2) hyperbilirubinemia. The implications of UGT polymorphisms in drug metabolism or hepatotoxicity are generally unknown. However, it has been proposed that a polymorphism in UGT1A6 may influence susceptibility to acetaminophen liver toxicity. [115] Anticonvulsants have been shown to induce some UGTs and may account for some drug interactions, particularly in patients treated for HIV infection. [30] The receptors involved in induction of UGTS are not currently known.

Multiple UGTs are expressed in the intestinal tract, [113] and in some cases, these are the identical enzymes expressed in the liver. However, some liver UGTs do not appear to be expressed in the digestive tract (e.g., UGT2B4), and other UGTs are expressed in intestine but not in liver (e.g., UGT1A8). It has been proposed that UGTs present in the colon may provide a protective function by glucuronidating compounds that are deconjugated by colonic bacteria. [113]

Glutathione *S*-Transferases

The GSTs involved in liver or intestinal drug metabolism are cytosolic enzymes belonging to eight separate gene families: a, µ, ?, and ?. [116] (Microsomal GSTs also exist, but these are generally not involved in drug metabolism.) Each family of cytosolic GSTs has several members designated by arabic numbers. For example, GSTM1 is the first of five members of the µ gene family. GSTs are expressed in many organs in addition to liver and intestine. The complements of GSTs present in liver and intestine are not identical. GSTs typically function to detoxify electrophilic metabolites of drugs, such as NAPQI produced from acetaminophen. In general, the reactions they catalyze are not rate-limiting in drug elimination. An exception may be busulfan, which requires glutathione conjugation catalyzed by GSTA1 for elimination. Studies have suggested that busulfan oral availability is limited by GST1A1 activity in the intestine. [117] Children appear to have a higher level of intestinal GST1A1 activity, and this has been proposed as the basis for an increased dosing requirement of busulfan in young children. [118]

Bile contains millimolar concentrations of glutathione, and it is believed that this serves to prevent intestinal cells from becoming depleted of substrate for GSTs. [119] A recent study has suggested that GSTs may exist outside enterocytes, within the overlying mucus, to detoxify electrophils present in the gut lumen. [120]

Polymorphisms in GSTs are common. [116] GSTM1 and GSTT1 are absent in 40% and 15% of whites, respectively. Ultrarapid metabolizers of GSTM1 substrates have also been identified, and this appears to reflect gene duplication. Because depletion of cellular glutathione enhances susceptibility to the toxicity of electrophilic metabolites, such as NAPQI, it is logical to assume that polymorphisms in GSTs could contribute to susceptibility to certain types of drug-induced liver disease. This appears to be the case for the anti–Alzheimer disease treatment tacrine; in patients receiving this drug who lack both GSTM1 and GSTT1, the incidence of treatment-associated alanine aminotransferase elevations appears to be increased. [121]

Sulfotransferases

Human liver and intestine are capable of sulfating a variety of xenobiotics by means of sulfotransferases, which are divided into five gene families. [122] A universal nomenclature has not yet been established for these cytosolic enzymes. The catalytic activity of the sulfotransferases varies considerably among individuals, and polymorphisms in specific sulfotransferases have been identified. Some sulfotransferases are inducible, at least in liver. For example, one study suggested that the loss of efficacy of birth control pills during treatment with antiseizure medications or rifampin might be caused by induction of sulfation, not just induction of CYP3A4 (see Table 26-1). [123]

ROLE OF TRANSPORTERS

It has been recently appreciated that, in addition to phase 1 and 2 enzymes, the disposition of drugs can be governed by the activities of proteins that function to transport the parent drug or its metabolites. [124] Some transport proteins function to secrete phase 1 or phase 2 metabolites from the hepatocyte into bile, [125] or into the intestinal lumen after they are formed in the enterocyte. [126] Such transporters are therefore sometimes collectively termed *phase 3*. The best-studied drug transporter is p-glycoprotein (Pgp), the product of the multidrug resistance gene MDR1. [127] Pgp is present in the biliary canaliculus, where if functions to pump some drugs and their metabolites into bile. Pgp is also present in the brush border of the enterocyte, where it secretes some drugs or metabolites into the lumen of the small bowel. Many, but not all, substrates for Pgp are also substrates for CYP3A4. In addition, Pgp is inducible by many of the drugs that induce CYP3A4, and this appears to be because activated PXR stimulates transcription of both genes. [128] Drug interactions that can be explained by the induction of CYP3A4 in liver or intestine may therefore also result from induction of Pgp in these organs. For example, induction of Pgp likely contributes to the interaction between rifampin and cyclosporine, a substrate for both CYP3A4 and Pgp. [10] Likewise, some drugs, such as ketoconazole, that inhibit CYP3A4 probably also inhibit Pgp.

Differentiating the contribution of Pgp from that of CYP3A4 in the disposition of a drug or in drug-drug interactions is not straightforward and is an active area of investigation. This is in part because CYP3A4 and Pgp may function synergistically. For example, mice lacking functional Pgp (because of targeted disruption of the mouse MDR genes) have higher rates of CYP3A-mediated demethylation of intravenously administered erythromycin. [129] This appears to result from increased hepatocyte concentrations of the parent drug secondary to decreased biliary secretion. In the intestine, Pgp may also function to increase CYP3A4-mediated metabolism by prolonging the absorption phase (i.e., increasing the duration of exposure of the drug to the enzyme), or by removing primary metabolites from the enterocyte, reducing secondary metabolism. [130], [131]

CHAPTER 27

David A. Brenner and Richard A. Rippe

PATHOGENESIS OF HEPATIC FIBROSIS

OVERVIEW: CIRRHOSIS AND FIBROSIS

Cirrhosis is defined by its histological features, consisting of nodules of regenerating hepatocytes and the abnormal deposition of connective tissue in and around the nodules (fibrosis) (Fig. 27-1). Although the injury that initiated the process of regeneration and fibrosis may cease (and histological or laboratory evidence of inflammation and injury disappear), the fibrosis may be fixed and irreversible. By obliterating sinusoidal fenestrations, obstructing the space of Disse, and replacing vascular channels, fibrotic tissue increases resistance to blood flow. The resultant elevation of sinusoidal pressure causes shunting of portal flow around the liver, both exaggerating cellular dysfunction and creating the devastating consequences of portal hypertension. In addition, excess fibrosis prevents nutrient and metabolite exchange, further exacerbating the ramifications of the fibrotic response. Thus, liver fibrosis is a sine qua non of cirrhosis and directly responsible for many of its clinical features.

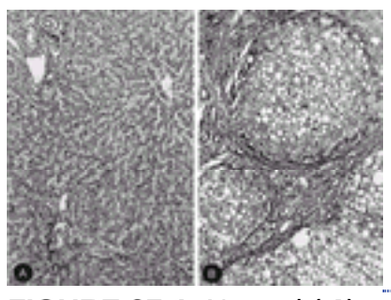

FIGURE 27-1. Normal (**A**) and cirrhotic (**B**) human liver. (From Brenner DA, Rippe RA. Pathogenesis of hepatic fibrosis. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Many different diseases may result in the common “end stage” of cirrhosis (Table 27-1). The spectrum of clinical abnormalities characterizing the cirrhotic stage of these diseases depends more on the extent of fibrosis, as well as the presence or absence of ongoing injury, than on the cause. Because so few of the underlying causes of cirrhosis are treatable, much attention has been focused on understanding, and potentially reversing, the generic process of fibrogenesis itself. However, it is unlikely that all diseases causing cirrhosis do so through the same initiating mechanism. For example, chronic hepatitis B, chronic ethanol abuse, and hemochromatosis may all result in cirrhosis. However, the liver in chronic hepatitis B characteristically demonstrates a lymphocytic infiltrate, whereas alcoholic liver disease is marked by hepatic infiltration with neutrophils, and infiltrates are absent in hemochromatosis. Furthermore, there are subtle differences in the specific content or location of deposited scar tissue in cirrhosis of different causes. Such differences may reflect differences in pathogenesis as well. If so, therapies successfully designed to limit fibrogenesis in one disease state may fail to work in another. One must bear this in mind when considering data obtained in any one model of hepatic fibrogenesis.

Infectious
Viral hepatitis (hepatitis B, C, D; cytomegalovirus infection)
Bacterial: brucellosis, syphilis
Parasitic: schistosomiasis
Environmental
Drugs: methyldopa, methotrexate, isoniazid, ethanol
Toxins: carbon tetrachloride, pyrrolidizine alkaloids
Metabolic
Hemochromatosis
Wilson disease
α_1 Antitrypsin
Glycogen storage disease
Gaucher disease
Other
Sarcoidosis
Chronic biliary obstruction
Cardiac cirrhosis

TABLE 27-1 Some Causes of Liver Fibrosis

This chapter reviews our current understanding of the pathogenesis of hepatic fibrosis and highlights those elements of the process for which intervention has been attempted. Conceptually, the process of hepatic fibrosis must, at some point, consist of the stimulation of excessive extracellular matrix (ECM) molecule synthesis by one or more populations(s) of cells (or an increase in the population of ECM-producing cells), or a decrease in the rate of ECM degradation or turnover.

HEPATIC CONNECTIVE TISSUE

For a parenchymal organ to maintain its cellular performance, a supporting framework of connective tissue must be present. The connective tissue may anchor the parenchymal cell, provide tensile strength for the tissue, control access to microorganisms or macromolecules, and act as a reservoir for growth factors. The nature and density of their ECM markedly affect the phenotypic features of many cells. Culturing hepatic stellate cells (HSCs), for instance, on laminin, type I collagen, or plastic can markedly change their shape, the type of ECM molecules they secrete, and their rate of production. [1], [2] and [3] At most epithelial-mesenchymal interfaces, this connective tissue is organized as a basement membrane. For instance, bile duct epithelium rests on a basement membrane. However, the hepatocyte is the only cell of ectodermal or endodermal origin in direct contact with plasma. Neither the hepatocyte nor the sinusoidal endothelial cells have the support of a complete basement membrane, so blood passing through the fenestrated sinusoidal endothelium need cross only the space of Disse to reach the microvilli of the hepatocyte cell surface. Thus, the connective tissue stroma of the normal liver has the difficult task of maintaining and supporting the structure of the organ without compromising the direct access of blood to the hepatocytes. By light microscopy, the only readily apparent connective tissue stroma in the liver is the basement membrane of the biliary ductules and blood vessels, and some less organized connective tissue within the portal tracts. However, immunohistochemical and electron microscopic studies have revealed that a complex low-density array of ECM molecules exists within the space of Disse. The primary constituents of this wispy sinusoidal stroma (as well as of basement membranes elsewhere) are glycoproteins, proteoglycans, and collagens. [4] Because liver collagen content markedly increases with

fibrogenesis, its biosynthesis represents a natural target for therapeutic intervention in liver fibrosis.

COLLAGEN SYNTHESIS

Collagen is the most abundant family of proteins in the vertebrate body. Collagen types I, III, IV, V, VI, XIV (undulin), and XVIII (endostatin) are the primary collagen types that have been identified in the liver. [5], [6] and [7] All collagen types share certain fundamental structural features. They are triple helical molecules, each strand of which is itself a helical polypeptide chain rich in proline and hydroxyproline and bearing a glycine residue at every third position. These strands, or a-chains, aggregate to form a triple helix interrupted in some collagen types by globular domains. The triple helices then cross-link to form collagen fibrils, each type with unique physiochemical properties.

Type I collagen forms large fibrils and is the major ECM protein of bone, tendon, skin, ligaments, fascia, and arteries. It is also the major collagen type synthesized in the fibrotic liver, and its production serves as a model for understanding collagen synthesis. Type I collagen undergoes a complex biosynthetic pathway (Fig. 27-2). [8], [9], [10], [11] and [12] The type I collagen molecule is composed of two a $_1$(I)-chains and one a $_2$(I)-chain that are produced by two separate genes located on different chromosomes. These genes are coordinately regulated in a tissue-specific, developmental, and inducible manner. Generally, twice as much of the a $_1$(I) collagen gene is transcribed as of the a $_2$(I) collagen gene. Once the two collagen genes are transcribed, the mRNAs are processed in the nucleus.

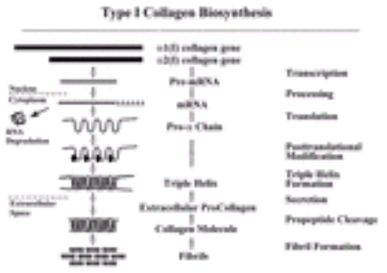

FIGURE 27-2. Type I collagen biosynthesis.

One of the consequences of HSC activation is a dramatic increase in the production of type I collagen. The increase results from a two- to threefold increase in the transcription rate of this gene, coupled with a 16- to 20-fold increase in the stabilization of the mRNA of the gene (Fig. 27-3). [13] The stabilization of the a $_1$(I) collagen mRNA is a complex process. One aspect of the stabilization process involves the binding of aCP2, an RNA-binding protein, to conserved elements located at the 3' end of the mRNA molecule. Interactions between aCP2 and poly-A binding protein decrease mRNA degradation. A conserved stem-loop structure located in the first exon of the a $_1$(I), a $_2$(I), and a $_1$(III) collagen genes interacts with a 120-kd unidentified protein. [14] This protein may also interact with aCP2 and with the cap-binding protein, a protein that binds at the 5' end of the mRNA molecule. [9] These interactions contribute to increased stability of the a $_1$(I) mRNA molecule and increase translation of the protein.

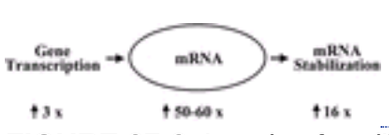

FIGURE 27-3. Levels of a $_1$(I) collagen mRNA increase following hepatic stellate cell activation.

Once processed, the mature mRNA molecule is transported to the cytoplasm, where it is translated into protein. Collagen I mRNAs code for “prepropeptide” chains, meaning that the translated products have “leader” sequences serving to guide the newly made molecules into the endoplasmic reticulum. Further, amino- and carboxyl-terminal “propeptides” are present on each chain. Inter- and intrachain disulfide bond formation in these globular terminal regions is necessary for a-chain aggregation. After removal, propeptides may regulate collagen gene transcription.

Leader sequences are cleaved as the prepropeptide a-chains enter the rough endoplasmic reticulum where important posttranslational modifications occur. Hydroxylation of some prolyl and lysyl residues to hydroxyproline and hydroxylysine is catalyzed by three hydroxylases, each requiring oxygen, a-ketoglutarate, ferrous iron, and ascorbate as cofactors. [15] Within the triple helical region, every third proline residue is hydroxylated, unlike every lysine residue present in the polypeptide chain. These reactions occur only when the prolyl or lysyl residue occupies specific positions in the a-chain and are a prerequisite for the a-chain interactions resulting in the triple helical procollagen molecule. [15] This posttranslational modification stabilizes the formation of the triple helical structure. [15] Additionally, some hydroxylated prolyl or lysyl residues are glycosylated. [11], [16] The procollagen molecule passes through the Golgi apparatus, and propeptides are enzymatically cleaved off at the time of collagen secretion into the extracellular space, which requires stable triple helix formation for maximal efficiency. Free propeptides may remain within the cell or between cells in the matrix, or they may enter the circulation, from which they are cleared by the kidneys and by endothelial cell uptake. [17] Once the propeptides are cleaved, spontaneous aggregation of mature collagen molecules takes place to form fibrils. For full tensile strength, the fibrils require covalent intramolecular and intermolecular cross-linkage. These extracellular cross-linkages are enzyme-catalyzed reactions. Finally, concomitant with collagen synthesis is collagen degradation, both intra- and extracellularly. The mechanisms controlling these pathways are poorly understood, but in some systems, most of the transcribed collagen is never deposited.

Several aspects of collagen synthesis deserve emphasis. First, the intracellular posttranslational hydroxylation of proline and lysine is required for pro-a-chain aggregation into triple helices. [11] Interruption of hydroxylation reduces the formation of procollagen. Extracellular lysyl oxidase activity is required for collagen cross-linking and stable fibril formation. [18] Inhibition of this enzyme results in unstable collagen. Ultimately, at least nine posttranslational enzymes are required for collagen production, so that opportunities for therapeutic intervention are numerous.

Hepatic Basement Membrane Proteins

Connective tissue organized as basement membrane is found throughout the body. The primary molecular constituents are collagen, glycoproteins, and proteoglycans. [4] Within the liver, these molecules make up the large vascular, bile duct, and neural basement membranes. Although the molecular details of organization are unclear, their structure results in a 20- to 60-nm-thick lamellar unit distinctly recognizable by electron microscopy.

Type IV collagen is the major collagen of basement membrane. It is an unusual collagen type in that the propeptides are not cleaved off on secretion, and the molecules cross-link at these globular domains to form a network resembling “chicken wire.” [19], [20] The major glycoprotein of the basement membrane is laminin, a large cruciform molecule bearing domains that bind to type IV collagen, fibronectin, heparin sulfate, nidogen (also called *entactin*), and specific cell surface proteins. [20] Laminin represents a family of large glycoproteins sharing some structural features and playing important roles in guiding normal embryogenesis and perhaps tissue repair. [20], [21] Nidogen, a smaller glycoprotein, is usually found bound to the center of the laminin molecule, where it may mediate binding to other matrix proteins. [22] Proteoglycans are a heterogeneous group of proteins, grouped together by their sulfated carbohydrate groups. The primary epithelial basement membrane proteoglycan is heparin sulfate, with polymers of *N*-acetylglucosamine and uronic acid attached to a protein core. [23] Proteoglycans may contribute to the basement membrane structure through binding sites for cell surface proteins or other ECM molecules. Thus, the structure and constituents of hepatic basement membranes resemble those of basement membranes elsewhere in the body. However, as already noted, the sinusoidal endothelial cells and hepatocytes lack basement

membranes, and it is the accumulation of sinusoidal fibrosis that characterizes hepatic cirrhosis.

Non–Basement Membrane Proteins

Although the molecules mentioned thus far are the primary constituents of basement membrane, they are also found in sparser, less organized fashion throughout the portal tract stroma and the space of Disse. Laminin and collagen IV, for instance, may be demonstrated by immunohistochemical staining to be discontinuously present throughout the space of Disse. However, other important hepatic ECM molecules, such as proteoglycans from the chondroitin sulfate/dermatan sulfate group, the glycoprotein fibronectin, and the major fibrillar collagens of the liver, types I and III, are not prominent in the basement membrane complex. These are the molecules in the space of Disse that make up the insoluble portion of the hepatocytes' ECM.

Approximately 40% of normal liver collagen is type I collagen. It is found in the stroma surrounding portal tracts, central veins, and the liver capsule, where it is probably the blue material visualized by trichrome staining. However, scattered strands may also be detected by immunohistological techniques along the sinusoids in the space of Disse, particularly at points of sinusoidal branching. Another 40% of hepatic collagen is type III, forming slightly smaller fibrils that distribute together with type I collagen. Collagen types V and VI are much less abundant in liver tissue. [24] Type V collagen is probably a pericellular collagen, acting perhaps as an "ectoskeleton" around cells. It represents no more than 2% of liver collagen. Type VI collagen is the rarest collagen in the liver and appears to form microfibrils, loosely connecting bundles of larger fibrillar collagen types I and III. [25]

Glycoproteins found in the space of Disse include laminin and the large glycoprotein fibronectin. A number of fibronectin types arise from alternative splicing of a single gene product. [26], [27] All have two subunits joined by disulfide bonds, and each type bears domains binding fibrin, heparin, bacteria, denatured collagen, cells, and probably other moieties as well. Fibronectin is found in the portal stroma and capsule, but it also may be identified in continuous contact with hepatocytes as the most prominent component of ECM within the space of Disse. A circulating form of fibronectin may lodge in the ECM, but deposition following local secretion also occurs.

Cell surface receptors have been identified for collagens, fibronectin, laminin, and proteoglycans, including integrins, dystroglycan, receptor tyrosine kinases or phosphatases, and syndecans. Integrins, the best studied of the cell matrix receptors, are a family of proteins that serve as transmembrane links between extracellular ligands and the cell cytoskeleton. Integrins are heterodimer molecules that contain one a-chain and one ß-chain. The several different a- and ß-chains allow for a wide variety of combinations of a-chains and ß-chains and multiple possibilities for ligand recognition. The primary collagen-binding integrins are a $_1$ß $_1$ and a $_2$ß $_1$. [2], [28], [29] and [30]

CELLULAR SOURCES OF EXTRACELLULAR MATRIX PROTEINS

Each of the liver cell populations may play a role in the production of ECM molecules, either directly by secretion or indirectly through the production of cytokines or mediators of inflammation. Knowledge of the cellular origins of these molecules could be very important therapeutically. For instance, because normal ECM production is critical to normal tissue function throughout the body, ideal therapy for liver fibrogenesis entails the delivery of antifibrogenic drugs only to liver cells producing excessive amounts of ECM proteins.

Although a variety of hepatic cells are capable of synthesizing collagen, a preponderance of experimental evidence incriminates the HSC as the main collagen-producing cell during hepatic fibrogenesis. [4], [5], [31], [32], [33] and [34] HSCs are located in space of Disse in close proximity to hepatocytes on one side and endothelial and Kupffer cells on the other side. HSCs (also called *fat-storing cells, Ito cells,* or *hepatic lipocytes*) are desmin-positive perisinusoidal cells that are the primary cell in the body responsible for vitamin A storage in the form of retinyl esters. These cells have the capacity to synthesize several ECM proteins and glycoproteins, including at least five collagen types, fibronectin, laminin, entactin, tenascin, and several proteoglycans. [35], [36], [37], [38], [39], [40], [41] and [42]

Another source of excessive ECM deposited in the liver is the portal fibroblast. In primary biliary cirrhosis, excess deposed collagen is characteristically located around the fibroblasts surrounding the portal tracts. [43]

Modulation of the ECM by a complex interaction of cytokines acting in paracrine fashion has provided insight into liver fibrogenesis. Cells producing these cytokines may have an indirect effect on the ECM by their secretion. Many of these modulating cells are of hematopoietic origin. For example, the degranulation of platelets may provide a rich source of transforming growth factor-a (TGF-a). This factor may influence both the proliferation and ECM production of fibroblasts, hepatocytes, and HSCs. Platelet-derived growth factor and TGF-a–like activity can both be derived from platelets, but their impact on fibrogenesis is less clear. Because platelets accumulate in the vicinity of injury, the paracrine effects of these compounds may be important in the fibrogenesis that follows some forms of chronic liver injury.

The resident macrophages of the liver, the Kupffer cells, probably along with itinerant monocytes and other hepatic cell types, are a rich source of cytokines and chemokines. [44], [45], [46] and [47] In addition to TGF-ß, macrophages can secrete tumor necrosis factor-a (TNF-a), interleukin-1 (IL-1), prostaglandins, interferons, and collagenase. Complex interactions can result from these substances under various conditions. Cytokines can either regulate the synthesis of other cytokines or can modify the actions of other cytokines at the target cell. Thus, macrophages may have an important role in fibrogenesis, but whether they augment or attenuate fibrogenesis is unclear. In many hepatic fibrotic diseases, a clear inflammatory process is accompanied by a polymorphonuclear infiltrate. However, not all hepatic fibrotic conditions are associated with this situation. In liver fibrosis induced by carbon tetrachloride (CCl_4), a clear fibrotic response develops, but without a polymorphonuclear infiltrate. Similar phenomena, less well studied, probably pertain to lymphocytes passing through the hepatic sinusoids. Neutrophils may also play a role in some states of hepatic fibrogenesis. Neutrophils may be responsible for local tissue destruction through the secretion of reactive oxygen species leading to accumulation and degranulation of platelets. Specific chemotactic substances, such as leukotriene B_4, can recruit and activate macrophages. Additionally, neutrophils produce collagenases that may have important local effects. [48], [49] Thus, the role of the neutrophil in liver fibrosis is probably a consequence of its ability to cause injury and activate cytokine-producing cells.

