Treatment is dependent on the type of lesion. [70] Low lesions can be treated by dilation of fistula tracts with or without anoplasty. Most healthy infants with low lesions do not require colostomies. Intermediate and high lesions are treated with an initial diverting colostomy to allow a period of stabilization and growth. A number of pull-through operations have been advocated. The posterior sagittal approach developed by Peña and deVries [71] identifies and divides the levator muscle complex. The rectal segment is then identified and brought through the center of the divided muscles. A coloanal anastomosis is performed in the location of the anal dimple. Most series have claimed a 70% to 82% success rate with intermediate and high lesions. [72] A greater success rate can be expected with low lesions.

Volvulus

Volvulus occurs whenever an air-filled segment of bowel twists about its mesentery and almost never occurs if the colon is filled with solid stool. A dilated, redundant colon with a narrow-based mesocolon is a prerequisite for colonic volvulus. In the United States, fewer than 10% of colonic obstructions are caused by colonic volvulus. In countries with high-fiber diets, volvulus has been reported as the most common cause of intestinal obstruction. [73] Volvulus is classified and treated according to its location in the colon.

Sigmoid volvulus accounts for approximately 60% of all volvulus seen in the United States. [74] It usually occurs in older adult or institutionalized patients or in patients with various neuropsychiatric disorders. Chronic constipation, laxative abuse, and colonic atony have been implicated as the causes of the dilated, redundant sigmoid

colon.

Patients usually present with abdominal pain, distention, and obstipation. Evidence of peritoneal irritation on physical examination, fever, or an elevated leukocyte count indicates gangrenous bowel. Plain abdominal radiographs showing an inverted, U-shaped, sausagelike loop with a dense line running toward the point of torsion are diagnostic for sigmoid volvulus. In questionable cases, radiologic enema examination with barium or with water-soluble contrast may be diagnostic. The "bird's beak" deformity forms where the contrast tapers to a point at the site of obstruction (Fig. 82-13). Reduction of the volvulus can occur during these examinations. If the patient has signs of peritoneal irritation or gangrene is suspected, barium or Gastrografin enema (Bracco Diagnostics, Inc., Princeton, NJ) should not be attempted, and the patient should undergo emergency exploration.

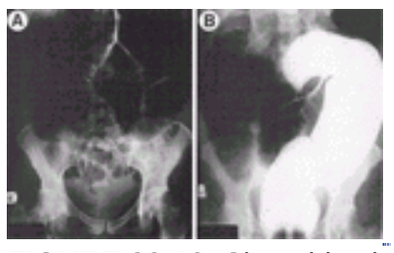

FIGURE 82-13. Sigmoid volvulus. **A**: The gas-filled, dilated colon is evident on a plain film of the abdomen. Note the paucity of gas in the rectum. **B**: Hypaque enema shows tapering of the column of contrast at the site of torsion ("bird's beak" sign) of the sigmoid colon.

If peritonitis is not present, sigmoidoscopy should be performed. Inserting a soft rectal tube past the point of obstruction can often reduce the volvulus. This results in dramatic decompression, and the rectal tube is left in place to assist with further decompression. Volvulus beyond the limits of the rigid sigmoidoscope may be reduced by flexible sigmoidoscopy or colonoscopy. [75] A 43% recurrence rate after nonoperative reduction can be expected. [76] Therefore, after reduction, medically stable patients should undergo mechanical bowel preparation and an elective resection. Evidence of mucosal ischemia, bloody discharge, or unsuccessful detorsion indicates strangulation and possibly gangrene. If this occurs, sigmoidoscopy should be terminated, and the patient should undergo an emergency exploration. Mortality is related to the presence of gangrenous bowel. [76]

Cecal volvulus accounts for fewer than 20% of all cases of colonic volvulus and is generally seen in younger patients. [75] It is thought to be caused by anomalous fixation of the right colon, leading to a freely mobile cecum. [77] Other precipitating factors include adhesions from previous surgeries, pregnancy, and obstructing lesions of the left colon. Ninety percent of patients with cecal volvulus have a full axial volvulus twisting the associated mesentery and blood vessels. [73] In the remaining patients, the cecum folds in an anterior cephalad direction (cecal bascule). The cecal bascule is not a true volvulus around a mesentery, but gangrene can result from tension on the bowel wall.

Abdominal pain, nausea, vomiting, and obstipation are common symptoms of cecal volvulus. Patients with cecal volvulus clinically appear to have a small bowel obstruction. Many patients give a history of similar, chronic, intermittent symptoms. [73] A plain abdominal radiograph may show the cecum as a kidney-shaped, air-filled structure in the left upper quadrant. Multiple air-filled levels may be seen and indicate a distal small bowel obstruction. Radiologic examination with barium or with a water-soluble contrast enema may show obstruction of the column of contrast at the level of the volvulus (Fig. 82-14). The tapered edge of the contrast points toward the site of torsion. Barium studies should not be routinely performed if the diagnosis is clear. Colonoscopy has been used to treat cecal volvulus with limited success and should rarely be attempted. [75], [78]

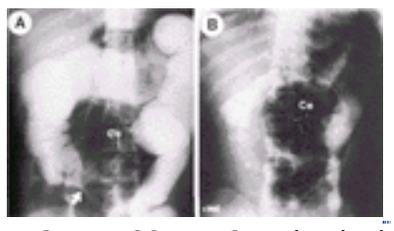

FIGURE 82-14. Cecal volvulus. **A**: Hypaque enema shows tapering of the column of contrast at the site of torsion (*arrow*) and displacement of the cecum toward the epigastrium. **B**: The gas-filled, dilated cecum (*Ce*) is evident in the epigastrium in this postevacuation radiograph. Note the paucity of gas in the normal location of the cecum in the right lower quadrant of the abdomen.

Operative detorsion alone, cecopexy, and cecostomy are associated with variable rates of recurrence. [73], [79] Right hemicolectomy with primary anastomosis or cecopexy and cecostomy is recommended if there is no evidence of gangrenous bowel. Resection, ileostomy, and mucous fistula are indicated if there is evidence of gangrene. Mortality is increased in the presence of gangrenous bowel.