MATRIX-DEGRADING ENZYMES

More is known about the constituents of the ECM structure than about the distribution and activity of ECM-degrading enzymes in the liver. Nevertheless, their importance is implied by the dynamic state of normal ECM structure. For instance, whereas fractional turnover rates for collagens in organs are generally 3% to 5% per day, some tissues may have rates as high as 10%. [50] Collagen degradation can take place either inside or outside the cell. The proportion of degradation occurring intracellularly before secretion ranges from 10% to 90% in various cell culture systems, apparently through degradation in lysosomes or endoplasmic reticulum. Furthermore, phagocytosis and intracellular degradation of collagen after secretion are well described, so that more than one route to intracellular degradation exists. The role of these pathways in states of active fibrogenesis is unknown. Whether similar intracellular degradation of other ECM molecules occurs is also unknown.

The matrix metalloproteinases (MMPs) are a family of at least 20 enzymes that degrade matrix proteins and are thus considered to be important in mediating matrix turnover. [51] They are secreted as inactive proenzymes and require proteolytic activation. Several enzymes can activate the pro-metalloproteinase; however, plasmin is the most common. [51], [52] and [53] The MMPs are regulated by several mechanisms, including transcriptional regulation, activation of the latent proenzyme, and extracellular inhibition by specific tissue inhibitors of metalloproteinases (TIMPs). The MMPs can be divided into four groups based on their substrate specificity. [52] Representing the first group are the collagenases, MMP-1 and MMP-2. These enzymes are involved in degrading fibrillar collagen, including collagen types I, II, and III. They cleave the triple helical structure of collagen, allowing for subsequent degradation of the molecule by other MMPs. [54] The second group of MMPs are the stromelysins, which degrade collagen types II, IV, IX, X, and XI, denatured collagens (gelatin), laminin, proteoglycans, and fibronectin. [54] The third group of MMPs include the gelatinases: MMP-2 (gelatinase A) and MMP-9 (gelatinase B). These enzymes degrade gelatins, elastin, and collagen types IV, V, VII, X, and XI. [54] The fourth group of MMPs represent a miscellaneous group that includes membrane-type MMPs, which degrade types I and III collagen, proteoglycans, and fibronectin. [52] The activity of active MMPs is regulated by a group of four proteins, the TIMPs. [52] TIMPs irreversibly bind to active MMPs to prevent their proteolytic activity. [54] In addition to regulation at the level of transcription, translation, and activation, these metalloproteinases may be affected by inhibitors such as a $_2$-macroglobulin, a circulating liver-produced protein. [54] Thus, a complicated interaction of factors controls normal and hepatic ECM degradation.

MMP-2, type IV collagenase/gelatinase, is a metalloproteinase produced by fibroblasts, macrophages, and HSCs. [55], [56] MMP-2 degrades denatured collagen as well

as collagen types IV and V. On activation both in vitro and in vivo, HSCs express type IV collagenase/gelatinase. [57], [58], [59] and [60] In vivo, the expression of MMP-2 may disrupt the basement membrane, which includes type IV collagen. Fibroblasts, endothelial cells, HSCs, and macrophages produce MMP-13 (also called *stromelysin* or *transin*), a metalloproteinase with broad activity, capable of enhancing the removal of propeptides from collagen I and III, thereby enhancing procollagenase activation, and digesting proteoglycans, collagen IV, laminin, fibronectin, and denatured collagen. [61], [62]

THE EXTRACELLULAR MATRIX IN CIRRHOSIS

The ECM has been examined in cirrhotic humans and in several animal models of hepatic fibrogenesis. In general, during fibrogenesis, collagen mRNA levels increase about fourfold, and liver collagen content increases about 10- to 20-fold. [4], [24], [63], [64] Lysyl oxidase activity increases as well.

Type III collagen is the first to increase after liver damage. [65] However, type I collagen becomes the dominant hepatic collagen type, exceeding collagen III by a ratio of 4:1, and may eventually account for 60% to 70% of total hepatic collagen. [4], [66], [67] Laminin mRNA levels also rise, and liver laminin content accordingly increases. [31], [68], [69], [70] and [71] The normal neural, ductular, and vascular basement membranes may remain undisturbed, but ECM molecules accumulate in the space of Disse, with fibronectin preceding type I collagen, type IV collagen, and laminin (Fig. 27-4). [69], [72], [73] Gradually, a continuous ECM accumulates between hepatocytes and endothelial cells, obliterating sinusoidal fenestrations and preventing the exchange of nutrients and metabolites between the hepatocytes and the hepatic sinusoid. This "capillarization of the sinusoids" and "collagenization of the space of Disse" precede the development of the signs and symptoms of chronic liver disease. Additionally, an early hallmark of alcohol-induced hepatic fibrosis is the deposition of excess ECM in the terminal hepatic venule.

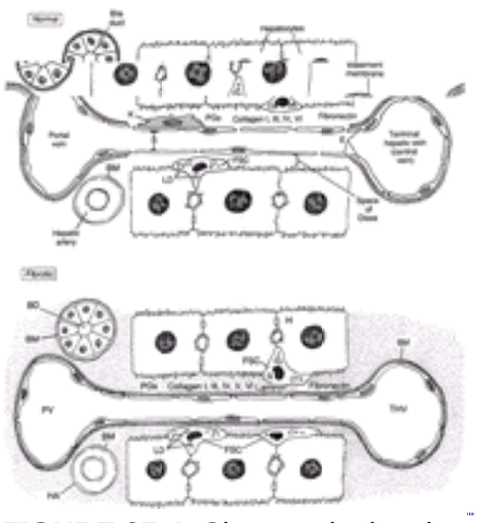

FIGURE 27-4. Changes in the sinusoidal space between normal and fibrotic liver. *BD,* bile duct; *BM,* basement membrane; *E,* endothelial cells; *FSC,* fat-storing (stellate) cells; *H,* hepatocyte; *HA,* hepatic artery; *K,* Kupffer cell; *LD,* lipid droplets; *PG,* proteoglycans; *PV,* portal vein; *S,* sinusoid; *THV,* terminal hepatic (central) vein. (From Brenner DA, Rippe RA. Pathogenesis of hepatic fibrosis. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

MMP (collagenase) activity has been reported to increase early during fibrogenesis, presumable less so than collagen deposition. Indeed, it has been suggested that excessive or inappropriate matrix degradation may be among the causes of fibrosis by eliminating or distorting the normal extracellular ECM "cues" guiding the normal expression of ECM genes. Later, collagenolytic activity declines and a new steady state is reached. Expression of the TIMPs is also increased during liver fibrosis. [74], [75] However, it is noteworthy that in a number of models of fibrogenesis, prolonged exposure to the injurious agent is required to achieve cirrhosis, whereas transient injury is followed by gradual resolution of the fibrosis. [76], [77] and [78] Possible explanations are that the gradual loss of collagenolytic activity with prolonged fibrogenesis leads to progressive fibrosis, or that the increase in type I collagen deposition occurring during fibrogenesis renders collagenolytic activity decreasingly effective in maintaining normal matrix integrity.

Mechanisms of Increased Collagen Production

Oxidative stress is an important factor in the development and progression of liver fibrosis of different causes, including alcohol ingestion, viruses, iron or copper overload, cholestasis, and hepatic blood congestion. In oxidative stress, highly reactive oxygen intermediate species (ROIs) are generated. The ROIs can oxidize many proteins, but lipids represent a major target. The oxidized molecules can have effects detrimental to cellular metabolism. The role of the oxidation of lipids, lipid peroxidation, has been extensively studied in liver fibrosis.

Lipid Peroxidation Lipid peroxidation is associated with the tissue injury and fibrogenesis of several pathological disorders, including atherosclerosis, iron overload, and porphyria, and also with ethanol-, bleomycin-, and CCl_4-induced liver toxicity. The polyunsaturated fatty acids of phospholipids in cell membranes are highly susceptible to attack by free radicals, and subsequent reactions with oxygen generate lipid peroxides. Lipid peroxides may be further oxidized to aldehydes, such as 4-hydroxy-2,3-nonenal (HNE) and malondialdehyde (MDA). Peroxidation resulting in these highly reactive aldehydes stimulates collagen gene expression in cultured fibroblasts. [79], [80] Incubating these cultures with exogenous MDA, a major product of lipid peroxidation, induces a similar increase in collagen gene expression. Furthermore, decreasing the basal level of lipid peroxidation in these cultures with a-tocopherol (vitamin E) prevents lipid peroxidation and blocks the stimulation of collagen production and collagen gene expression by ascorbic acid. Thus, it may be that the "direct" effects of ascorbate to increase collagen production actually reflect the effects of ascorbate-enhanced lipid peroxidation. The stimulation of lipid peroxidation with ascorbic acid, acetaldehyde, or MDA stimulates collagen gene transcription, and inhibition of lipid peroxidation with vitamin E or methylene blue inhibits transcription. HNE also increases collagen production in cultured HSCs. [81], [82] and [83] The stimulatory effect of lipid peroxidation products on collagen expression that occurs in vitro is also seen in vivo.

Ethanol-Induced Fibrosis Excess ethanol consumption represents the number one cause of liver fibrosis in the United States. Ethanol-induced liver fibrosis is strongly associated with oxidative stress. The fibrotic effect of ethanol is caused in part by the generation of ROIs (including 1-hydroxyethyl) via cytochrome CYP2E1. [84] Inhibiting CYP2E1 reduces the formation of ROIs and the generation of lipid peroxidation products in ethanol-fed animals. [85], [86] The generated ROIs are believed to affect HSCs directly, resulting in increased ECM production. In addition, ROIs can activate Kupffer cells, which may increase proinflammatory and profibrogenic cytokine production. ROIs also induce the formation of lipid peroxidation products from membrane lipids, of which HNE and MDA are the major species produced. Both HNE and MDA levels and their modified protein adducts are increased in alcoholic patients. [87] HNE and MDA levels are increased, along with collagen deposition, after the treatment of chronic alcoholism. [88] Alternatively, ROIs from ethanol can be generated by NADPH (reduced nicotinamide adenine dinucleotide phosphate) oxidase in Kupffer cells. [89] Ethanol also promotes fibrogenesis through its primary metabolite, acetaldehyde. The mechanism by which acetaldehyde increases collagen transcription is unknown. Acetaldehyde covalently binds to proteins via Schiff bases, especially with the a-amino group of lysines, forming acetaldehyde-protein adducts. These adducts can be detected in the liver of ethanol-fed rats, and antibodies to acetaldehyde adducts are present in the serum of most alcoholic individuals. [90], [91], [92], [93], [94] and [95] Perhaps the formation of adducts of acetaldehyde with proteins involved in transcriptional regulation is the mechanism by which collagen gene transcription increases. Acetaldehyde is a highly reactive compound that can form aldehyde adducts with many proteins, often altering their function. Acetaldehyde stimulates collagen expression in fibroblasts and in cultured HSCs. [96], [97] and [98] This stimulatory effect may be caused by acetaldehyde increasing the binding of transcription factors to the promoters of the collagen genes. [99], [100] and [101] The activation of c-jun nuclear kinase (JNK) appears to be involved in the mediation of the increase in collagen expression by acetaldehyde by increasing transcription factor binding to the collagen promoter. [102], [103] The interaction of acetaldehyde with xanthine oxidase may also promote lipid peroxidation. Differences in acetaldehyde metabolism, either genetically influenced or acquired, result in a range of hepatic acetaldehyde concentrations. If acetaldehyde plays a role in alcohol-induced fibrogenesis, then perhaps fibrosis develops only in those individuals with high hepatic concentrations of acetaldehyde. This could explain the predisposition of some, but not all, alcoholic individuals to the development of hepatic fibrosis. Acetaldehyde may also be an important mediator of hepatic fibrogenesis in nonalcoholic liver disease. High levels of acetaldehyde are generated in the CCl_4-injured rodent liver after the administration of ethanol (an endogenous source of acetaldehyde). CCl_4 liver injury promotes the excessive accumulation of acetaldehyde from ethanol by decreasing acetaldehyde production via an alternative degradation pathway. This observation provides support for the commonly held belief that patients with nonalcoholic liver disease should not drink alcohol.

Iron and Copper Overload Iron overload in hemochromatosis and copper overload in Wilson disease are other causes of ROI formation and fibrosis. The accumulation of iron results in the formation of reactive oxygen through the Fenton reaction. This leads to the oxidation of internal membrane lipids of the mitochondria, microsomes, and lysosomes; the resultant generation of lipid peroxidation products (HNE and MDA) and associated protein adduct formation in turn lead to cell injury caused by functional problems with cellular structures. [104], [105] and [106] Studies have shown that increased iron increases collagen gene expression. [107], [108] The role of oxidative stress in the development of iron-induced fibrosis has been confirmed in studies in which antioxidants, such as vitamin E and silybin, are used to reduce the levels of lipid peroxidation products and the development of fibrosis. [109], [110] Increased iron thus increases lipid peroxidation, causing irreversible cellular damage. This can activate Kupffer cells that produce ROIs and fibrogenic cytokines that stimulate the HSCs to produce excess ECM components. The molecular mechanisms responsible for iron-induced collagen gene expression are unknown; however, increased binding of Sp1 to the collagen gene promoter has been shown in HSCs following iron treatment. [111] The mechanisms by which iron overload causes fibrosis have been studied more than those for copper overload. Copper overload results in a chronic inflammatory response accompanied by significant fibrosis that can eventually lead to cirrhosis. Excess copper increases lipid peroxidation products that can be reduced with antioxidant (vitamin E) treatment. [112]

Transforming Growth Factor-ß TGF-ß belongs to a superfamily of growth hormones and cytokines that affects growth and tissue patterning in many tissue types. TGF-ß superfamily members regulate the transcription of several genes, including those involved with regulating the cell cycle, cell adhesion molecules, homeobox genes, and extracellular matrix proteins. TGF-ß represents a family of five peptide hormones (TGF-ß $_{1–5}$) that are primarily produced and secreted by inflammatory cells and platelets. Members of the TGF-ß family play important roles in several physiological processes, including embryogenesis, wound repair, inflammation, carcinogenesis, immunosuppression, and fibrogenesis. The exogenous administration of TGF-ß induces fibrosis in lung, kidney, and liver, [113] and TGF-ß is thus considered to be a potent fibrogenic cytokine. During experimental models of hepatic fibrosis, including bile duct ligation, CCl_4 administration, and schistosomiasis, a prolonged increase in TGF-ß expression is observed. [114], [115] Patients with alcohol- or virus-induced cirrhosis also exhibit increased TGF-ß mRNA levels. TGF-ß induces fibrogenesis by multiple mechanisms. It increases the production and decreases the degradation of ECM proteins, so that an overall net increase in the deposition of these proteins results. TGF-ß increases the expression of ECM proteins such as type I collagen and fibronectin and increases type I collagen synthesis in cultured HSCs. [116], [117] The increase is the consequence of an increase in both the transcription rate of these genes and posttranscriptional regulation. Three potential TGF-ß–responsive elements have been identified in the a_1(I) collagen gene. [10] An increase in TGF-ß receptor expression occurs following HSC activation, which may allow an autostimulatory loop to enhance the TGF-ß effects in HSCs. TGF-ß decreases the expression of Sp3, a negative regulator of transcription. This may allow for increased binding of Sp1 to the collagen gene promoter, thereby increasing collagen gene expression, as Sp1 is a potent transactivator of the a_1(I) collagen gene. [118], [119] TGF-ß also increases the levels of plasminogen activator inhibitor (PAI-1) and TIMPs, both of which inhibit the degradation of ECM components. [120] In addition, TGF-ß inhibits the production of MMP-1 (type I collagenase) and MMP-3 (stromelysin). TGF-ß also increases the rate of HSC activation. [121] This in vitro analysis is corroborated by in vivo analysis, which has shown increased levels of TGF-ß mRNA in liver biopsy specimens from patients with chronic fibrosing liver disease that was positively correlated with fibrosis. [122] TGF-ß was localized by immunohistochemical staining to areas of hepatic fibrosis in biopsy specimens of patients with cirrhosis. [122], [123] TGF-ß plays a central role in the production of pathological ECM deposition in the liver. HSCs in the liver respond to TGF-ß by increasing the secretion of collagen and fibronectin into the ECM. TGF-ß functions in part by stimulating transcription of the collagen and fibronectin genes. TGF-ß increases the transcription of type I procollagen genes in HSCs. [116], [117] An increase in fibronectin mRNA is also seen following TGF-ß treatment in HSCs. The increased transcription of collagen and fibronectin genes results in increased production of these proteins. TGF-ß is secreted as a homodimer latent peptide that is subsequently activated to an active form by the dissociation of the inhibitory latency-associated peptide. The active form of TGF-ß interacts with three specific cell surface receptors: RI, RII, and RIII (Fig. 27-5). Type III TGF-ß receptors contain short cytoplasmic tails and do not mediate TGF-ß signal transduction, but they may bind TGF-ß and present it to type II receptors. Types I and II receptors contain serine/threonine kinases that are directly responsible for cellular signaling of TGF-ß. Active TGF-ß initially binds to RII, which then recruits and phosphorylates the RI receptor. This initiates a specific intracellular signaling process. The SMAD proteins, and in particular SMAD2, SMAD3, and SMAD4, mediate the intracellular signaling of TGF-ß. [124], [125] Three main classes of SMAD proteins exist: the receptor-regulated SMADs (R-SMADs: SMADs 1, 2, 3, 5, and 8), the common-partner SMAD (co-SMAD: SMAD4), and the inhibitory SMADs (I-SMADS: SMADs 6 and 7).

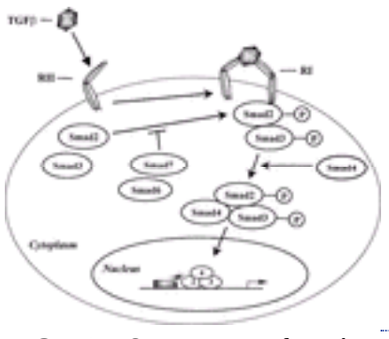

FIGURE 27-5. Transforming growth fac- tor-ß signaling.

The importance of SMAD proteins in the cell is demonstrated in knock-out animals. Both SMAD2 knock-out and SMAD4 knock-out result in embryonic lethality in mice. SMAD2 knock-out mice show a lack of anterior-posterior specification and do not develop mesoderm; SMAD4 knock-out mice fail to grow because of reduced cell proliferation, and they demonstrate gastrulation defects. SMAD3 knock-out mice are viable, survive to adulthood, and are fertile, but they are smaller, exhibit limb malformations, have a defective immune system, and develop colon cancer at approximately 6 months of age. Fibroblast cultures isolated from the SMAD3-deficient mice show an inability to form SMAD complexes on the DNA and fail to induce transcription from a TGF-ß–responsive promoter. SMAD3 is not required for HSC activation, but SMAD3 is required for maximal type I collagen gene expression in HSCs. [126] The HSC response to TGF-ß appears to wane over time in culture. During the early stages of HSC activation, these cells are fully responsive to TGF-ß; however, over time, fully activated HSCs lose their TGF-ß responsiveness. [127] This apparently is caused by a loss of TGF-ß–dependent SMAD2 phosphorylation. The molecular mechanisms underlying this unresponsiveness are not well understood.

ACTIVATION AND PROLIFERATION OF FIBROGENIC CELLS

An increase in the number of collagen-producing cells, including HSCs and fibroblasts, as a consequence of proliferation, migration, or transformation is a mechanism contributing to hepatic fibrogenesis.

In tissue injury and fibrogenesis, platelets may recruit collagen-producing cells by releasing two of their factors, platelet-derived growth factor (PDGF) and TGF-a. TGF-a and PDGF are chemoattractants for fibroblasts, smooth muscle cells, and monocytes. Furthermore, PDGF induces proliferation of fibroblasts, smooth muscle cells, and HSCs. [128] Monocytes, macrophages, and neutrophils may also be recruited by leukotriene, by the cell attachment segment of fibronectin, and by a polar lipid generated by hepatocytes metabolizing ethanol. [129] Activated monocytes, including Kupffer cells, are capable of generating fibroblast and HSC growth-promoting factors, including IL-1, PDGF, and fibroblast growth factor. [121], [130]

Regardless of etiology, hepatic injury induces the HSC to undergo a complex transformation or “activation” process into a myofibroblast-like cell (reviewed in ref. [34]; Fig. 27-6). Following a fibrogenic stimulus, the HSC undergoes activation with morphologic changes, including the loss of vitamin A stores and the appearance of rough endoplasmic reticulum. Early activation is also characterized by the expression of smooth muscle a-actin (which is why these cells have been called *myofibroblast-like cells*), cytokine receptors on the cell surface, and type IV collagenase that disrupts the normal basement membrane. If the fibrogenic stimulus persists, the cells continue to lose their vitamin A stores and become responsive to growth factors, of which PDGF is the most potent, and to fibrogenic cytokines, of which TGF-ß is the most potent. This amplifies the cell population and increases fibrogenesis. HSC activation is also associated with additional changes in the pattern of gene expression. These include the synthesis of several modulators of ECM homeostasis that ultimately alter the delicate balance between matrix synthesis and degradation and lead to fibrosis.

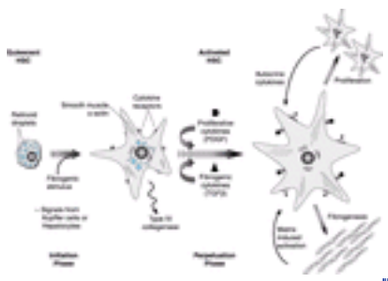

FIGURE 27-6. Hepatic stellate cell activation.