Volvulus of the transverse colon is rare because the mesentery is short and broad-based. Failure of the mesentery to fuse normally or narrowing of the mesenteric attachments may predispose the transverse colon to volvulus. Patients present with a clinical picture of large bowel obstruction. Barium enema is diagnostic and reveals the point of obstruction. Although rare successful attempts at colonoscopic detorsion have been reported, most patients require operative detorsion and resection of the redundant transverse colon. [80], [81]

CHAPTER 83

William F. Stenson and Joshua Korzenik

INFLAMMATORY BOWEL DISEASE

Ulcerative colitis and Crohn's disease, chronic inflammatory diseases of the gastrointestinal tract, are identified and diagnosed by the appearance of a set of clinical, endoscopic, and histological characteristics. [1], [2] and [3] The inflammatory response in ulcerative colitis is largely confined to the mucosa and submucosa, but in Crohn's disease inflammation extends through the intestinal wall from mucosa to serosa. Ulcerative colitis is confined to the colon, and colectomy is a curative procedure. Crohn's disease, in contrast, has the potential to involve the patient's entire gastrointestinal tract, even though only a small segment is involved initially. Resection of the inflamed segment is not curative in Crohn's disease, and inflammation is likely to recur in the gastrointestinal tract sometime after resection. Despite these differences in distribution, no single finding is absolutely diagnostic of one disease or the other. Moreover, a group of patients, accounting for 5% to 15% of those with inflammatory bowel disease (IBD), have characteristics of both diseases and cannot be cleanly classified; these patients are considered to have indeterminate colitis.

The genetic basis of these diseases is being elucidated. Both appear to be multigenic diseases. Patterns of family aggregation suggest that the genetic influences at least partially overlap. Relatives of patients with each disease have an increased risk of that particular disease as well as the other form of IBD. [4] Consequently, not only is there an increased incidence of Crohn's disease in relatives of those with Crohn's disease but their relatives also have an increased incidence of ulcerative colitis. This pattern holds for patients with ulcerative colitis as well.

In view of the similarities in clinical and histological presentation and the shared genetic background, these two diseases are presented in a single chapter. In the absence of established etiologic agents or definitive markers, it is possible that what is designated as ulcerative colitis or Crohn's disease may in fact be a mixture of

diseases of diverse causes but common clinical presentation. Actually, more than two diseases may be under the name of inflammatory bowel disease. Presentation in a single chapter emphasizes the common characteristics of these diseases and minimizes splitting into groups that may not be valid. This combined presentation allows the areas of similarity to be detailed without repetition and allows comparisons in areas of dissimilarity.

EPIDEMIOLOGY

The incidence and prevalence of Crohn's disease (1–6 and 10–100/100,000, respectively) and ulcerative colitis (2–10 and 35–100/100,000, respectively) vary greatly with geographic location. These rates are for Caucasian populations in northern Europe and North America. The countries of greatest incidence and prevalence encompass the industrialized world. Rates in central and southern Europe are somewhat lower. In South America, Asia, and Africa these diseases remain uncommon but appear to be increasing. Within geographic areas, ethnic and racial variations exist in the incidence of IBD. [5] Crohn's disease is three to eight times more common in Jewish than in non-Jewish persons. Similarly, the incidence of ulcerative colitis is two to four times higher among Jews. The incidence among Israeli Jews, however, is much lower than among American and European Jews. Furthermore, in Israel the incidence is lower among Sephardic or Oriental Jews of Asian or African origin than among Ashkenazi Jews of European or American origin. [5] In the United States, the incidence of both ulcerative colitis and Crohn's disease in the African-American population has been one-fifth to one-half that in the Caucasian population, but in recent years that gap appears to be narrowing. [6]

Some of the apparent increases in incidence of IBD over time may reflect greater awareness of these diseases, better diagnostic studies, and improved reporting. Moreover, some patients now diagnosed as having Crohn's colitis may have been diagnosed as having ulcerative colitis in the past. Despite these ambiguities, certain trends are apparent. [7], [8] In geographic areas where the incidence of these diseases has been slight, it is now increasing. In northern Europe and North America, where the incidence of both diseases has been substantial, the incidence of ulcerative colitis has leveled, but that of Crohn's disease is still increasing.

The peak age of onset for both diseases is between 15 and 25 years. In some but not all series, a second, lesser peak of incidence occurs between 55 and 65 years. [6] Both diseases occur in childhood, although the incidence is much lower before the age of 15 years than after. Ulcerative colitis is more common than Crohn's disease in children younger than 10 years. Most series show an approximately equal incidence of both diseases in males and females, but other studies show an incidence of Crohn's disease that is greater in females by up to 30% and an incidence of ulcerative colitis that may be greater among males. [6] These gender differences of disease distribution may represent confounding environmental factors such as use of tobacco. The similarities between ulcerative colitis and Crohn's disease in geographic distribution, racial and ethnic distribution, distribution by sex, and age of onset support the contention that the two diseases are related.

One fascinating but unexplained difference between patients with these two diseases is the incidence of smoking. Among patients with ulcerative colitis, the incidence of smoking is less than that in the general population. In several studies, the risk of developing ulcerative colitis was increased among nonsmokers compared with current smokers and increased even further among former smokers compared with lifetime nonsmokers. [9], [10], [11] and [12] Quitting smoking can provoke the emergence of ulcerative colitis, though still much less of a risk than smoking on overall health. [13], [14] In contrast, the incidence of smoking among patients with Crohn's disease is higher than in the general population. [10] Smokers have a more severe course of Crohn's disease, require more immunosuppressive medications, and demonstrate a faster recurrence after surgery. [15], [16] Cessation of smoking may moderate the clinical course although the greatest benefit of cessation is seen with the heaviest smokers. [17] The active ingredients in cigarette smoke that increase the risk of Crohn's disease or decrease the risk ulcerative colitis have not been defined, nor have mechanisms of action. On the assumption that nicotine is the active ingredient in cigarette smoke, trials of transdermal nicotine and nicotine gum for the treatment of ulcerative colitis have been performed; in two trials transdermal nicotine was somewhat effective. [18], [19]

Appendectomy strongly protects against the development of ulcerative colitis, while not having any influence on Crohn's disease. [20] This effect in ulcerative colitis is noted particularly when appendectomy is performed for an inflammatory problem, such as lymphadenitis or appendicitis and if done before the age of 21. [21] Poor sanitation in childhood is a protective factor against the development of Crohn's disease, though not against ulcerative colitis. [22], [23]

ETIOLOGY AND PATHOGENESIS

Genetics

Any theory of the pathogenesis of IBD must deal with the evidence for a genetic basis of the disease. The most firmly established and quantitatively greatest risk factor for developing IBD is a positive family history. [24] Approximately 15% of patients with IBD have first-degree relatives who also have IBD. [25] Lifetime risk of developing IBD among first-degree relatives of affected individuals is 8.9% for offspring, 8.8% for siblings, and 3.5% for parents. [26] The incidence of disease among first-degree relatives is higher in Crohn's disease than in ulcerative colitis. The incidence of IBD among first-degree relatives of IBD patients is 30 to 100 times that of the general population. Moreover, although the relatives of patients with Crohn's disease are more likely to have Crohn's disease than ulcerative colitis, the incidence of ulcerative colitis in this group is also higher than in the general population. [4] Similarly, relatives of patients with ulcerative colitis have a higher incidence of both ulcerative colitis and Crohn's disease than the general population. These data support the contention that ulcerative colitis and Crohn's disease are related diseases. The incidence of IBD is not increased in spouses of patients.