The stimuli that are responsible for HSC activation probably include signals derived from hepatocytes, Kupffer cells, and sinusoidal endothelial cells. The Kupffer cell plays a critical role in the development of liver fibrosis. Depletion of the Kupffer cell, the resident macrophage in the liver, with gadolinium chloride significantly reduces fibrosis in experimental animal models of fibrosis. [131] Endotoxin may be a key factor in the activation of the Kupffer cell. [132] Once activated, the Kupffer cell generates significant levels of ROIs. These molecules are believed to contribute to HSC activation either directly or through the generation of lipid peroxidation products. Antioxidants block HSC activation in oxidative stress conditions associated with high levels of ROIs. [133] TGF-ß, produced by activated Kupffer cells and activated HSCs, amplifies the fibrogenic response of the HSC. TGF-ß receptors on the cell surface are expressed by activated HSCs but not quiescent HSCs. [134] Autocrine stimulation of TGFß expression enhances activated HSC-mediated fibrogenesis. Expression of a fibronectin splice isoform that is expressed during early liver injury primarily by the sinusoidal endothelial cell can stimulate HSC activation. [73]

Two major events result in the HSC becoming a major contributor in liver fibrosis. These are the development of an active fibrogenic state and the amplification of the activated HSC population. Fibrogenesis is associated with an increased production of type I collagen as well as other ECM proteins and an increased production of TIMPs. Together, these changes in gene expression result in an imbalance of ECM biosynthesis, with a net increase in matrix deposition. The increased synthesis of type I collagen following HSC activation is caused by an increase in the transcriptional rate of the collagen genes, a stabilization of the collagen mRNA, and increased translation of the collagen mRNA. [9], [13], [14], [135] TGF-ß is a potent fibrogenic cytokine for the activated HSC. The activated HSC secretes TGF-ß and expresses TGF-ß receptors on the cell surface. This results in an autoregulatory loop to amplify matrix deposition. TGF-ß also increases the synthesis of other ECM constituents and decreases MMP expression. [120]

Amplification of the HSC population represents another major event in HSC activation that significantly contributes to the fibrogenic response. PDGF, the most potent proliferative cytokine known for the HSC, binds to a specific tyrosine kinase cell surface receptor. Binding of PDGF to its receptor initiates phosphorylation signaling cascades that leads to increased DNA synthesis and cell proliferation. PDGF activates the focal adhesion kinase (FAK)–phosphatidylinositol 3-kinase (PI3-K)–protein kinase B (AKT) signaling pathway transducing mitogenic signals for the cell and is critical for cellular chemotaxis. [136] PDGF also activates the ras-raf-MEK-ERK and MAPK-JNK signaling pathways transducing mitogenic signals for the cell. [137] PDGF also increases the migration of activated HSCs. [136]

Integrins also can activate the proliferative signaling pathway. The activated HSC responds to additional extracellular signals mediated through cell-matrix interactions. Depending on the composition of the ECM, different signals are transmitted into the cell that differentially regulate gene expression. Isolated HSCs grown on a basement membrane–like matrix, Matrigel, become activated at a much slower rate than cells grown on a type I collagen matrix or a plastic surface. [3] HSCs when grown on plastic increase collagen production and decrease collagenase production. [74], [138], [139]

The status of the extracellular environment is monitored by integrins, transmembrane proteins that associate with focal adhesion complexes. HSCs express a $_1$ß $_1$- and a $_2$ß $_1$-integrins on their cell surface. [28] These proteins sense the status of the extracellular environment and initiate signaling through the focal adhesion complex, a group of proteins that include FAK. Integrin binding to ECM components leads to integrin clustering, resulting in the activation of the focal adhesion complex that involves phosphorylation of FAK as well as other focal adhesion–associated proteins. Binding of a $_1$ß $_1$ to types I, III, and IV collagen activates the extracellular signal–regulated kinases 1 and 2 (ERK1, ERK2), which down-regulates type I collagen gene expression. [140] Another collagen receptor, discoidin domain receptor 2, is also expressed by activated HSCs. [141]

A key question surrounding the resolution of hepatic fibrosis is the fate of the amplified, activated HSC population. Recent evidence indicates that this cell population is cleared from the recovering liver by apoptosis. [78], [142] Nuclear factor-?B (NF-?B) expression protects the activated HSC from apoptosis. [143] Activation of PI3-K and AKT is also protective against apoptosis in several cell types.

MONITORING THE PROGRESSION OF FIBROSIS

The standard method to assess the degree of fibrosis and monitor its progression in patients is the liver biopsy. However, because this procedure is invasive and expensive and carries significant risk, noninvasive methods to assess the degree of fibrosis, especially the effects of antifibrotic treatment, are being explored. Several potential serum markers are being investigated, either singly or as a series, to monitor the level of fibrosis. These include collagen type IV, collagen type VI, collagen type XIV (undulin), the amino-terminal propeptide of collagen III (PIIINP), laminin, tenascin, hyaluronan, MMP-2, MMP-9 complexed with TIMP-1 (MMP-9/TIMP-1), and TIMP-1. Although not developed as a standard clinical test, increases in fibrosis correlate with serum levels of collagen IV, hyaluronan, TIMP-1, and PIIINP. [144]

ANTIFIBROTIC THERAPIES

Several stimuli are known to induce liver fibrosis (see Table 27-1). All these stimuli ultimately lead to activation of the HSC, resulting in a fibrogenic response. Therefore, therapeutic approaches to treat liver fibrosis directly may include (1) inhibiting HSC activation, (2) treating the consequences of HSC activation, and (3) inducing apoptosis of the activated HSCs (Table 27-2).

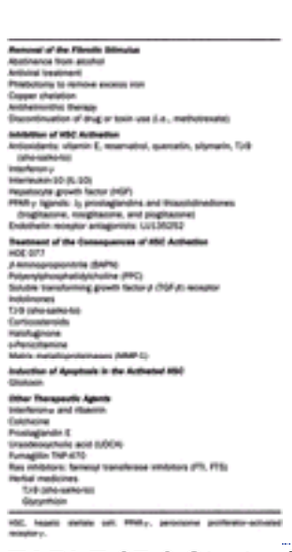

TABLE 27-2 Strategies for Antifibrotic Therapies

Because liver fibrosis is associated with HSC activation, a general approach to treat liver fibrosis may involve inhibiting activation of the HSC. Oxidative stress is associated with several animal models of liver fibrosis, including iron overload, CCl_4 intoxication, and excess ethanol administration. Oxidative injury causes injury to hepatocytes and other cells, resulting in the formation of ROIs that lead to the formation of lipid peroxidation products. Either ROIs or lipid peroxidation products can

interact with the HSC, resulting in cellular activation. Some antioxidants are efficient scavengers of ROIs. Vitamin E, the best-studied antioxidant, inhibits iron-induced fibrosis and decreases lipid peroxidation, HSC activation, and type I collagen gene expression. [145] Other antioxidants used to block oxidative stress include reservatrol, [146] quercetin, [146] silymarin, [147] and prostaglandin E_2. [148], [149] Sho-saiko-to (TJ-9), a traditional medicine composed of seven herbal components, has been used in Japan as a therapy for liver fibrosis. In vivo, TJ-9 has been shown to suppress fibrosis in animal models, and in cultured HSCs, TJ-9 inhibits cell activation and proliferation, and the oxidant burst. [150] Natural extracts are also being investigated for antifibrotic properties. In addition to TJ-9, glycyrrhizin, an extract of licorice root, has been shown to slow the progression of hepatitis C to hepatocellular carcinoma in animals and humans. [151] It is thought to inhibit I?B binding to the active NF-?B molecule.

Interferon-? inhibits HSC activation in culture and decreases ECM gene expression. In animal models of fibrosis, interferon-? decreases fibrosis induced by CCl_4 or schistosomes. IL-10 has also been shown to decrease fibrosis in patients with chronic hepatitis C who do not respond to interferon. Although no change in hepatitis C virus mRNA levels were noted, liver biopsy specimens showed decreased inflammation and fibrosis. [152] IL-10 probably decreases the proinflammatory helper T cell type 1 (Th1) response, leading to reduced fibrosis. Interestingly, a more severe fibrosis develops in IL-10 knock-out mice when they are challenged with a fibrogenic stimulus. Treatment of culture-activated HSCs with IL-10 also reduces type I collagen gene expression. [153] Colchicine and corticosteroids have been shown to inhibit fibrosis, probably by antiinflammatory mechanisms; however, the use of these drugs is controversial. [154]

Hepatocyte growth factor (HGF) is mitogenic for hepatocytes and other cell types. HGF is involved in hepatocyte development and regeneration and possesses anti-apoptotic activity in hepatocytes. In a rat animal model of liver cirrhosis induced by dimethylnitrosamine, administration of the human HGF gene into skeletal muscle induced high levels of circulating human and endogenous rat HGF. In addition, reduced levels of TGF-ß hepatocyte apoptosis, HSC activation, and fibrosis were noted, resulting in a complete resolution of cirrhosis and decreased mortality. [155]

Peroxisome proliferator–activated receptor-? (PPAR-?) represents another target for antifibrotic therapy aimed at inhibiting HSC activation. This nuclear receptor regulates gene expression associated with lipid metabolism. Although quiescent HSCs express PPAR-?, expression of PPAR-? decreases following HSC activation. Treatment of activated HSCs with PPAR-? ligands, prostaglandin J_2, and thiazolidinediones (troglitazone, rosiglitazone, and pioglitazone) restores PPAR-? expression and inhibits HSC proliferation and chemotaxis. A suppression of the activated phenotype, as assessed by decreased type I collagen and smooth muscle a-actin expression, occurs. [156], [157] and [158] Thus, PPAR-? ligands appear to inhibit HSC activation, leading to a decrease in the fibrogenic response.

Endothelin (ET) receptor antagonists may be another class of drugs with potential use as antifibrotic agents. Quiescent HSCs express primarily ET_A receptors, whereas activated HSCs express primarily ET_B receptors. [159] LU135252, an ET_A receptor antagonist, has been shown to decrease biliary fibrosis in the bile duct ligation animal model based on histological analysis, total liver collagen content, and mRNA expression for a $_1$(I) collagen, TIMP-1, and TIMP-2. [160], [161] and [162]

The complex biosynthetic pathway for type I collagen allows for multiple potential therapeutic targets (see Fig. 27-2). Prolyl 4-hydroxylase catalyzes the formation of hydroxyproline at every third amino acid, which is a specific posttranslational modification to the collagen chains that are required for the formation of a stable triple helical structure of collagen. Inhibitors of prolyl 4-hydroxylase include HOE077 and S4682. In animal models of fibrosis induced by CCl_4 treatment, a choline-deficient diet, or heterologous serum, simultaneous administration of HOE077 inhibited hydroxyproline content and histological liver fibrosis. HOE077 also inhibits stellate cell activation in culture [163] and in vivo. [163], [164] and [165] This may be the predominant mechanism for its antifibrotic effect. The potent and irreversible prolyl 4-hydroxylase inhibitor S4682 decreases hepatic fibrosis in the CCl_4 rat model, [166] with a concomitant decrease in morbidity, documented by improved liver function parameters and decreased ascites. Lysyl oxidase is responsible for cross-linking the secreted collagen triple helices in the extracellular space to form the characteristic collagen fibrils. This cross-linking protects the deposited collagen from nonspecific protease degradation. Expression of lysyl oxidase increases in cirrhosis. [167] A potent inhibitor of lysyl oxidase, ß-aminopropionitrile (BAPN), decreases the tensile strength of connective tissues; however, this drug is associated with skeletal deformities and aneurysms.

Polyenylphosphatidylcholine (PPC) can block collagen production and increase collagenase activity in cultured HSCs. [168] In vivo, PPC inhibits fibrosis in ethanol-induced fibrosis in baboons and in CCl_4-treated rats. [154] Because of the encouraging in vivo data, clinical trials are in progress. Halofuginone has also been shown to inhibit collagen production in thioacetamide-induced liver fibrosis in rats and may inhibit HSC activation. [169]

Activated HSCs are responsive to the fibrogenic cytokine TGF-ß and to the proliferative cytokine PDGF. A soluble TGF-ß receptor has been developed that consists of the extracellular portion of the TGF-ß type II receptor linked to human immunoglobulin G. Administration of the soluble TGF-ß receptor has been shown to significantly reduce experimentally induced liver fibrosis. [170] A group of compounds, indolinones, have been used to target the PDGF receptor. These compounds bind to the catalytic site of the PDGF receptor kinase, preventing downstream signaling. [171] A semisynthetic analog of fumagillin, TNP-470, inhibits the progression of fibrosis in both CCl_4- and dimethylnitrosamine-induced liver fibrosis by blocking cell cycle progression, thereby inhibiting HSC proliferation. [172]

The ECM is degraded by the MMP family of proteins, which have specific extracellular proteins as their substrates. Overexpression of MMP-1 (interstitial collagenase) can reduce collagen deposition following thioacetamide-induced fibrosis in the rat and thus represents another avenue for antifibrotic therapy. [173]

A final approach to treat liver fibrosis is to induce apoptosis in the HSC. In theory, this would lead to the reduction in the number of fibrogenic cells in the liver and consequently reduce ECM deposition. After a fibrogenic stimulus is removed in experimental cirrhosis, activated HSCs undergo apoptosis, not reversion to the quiescent phenotype. It has been shown that NF-?B, an inducible transcription factor, is protective against apoptosis in the HSC. [143] Therefore, blocking NF-?B activity should induce apoptosis in this cell. Accordingly, gliotoxin has been shown to inhibit NF-?B activity and induces apoptosis in the HSC. [174]

CHAPTER 28

Rebecca Taub

HEPATIC REGENERATION

The liver exhibits unusual properties of regeneration after partial hepatectomy or toxic injury. This evolutionarily conserved response is a logical adaptive response of organisms because the liver is the major detoxifying organ of the body and first in line to be injured by ingested toxins. Partial hepatectomy, the model that most clearly demonstrates the regenerative capacity of the liver, was first described by Higgins and Anderson in 1931. [1] It has been noted that after a partial hepatectomy in which two thirds of a rodent liver, including the left lateral and medial lobes, is removed intact, the remnant liver enlarges until the mass of the liver is restored, whereupon the process stops. [2], [3], [4], [5], [6] and [7] The mass of liver is reconstituted within 7 days, most recovery occurring within 3 days, whereupon the cells again become quiescent. Recovery from toxic liver damage and recovery from hepatitis require similar types of hepatic regeneration, the major difference from hepatectomy being that these insults cause hepatic necrosis and apoptosis. Central questions about the process of liver regeneration remain, including the following (1) What signals trigger the early events in regeneration? (2) How are the architecture and function of the liver retained during regeneration? and (3) What signals are responsible for turning off the growth response once the mass of the liver is reconstituted? Using molecular-cellular approaches and genetic animal models, investigators have begun to dissect the critical factors and identify the important regulatory proteins that control this process. [8]

Many growth factors, including hepatocyte growth factor (HGF), epidermal growth factor (EGF), transforming growth factors (TGFs), insulin, glucagon, and cytokines (tumor necrosis factor [TNF-a], interleukin-1 [IL-1], and interleukin-6 [IL-6]), have been implicated in regulating this process, but the mechanisms remain poorly understood. Thus, both cytokine-dependent and -independent pathways are critical for liver regeneration (Fig. 28-1).

FIGURE 28-1. Model for growth factor pathways postulated to regulate liver regeneration after injury or partial hepatectomy. Proposed model of growth factor and cytokine activation of transcriptional cascade and DNA synthesis during liver regeneration. After partial hepatectomy, either gut-derived cytokines or cytokines released de novo activate hepatic nonparenchymal cells, resulting in increased production of tumor necrosis factor-a (TNF-a), interleukin-1 (IL-1), and IL-6. Cytokines and growth factors are responsible for the activation of nuclear factor-?B (NF-?B), signal transducer and activator of transcription-3 (STAT3), and perhaps CCAAT/enhancer-binding protein-ß (C/EBP-ß) and other factors in remnant hepatocytes. As a result of the activation of these hepatocyte transcription factors, the primary growth-response program (immediate-early genes, glucose regulation) is initiated, finally leading to DNA synthesis.

Liver regeneration plays an important role in several clinical settings. For the most part, these settings involve instances in which liver cells have actually been damaged. Animal models in which hepatocytes are directly damaged (galactosamine, carbon tetrachloride [CCl_4] treatment) result in regeneration of the liver, but in addition to mature undamaged hepatocytes, which participate in the process, progenitor cells are recruited. [9] In humans, understanding liver regeneration will help explain how the liver responds to toxic damage by agents such as alcohol and acetaminophen in overdose, or infections like hepatitis. Additionally, increasing numbers of liver transplants are being performed, including living related donor and small-for-size transplants. Successful transplants require at least some liver regeneration and repair, and it is essential to understand the biologic and molecular bases for liver cell growth.

BASIC CHARACTERISTICS OF LIVER REGENERATION

The most commonly studied model of liver regeneration is the two-thirds partial hepatectomy model in rodents. In the partial hepatectomy model of liver regeneration, remnant liver cells are not injured because there is no wound or site of injury. The word *regeneration* is a misnomer because the lobes of the liver that are removed do not grow back, unlike the limbs in amphibian models. Instead, a hyperplastic response occurs that involves the replication of virtually all the cells in the remnant liver. Thus, in this model, liver regeneration does not require the recruitment of progenitor cells, but it involves replication of the mature functioning cells of the liver. Once the mass of the liver has been reestablished, proliferation stops. The process is compensatory because the size of the resultant liver is determined by the demands of the organism.

Cell division is rarely seen in hepatocytes in the normal adult liver, which are considered to be in the G_0 phase of the cell cycle. [2], [4] It has been shown that after partial hepatectomy, approximately 95% of hepatic cells that are normally quiescent rapidly reenter the cell cycle. In the rat liver, the rate of DNA synthesis in hepatocytes (S phase) begins to increase after about 12 hours and becomes maximal at about 24 hours. The induction of DNA synthesis occurs later in nonparenchymal liver cells. Subsequent cycles of DNA synthesis are decreased because complete restoration of liver mass requires only 1.6 cycles of DNA synthesis in all cells. In the mouse liver, the peak in DNA synthesis is later, 36 to 40 hours, and somewhat variable between strains. The onset of DNA synthesis is well synchronized and proceeds in a portal to central direction in hepatocytes. The incidence of mitosis (M phase) is lower than predicted based on the number of hepatocytes undergoing DNA synthesis. The general belief is that the ploidy of liver cells and percentage of binucleated cells change with rounds of DNA synthesis. [10] However, studies have shown that hepatocytes have incredible replicative function. In hepatocyte transplantation studies, only a few hepatocytes are required to restore the liver mass completely. [11], [12] The nonparenchymal liver cells, which constitute approximately 40% of liver cells, undergo DNA replication later: Kupffer cells, 48 hours; endothelial cells, 96 hours; biliary epithelial cells, 48 hours. Most of the increase in liver mass is seen by 3 days, and mass restoration is complete in 5 to 7 days. [13]

Liver regeneration following massive hepatocyte necrosis or apoptosis induced by hepatic toxins such as CCl_4 or Fas ligand also involves the proliferation of hepatocytes, but the cell cycle response is not as synchronized. As would be expected, dramatic changes in liver architecture take place during liver regeneration, whether after partial hepatectomy or liver necrosis. Induction of novel forms of fibronectin, cell adhesion proteins, and other basement membrane proteins is observed. Changes in gap junctions occur transiently, and re-formation of the normal architecture occurs after the restoration of mass. Little is known about the regulation of the complex process of reorganization of liver architecture.

Replicative Potential of Hepatocytes

Partial hepatectomy induces replication of 95% of the hepatocytes in the liver. However, only one to two rounds of replication are required for complete restoration of liver mass. These studies do not explore the full replicative potential of hepatocytes. Studies in which hepatocytes are serially transplanted into recipient damaged livers have clearly demonstrated that at least some populations of hepatocytes have a very high replication capacity, not unlike that of stem cells in other tissues. Original studies in urokinase plasminogen activator transgenic mice estimated that repopulation of the liver could be achieved by a small number of transplanted hepatocytes undergoing 12 to 18 rounds of replication. [11], [14] Subsequently, in another liver injury model caused by tyrosinemia, it was found that serial transplantations of hepatocytes resulted in at least 69 cell doublings, a massive expansion of cells equivalent to that of hematopoietic precursor cells. [12]

Apparently, the replicative capacity of hepatocytes is in part regulated by the ability of hepatocyte chromosomal telomeres to remain in a replication-competent state. Mice with mutations in the telomerase RNA (mTR) gene as a consequence of gene knock-out are normal. [15] However, after six generations, telomerase dysfunction occurs and affects highly proliferative tissues such as bone marrow and gut. Liver development is normal in these mice. When crossed with the Alb-UPA transgene that causes increased hepatocyte turnover, late generation mTR-/- livers fail to provide sufficient replicative hepatocytes to overcome the high hepatocyte turnover. Increased hepatocyte apoptosis is also observed. After partial hepatectomy, mTR-/- livers demonstrate delayed regeneration and reduced progression through mitosis because of the formation of aberrant mitotic spindles.

In response to certain types of injury, normal hepatocytes are unable to replicate. In cases in which agents such as dipin, retrorsine, or galactosamine have diminished the replicative capacity of most normal hepatocytes, a population of cells termed *oval cells* that are found in ductular regions proliferate to replace the hepatic parenchyma. [16] Studies suggest that even these oval cells may be derived from hepatocytes that have somehow escaped the injury. [17] Other liver repopulation and transplantation studies suggest that bone marrow stem cells may have the capacity to differentiate along hepatocyte lineages. [18] It is not clear whether transition from a bone marrow precursor into a hepatocyte is a rare event or the means by which the liver replenishes its hepatocyte pool in the face of certain types of injury.

MECHANISMS OF LIVER REGENERATION

Experiments performed by Moolten and Bucher [19] provided the first evidence that circulating growth factors are present in the serum of hepatectomized rats that induce hepatocyte replication in parabiosed nonhepatectomized animals. Much of the early work into the initiating signals of liver regeneration focused on isolated hepatocytes in which hepatocyte growth factors were first identified. These studies led to the identification of several potential hepatocyte growth factors, such as HGF and TGF, and antiproliferative factors, such as TGF-ß, that might have important roles in regulating hepatocyte growth during liver regeneration. However, it was difficult to prove that any of these factors had a critical role in liver regeneration itself. Molecular studies involving the analysis of gene expression cascades in the regenerating liver began to provide insights into signaling pathways that are rapidly activated in the remnant liver after hepatectomy. Specific transcription factors, such as nuclear factor-?B (NF-?B), signal transducer and activator of transcription-3 (STAT3), AP-1, and others, were shown to be activated in remnant hepatocytes rapidly, within minutes after a partial hepatectomy. The finding of activated transcription factors provided clues to the presence of cytokine-dependent (TNF-a, IL-6) and -independent (HGF, TGF, and unknown) pathways that might be important regulators of the regenerative response. [3], [6], [7] However, which of the many signals and induced gene products are critical for liver regeneration is not apparent from the large array of activated gene products.

Regeneration studies performed in mice harboring gene knock-outs have highlighted the importance of specific genes (Table 28-1). [8], [20], [21], [22], [23], [24], [25] and [26] Unfortunately, knock-out of some of the genes of greatest interest resulted in embryonic lethality. For example, HGF, c-Jun, and NF-?B/p65 are all required for normal liver development, and therefore studies of regeneration in these models are not possible. Nonetheless, the finding of apoptosis in the developing liver in these gene knock-outs provides evidence for the critical importance of these proteins in the liver. In the case of HGF, this is particularly frustrating because HGF has long been felt to be a critical regulator of liver regeneration. [2] It has been difficult to demonstrate that HGF is active during the initial phases of regeneration. Studies indicate that treatment with HGF promotes regeneration and hepatocyte proliferation and that it reduces hepatic apoptosis and fibrosis and CCl_4-mediated injury. [27], [28] Ultimately, other models in which HGF or Met receptors are conditionally eliminated from the liver after birth will allow for an assessment of the requirement for HGF during regeneration.

Gene deletions in mice that result in either abnormal liver development or defective liver regeneration:

Defective Liver Development
HGF
p65/TNF-a-ß
c-Jun
XBP-1
Defective Liver Regeneration
IL-6
TNFR1
iNOS
CREM
C/EBP-ß
Keratin-8
Plasminogen
Telomerase

C/EBP, CCAAT/enhancer-binding protein; CREM, cAMP regulatory element; HGF, hepatocyte growth factor; IL-6, interleukin-6; iNOS, inducible nitric oxide synthase; NF-a-B, nuclear factor-a-B; TNF, tumor necrosis factor; TNFR1, tumor necrosis factor receptor type 1.

TABLE 28-1 Mouse Genetics: Defining Molecular Pathways in Liver Development and Regeneration

Several of the gene knock-out models showing impaired liver regeneration involve cytokine-dependent pathways. For example, it appears that TNF-a is required for the induction of IL-6 after partial hepatectomy, and inducible nitric oxide synthase (iNOS), which helps prevent liver injury after hepatectomy, is a possible target gene of these cytokines. [20], [21], [26] TNF-a, IL-6, and normal iNOS regulation are all required for normal liver regeneration. The availability of mutant mice that are deficient in specific subunits of NF-?B makes it possible to directly test the significance of NF-?B during liver regeneration. It has been shown that mice that are missing the NF-?B/p65 gene through gene targeting die during embryogenesis, apparently because of the sudden death of hepatocytes at approximately 15 days of gestation. [29] The regenerative response of p50-deficient mice is largely normal because of a compensatory increase in the level of the NF-?B/p65 subunit as a consequence of reduced levels of the inhibitor I?B-a. [30]

CCAAT/enhancer-binding protein-ß (C/EBP-ß), a leucine zipper transcriptional factor that is considered to be a cytokine-regulated factor, is also required for normal liver regeneration. [22] How the activity of C/EBP-ß is regulated by extracellular signals after hepatectomy is not known. There is some support for the hypothesis that the relative levels of pro-proliferative forms of C/EBP-ß are important in supporting liver growth and balance antiproliferative forms and C/EBP-a, an antiproliferative factor. Interestingly, as described below, C/EBP-ß regulates a set of genes after hepatectomy distinct from those regulated by IL-6. [3] By examining which gene expression pathways are altered in each of the knock-out mouse models, it will ultimately be possible to determine the development of the various signal transduction pathways that lead to liver regeneration.

Induction of Primary Growth-Response Genes and Latent Transcription Regulatory Proteins

One way to address the central questions about the process of liver regeneration is by determining the critical molecules that regulate this process. Therefore, a number of studies were performed to determine what genes are expressed de novo in the remnant liver at the onset of liver regeneration. [31], [32] The cells in the normal liver are in the quiescent, nonproliferative G_0 phase of the cell cycle (see Fig. 28-1). Within minutes after a partial hepatectomy, in response to signals that initiate liver regeneration, these cells reenter the cell cycle in the G_1 phase. When this happens, signals transmitted to the nuclei of the liver cells result in transcriptional activation of primary growth-response genes, or “immediate-early genes.” [33], [34], [35], [36] and [37] Many of these genes (e.g., fos, myc, jun) encode proteins that have been identified as “protooncogenes” because somatic mutations or overexpression of these genes can lead to malignant transformation. In an unmutated form, these proteins are important for normal cell growth and cell cycle progression. Because many immediate-early genes encode proteins that are important for cell growth control, one can imagine how expression of the genes results in a cascade of events leading to DNA synthesis (S phase) and cellular division.

Several years ago, it was shown that more than 70 growth-response genes are activated in the remnant liver during the early stages of liver regeneration, [31], [38] and

that number has been expanded during subsequent years to more than 100. [39] In most cases, these genes are not expressed in the normal liver. However, within minutes to hours of a partial hepatectomy, the level of their expression in the remnant liver increases dramatically. Examination of the temporal course of expression of genes whose expression is activated during liver regeneration defined the boundaries between proliferation and cessation of growth (Fig. 28-2). In these studies, the genes themselves become “reporters” because the fact that they are being expressed indicates that growth-regulatory signals are being transmitted within the remnant liver cells. During regeneration, the major growth period of the liver ends at 60 to 72 hours after hepatectomy, when the liver has already more than doubled in size. There are two major patterns of growth-regulated gene expression. In the rat regenerating liver, *growth-regulated genes* demonstrate elevated expression throughout the entire growth phase, and expression returns to normal after about 3 days. *Cell cycle–regulated genes* show a sharp peak of expression that coincides with the G_1 phase of the hepatocyte cell cycle, including the first round of replication, and a second smaller round of replication that occurs 48 hours after the partial hepatectomy.

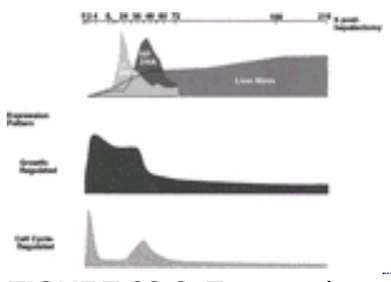

FIGURE 28-2. Temporal course and representative patterns of regulated gene expression during rat liver regeneration. The pattern of gene expression is indicated for growth-regulated genes (e.g., ß-actin) and cell cycle–regulated genes (e.g., insulin-like growth factor binding protein-1 [*IGFBP-1*]). Expression after the growth phase (CCAAT/enhancer-binding protein-a [C/EBP-a]) occurs when the gene is down-regulated during the period of maximal growth (not shown). Hours after partial hepatectomy and patterns of DNA synthesis in hepatocytes (*H*) and nonparenchymal cells (*NP*) and reaccumulation of liver mass [30] are indicated.

Not all these genes are immediate-early genes. A number of genes are first expressed a few hours after the initial induction of immediate-early genes. Termed *delayed-early genes,* these genes are regulated at a transcriptional or posttransciptional level by products of the immediate-early gene. In this way, a cell cycle regulatory cascade of gene and protein expression allows cells to progress through the G_1 phase of the cell cycle. Ultimately, changes in levels of cyclins and their regulatory kinases, the cyclin-dependent kinases (CDKs), by both transcriptional and posttranscriptional regulation allow for transition through the late phases of G_1 (D cyclins, CDK4, CDK6) into the S phase (cyclin E, CDK2) and later phases of the cell cycle (cyclin A, cyclin B). [40] Cyclin D/CDK4 complexes are important for progression beyond a late G_1 restriction in part because they phosphorylate retinoblastoma (RB) and E2F factors. The cyclin-associated inhibitors p21 and p27 are likely to be important for both progression through the cell cycle and inhibition of unregulated cell proliferation.

Rapid Activation of Latent Transcription Factors

In addition to the contribution of the liver-specific transcription factors in modulating liver function and growth in the regenerating liver, several transcription factors are activated de novo in the remnant liver. Of particular interest are those factors that are latent in normal liver cells and activated within minutes after the partial hepatectomy by the earliest signals that trigger regeneration. In other words, these proteins or transcription factors are activated in the first few minutes after hepatectomy by posttranslational modifications. Unlike immediate-early genes or primary growth-response genes, they are not activated by new mRNA synthesis and translation. In fact, these transcription factors actually turn on the transcription of the primary growth-response genes. Investigators reasoned that understanding the signal transduction pathways responsible for the activation of such transcription factors would provide insight into what growth factor and cytokine signals trigger liver regeneration.

For example, two different DNA binding complexes, NF-?B and STAT3, are present in an inactive form in the normal liver. [41], [42], [43] and [44] Both are downstream of cytokine signaling pathways. They are activated within minutes to hours after hepatectomy in the remnant liver cells, thus enabling these factors to turn on the expression of the primary growth-response genes. Because these factors are activated by the earliest signals that trigger liver regeneration, understanding the mechanism by which they are activated has provided clues to the initiating signals. These factors are not turned on in all growing cells, and therefore they could account for some liver-specific aspects of growth in the regenerating liver.

NF-?B is a transcription factor complex that forms when a 50-kd protein subunit and a 65-kd protein subunit unite to form a transcriptional complex in the nucleus of the cell. [45] Normally, the p65 subunit resides in the cytoplasm of hepatocytes in an inactive form bound to its inhibitor I?B-a (Fig. 28-3). After a partial hepatectomy, a signal that may be generated by a variety of growth factors and cytokines, including TNF-a, IL-1, and others, results in the dissociation of I?B-a from p65. This occurs because the I?B kinase (IKK) complex phosphorylates I?B-a, thereby leading to its degradation and release from p65. [16] Phosphorylation of p65 also occurs, and the net effect is that the p65 is free to move into the nucleus of cells, where it can complex with the p50 subunit, forming an active NF-?B transcription complex. This leads to the transcriptional activation of genes that are controlled by a ?B DNA binding site in their promoter. During liver regeneration, the signal leading to NF-?B activation occurs within a few minutes after the partial hepatectomy and is gone by 1 to 2 hours, when NF-?B levels are again virtually undetectable. In the regenerating liver, activation of NF-?B occurs in hepatocytes, but it may also occur in nonparenchymal cells, such as Kupffer and endothelial cells, that also have receptors for various cytokines.

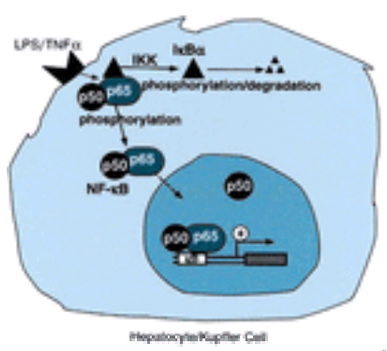

FIGURE 28-3. Model of nuclear factor-?B (NF-?B) activation in the hepatocyte and Kupffer cell after hepatectomy. Several different cytokines (transforming growth factor-a [TNF-a]) and LPS released into the portal circulation from the intestine signal via their extracellular receptor, resulting in phosphorylation by I?B kinase complex (IKK) and degradation and dissociation of I?B-a from cytoplasmic p65/p50. Subsequently, free, newly phosphorylated p65/p50 moves into the nucleus, where it is able transactivate target genes.

Another class of transcription factors that is rapidly activated in the remnant liver after a partial hepatectomy is the STAT family. These factors were first discovered as part of the intracellular response to a variety of different extracellular signals mediated by interferons, cytokines, and growth factors. [46], [47] However, the STAT factor that is specifically activated in the regenerating liver is STAT3, which has been shown to be induced in liver cells by IL-6, LPS (an endotoxin, probably via IL-6 activation), and EGF (Fig. 28-4). [3], [48], [49] After one of these factors is bound to its receptor, a Janus tyrosine kinase (JAK) is activated. This kinase phosphorylates the STAT3 factor on a specific tyrosine residue, resulting in its nuclear translocation and the ability to transactivate target genes.

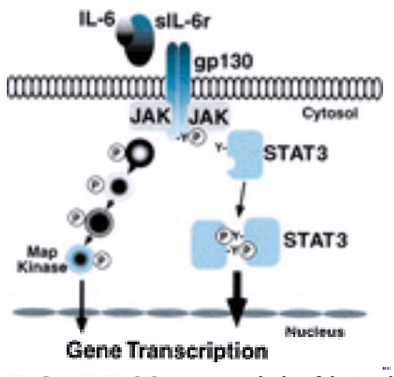

FIGURE 28-4. Model of interleukin-6 (IL-6) signaling. IL-6 binds to its soluble receptor complexed with the gp130 receptor. This results in the activation of a tyrosine kinase in the Janus kinase (JAK) family that phosphorylates cytoplasmic signal transducer and activator of transcription-3 (STAT3). Phosphorylated, dimerized STAT3 moves into the nucleus, where it is able to bind to and transactivate target gene promoters, resulting in increased gene transcription. IL-6 is also able to signal via the mitogen-activated protein kinase (MAPK) pathway.

During liver regeneration, the activation of STAT3 is quite dramatic, although later and more prolonged than NF-?B activation, showing peak activity between 1 and 3 hours and continued activity as late as 8 hours after hepatectomy. [20], [41] During liver regeneration, the major cytokine responsible for activating STAT3 is IL-6. The STAT3 response is specific for liver regeneration because little STAT3 activation is seen following sham surgery. STAT transcription factors are potent transcriptional activators that can both directly and indirectly lead to transcriptional activation of a large number of genes. Many of these genes, such as jun and fos, themselves encode transcription factors that make up part of the AP-1 complex. AP-1 activity is also induced early during liver regeneration, in part via new protein synthesis and in part via activation by early signals such as TNF-a. One may imagine that if STAT3 plays a role in the activation of these factors, it may be initiating a transcriptional cascade within the regenerating liver that ultimately leads to transition through G_1 and entry into S phase. Mutant mice that contain gene deletions for NF-?B, IL-6, and TNF receptors and conditional STAT3 knock-outs allow the significance of STAT3 and NF-?B activation during liver regeneration to be tested.

LIVER FUNCTION DURING LIVER REGENERATION

Interplay between Hepatic Transcription Factors and Growth-Induced Transcription Factors

The liver is a vital organ and must continue to function as its cells proliferate during liver regeneration. In most cells, such as the hematopoietic lineages, proliferation is not compatible with differentiated function. How the liver is able to function while undergoing regeneration is an important question in liver biology. By examining the immediate-early gene response in the regenerating liver, it was possible to find clues to how the liver is able to function as it regenerates. Although many immediate-early genes are expressed in common in the regenerating liver and other growing cells, approximately one third of the genes are expressed at a high level or specifically in growing liver cells. Both hepatocytes and the nonparenchymal cells of the remnant liver express most of these genes, but the expression of a subset of genes is limited to hepatocytes. [38] Several of these liver-restricted immediate-early genes encode proteins that are involved in the gluconeogenic response of the liver.

The induction of gluconeogenic genes represents an adaptive response of the liver whereby the remnant liver that comprises only one third of the original mass compensates by producing enough glucose for the whole organism. Liver-specific transcription factors have an important role in determining the level of liver-specific functions, including glucose production. They act by regulating the expression of genes encoding liver-specific enzymes (e.g., metabolic enzymes) and liver-specific secreted proteins (e.g., albumin). The adaptive response of the liver during regeneration that allows for the maintenance of metabolic homeostasis is accomplished by an interplay between growth-induced transcription factors and preexisting liver-specific transcription factors that regulate the differentiated functions of the hepatocyte.

After hepatic injury or stress, gluconeogenic and acute phase response genes are rapidly up-regulated to restore metabolic homeostasis and limit tissue damage. The gluconeogenic genes encoding phosphoenol pyruvate carboxykinase (PEPCK) and glucose 6-phosphatase (G6Pase) are induced, [50], [51] while, as others have noted, [52] the genes encoding proteins that oppose gluconeogenesis (glucokinase) are down-regulated during liver regeneration. This parallels acute hormonal changes that occur in the regenerating liver when insulin levels rapidly fall and glucagon levels increase. [53] Glucokinase is induced by insulin and down-regulated by glucagon; PEPCK and G6Pase show the opposite regulation.

In addition, regulation of the liver-restricted insulin-like growth factor binding protein-1 (IGFBP-1) gene is dramatically altered by changes in the metabolic state and hepatectomy in a manner analogous to that of the gluconeogenic genes. IGFBP-1 mRNA is induced more than 100-fold in the regenerating liver and also induced at a high level during fasting and insulin deficiency. [54] The IGFBP-1 gene thus provides an appropriate reporter to assess the transcriptional milieu that leads to activation of gluconeogenic genes during regeneration. Normally, the IGFBP-1 gene in the liver is regulated in the basal state by hepatic nuclear factor-1 (HNF-1), a homeodomain containing hepatic transcription factor that plays a prominent role in the regulation of many hepatic genes. The level of HNF-1 does not change appreciably during liver regeneration. During liver regeneration, IL-6 is in part responsible for induction of the IGFBP-1 gene. [55] This up-regulation is accomplished by physical interactions between growth-induced IL-6–regulated transcription factors, STAT3 and AP-1 (c-Fos, c-Jun), and the resident hepatic transcription factor, HNF-1. Activation by this complex of transcription factors is mediated through the HNF-1 DNA binding site immediately upstream of the IGFBP-1 promoter site (Fig. 28-5). [55] Similar regulation is observed when G6Pase and a-fibrinogen promoters are used, indicating that HNF-1/IL-6/STAT3/AP-1–mediated transactivation of hepatic gene expression is a general phenomenon after liver injury. These results demonstrate that the two classes of transcription factors, growth-induced (STAT3 and AP-1) and tissue-specific (HNF-1), can interact as an adaptive response to liver injury to amplify the expression of hepatic genes important for the homeostatic response during organ repair. In this way, the liver is able to maintain metabolic function despite the loss of two thirds of its functional mass.

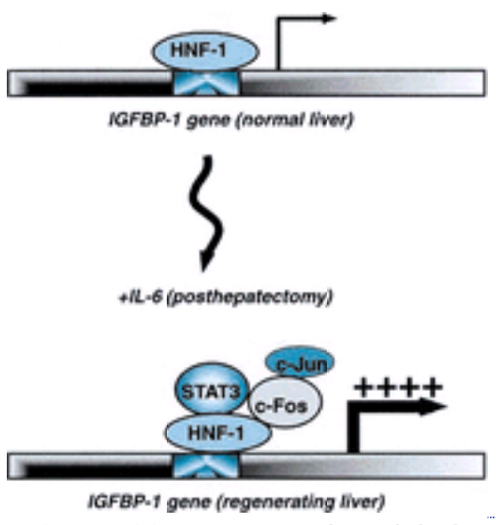

FIGURE 28-5. Proposed model of cooperative interaction between a growth-induced (c-Fos, c-Jun, signal transducer and activator of transcription-3 [STAT3]) and constitutive (hepatocyte nuclear factor-1 [HNF-1]) hepatic factor to up-regulate the level of a liver-specific target gene (insulin-like growth factor binding protein-1 [IGFBP-1]) after hepatectomy.

Regulation of Liver-Specific Transcription Factors

The levels of many hepatic transcription factors remain unchanged after partial hepatectomy, and this continued expression provides the regenerating liver with some of its maintained functional capacity. [56], [57] However, the liver-restricted transcription factors C/EBP-a (CCAAT/enhancer-binding protein) and C/EBP-ß show inverse

regulation during liver regeneration, so that the less antiproliferative form C/EBP-ß is relatively up-regulated and antiproliferative C/EBP-a is down-regulated during the phase of rapid liver growth. C/EBPs (including C/EBP-a and C/EBP-ß) are leucine zipper transcription factors that bind as homodimers or heterodimers to the recognized DNA sequence in the promoter of some liver genes, such as albumin, PEPCK, and many others. [58], [59], [60], [61], [62] and [63] The importance of C/EBP-a in controlling gluconeogenic genes was established by the finding that mice that are genetically missing the gene for C/EBP-a die at birth of hypoglycemia because of a lack of expression of PEPCK, G6Pase, and perhaps other metabolic enzymes. [64], [65] This finding directly connects C/EBP-a to the regulation of these genes. However, the C/EBPs have also been shown to have an antiproliferative effect, particularly C/EBP-a. [6], [22] Thus, during liver regeneration, an apparent paradox occurs because of the simultaneous need for gluconeogenic gene expression positively controlled by C/EBP-a and proliferation that is opposed by C/EBP-a. How is this accomplished?

During liver regeneration, an inverse regulation of C/EBP-a and C/EBP-ß proteins results in up to a sevenfold increase in the a/ß DNA binding ratio between 3 and 24 hours after hepatectomy that may have an important impact on target gene regulation. [62] However, total C/EBP binding activity in the remnant liver cell nuclei remains relatively constant during the 7-day period after hepatectomy. Both differentiation-specific liver functions and proliferation coexist in the same liver cells. This is unusual because in most cell types, growth and differentiation are uncoupled and mutually exclusive. The persistent expression of C/EBP-a and C/EBP-ß isoforms predicts that C/EBP proteins contribute to the function of hepatocytes during physiological growth, and that significant amounts of these proteins do not inhibit the progression of hepatocytes into S phase of the cell cycle. The importance of the induction of C/EBP-ß during liver regeneration was further demonstrated by studies in which C/EBP-ß-/- mice were subjected to partial hepatectomy (see below); it was shown that C/EBP-ß is important for the regenerative response and the expression of some cell cycle regulatory genes and proteins.

CYTOKINE-DEPENDENT AND -INDEPENDENT PATHWAYS IN REGENERATION

Both NF-?B and STAT3 are frequently activated in cells by cytokines. Cytokines bind to their cellular receptors and generate intracellular signals that lead to transcription factor activation. [66] The finding that these transcription factors are induced during liver regeneration raised the interesting possibility that cytokines released after a partial hepatectomy either from the gut or from neighboring Kupffer and other liver nonparenchymal cells may act on hepatocytes to stimulate the activation of the latent NF-?B and STAT3 transcription factors. C/EBP-ß, which increases during liver regeneration, has also been linked to activation by cytokines. [67], [68]

Studies linking cytokines, particularly TNF-a, IL-1, and IL-6, to liver regeneration were relatively limited before studies in knock-out mice demonstrated a requirement for TNF-a and IL-6 in the regenerative response. [69], [70] Other studies suggested that circulating endotoxin LPS derived from the gut increases after a partial hepatectomy, and that animals that have been rendered germ free or that are deficient in the LPS response demonstrate blunted liver regeneration. [40] However, high levels of these cytokines, seen in CCl_4-induced liver damage or sepsis, may actually be detrimental to liver function and recovery. [71] The well-modulated levels of cytokines seen following partial hepatectomy are necessary for normal liver regeneration, and the excessive levels of cytokines seen in pathological processes may lead to liver damage. [72]

Normal liver regeneration after partial hepatectomy requires the IL-6 cytokine (see model, Fig. 28-1). [20] After partial hepatectomy, IL-6-/- livers exhibit impaired liver regeneration, characterized by liver necrosis and failure, a blunted DNA response in hepatocytes, and discrete G_1 phase abnormalities, including absence of STAT3 activation and selective abnormalities in gene expression. Treatment of IL-6-/- mice with a single preoperative dose of IL-6 returns STAT3 binding, gene expression, and hepatocyte proliferation to near normal and prevents liver damage, establishing IL-6 as a critical component of the regenerative response after partial hepatectomy. Most of the actions mediated by IL-6 occur within the first few hours after hepatectomy and lead to progression through the early to middle phases of G_1 and ultimately to DNA synthesis and mitosis. TNF-a signaling is also required for a normal proliferative response after hepatectomy, and this effect appears to be mediated largely by the ability of TNF-a to induce IL-6. [21] Specific cell cycle progression pathways and patterns of induced gene expression are dependent on IL-6, whereas others are normal in the absence of IL-6. [39]

To determine the percentage of immediate-early genes regulated by IL-6 after partial hepatectomy, the gene expression program in the IL-6+/+ and IL-6-/- livers at 2 hours after hepatectomy was examined with a cDNA array representing 588 highly regulated mouse genes. [39] Thirty six percent of the 103 immediate-early genes are induced differently in IL-6+/+ and in IL-6-/- livers, implying IL-6 regulation. IL-6 treatment of the IL-6-/- mice in the absence of hepatectomy induces a much smaller set of genes in the liver, suggesting that IL-6 cooperates with other hepatectomy-induced factors to activate the large number of genes. The mitogen-activated protein kinase (MAPK) pathway is activated in IL-6+/+ livers early during regeneration but is remarkably delayed in IL-6-/- livers. This pathway has been shown to be critical for cell growth in general and for liver regeneration specifically. [73] Defective liver regeneration may be explained by the large number of gene activation pathways altered in IL-6-/- livers and further supports the finding that IL-6 is necessary for normal liver regeneration. However, IL-6 is not a complete growth factor in that it does not stimulate much hepatic proliferation in the absence of hepatectomy. Therefore, other pathways must be activated in addition to the IL-6/TNF-a pathway for regeneration to proceed normally.