Studies of twins also support the presence of a genetic basis for these diseases. A study of unselected twins from a Swedish twin registry demonstrated that dizygotic twins have the same rate of concordance as would be expected for siblings. There was concordance for Crohn's disease in 8 of 18 monozygotic twin pairs; whereas there was concordance for ulcerative colitis in only 1 of 16 monozygotic twin pairs. [27] No case has been reported of monozygotic twins in which one twin had Crohn's disease and the other ulcerative colitis, suggesting that these diseases have a similar but not identical genetic background.

No clear-cut mendelian pattern of inheritance in IBD has been established. There are, however, human leukocyte antigen (HLA) class II genes that have been associated with Crohn's disease and ulcerative colitis. The *DR1/DQw5* and *DRB3*0301* haplotypes have been associated with Crohn's disease, [28] and HLA-DR2 has been associated with ulcerative colitis. [29] Linkage analysis has identified two susceptibility loci; IBD1 on chromosome 16 [30] and IBD2 on chromosome 12. [31] IBD1 has been associated primarily with Crohn's disease, whereas, IBD2 has been associated with both Crohn's disease and ulcerative colitis. Work by two different groups has led to the identification of NOD2 as the gene associated with IBD1. [32], [33] NOD2, a cytosolic protein expressed in monocytes, functions as an intracellular receptor for lipopolysaccharide. Crohn's disease is associated with frameshift mutations in NOD2 resulting in a truncated and nonfunctioning protein. Although NOD2 mutations are seen much more commonly in Crohn's disease than in the general population, only a small portion (~15%) of all Crohn's disease patients have a mutation in NOD2. This demonstrates that Crohn's disease is genetically heterogeneous and suggests that other mutations in other genes may contribute to Crohn's disease in other populations.

It has become increasingly clear over the last few years that Crohn's disease is clinically heterogeneous and that there is a genetic basis for the clinical heterogeneity. Not only are patients with Crohn's disease more likely to have relatives with Crohn's disease, but those relatives are likely to have Crohn's disease that is similar to that of the proband in terms of anatomic location, age of onset, and disease behavior (inflammatory vs. fistulizing vs. stenotic). [34], [35], [36] and [37] In affected parent-child pairs, the age of onset for the parents was significantly higher. In contrast, affected siblings were highly concordant for age of onset. [35] It is not clear whether these genetically based clinical patterns reflect differences in the genes associated with Crohn's disease or the presence of another set of genes that affect the timing and location of the appearance of Crohn's disease in patients who are genetically disposed. Genetic markers have been implicated as predictive of disease severity in ulcerative colitis. [38] HLA *DRB1*0103* and allele 2 of the interleukin 1 (IL-1) receptor antagonist are associated with extensive disease.

Another approach to understanding the genetic basis of IBD is the search for subclinical markers, that is, parameters used to detect the abnormal genotype in the absence of the full clinical phenotype. The two subclinical markers that have received the most attention are increased intestinal epithelial permeability in Crohn's disease and antineutrophil cytoplasmic antibodies (ANCA) in ulcerative colitis. There is a report of increased intestinal permeability to PEG-400 in Crohn's disease patients and their first-degree relatives. [39] A genetic defect of intestinal epithelial cells allowing permeation of lumenal antigens across the epithelial monolayer could result in nonspecific activation of the intestinal immune system; however, subsequent studies have yielded inconclusive data. [40], [41] The other subclinical marker that has received considerable attention is the presence of ANCA in the sera of patients with ulcerative colitis and Crohn's disease. [42] Two groups of ANCA-positive patients have been defined based on this intracellular staining pattern: pANCA positivity reflects a perinuclear pattern, whereas cANCA reflects a diffuse cytoplasmic pattern. About 70% of patients with ulcerative colitis are pANCA positive, with no correlation with disease extent or activity. Fewer than half of patients with Crohn's disease are ANCA-positive and these patients are about evenly divided between cANCA-positive and pANCA-positive. Many patients with Crohn's disease who are pANCA-positive have left-sided colitis and a clinical picture similar to ulcerative colitis. [43] The role, if any, of ANCA in the pathogenesis of IBD is unknown; however,

clinically healthy relatives of patients with ulcerative colitis have an increased incidence of ANCA positivity compared with the general population, suggesting that ANCA is more than just a marker for colonic inflammation. [44]

H4>Potential Etiologic Agents and Antigenic Triggers

Clear evidence exists for the activation of the immune response in IBD. The lamina propria is infiltrated with lymphocytes, macrophages, and other cells of the immune system. A gene chip analysis of gene expression in ulcerative colitis mucosa demonstrated up-regulation of many genes associated with immune activation. [45] In any immune response, a specific antigen serves as a trigger for the response and as a target for the effector arm of the response. Over the past 30 years, an intensive search has been conducted for the antigens that trigger the immune response in IBD. Immune activation in IBD is largely confined to the gastrointestinal tract; therefore, the search for the antigenic trigger has focused on the intestinal lumen, where most of the antigens are of microbial or dietary origin. Three major hypotheses as to the antigenic triggers in IBD have been postulated.