Both C/EBP-ß and IL-6 are involved in cytokine activation pathways during the acute phase response in the liver, and IL-6 is increased in the cytokine activation network in liver regeneration. As in IL-6-/- livers, regeneration is impaired in C/EBP-ß-/- livers, but the genes and pathways affected are distinct from those regulated by IL-6. [22] The mechanism by which C/EBP-ß is activated and induced during liver regeneration remains unknown. In some early studies, it was felt that IL-6 regulated the level of the C/EBP-ß leucine zipper transcription factor, and conversely, that C/EBP-ß was important for the induction of IL-6. Studies of C/EBP-ß-/- and IL-6-/- animals indicated no positive correlation between IL-6 and C/EBP-ß levels. In fact, IL-6 levels are elevated in C/EBP-ß-/- animals. [22] Moreover, some genes are induced relatively normally in both C/EBP-ß-/- and IL-6-/- livers after hepatectomy, further indicating the complexity of the regenerative response.

Both C/EBP-ß-/- and IL-6-/- mice show impaired responses after hepatectomy characterized by a DNA synthetic defect. The defect in IL-6-/- livers is more severe in that the animals exhibit increased morbidity and mortality and evidence of liver necrosis. Mass restitution occurs but is delayed in IL-6-/- animals that survive the surgery, whereas liver mass restitution is not impaired in C/EBP-ß-/- livers. Mass restitution largely occurs as a function of progression through the G_1 phase of the cell cycle and may not be different in livers that show primarily a defect in S phase entry, as in the C/EBP-ß-/- livers. [74] In IL-6-/- livers, all these defects can be corrected by a single dose of IL-6. On the other hand, treatment of C/EBP-ß-/- animals after hepatectomy with IL-6 actually worsens the outcome; the animals become ill. This result is compatible with the observation that C/EBP-ß-/- animals actually have elevated levels of IL-6, and the hypothesis that C/EBP-ß and IL-6 mediate their effects through largely nonoverlapping intracellular signals.

These differences are particularly well demonstrated by examining the genes that are expressed differently in IL-6-/- and C/EBP-ß-/- livers after hepatectomy. A number of the same genes have been examined in the two animal models. The only gene that shows reduced induction in both models is SAP, an acute phase gene that is known to be regulated by both IL-6 and C/EBP-ß. [75] For example, IL-6-/- livers show particular defects in genes encoding AP-1 DNA binding proteins (c-fos, JunB, LRF-1) and c-myc. These transcription factors are purported to be important for the regulation of cyclin D_1 expression, which is predictably abnormal in IL-6-/- livers. On the other hand, AP-1, c-myc, and cyclin D_1 genes are normally induced in C/EBP-ß-/- livers. Gluconeogenic genes are normally regulated in IL-6-/- livers but not in C/EBP-ß-/- livers, in which they are elevated to compensate for the hypoglycemia. The HGF gene has been shown to be regulated by both IL-6 and C/EBP-ß in vitro, [76] but normal induction of HGF mRNA is observed in both IL-6-/- and C/EBP-ß-/- livers. Unique among the genes that were studied is PRL-1, which shows normal induction in both C/EBP-ß-/- and IL-6-/- livers after hepatectomy.

Gene expression studies have helped determine which aspects of hepatic regeneration are independent of cytokine activation pathways involving IL-6, TNF-a, and C/EBP-ß. As indicated, C/EBP-ß regulation may be independent of these cytokines but still linked to a cytokine response. It was determined that PRL-1, a gene that encodes a nuclear protein tyrosine phosphatase, is induced equally well in both IL-6-/- and C/EBP-/- livers after partial hepatectomy. [3] The Egr-1 transcription factor is responsible in part for the activation of the PRL-1 gene. [77] Like STAT3 and NF-?B, Egr-1 is induced in the regenerating liver in the absence of de novo protein synthesis and reflects activation by a cytokine-independent pathway in liver regeneration. As yet, it is not clear which growth factor signal during liver regeneration is responsible for the activation of Egr-1 and genes that are regulated normally after hepatectomy in C/EBP-ß-/- and IL-6-/- livers. Further analysis of gene expression patterns in these and other gene knock-out mice with impaired liver regeneration will provide insight into regulatory pathways, actions of specific growth factors (HGF and TGF), and cross talk between cytokine-dependent and -independent pathways.

The relationship between normal liver proliferation after hepatectomy and the acute phase response is interesting. The same cytokines that may promote normal liver regeneration are also activated during the acute phase response. The acute phase response, a first line of defense against wounds and infection, results in high levels of some circulating proteins produced by the liver. [78], [79] Although an acute phase response occurs in the regenerating liver after hepatectomy, it is of relatively

low grade in comparison with the response induced by LPS or turpentine injection. [80] Although common intracellular pathways mediated by cytokines may be seen in both liver regeneration and the acute phase response, the end results are quite different. In liver regeneration, the response is mitogenesis; in the acute phase response, the production of acute phase reactants leads to wound healing.

Interleukin-6–Induced Liver Regeneration after Liver Injury: Reduced Hepatocyte Proliferation and Persistent Injury

In addition to hepatectomy, IL-6-/- livers have been shown to respond abnormally to a variety of liver injury models, including CCl_4, ischemia/reperfusion, fas activation, and bile duct ligation. [20], [81], [82], [83], [84], [85] and [86] As such, IL-6-/- mice provide an excellent model system for examining the relationship between liver regeneration, repair, and ultimately fibrogenesis. Several studies have examined the role of IL-6 in liver injury following ischemia/reperfusion. In one study, both hepatectomy and ischemia were simultaneously applied. It was found that hepatic ischemia in combination with hepatectomy significantly reduces the mitogenic response in mouse livers. [84] Treatment with IL-6 improves the mitogenic response in the face of ischemic injury back to the normal level. In warm ischemia/reperfusion models, IL-6 is protective against ischemic injury, and IL-6-/- livers show increased injury. In this model, TNF-a results in injury, as antibodies to TNF-a are able to reduce ischemic injury to a similar degree as administration of IL-6. [82] A program of gene expression, activation of STAT3 and NF-?B, and a high degree of hepatocyte proliferation similar to that in the hepatectomy model have been observed in transplanted rodent livers subjected to prolonged warm ischemia, [83] indicating that IL-6–dependent hepatic regeneration occurs following ischemic liver injury.

Studies supporting TNF-a as one of the factors that promotes liver regeneration indicate that one of the actions of TNF is to regulate the expression of IL-6. TNF receptor type 1 (TNFR1) knock-out mice have defects in liver regeneration very similar to those of IL-6 knock-outs, including major reductions in STAT3 activation and IL-6 mRNA levels. [21] These animals are deficient in the TNFR1, which appears to mediate most of the effects of TNF-a in the liver. The DNA synthetic response of TNFR1-/- livers is restored by treatment with IL-6, so that the need for TNF-a is bypassed. This therapeutic intervention could have important consequences because it has been shown that too much TNF-a is deleterious in the liver and contributes to liver injury. A notable difference between TNFR1-/- and IL-6-/- livers is that induction of NF-?B after hepatectomy is relatively normal in IL-6-/- but virtually absent in TNFR1-/- livers. This is presumably because TNF-a is directly responsible for activating NF-?B in the liver after hepatectomy. Because IL-6 is a known NF-?B target gene, the reduction of active NF-?B provides a mechanism by which IL-6 and STAT3 levels are reduced in TNFR1-/- livers after hepatectomy.

Although IL-6 and TNF appear to be beneficial and required for liver regeneration after a partial hepatectomy, the need for these factors has not been as clearly established after liver injury, a more common regenerative stimulus. A number of studies have suggested that TNF-a increases liver injury after toxic damage. For example, TNFR1-/- livers are less susceptible to liver failure and fulminant hepatitis after damage with LPS and galactosamine. [87] In addition, studies have shown that blocking TNF-a with anti–TNF-a antibodies reduces the level of hepatic injury after treatment with the toxin CCl_4. [71] Several of these cytokines, including both IL-6 and TNF-a, have been implicated as profibrogenic in chronic liver injury leading to cirrhosis. Studies indicate that TNFR1-/- livers regenerate less well than wild-type livers after CCl_4 treatment, but the effect on the degree of liver injury was not as clear. [88] TNF-a itself may increase the degree of liver injury because the level of TNF-a after toxic damage is in relative excess, and the amount of IL-6 produced is relatively deficient to maximally stimulate regeneration and repair.

IL-6 also mitigates acute toxic liver injury. [81] CCl_4 is a hepatotoxin that causes direct hepatocyte injury by altering the permeability of cellular, lysosomal, and mitochondrial membranes. [89] Highly reactive free radicals are also formed from the metabolism of CCl_4 by cytochrome P450 2E1 of the hepatocyte, causing centrizonal necrosis. CCl_4 causes not only primary liver necrosis but also hepatocyte apoptosis. [90], [91] Following acute CCl_4 treatment, increased hepatocellular injury and defective regeneration with significant blunting of STAT3 and NF-?B activation and reduced hepatocyte DNA synthetic and mitotic responses are seen in IL-6-/- mice. [81] CCl_4 treatment, unlike partial hepatectomy, is followed by increased hepatocyte apoptosis in IL-6-/- livers. Pretreatment with IL-6 before CCl_4 reduces acute CCl_4 injury and apoptosis and accelerates regeneration in both IL-6+/+ and IL-6-/- livers.

Two major defects are seen in IL-6-/- livers subjected to a single dose of CCl_4. First, despite more extensive injury, IL-6-/- livers show reduced hepatocyte proliferation. Unlike the hepatectomy model, in which additional IL-6 given to wild-type mice has little impact on the course of regeneration, treatment with IL-6 clearly accelerates the proliferative response in both IL-6+/+ and IL-6-/- livers. Peak entry into S phase occurs at 36 rather than at 48 hours. This response further defines the role of IL-6 as a cell cycle progression factor. The second major finding in IL-6-/- livers is a dramatic increase in the degree of liver injury following CCl_4 toxicity (roughly two-thirds greater than in the wild type). Treatment with IL-6 has a profound impact on both IL-6-/- and IL-6+/+ livers in reducing the amount of CCl_4-induced injury. IL-6 treatment also reduces the number of apoptotic hepatocytes in both IL-6-/- and IL-6+/+ livers.

In another model of liver injury associated with high levels of TNF-a, the concanavalin A T-cell activation liver model, antibodies to TNF-a reduced injury, as did injection of recombinant IL-6. [92] In addition to decreasing CCl_4-induced liver injury, IL-6 decreases hepatocyte apoptosis, a component of CCl_4-induced liver injury. In this model, it is not clear whether reduction in apoptosis is the consequence of an overall reduction in injury or whether IL-6 exerts a primary anti-apoptotic effect that serves to rescue hepatocytes. Fas ligation, a purer model of hepatocyte apoptosis than CCl_4 toxicity, provides more insight into mechanisms by which IL-6 reduces hepatocyte apoptosis. Il-6-/- mice are more susceptible to Fas-mediated death than wild-type animals. [93] The direct anti-apoptotic effects of IL-6 are demonstrated in vitro as IL-6 decreases Fas-mediated apoptosis in both IL-6-/- and IL-6+/+ primary hepatocyte cultures, suggesting that IL-6-/- hepatocytes have a preexisting defect in anti-apoptotic pathways. After Fas activation, IL-6-/- livers show evidence of both proximal and distal alterations in the apoptotic pathways, including elevated caspase 8 and caspase 3 activation–associated fragments and loss of cytochrome *c* staining. IL-6-/- livers show reduced preexisting protein expression of the anti-apoptotic factors Bcl-2 and Bcl-xL, as well as more rapid degradation of FLIP following Fas treatment that appears to be posttranscriptionally regulated (Fig. 28-6).

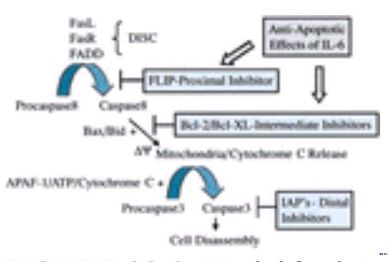

FIGURE 28-6. Model for interleukin-6 (IL-6) protection against Fas-mediated liver apoptosis. IL-6 may protect the liver from apoptosis after Fas agonist treatment by regulating several anti-apoptotic factors in the Fas signaling cascade. As shown in the model, when bound by its ligand, Fas receptor forms trimers and binds the adapter protein FADD. FADD can then bind, via a death effector domain, the zymogen form of caspase 8 (FLICE/MACH). Caspase 8 then oligomerizes and activates through self-cleavage. Caspase 8 is an initiator caspase and proximal in the apoptotic cascade. If inactivated by FLIP (I-FLICE), the apoptotic signal will be terminated, and the cell survives. IL-6 maintains the FLIP protein level in the liver after Fas agonist treatment and prevents it from rapid degradation. Caspase 8 activates a complex and poorly understood process that culminates in mitochondrial membrane depolarization (mitochondrial permeability transition) and the translocation of cytochrome *c* from the inner mitochondrial membrane to the cytoplasm. Cytochrome *c* binds to apoptotic protease-activating factor-1 (Apaf-1) and in the presence of ATP activates caspase 3. This executioner caspase cleaves intracellular substrates, resulting in the characteristic morphologic and biochemical changes of apoptosis. [104], [105] Bcl-2 and Bcl-xL are anti-apoptotic proteins that function to maintain mitochondrial membrane integrity and prevent the release of cytochrome *c*. Bcl-xL has also been shown to inhibit the association of Apaf-1 to downstream caspases. [106] Likely through posttranscriptional mechanisms, IL-6 establishes an adequate level of Bcl-2 and Bcl-xL proteins in the liver cells to render them more resistant to Fas-mediated apoptosis. (From ref. [93].)

Cytokine-Independent Pathways: Roles of Hepatocyte Growth Factor and Transforming Growth Factor-a

In addition to cytokine-dependent pathways, several growth factors are felt to play an important role in promoting cellular replication during liver regeneration. Two of the most important based in part on in vitro studies in isolated hepatocytes and in part on in vivo studies are TGF-a and HGF. Like IL-6, HGF regulates a variety of processes in the liver in addition to being a direct stimulant of hepatocyte proliferation. [2] HGF is a potent inducer of DNA synthesis in hepatocytes in culture but also alters morphology and motility of cells. In vivo, HGF is synthesized in nonparenchymal cells and acts on hepatocytes in a paracrine fashion. It has been proposed that

HGF is activated by proteases after hepatectomy. Antibodies to HGF at the time of CCl_4 injection block the regenerative response. In this study, the degree of injury (and therefore the requirement for regeneration) was not assessed. [94] It has been shown that infusion of HGF into rodents reduces the level of CCl_4-induced hepatic injury. [27], [28] The effect on specific signaling pathways leading to regeneration has not been studied. In a rat model of liver cirrhosis produced by dimethylnitrosamine, HGF produced after gene transfections into skeletal muscles induces a high plasma level of human HGF, resulting in activation of the c-Met/HGF receptor. [27] The increase in TGF-ß $_1$ normally associated with dimethylnitrosamine is reduced, but it is not clear whether this is a direct effect of HGF or results from the fact that liver injury is less severe in the HGF-infused animals. HGF infusion inhibits fibrogenesis and hepatocyte apoptosis. It produces resolution of fibrosis in an already cirrhotic liver and improves the survival rate of rats. Again, as in the case of IL-6, conclusions cannot be drawn regarding whether the effect of HGF on cirrhosis is limited to its effect on hepatocyte injury or whether it reduces stellate cell activation directly.

The effects of HGF on liver injury are very similar to those of IL-6, but thus far, attempts to link these two cytokine/growth factors have failed. Although HGF may be directly up-regulated by IL-6 treatment in vitro, no change in HGF signaling or HGF mRNA levels is observed in IL-6-/- livers. [20] Moreover, although abnormal regulation of plasminogen that regulates HGF activity is seen in IL-6-/- livers, [39] no difference in HGF-mediated signaling has been detected. It remains to be seen whether the similar effects of IL-6 and HGF on hepatocyte apoptosis, injury, and regeneration are mutually exclusive yet overlapping.

The genetic evidence for a role for TGF-a in liver regeneration is complicated by the fact that there are multiple TGF ligands and receptors in the liver. [16] TGF-a knock-out mice show normal liver regeneration, and TGF-a receptor mutation is associated with embryonic lethality. The presence of multiple ligands for the TGF-a receptor makes it difficult to assess the importance of this strong hepatocyte mitogen in the process of liver regeneration.

LIVER REGENERATION IN HUMAN DISEASE

Many types of liver disease, including hepatitis and cirrhosis, are accompanied by some degree of liver regeneration. In part, this is compensatory as the liver attempts to restore liver mass lost as a result of the pathological process. However, in addition, the disease itself may be accompanied by elevations of cytokines and transcription factors that promote hepatocyte and nonparenchymal cell proliferation. These pathophysiological responses of the liver may exacerbate the disease process, leading to increased fibrogenesis in cirrhosis and the accumulation of mutations in proliferating hepatocytes and progenitor cells that ultimately lead to hepatomas.

It has been found that the X protein and MHBs ^{t} transactivators encoded by the hepatitis B virus induce the NF-?B transcription factor in infected hepatocytes, perhaps by modulating the oxidative state of the cells. [95], [96] and [97] Increased NF-?B may result in the initiation of a growth program and prevent apoptosis. The recruitment of immune cells as a result of increased cytokine production (e.g., IL-8) leads to additional increases in circulating cytokines, which may act as mitogens in both hepatocytes and nonparenchymal cells, leading to fibrogenesis and cirrhosis. [96] Thus, a pathological state of the liver, such as hepatitis, may inappropriately activate pathways that are normally part of a physiological response to reestablish liver mass.

The number of liver transplants performed is growing. Several centers are dramatically increasing the number of living related donors and examining the possibility of using split-liver transplants to increase the availability of organs. [98], [99] In instances in which a small-for-recipient liver is used, a hyperplastic response clearly must occur in the recipient, similar to the type of regeneration that occurs after a partial hepatectomy. Even in an appropriately sized liver transplant, because of the cellular damage that occurs in the donor liver before transplantation, a certain amount of cellular replication and repair may be required after transplantation for normal liver function to be established. Many cases of primary graft failure in liver transplantation result not from the immunologic response but from malfunction of the donor liver cells. Studies suggest that liver regeneration is an important component of the survival of the transplanted liver. [100], [101] and [102] In successfully transplanted livers, and in short-term ischemia when shunting has been performed, a rapid induction and return to normal of the immediate-early genes, jun and fos, occurs, similar to the kinetics of expression seen during liver regeneration. A high percentage of hepatocytes undergo DNA replication, [83] further supporting a role for regeneration in transplant survival. If cytokine release is important for liver recovery after transplantation, cytokine release may also be somewhat deleterious in that it may activate an immune response within the transplanted liver. However, agents that block the immune response, such as steroids, may also hamper the regenerative response by blocking NF-?B or STAT3 activation. [103] Thus, an understanding of the extent of liver regeneration, and the degree of cytokine and growth factor activation after liver transplantation, is clearly needed.

CONCLUSIONS

Liver regeneration after partial hepatectomy represents a physiological response of the body to the loss of liver mass. Based on a molecular analyses of regeneration, it is now better understood how the liver is able to regenerate and have the functional capacity that is required to maintain metabolic homeostasis during proliferation. In pathological processes such as fulminant hepatic failure and sepsis, in which hepatic function may be lost, it is now possible to assess parameters of liver function, such as the levels of hepatic gluconeogenic enzymes and mRNAs and transcription factors necessary to maintain adequate liver function. In regeneration, a correct balance of liver-specific transcription factors such as the C/EBPs is maintained, whereas in hepatic dysfunction, one can predict that the levels of these factors will be abnormally low. Studies will allow for a better understanding of the mechanism by which liver function is lost and may ultimately lead to therapeutic interventions.

Cytokines (TNF-a, IL-1, IL-6), which may be derived from liver nonparenchymal cells (Kupffer and endothelial cells), have an important role in promoting normal liver regeneration. Although more difficult to demonstrate in genetic models, HGF, TGF-a, and other growth factors are likely to be required for normal regeneration. However, it seems clear that the levels of these cytokines and growth factors must be well modulated for the outcome to be effective regeneration rather than liver damage. For example, abnormally high levels of cytokines, seen during pathological processes such as toxic damage to the liver, lead to liver injury and cell death. In other processes, like cirrhosis and hepatitis, high levels of cytokines may lead to an aberrant proliferative response that ultimately leads to fibrosis and hepatomas. HGF and IL-6 have pleiotropic effects in the liver, including growth-promoting, anti-injury, and anti-apoptotic effects. They are more beneficial in inducing proper regeneration than TNF-a, which may have both growth-promoting and growth-inhibiting properties. In processes leading to liver damage, it may be possible to modulate the levels of these cytokines therapeutically to obtain the correct balance of specific cytokines, thus promoting restoration of mass and minimizing injury.

The complexity of the regenerative response, which requires several parallel signals, is highly protective to the organism. If IL-6 alone could induce hepatic hyperplasia, then any condition in which IL-6 was elevated would be detrimental to the animal. For example, during an acute phase response, elevated IL-6 levels aid recovery from injury, but the liver does not undergo rapid expansion. Animals overproducing hepatic IL-6 show high levels of STAT3 and other acute phase genes, but their livers are histologically normal and show little increase in proliferation. However, the introduction of an additional signal, overproduction of the soluble receptor for IL-6 in their livers within the portal spaces, overwhelms the growth-inhibiting signals, and hyperplastic changes, adenomas, and endothelial cell proliferation develop in the livers. [86] Thus, under normal physiological signals, and in response to stress, homeostasis is maintained. A loss of liver mass, through either surgery or toxic damage, is required to provide the complex signals, both cytokine-dependent and -independent, that are required for liver regeneration.

CHAPTER 29

Douglas A. Drossman and Lin Chang

PSYCHOSOCIAL FACTORS IN THE CARE OF PATIENTS WITH GASTROINTESTINAL DISORDERS

BIOPSYCHOSOCIAL MODEL OF ILLNESS AND DISEASE

Experienced physicians recognize that a clinical approach that focuses entirely on the physical or organic nature and origins of disease has limitations. Even sophisticated diagnostic methods such as endoscopy, manometry, and imaging are not sufficient to explain the degree and variability or even the presence of many gastrointestinal symptoms, or the patient's behavior in the face of these symptoms. Furthermore, such data are insufficient to plan treatment. [1] In other words, abnormalities of structure and function, the *disease,* does not explain the patient's experience of ill health, the *illness*. [2] Failure to link the physical (i.e., disease) and the psychological (i.e., illness) components will reduce the likelihood for more effective treatments.

Consider the following case:

Case Example

A 42-year-old man describes severe chronic epigastric burning and occasional associated mild lower abdominal discomfort that he has had for 10 years. An upper gastrointestinal barium series reveals a hiatal hernia, and barium enema examination demonstrates a "spastic colon." H_2 antagonists and antacids provide some relief of his symptoms, but they recur over time. Upper gastrointestinal (GI) endoscopy reveals a small linear erosion in the distal esophagus, but no evidence of Barrett esophagus. A 24-hour pH study demonstrates significant gastroesophageal reflux. High-dose proton pump inhibitors relieve the epigastric burning, but soon afterward, the patient reports worsening of his lower abdominal discomfort, rectal fullness associated with alternating diarrhea and constipation, and a sensation of incomplete evacuation and bloating.

His mother had had ill-defined upper gut symptoms. The patient reported that stress exacerbates both his upper and lower abdominal and rectal symptoms. He also admits to an obsessive preoccupation that his symptoms will worsen. Results of a colonoscopy with colonic biopsies are normal. When he turned 40, he felt that his life was "not where he wanted to be." He is not married and has no children. He is an unpublished novelist and writer for television. He later discloses that some of his anxiety concerning his rectal symptoms is related to being sexually abused in childhood by a distant relative. He never discussed this with his family or close friends. He feels nervous, caught in a "vicious cycle" of increasing symptoms, recurrent anxiety, and then further worsening of the symptoms.