1. One hypothesis is that the antigenic triggers are microbial pathogens that have not yet been identified because of fastidious culture requirements. According to this hypothesis, the immune response in IBD is an appropriate but ineffective response to these pathogens. Various viruses and bacteria have been proposed as candidate organisms, but little evidence has been found to support any of these organisms as having a causative role in IBD. One organism that created some interest is a species of mycobacteria similar to or identical with *Mycobacterium paratuberculosis*; however, there is little data to support this organism as a causal agent in Crohn's disease. [46], [47] and [48]
2. The second (and best supported) hypothesis as to the antigenic trigger in IBD is that it is some common dietary antigen or usually nonpathogenic microbial agent against which the patient mounts an abnormal immune response. In healthy persons, a finely tuned, low-grade chronic inflammation is present in the intestinal lamina propria. Presumably, this chronic inflammation is a product of chronic exposure of the lamina propria to lumenal antigens. Failure to suppress this inflammatory response could result in the uncontrolled immune activation seen in IBD. As a result of failure of normal suppressor mechanisms, immune activation in IBD may be an inappropriately vigorous and prolonged response to some normal lumenal antigen. The genetic basis of IBD may relate to a genetically determined ability to mount an immune response to a specific lumenal antigen. It may be that patients with IBD are genetically programmed to mount an intense immune response to some common lumenal antigen—either dietary or microbial—to which most people do not respond. In genetically based mouse models of colitis, defects in T-cell function or cytokine production result in uncontrolled immune responses to normal colonic bacteria. [49] In IL-10(-/-), IL-2(-/-), and T-cell receptor (TCR-/-) mice inflammation only develops in the presence of normal colonic flora. If these mice are grown under germ-free conditions they do not develop inflammation. These studies demonstrate that normal colonic flora can stimulate a pathological inflammatory response in the presence of a defect in immune regulation. Moreover, a number of quite different defects in immune regulation result in a mucosal inflammatory response to normal colonic flora. This has two potential implications for IBD. The first is that IBD may result from the initiation of an immune response to normal flora as a result of a defect in immune regulation. The second is that ulcerative colitis and Crohn's disease may be a group of diseases resulting from a number of defects in immune regulation but all manifesting themselves as a mucosal inflammatory response to normal flora. The demonstration that a fraction of patients with Crohn's disease have mutations in NOD2, a gene that codes for a protein involved in the response to bacterial products, supports both the suggestion that Crohn's disease involves a dysregulated immune response to bacteria and the suggestion that Crohn's disease is genetically heterogeneous. [32], [33]
3. The third hypothesis (autoimmunity) as to the antigenic trigger in IBD is that it is one expressed on the patient's own cells, particularly intestinal epithelial cells. In this theory, the patient mounts an appropriate immune response against some lumenal antigen, either dietary or microbial; however, because of similarities between proteins on the epithelial cells and the lumenal antigen, the patient's immune system also attacks the epithelial cells. Under the autoimmune theory, the immune response is directed specifically toward the epithelial cell, and the epithelial cell is destroyed by one of two immune effector mechanisms, either antibody-dependent cellular cytotoxicity, which requires an antibody directed against an epithelial cell surface antigen, or direct cell-mediated cytotoxicity. Although little evidence exists to support a role for autoimmunity in Crohn's disease, several investigators have reported the presence of anticolon antibodies in the sera of ulcerative colitis patients; [50], [51] however, similar antibodies have been found in the sera of healthy persons and in patients with systemic lupus erythematosus in whom there was no intestinal inflammation. [52] Das and colleagues [53], [54] demonstrated the presence of a tissue-bound antibody that could be eluted from ulcerative colitis surgical resections; this antibody is directed against tropomyosin. Whether this antibody participates in the pathogenesis of ulcerative colitis or is just a marker for immune activation is not clear. The presence of an anticolon antibody does not necessarily mean that the antibody plays a pathogenetic role. A more convincing case for a pathogenetic role could be made by the demonstration that this antibody participates in antibody-dependent cellular cytotoxicity.

Immune Response

The first step in the immune response to an antigen is the uptake and processing of the antigen by macrophages or other antigen-presenting cells (Fig. 83-1). CD4 (helper/inducer) T cells recognize soluble antigens in conjunction with HLA class II molecules (HLA-DP, -DQ, and -DR) present on macrophages. Class II antigens on intestinal epithelial cells also may play a role in antigen processing within the intestinal immune compartment. Class II molecules are present on epithelial cells of the normal human small intestine but not on those of the colon. Class II antigen expression on small intestine epithelial cells is retained in patients with Crohn's disease. HLA-DR-like molecules on human intestinal epithelial cells may be involved in antigen-induced triggering of intraepithelial lymphocytes. Marked enhancement of colon epithelial cell HLA-DR staining occurs in active ulcerative colitis and Crohn's colitis, and intestinal epithelial cells from patients with IBD are capable of processing and presenting antigens in vitro. [55]

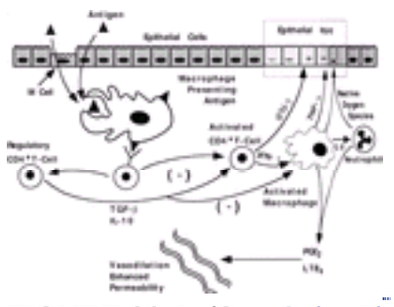

FIGURE 83-1. (See Color Fig. 83-1.) An immunologic sequence that has been postulated to account for the inflammatory response observed in inflammatory bowel disease starts with an exogenous sensitization to lumenal antigens, presumably bacterial, possibly facilitated by undefined genetic influences. The first cell population involved is the intestinal macrophage, which phagocytoses and processes antigen and presents it to a $CD4^+$ T cell. Two populations of $CD4^+$ T cells are produced: one an activated population and the second a population of CD45RBlo $CD4^+$ regulatory T cells. The activated T cells produce interferon-? (*IFN*-?), which activates macrophages and participates in epithelial injury. The CD45RBlo $CD4^+$ regulatory T cells produce transforming growth factor-ß (*IFN*-ß) and interleukin-10 (IL-10), which down-regulate both the activated $CD4^+$ cells and the activated macrophages. Activated macrophages participate in epithelial injury by producing tumor necrosis factor-a (*TFN*-a) and reactive oxygen species and by recruiting neutrophils, which also produce reactive oxygen species. Macrophages and neutrophils also produce prostaglandin E_2 (PGE_2) and leukotriene B_4 (LTB_4), which contribute to the vasodilation and enhanced vascular permeability that is characteristic of inflammatory bowel disease.

The activated macrophage, in addition to presenting antigen to the T cell, releases IL-1, which activates the T cell. The activated T cell releases IL-2, which promotes the clonal expansion of cytotoxic T cells and increases the function of helper T cells and B cells. Cell-mediated immune responses may be involved in the pathogenesis of IBD. There is a finely balanced chronic low-grade immune response in the normal intestine and colon. The immune response is a product of $CD4^+$ T-cell activation by bacteria in the lumen, as the response is largely absent in germ-free animals. This activation is promoted by interferon-? (IFN-?) and is down-regulated by IL-10 and transforming growth factor-ß (TGB-ß) produced by regulatory T cells (see Fig. 83-1). The current data suggest that IBD is a product of genetically determined immune dysregulation to lumenal antigens. Whether the immune dysregulation produces an overly active up-regulation of the immune response or an inadequate down-regulation is not clear. It is also not clear whether this dysregulation is specific to certain antigens.

Antibody Secretion

In view of the increased access of lumenal antigens to the immune cells of the lamina propria, it is not surprising that there is increased antibody secretion by

intestinal mononuclear cells in IBD. Not only is the number of antibody-secreting cells increased, but the distribution of immunoglobulin (Ig) classes is changed. In healthy persons, the vast majority of the immunoglobulin secreted by intestinal mononuclear cells is IgA. In IBD, there is markedly increased production of IgM and IgG. IgA does not fix complement, whereas IgM and some IgG subclasses do. There are subclasses of IgG that are defined by the structure of their constant regions. There is some subclass specificity in the increase in IgG production seen in IBD. Ulcerative colitis is associated with increased production of IgG1 and IgG3, whereas Crohn's disease is associated with increased production of IgG2. IgG1 and IgG3 antibodies account for the predominant IgG response to proteins and T cell–dependent antigens. IgG2 provides the predominant IgG response to carbohydrates and many bacterial antigens. Delineation of the stimuli and antigens that induce the increased secretion of IgG subclasses may provide insight into the etiology and pathogenesis of IBD.

Cytokines

Cytokines are glycosylated proteins that mediate potent biologic function at low concentrations in a hormonelike fashion (see section " Cytokines", Chapter 7). Like hormones, they act through receptors, but unlike hormones, which act on cells at a distance from their cell of origin, cytokines act on neighboring cells. Originally, cytokines were described as being produced by immune cells and acting on immune cells, but it is clear that they are both produced by and act on nonimmune cells. Cytokines almost certainly play important regulatory roles in IBD, as they do in other chronic inflammatory states. [56], [57] The best developed data are those demonstrating increased production of most of the major proinflammatory cytokines (IL-1, IL-6, IL-8) and tumor necrosis factor-a (TNF-a). The proinflammatory cytokines contribute to many of the characteristic attributes of IBD: neutrophil infiltration (IL-8), T-cell activation (IL-1), expression of adhesion molecules (IL-1 and TNF-a), and enhanced epithelial permeability (IFN-?). TNF-a and IFN-? may contribute directly to epithelial injury (see Fig. 83-1). The natural inhibitor of IL-1, IL-1 receptor antagonist (IL-1ra), is a protein produced by macrophages in parallel with IL-1. The ratio of IL-1ra to IL-1 is lower in IBD mucosa than in normal mucosa. Other cytokines, including IL-10 and TGF-ß serve to down-regulate the immune response (see Fig. 83-1). Genetic mouse models in which IL-10 or TGF-ß is disrupted have colitis as their phenotype. These models demonstrate that failure of the regulatory processes that down-regulate the immune response can lead to chronic inflammation.

$CD4^+$ T cells have been divided into subsets based on the profile of the cytokines produced. IL-12, which is produced by macrophages, causes naive lymphocytes to differentiate to Th1 lymphocytes. The cytokines produced by Th1 lymphocytes, IL-2 and IFN-? are associated with cellular immune responses and increased IgG2 production. IL-4, which is produced by macrophages, causes naive lymphocytes to differentiate to Th2 lymphocytes. The cytokines produced by Th2 lymphocytes, IL-4, IL-5, IL-6, and IL-10, are associated with hypersensitivity reactions and increased IgG1 production. Crohn's disease appears to be associated with activation of Th1 lymphocytes as demonstrated by increased levels of IL-2, IL-18, IFN-?, and IgG2. [58], [59], [60] and [61] Ulcerative colitis is associated with activation of Th2 lymphocytes as demonstrated by increased IL-5, IL-10, and IgG1. [58] These findings indicate that Crohn's disease is characterized by a dysregulated Th1 response and ulcerative colitis by a dysregulated Th2 response but they do not reveal the mechanisms involved in the induction of these dysregulated responses. Genetically based animal models of colitis are also characterized by dysregulated Th1 and Th2 responses. In these animal models it is clear that an abnormal immune response is mounted against normal bacterial flora raising the possibility that the antigenic trigger for the dysregulated immune response in IBD is the normal flora. The evidence for dysregulation of the Th1 and Th2 systems in IBD is quite strong. A number of therapeutic strategies that target these pathways are sure to be tested. [62]

The major cell source of the proinflammatory cytokines is almost certainly activated macrophages in the lamina propria, although other cell types may make important contributions. Cytokines, particularly IL-1, TNF-a, and IFN-?, stimulate epithelial, endothelial, and mesenchymal cells and activate immune cells. [63] They also are involved in the regulation of wound healing and fibrosis. [64] Cytokines may be useful as markers of disease activity, especially tissue IL-1 levels in ulcerative colitis and serum IL-2 receptor levels in Crohn's disease. [65], [66]

The demonstrated efficacy of infliximab, a chimeric antibody to TNF-a, in Crohn's disease supports the key role of cytokines in IBD pathogenesis. [67] TNF-a is produced in Th1-mediated immune responses and the effectiveness of infliximab in Crohn's disease supports the suggestion that Th1 lymphocytes are important in mediating immune activation in Crohn's disease. The success of infliximab will certainly lead to other attempts to treat Crohn's disease by modulating Th1 cytokines.

Genetically Based Animal Models of Colitis

A number of genetically based animal models of IBD have been developed. [49], [68], [69] In most cases, these models were developed to study the effects of specific genetic perturbations of the immune system rather than as models of colitis. A surprising product of these manipulations of the immune system was the discovery that many genetic abnormalities in the systemic immune system have as their only phenotype the development of colitis. Furthermore, the development of colitis in these genetic models requires the presence of intestinal bacteria. The genetic defects that have colitis as their phenotype in animals with conventional bacterial flora have no phenotype in germ-free animals.