The key, in terms of treatment, is to break the cycle, both medically and behaviorally. A low-dose tricyclic antidepressant, a short course of a benzodiazepine, and cognitive-behavioral psychological treatment with relaxation training are recommended as a means to reduce the anxiety and maladaptive thought patterns that may be perpetuating his illness experience.

This case illustrates several points. Organic (gastroesophageal reflux disease [GERD]) and functional (IBS) bowel symptoms are present, but in both conditions, the symptoms are influenced by psychological factors [3] and exacerbated by stress. Furthermore, an obsessive preoccupation that his symptoms will worsen further amplifies the perceived symptoms. Notably, following successful treatment of the reflux symptoms, his IBS symptoms worsened, thus perpetuating the illness condition. Other psychosocial influences include the perception of "failure" at age 40, symptom identification stemming from his mother's long-standing GI illness, and a history of childhood trauma. All these factors, including the history of childhood sexual abuse, can be addressed in therapy, thereby reducing the anxiety component exacerbating his symptoms.

The physician helped the patient by interpreting his clinical condition as a "vicious cycle," thus communicating that both psychosocial and medical issues are important. By acknowledging the legitimacy of the symptoms while communicating the influencing effects of psychosocial factors on them, the physician could then institute a multicomponent treatment. The patient was now more accepting of both pharmacological and psychological treatments.

To integrate the interacting roles of psychosocial and medical factors, a biopsychosocial model needs to be considered (Fig. 29-1). [1] Thus, a biologic event, such as the development of Crohn's disease or human immunodeficiency virus (HIV) infection, can affect cellular and organ function, the person, family, and society, while a psychosocial change, such as the death of a spouse or abuse, affects not only the person's psychological status and illness behavior, but also cellular immunity and possibly susceptibility to or activity of the disease. [4]

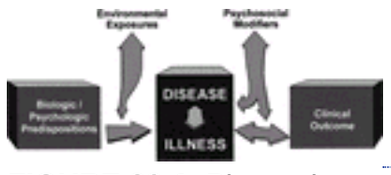

FIGURE 29-1. Biopsychosocial model–conceptualization. Both biologic and psychosocial predispositions (e.g., genetic influences on disease susceptibility and behavior) contribute to the expression of disease and illness. Furthermore, environmental exposures (e.g., infection, family influences on attitudes toward illness), as well as existing psychosocial modifiers (e.g., concurrent psychiatric diagnosis, life stress, social support, coping style), ultimately determine the clinical outcome. (From ref. [1].)

The biopsychosocial model [1, 5] explains the clinical variability among individuals with a given medical condition and provides a framework to integrate both biologic and psychosocial processes and to optimize diagnosis and patient care. In contrast, the biomedical model, which assumes a disease-based single etiology, places "blinders" on the physician, so that psychosocial data either are not recognized or are perceived as irrelevant.

INTERACTIONS OF BIOLOGIC AND PSYCHOSOCIAL FACTORS IN GASTROINTESTINAL ILLNESS

Support for a role for psychosocial factors in GI illness has lagged for the following reasons [6, 7, 8, 9 and 10]:

1. The traditional, biomedical model is inherently slow to change. [7]
2. Only recently have newer techniques (e.g., ambulatory monitoring of motility, visceral pain assessment, standardized psychiatric diagnostic criteria, health-related quality-of-life assessment) been integrated with multidisciplinary research methods. [8]
3. The complexity of psychosocial investigation makes data difficult to obtain and interpret. [8]
4. Research in brain-gut neurophysiology (e.g., positron emission tomography [PET], functional magnetic resonance imaging [fMRI]) is only beginning. [1]

Psychophysiological Factors

Healthy subjects frequently report abdominal discomfort or bowel dysfunction when upset or distressed, [11] and it is well established that stressful stimuli can produce disturbances in intestinal vascularity, secretion, motility, and pain perception. [9] In addition, disturbances in bowel function can reciprocally affect emotional centers in the brain, such as the locus ceruleus. [12]

Stress can also heighten an individual's perception of a physiological stimulus, as in the preceding case example. In patients with GERD, acute psychological stress produced more heartburn, autonomic arousal, and anxiety in patients with preexistent anxiety without a change in the degree of acid reflux (pH probe). [3] Therefore, the increased heartburn resulted from enhanced perception of visceral sensation rather than a physiological increase in acid reflux.

Psychoimmunologic Factors

During the past 25 years, we have learned that environmental stress, via the central nervous system (CNS), influences immune function, susceptibility to disease, and regulation of disease activity. [4] For example, altered in vitro responsiveness to mitogens and antigens, reduced lymphocyte-mediated cytotoxicity and delayed hypersensitivity, diminished skin graft rejection and graft versus host reactivity, and suppressed antibody response have been noted after stressful experiences such as bereavement and marital disruption or stress-inducing experiments in college students. [9] In a study of 394 healthy subjects, there was a significant ($P < .005$) dose-response association between psychological stress and the frequency of respiratory infections in response to the intranasal inoculation of virus. [13] Anxious medical students taking examinations seroconverted to hepatitis B vaccine later than those less anxious, and those with greater social support developed higher antibody titers to the vaccine. [14] These immune effects may be environmentally conditioned. Mucosal mast cells have been classically conditioned to secrete an immune mediator (protease II) in response to an audiovisual cue. [15] By linking the taste of saccharine to cyclophosphamide, immune function was suppressed in NZB-NZW mice, thereby delaying the development of murine lupus erythematosus and prolonging survival. [16]

Finally, behavioral treatment may have clinical consequences. A stress management program of patients with stage I and II malignant melanoma demonstrated a 25% increase in the number of natural killer (NK) cells and in NK cytotoxic activity 6 months after treatment in the stress management group. Six years later, the treatment group had significantly lower mortality, with a trend toward fewer tumor recurrences than the control group. [17]

The Brain-Gut Axis

The brain-gut axis describes the bidirectional neural pathways that link cognitive and emotional centers in the brain with the neuroendocrine centers, the enteric nervous system, and the immune system. [18, 19] For example, extrinsic (vision, smell) or enteroceptive (emotion, thought) information has, via neural connections from the CNS, the capability to affect gastrointestinal sensation, motility, and secretion. Conversely, viscerotopic effects (e.g., nociception) reciprocally affect central pain perception, mood, and behavior. [18]

Modulation of visceral afferent information is discussed in detail in Chapter 38. It occurs at multiple levels:

1. CNS modulation of enterochromaffin cells and immune cells can change the sensitivity of peripheral sensory nerve endings in the gut wall.
2. Descending pathways from the brainstem to the dorsal horn of the spinal cord modulate the amount of information that ascends from the periphery to the brain. [20]
3. Ascending arousal systems from the brainstem to the thalamus and cortex determine how the information is consciously perceived. [10, 21]

The activation of these modulatory systems is dependent on peripheral and, importantly, central events, such as acute gut inflammation [18] or chronic inflammation. [22, 23] Anxiety or recall of aversive memories can enhance, [24] while distraction, hypnosis, and relaxation can decrease, the perception of painful events. [25, 26]

Regulation of these anatomic connections occurs via various brain-gut neurotransmitters. Neurotransmitters are not site specific; rather, they lead to varied effects on gastrointestinal, endocrine, and immune function, as well as neural function and human behavior. For example, the enkephalins can variably affect pain control, [27] GI motility, [28] feeding activity, [29] emotional behavior, and immunity. [30] Cholecystokinin (CCK) increases small intestinal motility, slows gastric emptying, and has a central satiety effect. [31] Meal-associated secretion of CCK may influence bulimia nervosa. [32] 5-HT receptors in both brain and gut are implicated in functional GI disorders, [33, 34] migraine headache, [35] alcoholism, and disorders of mood. [36] Lymphocytes, mast cells, and macrophages contain receptors that respond to neurotransmitters and neuropeptides (e.g., endorphins, vasoactive intestinal peptide, substance P), and this provides the basis for stress and emotion to influence gastrointestinal inflammation and immune function. [37] Nitric oxide can increase the expression of protooncogenes (e.g., c- *fos*) involved in the transcriptional control of genes that encode the production of other neuropeptides (e.g., dynorphin), and this can lead to semipermanent changes in brain or gut function, including the development of visceral sensitization. [38] Corticotropin-releasing factor (CRF), which has central and peripheral receptors, can delay gastric emptying (via CRF-2 receptors), [39] accelerate colonic motility (via CRF-1 receptors), [40, 41] and lower rectal perceptual thresholds. [42]

Dysregulation of the Brain-Gut System in Functional Gastrointestinal Disorders

A unifying hypothesis to explain the functional GI disorders [43] is that they result from dysregulation of "brain-gut" neuroenteric systems. When compared with healthy subjects, these patients exhibit, with considerable variation, increased motor reactivity to several stressors, including balloon distention, food, various peptides, and physical and psychological stressors. [10, 44] Furthermore, patients with functional esophageal, [45, 46] gastroduodenal, [47] and bowel [48] disorders have decreased pain

thresholds to balloon distention and other stimuli (visceral hypersensitivity).

Evidence supports a prominent role of stress in the pathophysiology and clinical presentation of functional GI symptoms. [8], [49] In a predisposed individual, stress can result in permanent, irreversible increased responsiveness of central stress circuits and vulnerability to the development of functional and affective disorders. Gwee and colleagues [50] found that chronic life stressors predict the development of IBS symptoms following gastroenteritis. Alterations in central stress circuits affect the perception of incoming visceral signals [51] as well as output systems to the gut resulting in motility, sensory, and immunologic disturbances, which may be manifested as pain, diarrhea, and constipation. The CNS and spinal cord are able to up-regulate and down-regulate visceral sensation [18] and respond to environmental or psychological stress, personality, or emotions to regulate gut function. Such explains dichotomous symptoms in these disorders: both constipation and diarrhea, or disturbed motility without pain, or even pain without disturbed motility ("altered perception of normal function"). It also explains how psychosocial trauma, such as a history of physical or sexual abuse, [52] or a poor coping style, such as "catastrophizing," [53] profoundly affects symptom severity, daily function, and health outcome.

Recent studies using PET and fMRI indicate that cerebral function differentiates IBS patients from normals. [54], [55] and [56] Using distal colonic stimulation, two studies demonstrated a greater activation in IBS patients of the anterior cingulate (caudal anterior cingulate or rostal midcingulate) cortex, a brain region concerned with organizing the most appropriate behavioral response to sensory stimuli, while taking into account its affective component. [57] Modulation of this region by hypnotic suggestion was associated with changes in the subjective intensity and unpleasantness of a somatic pain stimulus. [26], [57] These findings suggest that IBS patients may fail to use CNS down-regulating mechanisms in response to incoming or anticipated visceral pain. Instead, they may activate areas of the brain that amplify pain perception.

Stress typically produces analgesia of the body, but it has been shown to result in visceral hyperalgesia in recently developed animal models that mimic some pathophysiological features of IBS. [58] These support the observation that early life stress and trauma can influence the development of functional GI disorders later in life. Al-Chaer and colleagues [59] demonstrated that colonic irritation in neonatal rats results in chronic visceral hypersensitivity that persists into adulthood even after the inflammation has resolved. In another rat model, neonatal stress (maternal separation) results in permanent changes in the CNS, which are associated with depression-like behaviors, increased fearfulness, and hypothalamic-pituitary-adrenal responsiveness to stressors and a predisposition to the development of visceral hyperalgesia, somatic hypoalgesia, and increased colonic motility in response to psychological stress. [58], [60]

Implications of Brain-Gut Activity in Inflammatory Bowel Disease

Inflammation may be modulated by disruption of brain-gut pathways. [19], [61] The hypothalamic-pituitary-immune axis is critical to the body's homeostatic regulation of stress, physiological functioning, and disease susceptibility. [19], [62] Through this system, stress influences the immune response, [63] as shown in Figure 29-2. [19]

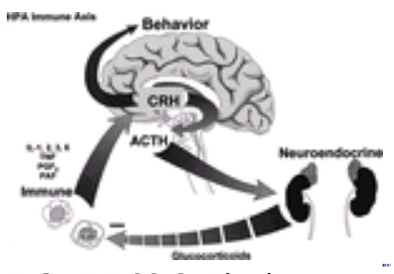

FIGURE 29-2. The immune–central nervous system–endocrine feedback system. Stimulation by immune cytokines and inflammatory mediators facilitates a hypothalamic-pituitary-adrenal response, beginning with release of corticotropin-releasing hormone (*CRH*). This in turn leads to the release of adrenocorticotropic hormone (*ACTH*), which stimulates glucocorticoid release from the adrenal glands. Finally, the glucocorticoids suppress inflammation (*broken arrow*) and the immune response, thereby completing the negative feedback circuit. Homeostasis is maintained through the dynamic and integrated responses of these systems in response to intrinsic or extrinsic forces (e.g., stress, infection, other illnesses) that can disturb the steady state. *IL-1,* interleukin-1; *PAF,* platelet-activating factor; *PGF,* prostaglandin F; *TNF,* tumor necrosis factor. (From ref. [19].)

Chronic psychological stress appears to be capable of exacerbating previously quiescent ulcerative colitis. [64] However, short-term stressful events (past 6 months), perceived stress (past month), or depressive symptoms do not. This suggests that the long-term effects of psychoimmune factors may modify the disease activity in inflammatory bowel disease (IBD). [62] Although psychosocial stressors may not initiate the inflammation, they may dysregulate the immune response, [19], [61] thereby increasing disease activity. The association of long-term stress with the exacerbation of IBD is likely mediated by hypothalamic-pituitary-immune axis, as demonstrated in various animal modules. [19]

The brain and gut are interdependent, and this is best understood from a biopsychosocial framework. Thus, it is no longer rational to try to discriminate whether GI symptoms are gut-related or psychiatric. The clinician's task is to determine the degree to which central and peripheral factors affect the illness condition.

The Experience of Illness and Its Consequences

Illness behavior is determined by sociocultural norms [65] and family beliefs, as well as personality, loss, a history of abuse and other major stressors, daily "hassles," and one's previous experiences with illness. The disease and the patient's behavior affect several health outcomes: symptoms, degree of psychological distress, quality of life, health care visits, and the development of iatrogenic complications (see Fig. 29-1). [8], [52], [66], [67] and [68] The outcome can also be modified through certain coping strategies, [53], [67], [69] by adequate social support networks, [70] and by the effectiveness of the physician-patient interaction. [71], [72] and [73]

Because attention to psychosocial features is likely to improve the patient's clinical condition, clinicians should assess the contribution of these factors to the GI illness and apply this to daily care. The following sections focus on how clinicians can accomplish this.

ESTABLISHING A THERAPEUTIC PHYSICIAN-PATIENT RELATIONSHIP

Obtaining high-quality clinical information and optimally effecting the plan of care require an effective physician-patient relationship. Physicians may feel "at odds" caring for patients with chronic illness for several reasons:

1. Their biomedical training limits their ability to seek out and obtain psychosocial data.
2. They may believe that psychosocial factors are "soft" data and not relevant.
3. They may perceive they have little time to integrate these factors into the diagnostic and treatment plan.
4. They are dissatisfied with the course of treatment.
5. They have a sense of not "connecting" with the patient or the patient's problem(s).

Why do physicians and patients sometimes not "connect"? [73] Some patients may seem demanding when they expect physicians to make them better or contact them frequently with requests. Experience suggests that patients may be responding to feelings of ineffectiveness in managing their own illness, and this may generalize to feeling that they are not in control of their lives. So the expectation for care is off-loaded to the physician. However, we physicians also have expectations and needs as caregivers. The degree to which they are met affects our attitudes and behaviors in administering care. Our responsibility is not to pick up an unachievable burden of responsibility for the patient's care, nor to push it back to the patient ("You'll have to learn to live with it"). Instead, we should share the responsibility to achieve realistic goals. We should facilitate a process in which patients can regain their self-esteem by validating that their feelings are legitimate. We then should help patients to regain control (and self-esteem) by finding ways for them to learn to help themselves as we work to reduce symptom distress and provide support and hope. We also must be vigilant to establish care that is rendered in a time-efficient manner: to work from priorities rather than address all the problems, and to

establish regular brief visits over time.

The physician-patient relationship is evolving from a traditional model, in which the physician assumes a dominant role, to a more negotiated, patient-centered or "participatory" arrangement. [74], [75] Although physicians must take charge of acute disease and medical emergencies, they must encourage shared responsibility for chronic illness. [72], [76] This approach offsets any tendency for patients to assume passive and dependent roles that impair psychological well-being, and it relieves physicians from taking on too much responsibility. Furthermore, this approach is associated with greater patient and physician satisfaction and an improved clinical outcome. [77]

The following guidelines are recommendations for establishing an effective physician-patient interaction [72], [78]:

1. **Listen actively.** Clinical data are obtained through an active process of listening, observing, and facilitating. It is a question of focus—hearing the patient's story, rather than attempting to "fit" the story into a specific disease. It also involves paying attention to the patient's tone of voice, facial expressions, and "body language," and it need not take extra time.
2. **Validate the patient's feelings.** Physicians must validate any feelings of shame or embarrassment that may arise when patients disclose personally meaningful information. Avoid making personal judgments or closing communication with quick reassurances or solutions. For example, statements such as "Don't worry, it's nothing serious" or "Your problem is due to stress" are frequently perceived by patients as dismissive or judgmental. Patients usually do perceive their condition as serious, and for various reasons, [79] they may not consider it to be caused by stress.
3. **Provide empathy.** Empathy involves demonstrating an understanding of the patient's distress while maintaining an objective and observant stance. An empathic statement would be, "I can see how difficult it has been for you to manage with your pain." This communicates the physician's understanding of the issues from the patient's perspective. Providing empathy improves patient satisfaction and adherence to treatment. [80], [81]
4. **Identify the agenda(s)—the patient's expectations and concerns.** The reason(s) for the patient's visit (e.g., "What led you to see me at this time?" "What are your concerns and expectations?") identify the patient's expectations and increase satisfaction with care. [82] Possible reasons include the following: (1) new or exacerbating factors (e.g., dietary change, concurrent medical disorder, side effects of new medication); (2) personal concern about a serious disease (family death or cancer); (3) environmental stressors, including recent losses or abuse; (4) psychiatric comorbidity, particularly depression or anxiety; (5) impaired daily function, with inability to work or socialize; (6) a "hidden agenda," such as narcotic or laxative abuse, pending disability, or litigation. Once the patient's agenda has been obtained, the physician must also communicate an agenda and work toward a mutually specified set of goals.
5. **Limit the discussion of psychological issues to what is consistent with the patient's beliefs.** Many patients are unable or unwilling to report feeling states or acknowledge a relationship between psychological stresses and their symptoms. [79], [83] Therefore, patients may reject the offer of "insight" about the possible role of psychological factors in their illness. The information provided must be consistent with the patient's frame of reference. For example, a behavioral intervention can be explained as a way to help the patient cope with the psychological distress or dysfunction resulting from the illness, and a tricyclic antidepressant can be offered as a centrally acting analgesic.
6. **Don't overreact.** Some patients interact in ways that are perceived as dependent, demanding, or adversarial, such as making frequent phone calls or visits for narcotics, disability, or diagnostic studies. Physicians may *overreact* by becoming angry, performing unneeded studies, or overmedicating. [84] It helps to understand these behaviors as ineffective communications rather than patient problems, and to "tune in" on inner thoughts and feelings ("What is it about this patient's response that makes me feel irritated?") before acting impulsively. For example, when addressing the influence of stress on IBS symptoms, a physician may react defensively to a patient who replies, "Do you mean this is in my head?" by saying, "Oh no, I didn't mean that. This is a real problem in your intestines." Or the physician may become angry: "Well, it is due to stress, and you'll have to learn to live with it." However, the patient has not been given the opportunity to elaborate on the underlying concern, and these statements reduce the patient's ability to appreciate the symptoms as an integrated effect of mind and body. A more appropriate response (after the patient elaborates on the reasons for this concern) would be, "I can see how you *might* feel that way. But I know that the symptoms you're having are real and are due to your irritable bowel. Also, psychological stress, just like overeating or changes in activity or lifestyle, are part of everyone's life, and it makes bowel symptoms act up more in IBS. I'm prepared to work with you to find out all the things that make your symptoms worse, and we can use that information to help manage your symptoms."
7. **Provide education.** Education involves (1) eliciting the patient's understanding and concerns related to the condition, (2) addressing them, (3) providing information that is consistent with the patient's frame of reference or knowledge base, and (4) checking the patient's understanding of what was discussed.
8. **Reassure.** Patients may fear serious disease or surgery and feel helpless, and they need reassurance. The physician should (1) identify the patient's worries and concerns, (2) acknowledge and validate them, (3) respond to the specific concerns, and (4) avoid "false" reassurances ("Don't worry, everything's fine"), particularly before the medical evaluation is complete, because the patient may view this as a doctor's lack of commitment. For example, for the patient with IBS who is worried about an underlying cancer, the physician might say, "I can understand your concern about the possibility of cancer. However, the symptoms you have and the results of the studies are typical of IBS, and this does not turn into cancer. If new symptoms develop, we'll address them, and when you turn 50 (even if you don't have symptoms), we'll also begin the recommended screening program for polyps and early cancer."
9. **Set realistic, shared goals.** A primary goal is to focus the care on improving daily function and quality of life, rather than on attempting to achieve complete relief of symptoms or cure, which is rarely possible. If a patient expects a cure, the physician should acknowledge an awareness of the patient's expectations but indicate that this is not likely. Efforts are better directed toward achieving relief of symptoms and improving daily function and quality of life. This approach leads to achievable shared goals and frees the physician from the unrealistic burden of taking full responsibility for the patient's well-being. The responsibility for the treatment of chronic illness should be assumed by the patient and facilitated by the doctor.
10. **Negotiate.** The patient and physician must agree on the treatment. After an adequate evaluation has been performed, and with the patient's full understanding of the condition, the physician should ask about the patient's experience and understanding of and interest in various treatments, and then provide choices (rather than directives) that are consistent with these beliefs. If the patient does not believe that stress exacerbates symptoms, then stress reduction techniques are not likely to work and should not be initially recommended. Treatment options that harmonize with the patient's beliefs will be accepted. Negotiation is particularly important when an antidepressant is recommended, or when a referral to a psychologist for pain management techniques is offered.
11. **Help the patient take responsibility.** Patients who continually rely on the physician to make treatment decisions and on family and friends to take care of personal responsibilities, and who frequently worry about their illness or inappropriately seek disability, are abrogating their responsibility for the treatment. Patients need to participate actively in their health care, and this can be communicated in several ways. For example, rather than asking the patient, "How is your pain?" one might say, "How are you managing with your symptoms?" The former question leaves the responsibility for dealing with the pain with the physician, whereas the latter assumes the patient's involvement. Another method includes using a diary. [78] This allows the patient to identify exacerbating factors so as to be able deal with them, or to offer treatment approaches with a discussion of their risks, so that the patient can make the choice. If a treatment does not work, then the patient and physician can consider other options together. The responsibility for treatment should be assumed by the patient and facilitated by the physician.
12. **Reinforce health-promoting behaviors.** Patients with chronic illness may receive attention from family and friends and obtain privileges (e.g., time off from work or other responsibilities, disability) by focusing on symptoms and communicating suffering, and this may reduce the patient's motivation toward achieving health. Therefore, the physician has a role to reinforce more healthful behaviors by minimizing diagnostic strategies, providing symptomatic treatment when needed, and rewarding the patient's ability to adapt to and function in the presence of the illness. For example, if the patient reports numerous symptoms, maintain a neutral manner and do not feel compelled to ask the patient to elaborate on all of them. If the information suggests a need for further medical evaluation, act accordingly; however, if not, redirect the inquiry toward management: "I see, and have you still been able continue your household activities?" If the patient discusses positive steps taken towards new activities, nonverbal reinforcement can encourage healthful behaviors; the physician can engage the patient to elaborate by leaning forward, nodding, and smiling. Because patients may not self-initiate behaviors because of feelings of ineffectiveness, it is important for the physician not to set the patient up to fail. For example, if the patient proposes to begin an exercise program or take on a new hobby, do not say, "That's a great idea, I'm sure you can do it." For if the task is not accomplished, the patient may perceive it as a failure. The physician might say, "Given your pain, it will be a difficult task, but well worth the effort. I'm pleased to hear that you're thinking of ways to get yourself better."
13. **Establish limits.** For some patients, limits with regard to frequent phone calls, unexpected or lengthy visits, or unrealistic expectations for care must be maintained. Some physicians, in their desire to help, may extend the care beyond what feels right, and they subsequently feel trapped when these expectations continue. When this occurs repeatedly, the physician might consider and address whether the patient's behavior reflects certain psychosocial agendas (e.g., concerns about loss or rejection, need to be in control, somatization). Physicians should also assert their needs in terms of time and availability. Not to do so poses the risk of the physician feeling angry or helpless, and this is counter-therapeutic. The physician should present personal needs in a way that is not perceived as rejecting or belittling. For example, setting time limitations on visits can be accomplished by scheduling brief but regular appointments of a fixed duration, rather than by extending the time of a particular visit. Patients should be encouraged to bring up the most important concerns first. When the appointment is about to end, the patient should be reminded that about 5 minutes are left. If time runs out and the patient continues to talk, the physician can indicate nonverbally that the visit has ended (e.g., close up the chart, shift to get up) and mention that what is not finished can be brought up the next time. If the patient still continues to speak, the physician can quietly state that the visit has ended and begin to stand up. If the physician is consistent in this approach, the patient will accept the time-structured visit, provided that the physician maintains a commitment to continuing care. Similarly, frequent unneeded phone calls not requiring immediate intervention are addressed by politely reducing the length of the discussion and referring the issue to the next scheduled appointment. Demands for narcotics can be addressed as, "I appreciate how bad the pain is, but narcotics are not indicated and can be harmful because they are addicting

and may harm bowel function and increase pain. I think we need to identify other, more effective treatments for your pain."