These genetically based models of colitis fall into three groups. One group of models includes three cytokine knockouts. Mice with disruption of the genes for IL-2, IL-10, and TGF-ß $_1$ all develop colitis. [70], [71] and [72] The second group of models includes mice or rats with T-cell defects. Among these are mice with defects in the T-cell receptor and transgenic rats into which the human *HLA-B27* gene has been introduced. [73], [74] In the *HLA-B27* transgenic rats, colitis is not the only phenotype; these animals also have gastritis and arthritis. An especially interesting model is severe combined immunodeficiency disease (SCID) mice repleted with CD45RBhi $CD4^+$ T cells. [49] SCID mice lack all $CD4^+$ cells yet develop no colitis; however, when these mice are repleted with a subset of $CD4^+$ cells, they develop colitis. The third group of models includes mice lacking Ga_{12}, a subunit of a G-protein. [75] Whether T cells are the important target in this genetic model is not clear.

It is possible that all these models relate to T cells and their regulation by cytokines. One could imagine a model in which immune activation in the intestinal lamina propria in response to lumenal bacteria is kept in check by a population of regulatory T cells through the secretion of down-regulatory cytokines, such as IL-10 or TGF-ß (see Fig. 83-1). Defects in that T-cell population or in its ability to produce down-regulatory cytokines would remove the brake on immune activation induced by bacterial stimulation of other T-cell populations. The interaction of T cells and cytokines was demonstrated further in studies with the CD45RBhi $CD4^+$ T- cell repleted SCID mice. Administration of a monoclonal antibody against IFN-? to these animals completely eliminated the colonic inflammation, and administration of a monoclonal antibody against TNF-a reduced it significantly. These studies raise the possibility that the intestinal damage caused by unrestrained T-cell activation is mediated by IFN-? and TNF-a.

In general the animal models that most resemble Crohn's disease are those associated with abnormalities in Th1 cytokines. Colitis induced by rectal administration of trinitrobenzene sulfonic acid has a histological picture consistent with Crohn's disease. There are high levels of IFN-? in the colons of mice receiving trinitrobenzene sulfonic acid and the colitis can be abrogated with antibodies to IL-12. [76] Both these findings are consistent with inflammation mediated by Th1 lymphocytes. There is an especially intriguing spontaneous mouse model, called the SAMP1/Yit mouse, that closely resembles Crohn's disease. [77] Adoptive transfer studies demonstrate that $CD4^+$ T cells that produce a Th1-like profile of cytokines mediate intestinal inflammation in this model. In contrast animal models that most resemble ulcerative colitis are those associated with elevated levels of Th2 cytokines. A histological picture similar to ulcerative colitis develops in mice with a mutant T-cell receptor alpha gene. [73] Analysis of spontaneous cytokine expression by mesenteric lymph node cells showed a decrease in IL-2 and an increase in IL-4 in the TCRa(-/-) mice with colitis. The decrease in IL-2 and increase in IL-4 is consistent with a Th2 mediated response.

Two of the major themes in the pathogenesis of IBD have been the importance of the lumenal bacteria driving the immune response and the importance of Th1 and Th2 T cells in mediating the immune response. These two themes were combined in a study of a spontaneously occurring model of colitis in the C3H-HeJBir mice. [78] Adoptive transfer of bacterial antigen–activated $CD4^+$ T cells from colitic C3H/HeJBir mice to SCID mice induced colitis. This study demonstrated that T cells reactive with conventional antigens of the enteric flora can mediate IBD.

Although most animal models of colitis involve defects in lymphocyte regulation, enhanced Th1 activity and chronic colitis occur in mice with a cell type–specific disruption of the *Stat-3* gene in neutrophils and macrophages. [79] *Stat-3* codes for a protein involved in the signal transduction of the receptor binding of a number of cytokines and growth factors including IL-6, IL-10, and granulocyte colony-stimulating factor. There are other genetic models of intestinal inflammation based on defects in epithelial cells. N-cadherin is a protein involved in the attachment of adjacent epithelial cells. Mice expressing a dominant-negative N-cadherin along their crypt-villus axis develop IBD. [80] Keratin 8 is a cytoskeletal molecule in epithelial cells. Mice in which the keratin 8 gene is disrupted develop crypt abnormalities and inflammation of the lamina propria and submucosa. [81]

The finding that a wide variety of defects in the systemic immune system and epithelial cells results in colitis is informative in defining the regulation of the mucosal immune system. It is less informative in defining the defects in immune regulation or epithelial cells that may be involved in the mediation of human IBD. The

pathogenesis of IBD may involve one or more of these regulatory systems or, more likely, may involve other regulatory systems.

Inflammation

IBD is considered a disorder of chronic inflammation, a view reinforced by the large numbers of lymphocytes and histiocytes in the diseased mucosa and submucosa. Ulcerative colitis and Crohn's disease also have histological characteristics of acute inflammation, including an intense infiltration of the mucosa and submucosa with neutrophils. Large numbers of neutrophils leave the bloodstream and enter the inflamed mucosa and submucosa of the bowel. [82] Some neutrophils migrate across the epithelium into the lumen and are passed in the stool, and others are destroyed in the inflamed tissue before they have a chance to migrate into the lumen. This constant flux of neutrophils is mediated by the expression of adhesion molecules on circulating neutrophils and vascular endothelial cells, which allow the neutrophils to bind to the endothelium before migrating into the tissue. Both the expression of adhesion molecules and the migration of neutrophils are regulated by inflammatory cytokines (IL-8 and TNF) and lipid mediators of inflammation, including platelet activating factor and leukotriene B_4 (LTB_4). Neutrophil activation in the inflamed gut results in the release of granule-bound proteases and the production of superoxide and other reactive oxygen species (see Fig. 83-1). [83] These products of activated neutrophils probably play a role in the destruction of epithelial cells in IBD.

Some of the functional and macroscopic changes seen in IBD, including mucosal hyperemia and edema, are typical of changes seen in any inflammatory state, no matter which organ system is involved. These changes are the products of soluble mediators released in the process of inflammation. Mediators cause tissue edema by increasing vascular (postcapillary venule) permeability to albumin and other macromolecules; hyperemia results from mediators that induce vasodilation. Progress has been made in characterizing the soluble mediators of inflammation and their role in the amplification of the immune response in IBD. There are two reasons for defining their pathogenic role. First, the soluble mediators appear to be largely responsible for the clinical and histological changes seen in the disease. Second, the drugs that have proved to be beneficial for ulcerative colitis and Crohn's disease appear to exert their therapeutic effects by blocking the synthesis of those mediators. Corticosteroids down-regulate the expression of proinflammatory cytokines and block the migration of neutrophils out of the bloodstream. 5-aminosalicylate (5-ASA) appears to act farther downstream; it is an antioxidant and thus may act to block the tissue damage induced by reactive oxygen species. Corticosteroids and sulfasalazine block the synthesis of prostaglandins and leukotrienes in vivo and in vitro. [84], [85] Until the etiologic agents of ulcerative colitis and Crohn's disease are identified, it is likely that advances in medical therapy will be in the area of regulation of the synthesis of soluble mediators of inflammation.

Almost all mammalian cells, including intestinal epithelium and cells associated with inflammatory events (e.g., mast cells, macrophages, platelets), produce prostaglandins. Prostaglandins, particularly those of the E series, have biologic properties that are proinflammatory, including enhanced vascular permeability, vasodilation, and production of pain. Prostaglandin levels are elevated in mucosa and serum in IBD and correlate with disease activity. [86] There are two cyclooxygenases that synthesize prostaglandins. Cyclooxygenase-1 (COX-1) is a constitutive enzyme, whereas COX-2 is induced by proinflammatory cytokines. COX-2 is not expressed in colonic epithelial cells in the absence of inflammation but is expressed in epithelial cells from areas of inflammation in ulcerative colitis. [87] Nonsteroidal antiinflammatory drugs (NSAIDs), which are potent inhibitors of prostaglandin production through both pathways, reduce inflammation in chronic inflammatory diseases, such as rheumatoid arthritis, but are not effective in IBD. Small trials of indomethacin administered orally and rectally revealed no improvement in ulcerative colitis; there was even some suggestion that indomethacin causes clinical deterioration despite decreasing prostaglandin production. [88], [89] Prostaglandin E_2 (PGE_2) produced through COX-2 appears to be important in gastrointestinal wound healing. [90] The negative effects of NSAIDs in IBD may be related to impaired wound healing.

IBD mucosa contains large amounts of LTB_4, [91] a neutrophil chemotactic factor. [92] The concentrations of LTB_4 are markedly higher in rectal dialysates from patients with ulcerative colitis than from controls. [93] In vitro studies indicate that LTB_4 is the major neutrophil chemotactic agent in IBD mucosa. [92] Despite the strong evidence that LTB_4 is the major neutrophil chemotactic factor in IBD, clinical trials of inhibitors of LTB_4 synthesis in ulcerative colitis have failed to demonstrate clinical efficacy. [94] Dietary supplementation with fish oil containing eicosapentaenoic acid, which reduces LTB_4 production by acting as a competitive substrate for 5-lipoxygenase, results in significant but modest improvements in ulcerative colitis symptoms. [95]

Nitric oxide is found in large amounts in IBD mucosa, and inducible nitric oxide synthase is expressed in epithelial cells in patients with IBD but not in epithelial cells from healthy persons. [96] Nitric oxide may contribute to vasodilation and mucosal edema. Whether the net effect of nitric oxide in IBD is to promote tissue injury or tissue repair is not clear.

The inflammatory response can be viewed as a component of the larger process of wound healing. The inflamed mucosa in IBD is characterized by the activation not only of typical inflammation-associated genes, such as COX-2 and IL-8, but also by the activation of genes associated with wound healing including growth factors and metalloproteinases. [97], [98]

ULCERATIVE COLITIS: CLINICAL FINDINGS AND NATURAL HISTORY

Symptoms and Physical Findings

The dominant symptom in ulcerative colitis is diarrhea, which is usually, but not always, associated with blood in the stool. [99] Bowel movements are frequent but small in volume as a result of irritability of the inflamed rectum. [100] If inflammation is confined to the rectum, blood is seen only on the surface of the stool, but if inflammation is more extensive, blood is mixed in with the stool. Other symptoms include fever and pain, which may be in either the lower quadrant or the rectum. Many patients also experience weight loss. The patient's symptoms are a function, in part, of the extent of the disease. Systemic symptoms—fever, malaise, and weight loss—are more common if all or most of the colon is involved. Fatigue and malaise are major problems and may have a greater effect than diarrhea on the patient's ability to function. If disease is confined to the rectum, the patient may complain only of urgency and tenesmus with or without blood and diarrhea. Although bloody diarrhea is considered the dominant symptom in ulcerative colitis, urgency and fecal incontinence bother many patients more. Few patients will volunteer complaints of incontinence but, if pressed, will reveal that incontinence and the fear of incontinence are the most limiting aspects of their disease. The inflamed rectum loses its ability to relax and distend when stool enters; as a result, the entry of small amounts of stool into the rectum results in the urge to defecate immediately. Some patients, especially older adults, complain of constipation rather than diarrhea. In these patients, rectal spasm may prevent the passage of stool.

In ulcerative colitis of mild to moderate severity, the physical findings are minimal. There may be tenderness over the affected area of the colon, and rectal examination may reveal tenderness or blood on the glove. In severe disease, the patient is more likely to be febrile and tachycardic. Prolonged episodes of severe disease lead to muscle wasting, edema, and other signs of malnutrition. Chronic blood loss results in pallor. Children with severe disease may have retarded growth and development.

Classification by Severity

Assessment of disease severity in ulcerative colitis is important for clinical management and in the design of drug trials. Truelove and Witts [101] devised a system for dividing ulcerative colitis patients into those with mild, moderately severe, and severe disease based on their symptoms, physical findings, and laboratory values (Table 83-1). This classification is useful and helps the clinician to predict both the anatomic extent of the patient's disease and the range of likely outcomes based on the presentation. This classification also helps the clinician to judge how vigorously the patient needs to be treated.

Severe
Diarrhea: six or more bowel movements per day, with blood
Fever: mean evening temperature higher than 37.5° C., or higher than 37.7° C on at least 2 of 4 days at any time of day
Tachycardia: mean pulse rate higher than 90 beats/min
Anemia: hemoglobin of 75 mg/dl, or less compared with normal values, allowing for recent transfusions
Sedimentation rate: more than 30 mm/h
Mild
Mild diarrhea: fewer than four bowel movements per day, with only small amounts of blood
No fever
No tachycardia
Mild anemia
Sedimentation rate: below 30 mm/h
Moderately severe
Intermediate between mild and severe

Adapted from Truelove SS, Witts LJ. Cortisone in ulcerative colitis: final report on a therapeutic trial. BMJ 1955;2:1041.