14. **Maintain continuity of care.** An important therapeutic effect takes place when the patient learns that the physician will "be there." This involves a belief that the physician is interested and approachable rather than that the physician is constantly available. Establishing ongoing but brief appointments for patients is also helpful. When the symptoms are particularly difficult to manage, or when coexisting psychological difficulties are recognized, concurrent treatment by a psychologist, psychiatrist, or pain center may be needed.

Once established, an effective physician-patient relationship provides the basis for the efficient acquisition of medical and psychosocial data and a mutually satisfying plan of care.

OBTAINING PSYCHOSOCIAL DATA THE INTERVIEW

The medical interview is the *process* of obtaining data to diagnose, treat, and determine prognosis. It is a natural form of inquiry, although all too often the physician's style may interfere with accurate data collection. When properly carried out, the interview also facilitates the development of an effective physician-patient relationship.

Sample Interviews

Observe the following hypothetical example [1]:

Interview 1 The patient is seated, looking down and with shoulders slumped, as the physician enters the room and sits down.

1. Doctor: "Mr…. uh… *(looks at chart)*… Jones? How can I help you?" Patient: *(speaking slowly, looking down)* "Well, it's this aching… right here… *(points to upper abdomen)*… and diarrhea. I've had it for weeks and…" *(briefly looks up at doctor)*…
2. Doctor: *(writing in chart)* "Epigastric pain and diarrhea… any other symptoms?" Patient: "Well, this achi… this pain makes me not want to eat… and I'm sick to my stomach and tired… I live alone now, and…"
3. Doctor: "Hmm… does eating cause the pain and give you diarrhea?" Patient: "Uh, maybe, I guess…"
4. Doctor: "Can you tell me more about the diarrhea?" Patient: "Well, it's loose… *(pause)*… uh, what do you want to know?"
5. Doctor: "How often do you go?… and is there any blood in the stool?" Patient: "About two or three times a day; no, I don't see any blood."
6. Doctor: "Any other symptoms?… fever, weight loss, or vomiting?" Patient: "Yes."
7. Doctor: *(more hurried)* "Well, fever, weight loss, or what?" Patient: "Don't think I've had any fever. I've lost about 10 pounds, and I'm so tired… don't feel like doing anything." Later, in the interview:
8. Doctor: "Well, it seems like you've had these symptoms for a while. What I'd like to do now is examine you and then order some tests… to make sure there's nothing serious… but from what you've said, I don't think that'll be the case. Uh… is there anything you know that could be causing this?… Are you under any stress?" Patient: Well, I'm having a lot of pressure at work."
9. Doctor: *(smiles, closes chart)* "I can understand that."

Later, the physician obtained blood and stool samples, ordered a small bowel series, and performed a small bowel biopsy and flexible sigmoidoscopy. The results were negative, and the doctor reassured the patient and gave him a diagnosis of IBS. This physician believed he had obtained enough data to make a medical diagnosis. However, the questioning style raises some doubt as to the accuracy and completeness of the medical and psychosocial data, and it is likely that the patient was not satisfied in presenting his concerns. Table 29-1 describes several interviewer behaviors that can influence the quality of the data.

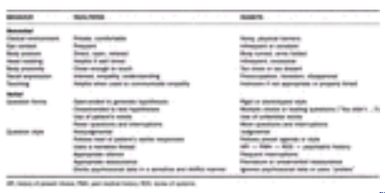

TABLE 29-1 Physician Behaviors Influencing Accurate Data Collection

Several difficulties with the above interview are to be noted:

1. The doctor does not know the patient's name when he greets him (1).
2. Writing in the chart interferes with attention to the patient (2).
3. He interrupts the patient (2, 3, 4, 7).
4. He restates the patient's "aching" as "pain" (2).
5. He asks vague (4) and multiple closed-ended questions (3, 5, 6, 7) that seem to confuse the patient. In general, closed-ended questions are less efficient than a combination of open and closed questions in obtaining medical information. [85]
6. He does not attend to or acknowledge the patient's nonverbal communication (poor eye contact, slumped posture) (1).
7. He does not respond to the patient's verbal cues relating to psychosocial issues (2, 7).
8. He maintains control of the interview, focusing on disease-related questions, without eliciting the patient's agenda (2, 3, 4, 5, 6, 7).
9. He communicates a mixed message about the cause of the illness—that is, he plans to order tests, although he prematurely reassures the patient (8).
10. He "probes" for psychosocial factors only after the medical data have been obtained, implying that the problem is psychological (8).
11. He communicates a lack of interest in exploring psychosocial issues (9).

Consider the differences with another interview style:
Interview 2

1. Doctor: "Hello, Mr. Jones… *(handshake)*… I'm Doctor Smith. How can I help you?" Patient: *(speaking slowly)* "Well, it's this aching… right here… *(points to upper abdomen)*… and diarrhea… I've had it for weeks and… *(briefly looks up at doctor who is attentive)*… I just feel bad."
2. Doctor: "So, you have aching and diarrhea… anything else?" Patient: "Well, I don't feel like eating… and I'm sick to my stomach and tired."
3. Doctor: *(after brief pause)* "Yes?" Patient: *(continues)* "I've lost 10 pounds since this began… *(pause)*… and it keeps me from working."
4. Doctor: *(speaking more slowly)* "So this is affecting your work?" Patient: "Yes… *(briefly looks up as if to say something and then quickly down)*… I worry if it's something serious."
5. Doctor: *(nods, maintains silence)*… Patient: *(continuing)* "I live alone now." *(long silence, nervously looking up and then down)*…
6. Doctor: *(leans forward slightly, looking concerned, and speaks slowly and deliberately)* "Mr. Jones, you seem a bit tense now… Is there anything else you'd like to tell me?" Patient: *(looking down)* "Well,… *(pause)*… I had a roommate who had similar symptoms." *(pause)*…
7. Doctor: *(speaking more softly)* "So you thought you may have caught something? *(patient nervously looks up and then down)… (pause)*… Why do you think that?" Patient: "Well, he was a very close friend… *(long silence, begins to wipe eye and then continues)*… first they didn't know what was wrong… then they found he had AIDS." *(starts to sob)*…
8. Doctor: *(moves closer and after long period of silence)* "I can understand how difficult this has been for you. You've lost someone very close to you and are also concerned about your own health, and it's all affecting your ability to work… *(pause)*… I'd now like to ask you a few more questions about your illness, and then I'll examine you. Whatever we find, we'll need to talk more about what can be done to help you. Is there anything else you'd like to tell me?" Patient: *(looks up)* "No… *(brief smile)*… Thank you, Doctor."

In this interview, the physician obtained additional data that expand the differential diagnosis: The patient may have been exposed to HIV, and depressive symptoms related to the possibility of acquiring the disease and the loss of his close friend may also be contributing to the symptoms. All these possibilities need to be addressed. As noted in Table 29-1, several facilitative behaviors used by this physician are worthy of comment [86]:

1. He readjusts the tempo of his questioning to match that of the patient (4, 6, 7).
2. He uses silence and brief facilitating statements to encourage the patient to elaborate (3, 5).

3. He uses nonverbal behaviors to communicate interest and support (1, 6).
4. He encourages the patient to elaborate by restating his earlier responses (2, 4, 7) without introducing bias.
5. He elicits psychosocial data by facilitation rather than direct inquiry (e.g., probing). This is accomplished nonverbally (e.g., silence, attentiveness [5]) and by a more open-ended interview style that encourages the patient to elaborate on previous cues (4, 7).
6. He acknowledges (and validates) the patient's mood disturbance (6).
7. He simultaneously obtains both psychosocial and medical data. This is done through more open-ended inquiries that explore the symptoms and their psychosocial context (4, 7, 8).
8. He ends by summarizing the patient's concerns and commits himself to help regardless of cause (8). The focus is on the patient's well-being rather than solely on the diagnosis and treatment of disease.

Interview Technique

These vignettes illustrate several important points [87]:

1. The physician seeks to understand the illness from the *patient's perspective* and uses the knowledge to reorient the data into disease-related and behavioral categories. [88]
2. The physician has to have a flexible technique. [89] For example, more open-ended questions are used for patients with unexplained or chronic symptoms, whereas more directed questions are required for medical emergencies. The physician needs to slow his pace to permit a more passively responding patient to elaborate, and to use a more directed style if the patient is garrulous or controlling.
3. The psychosocial and biomedical data are obtained concurrently rather than sequentially. [86] This saves time, yields quality information, and avoids shifting between medical and psychosocial issues that are experienced together. Furthermore, the patient learns to accept the legitimacy of this association, and the physician's interest in hearing about it. It is poor interview technique to avoid psychosocial issues by overly controlling the questions. [90], [91]
4. Addressing the patient's thoughts, concerns, and emotional state facilitates a therapeutic relationship. Being open to communication and caring behavior are major factors in patient adherence to treatment, satisfaction, and continuation of the therapeutic relationship. [77], [92], [93]

UNDERSTANDING THE DATA

Once the medical and psychosocial data have been obtained, their relative contributions to the illness must be determined. Several questions (Table 29-2) can help prioritize these data. [78]

1. Does the patient have an acute or chronic illness?
2. What is the patient's life history of illness?
3. Why is the patient coming now?
4. Is there a history of unresolved major loss or trauma?
5. What are the patient's perceptions and expectations?
6. Does the patient exhibit abnormal illness behavior?
7. What is the impact of the illness?
8. Is there a psychiatric diagnosis?
   a. Depression
   b. Anxiety Disorder
   c. Somatization-Somatoform Disorders
   d. Factitious Disorder
9. Are there cultural or ethnic influences?
10. How does the family interact around the illness?
11. What are the patient's other psychosocial resources?
12. How far do you go in the workup?
13. When do you obtain a mental health consultation?

TABLE 29-2 Questions to Consider When Obtaining and Using Psychosocial Data

Does The Patient have an Acute or Chronic Illness?

Regardless of cause, the longer an illness continues, the more likely psychosocial processes contribute. Medical patients with long-standing unexplained pain are unlikely to have a specific medical disease diagnosed, and psychological assessment usually identifies contributing psychosocial factors. [94]

What Is the Patient's Life History of Illness?

The frequency of other physical complaints and health care visits is an important diagnostic and prognostic indicator. Patients with a history of multiple illnesses and frequent physician visits are more likely to continue to seek health care during future illnesses [68] and have a higher level of life stress and psychosocial disturbances that will require behavioral interventions for improvement. [68] Conversely, patients without a history of medical complaints are likely to require further medical investigation for new symptoms.

Why Is the Patient Coming Now?

With nonemergent symptoms, it is important to determine what factors influenced the patient's decision to seek medical care. These factors are not always volunteered and often must be elicited in a skillful and sensitive manner. For example, asking, "Why did you come now?" may be interpreted as more rejecting than asking, "Was there anything else that led you to see me?" Table 29-3 [95] lists reasons why patients may seek medical care and offers suggestions for treatment.

REASON	PHYSICIAN'S APPROACH
Recent symptom exacerbation	1. Identify exacerbating factors (e.g., diary). 2. Encourage patient to modify them.
Fear of serious disease	1. Determine underlying concerns (e.g., recent family death/illness, prodding by spouse). 2. Offer reassurance. 3. Avoid premature or false reassurance ("There's nothing wrong ... it's nerves").
Environmental stressor(s)	1. Identify stressor(s). 2. Determine patient's insight and ability to work toward changing stressor(s). 3. Determine best treatment approach: a. Wait for resolution. b. Counsel patient. c. Suggest stress reduction techniques. d. Refer for psychological counseling.
Psychological distress	1. Is there a psychiatric diagnosis? a. Anxiety b. Depression c. Somatization 2. Consider psychopharmacological treatment. 3. Consider psychiatric consultation.
Functional impairment	1. Determine change in functional status. 2. Set treatment goal to improve function rather than relief of symptoms.
"Hidden agenda"	1. Determine the hidden agenda: a. Narcotics b. Laxative abuse c. Disability d. Keep sick role privileges (work/home) 2. Clarify limits of your role in treatment.
Social/cultural factors	1. Determine if a. Physician visits are for social support. b. There are cultural effects (e.g., "roots," folk remedies). c. There is a need to legitimize to family/friends. 2. Adapt treatment to be consistent with patient beliefs or expectations: a. Set up brief, regular appointments. b. Permit "folk" remedies if not harmful.

TABLE 29-3 Why Is the Patient Coming to the Doctor?

Is There a History of Unresolved Major Loss or Trauma?

Unresolved losses (e.g., the death of a parent or spouse), personally meaningful operations (e.g., hysterectomy, ostomy), or interference with the outcome of a pregnancy (abortion, stillbirth), may be associated with symptom exacerbations or difficult adjustments to medical disease soon after these events, on their anniversary, or during the holiday season. [96], [97] The physician should realize that illness sometimes serves as an unconscious adaptive mechanism to minimize the

reality of the loss. [98] Although patients may initially deny this association, the loss and its effects (which may require psychological adjustment or counseling) can be acknowledged without linking them to the symptoms.

A history of physical or sexual abuse in medical patients, [99] and particularly in GI patients, [100] is associated with a poor health outcome: more severe pain, symptoms (somatization), health care use, and surgery. [52], [101] These effects of trauma may be related to an increased awareness of bodily sensations, comorbid psychosocial disturbances or poor coping strategies, or a reduction of the pain threshold by peripheral or central mechanisms. [102] The case of the male patient with GERD and IBS presented at the beginning of this chapter illustrates this point.

It is important for physicians to consider prior abuse, particularly among patients with chronic unexplained symptoms. Patients do not usually volunteer this type of information. [101] A history of abuse should be considered in patients with any of the following: severe chronic pain (particularly abdominal or pelvic), severe constipation (pelvic floor dyssynergia), eating disorders (bulimia nervosa, morbid obesity), a history of multiple operations, sexual dysfunction, and severe psychological disturbances (somatization, dissociation or borderline or multiple personality disorder, posttraumatic stress disorder, substance abuse). [100]

It is important to obtain this history in a sensitive and caring manner because further counseling or support groups may facilitate psychosocial adjustment. [100] The patient should first be given the opportunity for voluntary disclosure: “Is there anything else you would like to discuss that you think is important?” If the patient says, “Things were pretty bad then,” elaboration should be encouraged. If no history of abuse is volunteered, the patient might be asked, “Are there any experiences we haven’t discussed that have been particularly painful or difficult?” A negative response is satisfactory; however, a mixed response is still concerning. The patient can be asked more directly, “As you may know, it’s not uncommon for women to have been emotionally, physically, or sexually victimized at some time… has that ever happened to you?”

If the patient denies a history of abuse but the nonverbal behavior is incongruent, it is best to register that information for future inquiry and say no more. If the patient acknowledges abuse, remain nonjudgmental and provide support and gentle encouragement to continue. However, learning the details of the experience is not as important as sustaining an empathic environment for possible future disclosure. When a history of trauma is acknowledged, it is important to inquire whether the patient would like to discuss these thoughts and feelings further with others having similar experiences, or with professionals trained to address the issue further.

What Are the Patient’s Perceptions and Expectations?

Case Example [62]

A 27-year-old homemaker with chronic, moderately active ulcerative colitis for 13 years and high-grade epithelial dysplasia on colonoscopic biopsy on two occasions refused colectomy. During several unsuccessful attempts to “educate” regarding the “medical” reasons for the procedure, she expressed the fear that she would be unable to have children; she and her husband were childless. When these unrealistic fears were addressed, she consented.

This vignette illustrates the need to identify patient misperceptions or unrealistic expectations. Important questions to ask include, “What do you think is causing this problem?” “What are your concerns or fears about this illness?” “What kind of treatments do you think you should receive?” and “What do you hope I will be able to do for you?” [103] Patients who respond, “That’s why I came to you” or “You’re the doctor” should be encouraged to assume greater responsibility for their health care (see below).

Some patients with chronic illness may have unrealistic expectations of another diagnosis or a cure and must be encouraged to state their expectations to work toward realistic treatment goals. Many patients believe that a negative evaluation means that the illness is imagined or psychiatric, which may lead to further requests for unneeded diagnostic tests. This issue needs to be addressed in a manner that does not undermine the patient. For example, consider a patient with chronic abdominal pain who urgently requests that another unnecessary computed tomogram be obtained to rule out a cancer. [72] Rather than trying to “convince” the patient that “nothing is wrong” (by pathological standards), the physician should acknowledge the concern that a cancer must not be overlooked, and that many patients with chronic pain have “real” pain not identified by imaging. [72] Then, the physician can state that based on the clinical data, this test is not indicated but might be performed if, for example, the results of certain laboratory tests became abnormal. Avoid ambiguous behaviors that increase doubts or fears (e.g., ordering studies to convince the patient or “just to be sure”). A commitment to maintain vigilance for new developments and ongoing care reduces the need to perform unneeded diagnostic studies or administer unnecessary treatments.

Does the Patient Exhibit Abnormal Illness Behavior?

The varying patterns of how symptoms are perceived, evaluated, and acted on are designated *illness behaviors*. [104], [105] These are determined by current and prior experiences with illness, the attitudes and behaviors of family, friends, culture, and society, and the patient’s personality, current psychological state, and coping style. *Maladaptive* illness behavior [106], [107] should be considered when there is (1) disability disproportionate to detectable disease, (2) a relentless search for validation of disease, (3) placement of control and responsibility for health care with the physician, (4) a continued sense of expectation to be cared for by others, (5) a tendency to avoid health-promoting roles, and (6) adoption of and (7) display of behaviors oriented toward exemption from work or family obligations, avoidance of stressful situations, or dependence on the physician, with abrogation of personal responsibility in the plan of care.

What Is the Impact of the Illness?

Physicians must decide whether, when, and to what degree medical or behavioral intervention is necessary. Particularly in cases of chronic illness, this decision is best made based on the effect the illness has on the patient’s daily life. For example, pain that leads to decreased activity or ongoing loss of time at work will require more intervention than pain that does not interfere with the performance of daily activities.

Health-related quality of life (HRQOL) incorporates the patient’s perceptions, experiences, and functional status during an illness. [108] This evaluation differs from disease assessment in that psychosocial (e.g., daily function, recreation, sexual function) *and* symptom- or disease-related factors are considered, and its validity rests with the patient rather than on biologic or physician-based standards. Research in HRQOL is growing for gastrointestinal disorders [109], [110], [111] and [112] and postsurgical outcomes. [113], [114]

Is There a Psychiatric Diagnosis?

Psychological illness, such as depression and anxiety, are the common underrecognized diagnoses frequently associated with physical symptoms. [115], [116] A psychiatric diagnosis will modify the patient’s experience of medical disease. Proper disease management may also include antidepressant or antianxiety drugs or behavioral interventions.

In recent years, psychiatric diagnosis has become standardized through the use of the *Diagnostic and Statistical Manual of Mental Disorders,* published by the American Psychiatric Association and currently in its 4th edition (DSM-IV). [117] Because many psychiatric diagnoses (anxiety, panic, somatization) rely on gastrointestinal symptoms, care should be taken not to overdiagnose a psychiatric disorder when the symptoms can be explained by a GI condition (e.g., IBS or IBD).

Depression Depression exists on a clinical continuum ranging from a normal emotional response to loss (the “blues”), to a more intense expression of mood (depressive symptoms), to a collection of signs and symptoms (syndrome of depression), to a severe state of neurochemical disturbance (disease). Similarly, the therapeutic interventions for depression (e.g., “tincture of time,” counseling, pharmacotherapy) are determined by the degree and persistence of the disorders on this continuum. The DSM-IV [118] lists several diagnostic categories of depression: *Major Depression, Single (296.2x)* or *Recurrent (296.3x), Dysthymic Disorder (300.40),* and *Depressive Disorder Not Otherwise Specified (311). Major Depression* is characterized by one or more episodes lasting for at least 2 weeks of depressed mood or diminished interest or pleasure in activities and associated symptoms that may include the following: change in weight, sleep disturbance, psychomotor agitation or retardation, loss of energy, feelings of worthlessness or inappropriate guilt, decreased concentration, and recurrent thoughts of death. *Dysthymic Disorder* is a more chronic (lasting longer than 2 years) disturbance of depressed mood with the same associated symptoms. Finally, *Depressive Disorder Not Otherwise Specified* includes depressive features that do not meet more specific criteria for a mood disorder. It is important to rule out other conditions, including other medical or

psychiatric disorders (e.g., dementia), uncomplicated bereavement, and effects of drugs (corticosteroids, cimetidine, alcohol, benzodiazepines, and a variety of antihypertensive agents) that may mimic or exacerbate an affective disorder. Primary depression may be manifest more in terms of somatic complaints or pain than mood disturbance. If a patients exhibits loss of interest (anhedonia), a depressed affect may not be required to make the diagnosis of depression. [118] Treatment may include antidepressant drugs, psychological (e.g., cognitive-behavioral) therapy, or both. Patients with chronic pain and disability usually have comorbid depression [119], [120] and, not infrequently, a history of loss or abuse. Depending on the severity, treatment may include psychological care by the medical physician or a mental health professional, or antidepressant drugs. Using the previously described interview style, the physician may determine that the patient is depressed and may elicit contributing factors, such as childhood abuse. If there is a long-standing history of pain and the negative studies to date preclude further extensive diagnostic evaluation, the focus should now be on treatment and adaptation to the chronic disorder. Patients may be offered psychological counseling to help them cope with the condition. If this is refused, antidepressant medication may be prescribed to reduce pain and associated symptoms, such as fatigue and poor sleep. Monthly follow-up visits oriented toward improvement in function may be scheduled. Although the sleep disturbance, fatigue, and sense of hopelessness may improve, the long-standing history of pain and chronic illness may preclude complete pain relief. Treatment should therefore be directed toward improved function and adaptation to the chronic illness.

Anxiety Disorders Anxiety is perceived as an impending threat or danger from an unknown or irrational source. It may be associated with a specific stimulus (e.g., phobia), or it may not (e.g., “free-floating” anxiety). It may cause autonomic activation (“flight-fight” response), with symptoms of breathlessness, palpitations, chest or abdominal discomfort, diaphoresis, and diarrhea. An anxiety disorder should be considered in the differential diagnosis of patients presenting with GI symptoms. However, symptoms of anxiety not related to the psychiatric disorder can be caused mainly by the effects of disruptive GI symptoms, such as diarrhea. *Panic Disorder (300.01)* [121] may be the most common anxiety disorder leading to medical visits. It is characterized by recurrent unexpected episodes of panic associated with any the following for at least 1 month: persistent concern about having additional attacks, worry about the implications of the attack, or a change in behavior related to the attacks. At least four or more of the following must be present to define a panic attack: palpitations, sweating, trembling, sensation of shortness of breath or smothering, choking sensation, chest discomfort, nausea or abdominal distress, dizziness or lightheadedness, feelings of derealization, fear of losing control or going crazy, fear of dying, paresthesias, or chills or hot flushes. Another anxiety disorder is *Generalized Anxiety Disorder (300.02),* which is characterized by chronic (lasting at least 6 months) unrealistic or excessive anxiety about life circumstances (e.g., finances, health) that are difficult to control and associated with three or more of the following: restlessness or feeling on edge, being easily fatigued, difficulty concentrating, irritability, muscle tension, and sleep disturbance. Similar disorders include *Panic Disorder with Agoraphobia (300.21)* (symptoms lead to avoidance of places or situations), *Simple (300.29)* or *Social (300.23) Phobias, Posttraumatic Stress Disorder (309.89),* and *Obsessive-Compulsive Disorder (300.30)*. Benzodiazepines are effective in the short-term treatment of anxiety disorders [122]; however, withdrawal rebound is a risk, and tricyclic antidepressants [123] and selective serotonin reuptake inhibitors [124] are also effective and favored for long-term use. Relaxation exercises with respiratory control and cognitive maneuvers improve the patient’s sense of control and help reduce the frequency and severity of panic attacks. [125], [126] and [127]

Somatization-Somatoform Disorders Somatization is the tendency to experience and communicate psychological distress as physical symptoms that are misinterpreted as serious physical illness. *Somatization Disorder (300.81)* is characterized by numerous physical complaints beginning early in life. With this presentation, a prior history of abuse should be considered. [128] A history of many unexplained physical complaints leads to medical visits and impaired social functioning. The complaints must include the following: at least four pain symptoms (e.g., head, abdomen, back, joints, chest), two GI symptoms (e.g., nausea, bloating, vomiting, diarrhea), one sexual symptom (e.g., sexual indifference, irregular menses, vomiting in pregnancy), and one pseudoneurological symptom (e.g., impaired balance, paralysis, hallucinations, loss of sensation, blindness). Other somatoform disorders to consider are *Conversion Disorder (300.11), Hypochondriasis (300.70), Undifferentiated Somatoform Disorder (300.81),* and *Pain Disorder*. Medical or psychiatric diagnoses, or drugs that explain these symptoms, must be excluded. Treatment usually involves behavioral interventions that help reduce the patient’s tendency to communicate via bodily complaints. Antidepressants may be empirically tried as a means to increase the symptom threshold.

Factitious Disorder Patients who have *Factitious Disorder with Predominantly Physical Signs and Symptoms (300.19)* [129] simulate illness (e.g., surreptitiously ingest laxatives or anticoagulants, inject stool, produce false elevation of temperature) in a manner not likely to be discovered. Unlike the motives of patients who malinger, consciously feigning illness for obvious gain (e.g., to obtain drugs, be excused from work, be placed on disability), the motives of these patients are more enigmatic; they usually are attempting to obtain certain benefits (e.g., to be taken care of) in the sick role. An important subgroup of patients with Factitious Disorder are GI patients with laxative-induced factitious diarrhea. [130], [131] Because patients will deny the use of laxatives, the diagnosis usually is based on detecting the substance by stool examination. Phenolphthalein-containing laxatives (e.g., Ex-Lax and Correctol, recently removed from U.S. products) turn pink on alkalinization of the stool or urine. The anthraquinones (e.g., senna, cascara) cause melanosis coli, which can be detected at sigmoidoscopy, and the osmotic laxatives (e.g., sodium phosphate) can be detected by stool electrolyte analysis. In addition, increasing the stool volume with urine or water can be detected by a high stool urea concentration or a low stool osmolality, respectively. If the patient’s activities are a threat to life, a room search may be ethically justified. The findings must be disclosed in a nonpunitive manner, and only when the diagnosis is certain. The problem should be presented as a difficult-to-control compulsive disorder that requires treatment; a confrontation because of unacceptable behavior should be avoided. If the patient refuses psychiatric help, the physician can continue to monitor the medical status. Patients with depressive features may benefit from antidepressants.

Are Cultural or Ethnic Influences Involved?

Cultural or ethnic beliefs may modify clinical illness or the patient’s interactions with traditional health care systems. Strong cultural beliefs regarding illness exist in many ethnic groups, including African Americans, Hispanics, Native Americans, and Gypsies. [132] Physicians should inquire about the patient’s beliefs regarding the onset, pathophysiology, expected course, and desired or expected treatment. [65] When possible, the patient’s illness model should be considered in planning treatment, and doing so may lead to effective interventions.

How Does the Family Interact Around the Illness?

For the most part, early family experiences with illness are associated with some attention and support, although with an orientation toward recovery and health, and usually this carries through to adult life. However, undue attention to illness during childhood may affect later illness behaviors, such as health care visits and costs. [133], [134]

In certain “psychosomatic families,” attention to an illness serves to maintain family harmony. When tensions arise in emotionally linked (“enmeshed”) families, an afflicted child (with diabetes, asthma, inflammatory bowel disease, or anorexia nervosa) is conditioned to focus on the illness, thereby diverting attention from the family distress. [135] This conditioning may inhibit the child’s later ability to achieve autonomy, and the pattern may continue even into adulthood. If the patient is married, at some time the patient and spouse should be seen together. Inquiry should be made about how the spouse perceives and responds to the patient’s illness. When healthy family behaviors are seen, the members can be recruited into helping the patient toward recovery.

What Are the patient’s Other Psychosocial Resources?

Psychosocial factors that promote health (by providing social support, such as churches, recreational clubs, and community organizations) play a role in “buffering” the adverse effects of stress on physical and mental illness and need to be identified. Patients with good social support experience a sense of control over their illness and report lower stress levels than with less social support. [136], [137] Coping, defined as “efforts, both action-oriented and intrapsychic, to manage (i.e., master, tolerate, minimize) environmental and internal demands and conflicts, which tax or exceed a person’s resources,” [138] is another mediating psychosocial factor that promotes health. Among GI patients, a maladaptive coping style such as “catastrophizing” exacerbates symptoms and psychological distress, adversely affects quality of life, and increases physician visits and the risks of surgery. [53], [139]

How Far Do You Go in the Workup?

Abnormal findings on the physical examination or abnormal results of screening tests (e.g., blood in stool, fever, abnormal liver chemistries, abdominal mass) will determine whether further diagnostic studies are needed. [140] In their absence, and particularly in cases with psychosocial difficulties, it is wise to follow the illness over time before making diagnostic decisions. A common pitfall is to overdo diagnostic studies when the physician is uncertain and when the patient insists that “something be done.” [73], [84]

When Do You Obtain A Mental Health Consultation?

When psychosocial factors (e.g., psychiatric diagnosis, psychosocial trauma, impaired functioning) strongly contribute to an illness, a mental health onsultation should

be considered. The consultant will help determine whether pharmacological or additional psychological treatments are needed.

TREATMENT

Psychopharmacotherapy

Psychopharmacological agents may be used to treat patients with moderate to severe functional GI disorders, and as an adjunct in the treatment of patients who have other GI diseases with or without evidence of a primary psychiatric disorder.

Antidepressants The rationale for the use of antidepressants, either tricyclic antidepressants (TCAs; e.g., amitriptyline, imipramine, desipramine), selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine, sertraline, paroxetine, citalopram), or less frequently novel antidepressants (e.g., venlafaxine, mirtazapine), may be based on several possible mechanisms and includes the following: (1) treatment of psychiatric comorbidity (with full therapeutic doses) associated with IBS, (2) alteration of gastrointestinal physiology (e.g., visceral sensitivity, motility, and secretion), [141], [142] and [143] and (3) reduction of central pain perception arising from afferent signals in the gut, possibly via facilitation of descending corticofugal pain modulator pathways. [144], [145] The choice of an antidepressant will often depend on its known side effects. The *TCAs* appear to be effective in GI and other conditions. [8], [146] In addition to primary actions on noradrenergic and serotonergic receptors, they also have antimuscarinic and antihistaminic effects leading to symptoms of orthostatic hypotension, constipation, sicca syndrome, sedation, fluid retention, cardiac arrhythmias, and weight gain. Amitriptyline and doxepin have strong sedative effects, so that a single nighttime dose can promote sleep. It has been shown that poor sleep quality is associated with increased bowel symptoms, [147] and therefore these agents can potentially improve both GI and extraintestinal symptoms. However, desipramine or nortriptyline may be chosen if less anticholinergic and sedative effects are desired. The TCAs also decrease phase III propagation velocity and increase orocecal transit time, [142] and clinically they can reduce diarrhea symptoms in patients with IBS. [148] Although full antidepressant doses of TCAs are less frequently used today to treat psychiatric conditions (mainly because of their side effects), smaller doses are widely used to treat a wide variety of chronic pain conditions and functional disorders, [146] including IBS. At lower doses than those usually used to treat depression (up to 75 mg nightly), amitriptyline has been found to be significantly more effective than placebo in reducing abdominal pain and producing global improvement in patients with IBS. [146], [149] Antidepressants have neuromodulatory and analgesic properties, which may benefit patients independently of the psychotropic effects of the drugs. Neuromodulatory effects may occur sooner and at lower doses than those used to treat depression (e.g., 10 to 25 mg of amitriptyline or 50 mg of desipramine). Treatment with TCAs should begin with low doses (e.g., 25 mg/d) and be increased as needed up to full therapeutic doses. The *SSRIs* have not been adequately studied in the treatment of patients with GI disorders and are more expensive, but empirically they help reduce painful symptoms and improve general well-being. [144] They may be particularly helpful for patients with coexistent anxiety, paniclike symptoms, or obsessional behaviors. [124] In addition, they are safer and better tolerated than the TCAs and produce little risk from overdose. Their side effects include nausea, agitation, sleep disturbance (insomnia more often than somnolence), vivid dreams, sexual dysfunction (delayed ejaculation or anorgasmia), night sweats, and possibly weight loss (particularly with fluoxetine). Especially with sertraline or fluoxetine, up to 15% of patients experience diarrhea. However, paroxetine has more antimuscarinic effect than the other SSRIs and may be associated with constipation. [124] Most patients will benefit from a single morning dose (10–20 mg of fluoxetine or citalopram, 50 mg of sertraline, 20 mg of paroxetine, 50 mg of luvoxamine). However, lower doses may be required for the elderly or for patients with liver disease because of the prolonged half-life of the metabolites in these cases. In addition, because of their high affinity for the cytochrome P450 system (particularly paroxetine), the SSRIs should be used with caution if given with TCAs, benzodiazepines, anticonvulsants, antiarrhythmics, or warfarin. [124] Some psychiatrists take advantage of this effect by adding a low dose of an SSRI when patients show an incomplete response to a TCA. Within the SSRI class, fluoxetine may be selected when poor compliance is an issue because the drug has a long half-life; citalopram has been considered to have the lowest side effect profile and may be of particular benefit because of its ability to relieve symptoms via peripheral effects on colonic tone and sensitivity in IBS, and paroxetine has more anticholinergic effect and therefore may be selected for patients with significant diarrhea. Table 29-4 compares low- and high-dose TCAs and SSRIs. In addition, other, novel antidepressants are available; for example, mirtazapine has a potentially beneficial 5-HT $_3$ receptor–blocking effect and should be considered for patients with poor sleep, an inability to gain weight, and diarrhea. Venlafaxine, which produces combined serotonin and norepinephrine uptake inhibition, has been shown to increase stimulated pain thresholds [150] and has been suggested for the treatment of certain chronic painful disorders. [151]

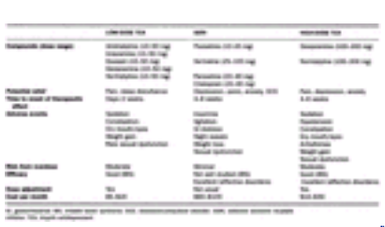

TABLE 29-4 Psychotropic Agents

Most clinicians choose an antidepressant when symptoms of abdominal discomfort are frequent or severe or lead to a loss of usual daily function. It should be continued for 6 to 12 months before tapering is considered. To encourage compliance, patients should be informed that the medication is not addictive and acts as a central analgesic that controls pain in various medical conditions by reducing visceral afferent function or facilitating descending pain inhibitory pathways. However, it also treats depressive symptoms induced by the illness. [78] Patients should also be informed that it can take up to several weeks to work, and that side effects, if they occur, abate over 1 to 2 weeks. A poor clinical response may be caused by noncompliance or a dose that is lower than adequate. [152]

Anxiolytics The benzodiazepines (e.g., diazepam, lorazepam, alprazolam) are most frequently used to treat the experience and behavioral effects of anxiety and stress-induced symptom exacerbations. In view of their weak treatment effects and a potential for physical dependence and interaction with other drugs, benzodiazepine anxiolytics should be prescribed with caution and for a limited period of 1 to 3 weeks. Overall, a benefit for patients with chronic GI disturbances remains to be proved. Also, benzodiazepines may be contraindicated for patients with chronic pain and depression because they decrease serotonin levels and lower pain thresholds, and by stimulating ?-aminobutyric acid receptors, they may actually contribute to depression. [153] Newer antianxiety agents, such as buspirone, do not act on the benzodiazepine receptor, so they may have fewer short- and long-term side effects. [154] Preliminary evidence suggests that 5-HT $_1$ agonists such as buspirone may have a role in decreasing GI symptoms because of their relaxing effects on visceral organs. [155] However, it is not clear whether central or peripheral effects mediate the therapeutic effects in IBS, and further studies are needed.

Antipsychotic Drugs Also called *major tranquilizers* or *neuroleptics,* the phenothiazines (e.g., chlorpromazine) and butyrophenones (e.g., haloperidol) and newer agents (e.g., risperidone) produce improvement in disordered thought, perception, and behavior among psychotic patients. They are of limited value for medical patients, although have been used for nighttime sedation (phenothiazines) and to treat acute agitation or alcohol withdrawal.

Opiates These agents have little or no role in treating patients with chronic pain or psychosocial disturbances because of their potential for tachyphylaxis, abuse, and dependency. Furthermore, they may produce “narcotic bowel syndrome,” leading to worsening abdominal pain and secondary pseudo-obstruction with ileus and vomiting. [156], [157]

Psychological Treatment

Referral for psychological treatment can be proposed as part of a multicomponent treatment package to help patients better manage their symptoms or to address psychosocial difficulties (e.g., abuse, loss) that may interfere with daily function and ability to cope with the illness. In general, these treatments are reserved for patients with moderate to severe symptoms, particularly if they experience psychological distress. However, patients must perceive the treatment as relevant to personal needs. One study found that patients who do not recognize an association between stress and GI symptoms are less likely to respond to psychological treatment. [158]

Some patients may be reluctant to see a psychologist or psychiatrist because they do not understand the benefits of a referral, viewing it as a rejection by the medical physician because of a psychiatric rather than a physical problem. It helps to explain that the mental health professional is a member of a treatment team involved in the patient’s overall management. For patients who do not associate stressors with symptom exacerbation, the physician should indicate that psychological treatment also helps to reduce the psychological distress associated with the symptoms. Furthermore, the psychiatrist may also recommend a pharmacological agent to help with pain control. Continued medical care is essential, even in cases in which the primary focus of treatment involves psychological techniques.

In recent years, specific treatments based on psychological methods to achieve symptom reduction or help patients adapt to their medical condition have become more widely used and accepted by patients. Most of these treatments have been administered to patients with IBS, although they may be potentially beneficial for

patients with other GI conditions.

In a review of the best-designed studies of the treatment of IBS, psychological treatment was superior to conventional medical therapy in 8 of 13 studies. [8] In 7 of 8 studies, psychological treatment continued to be superior to placebo during follow-up (duration, 9–40 months), indicating the these methods have lasting value. The choice of treatment will depend on the patient's requirements, available resources, and the experience of the therapist. The most commonly used psychological treatments in the management of functional GI symptoms are summarized below.

Cognitive-Behavioral Treatment Cognitive-behavioral treatment identifies maladaptive thoughts, perceptions, and behaviors and attempts to "reframe" or modify them to increase control of symptoms. A symptom diary can demonstrate that symptoms are triggered by stressors or lead to negative cognitions (e.g., fear of dying or of cancer, feelings of hopelessness or lack of control, "catastrophizing"). [78] Controlled studies have shown a benefit [8] and a reduction in health care costs [159] for cognitive or behavioral techniques in the treatment of IBS.
Stress Management Stress management is usually taught in small groups in which education and relaxation techniques are provided. Such a treatment program was shown to be superior to a phenothiazine/tricyclic combination (Motival) for IBS. [160]
Dynamic (Interpersonal) Psychotherapy This type of treatment proposes that psychological and physical distress is exacerbated by difficulties in interpersonal relationships, leading to feelings of anxiety. [158], [161] Addressing the psychological issues helps the patient achieve symptom control, which in turn helps prevent recurrences of bowel symptoms. Trials have shown greater and sustained improvement in physical and psychological symptom scores in psychotherapy groups than in support control groups in refractory IBS [158] and functional dyspepsia. [162]
Hypnotherapy Hypnotic induction involves eye fixation, hand levitation, and other techniques to deepen the hypnotic state and increase the subject's openness to progressive muscle relaxation and "gut-directed" hypnotherapy. [163], [164] Patients who undergo hypnosis have fewer bowel symptoms and an improved sense of well-being in comparison with patients in psychotherapy or controls, [163] even after 18 months. [165] Its effect is associated with reduced colonic contractile activity [166] and normalized thresholds for pain caused by distention with a rectal balloon. [167]
Relaxation (Arousal Reduction) Training Reduction in skeletal muscle tension helps counteract the physiological effects of stress or anxiety by decreasing autonomic arousal, tension, and anxiety, and possibly gut motility. Transcendental meditation, mindfulness meditation, and yoga are methods used to achieve these goals.

Behavior Modification

Withdrawal from Narcotics Narcotic abuse is a common problem in patients with chronic pain and other functional GI disorders. Outpatient efforts to reduce narcotic medication gradually are frequently unsuccessful. One approach [168] involves the gradual reduction of a narcotic given on a noncontingent basis in an inpatient setting. The patient must understand and agree to all aspects of the protocol, except for the percentage and timing of the dose reduction. The method involves gradually reducing the usually prescribed dose of the narcotic, generally by giving a long-acting agent (e.g., methadone) over several days and using frequent dosing (to avoid withdrawal effects) in a noncontingent fashion. Clonidine (0.1 mg orally twice daily, or as a patch) is given to minimize withdrawal effects [169] and to help reduce GI symptoms. [170] In addition, a long-acting benzodiazepine is given during the withdrawal phase, and a TCA is begun to provide long-term analgesia if pain is a problem.
Bowel Retraining Bowel retraining can be recommended for patients with habit constipation resulting from poor bowel training or laxative abuse. The technique assumes that the patient has lost the normal physiological response (the "call to stool") and has no underlying organic disturbance in bowel function. All stimulant laxatives are withdrawn or discontinued. The patient is prescribed a high-fiber diet or a daily fiber supplement and an osmotic cathartic (e.g., lactulose or sorbitol). The fiber is not taken if the patient shows evidence of a markedly delayed transit time. The patient eats breakfast and drinks coffee or tea to stimulate the bowels, and then sits for 15 to 20 minutes on the commode. While on the commode, the patient should read for relaxation. There should be no obligation to "perform"; the effort is to identify a time when bowel function can naturally resume. If the patient does not have a bowel movement in 48 to 72 hours, an enema is taken.

CONCLUDING COMMENT: PHYSICIAN CONSIDERATIONS

Physicians have certain desires and expectations in their work [73]: to make a definitive (and at times challenging) diagnosis, to experience intellectual "closure"—an understanding of the medical issues based on existing knowledge, to facilitate a gratifying treatment response (or cure), to feel accomplished (and sometimes praised) in their work, and to establish a mutually gratifying physician-patient relationship.

Unfortunately, these expectations are not met with all patients. In patients with functional (e.g., IBS, functional dyspepsia) or organic (e.g., IBD, GERD, pancreatic or liver disease) GI disorders, psychosocial factors may influence symptoms and behavior in ways that are not understood in terms of the disease or treatable by disease-specific measures. [1] This uncertainty may lead some physicians to feel ineffective in their diagnostic and treatment efforts, [171] and these feelings can be heightened by patients who continue to suffer, and who fail to praise or even criticize the physician.

Some summary guidelines can be offered to help physicians feel more satisfied with their care of patients under these conditions:

1. Make an effort to understand the illness from the patient's perspective, including the psychosocial correlates of the illness.
2. Accept and acknowledge the degree of discomfort or suffering that patients may report.
3. Once the diagnostic issues are clear, accept the uncertainty inherent to medical practice and do not overreact to the patient's distress.
4. Be aware of the "process" of interaction with the patient. "It's not what you do, but how you do it that makes a difference."
5. Refocus the treatment from "cure" or rapid recovery to symptom management and adaptation to illness, including improvement in psychosocial function and quality of life.
6. Work toward achieving mutually determined long-term goals (e.g., return to work, exercise program).
7. Attempt to increase the patient's responsibility ("empowerment") for the plan of care.
8. For patients with seemingly unrealistic needs and demands, determine if they are important from the patient's perspective, and if so, attempt to find a compromise. If they are unrealistic (e.g., undergoing surgery for chronic pain), clearly present your views and limitations in a respectful manner.
9. Remain aware of your thoughts and feelings in the interaction, which will help avoid decisions that later may be regretted (*furor medicus*). [172]
10. Set up and adhere to realistic goals regarding personal time and effort.
11. Finally, some physicians may feel unable or unwilling to work in this manner with patients. They continue to feel frustrated in the effort, and to continue benefits neither the patient nor the physician. When this occurs, appropriate referral is recommended.