TABLE 83-1 Truelove and Witts' Classification of Ulcerative Colitis

Edwards and Truelove [102] found that in 54% of their ulcerative colitis patients, the first attack was mild. Mild disease usually is associated with inflammation confined to the rectum and sigmoid, but it can occur even in the presence of pancolonic involvement. Diarrhea and rectal bleeding are usually the only complaints in mild disease. Patients with diarrhea but without rectal bleeding may be misdiagnosed as having irritable bowel syndrome, and those with rectal bleeding but without diarrhea may be misdiagnosed as bleeding from hemorrhoids. Mild disease, especially if confined to the rectum, frequently is associated with a normal physical examination.

Most patients with ulcerative proctitis have disease of mild severity. Ulcerative proctitis should not be viewed as a separate entity but rather as part of the spectrum of ulcerative colitis. Although most patients who present with proctitis continue to have disease confined to the rectum, there is extension to involve the more proximal colon in 15% of cases with follow-up of 10 years, [103] with extension to the hepatic flexure in 7%.

In 27% of patients with ulcerative colitis, the first attack is of moderate severity. These patients typically present with five or six bloody bowel movements per day. Abdominal pain, which is uncommon in mild disease, may be present. Patients are fatigued and may have a low-grade fever. In moderate disease, there is often some degree of abdominal tenderness, but bowel sounds are usually normal. Initial attacks of moderate severity may be misdiagnosed as infectious colitis.

Edwards and Truelove [102] found that 19% of their patients with ulcerative colitis presented with severe disease. In addition to having frequent episodes of bloody diarrhea, a patient with severe colitis is likely to be weak and may even be bedridden. If the attack is sustained, the patient develops weight loss, marked anemia, and hypoalbuminemia. Fever, tachycardia, and postural hypotension indicate severe disease. Some abdominal tenderness is common even in mild disease, but significant abdominal tenderness, particularly with rebound over the colon, suggests severe disease. Markedly hypoactive or absent bowel sounds, indicating that the colon has lost all motility, is also a sign of severe disease. Protuberance of the abdomen, reflecting atony and dilation of the colon, raises the possibility of toxic megacolon.

Initial Attack

The initial attack of ulcerative colitis may be fulminant, with bloody diarrhea present from the beginning; more commonly, the disease begins indolently, with nonbloody diarrhea progressing to bloody diarrhea. [104] Symptoms often gradually worsen over the course of a few weeks. Ulcerative colitis can present initially with any extent of anatomic involvement, from disease confined to the rectum to pancolitis, and with any degree of activity, from mild diarrhea to toxic megacolon. At initial presentation, colitis extending to the cecum is seen in only about 20% of patients. Limited colitis is more common, with 75% of patients having no disease proximal to the sigmoid. [105] The greater the anatomic extent of disease at the first presentation, the more severe the symptoms are likely to be. [104] Extraintestinal manifestations, most commonly arthralgias and mild arthritis, are present in fewer than 10% of patients at initial presentation. In mild ulcerative colitis, the rectal mucosa is erythematous and edematous on endoscopic examination. In more severe disease, edema is more marked, the mucosa bleeds spontaneously, and there is an extensive purulent exudate. In the most severe cases, frank ulceration is seen.

The outcome of the first attack of ulcerative colitis can be predicted on the basis of the extent of the disease and the severity of the symptoms. [105] More than 90% of patients with mild disease go into remission after the first attack. Among patients with more severe disease, a significant number require colectomy, and a few worsen and die; death occurs primarily in patients who present with toxic megacolon.

Clinical Evaluation

Management of ulcerative colitis involves repeated evaluation of the patient's clinical condition over time. These evaluations are required at the initial presentation, at the beginning of each subsequent attack to define the severity of the attack, and at multiple points during each attack to determine whether the clinical picture is worsening or improving. The extent of the clinical evaluation is guided by the presentation—the milder the presentation, the less extensive the evaluation that is required. The most important parts of the clinical evaluation are the history and physical examination. The frequency and severity of diarrhea is a good first guide to the severity of the disease. More than six bowel movements per day usually is associated with severe disease; however, comparison of the number of bowel movements with the patient's normal bowel habits may be more informative than the absolute number. Moreover, the number of bowel movements is a more useful indication of severity in acute rather than in chronic disease. Systemic signs and symptoms (fever, hypotension, tachycardia) are markers for the presence of severe disease and demand a more extensive evaluation. Coexistence of irritable bowel syndrome with ulcerative colitis makes evaluation of the patient's symptoms more difficult.

Endoscopic examination is required at the initial presentation to help establish the diagnosis and to define the extent of disease. [106] The initial endoscopic examination is usually a colonoscopy unless severe disease is present; in patients with severe disease, proctoscopy or sigmoidoscopy carries less risk. Endoscopic examination may be useful at presentation of subsequent attacks if there is any question as to whether the attack is a recrudescence of ulcerative colitis. In patients with a past history of ulcerative colitis who develop diarrhea, proctoscopy is a useful method for distinguishing recurrences of ulcerative colitis from infectious diarrhea. Endoscopic examination also may be indicated if a recurrence of ulcerative colitis is more severe than earlier occurrences, suggesting anatomic extension of the disease. For patients with long-standing disease, colonoscopic examination is used for surveillance for dysplasia. [107], [108] Some clinicians routinely follow the course of ulcerative colitis exacerbations by repeated proctoscopy or sigmoidoscopy, with the thought that the endoscopic picture provides important information about the response to drug therapy; however, there is no definitive evidence that the information yielded is any more useful than that gained by asking the patient about the severity of symptoms.

One of the most important functions of clinical evaluation in exacerbations of ulcerative colitis is the identification of patients who are progressing to toxic megacolon. [109], [110] Fever, leukocytosis, and marked abdominal tenderness all indicate severe disease. Plain films of the abdomen demonstrate whether there is colonic dilation consistent with toxic megacolon. Colonic dilation usually occurs without obvious abdominal distention.

Laboratory studies also play a role in the clinical evaluation of ulcerative colitis. If the history and physical examination indicate mild disease activity, laboratory studies are likely to add little to the evaluation. They are most useful in confirming a clinical impression of severe disease and in following the clinical course of a severe exacerbation. The laboratory studies most likely to reflect disease activity are hemoglobin level, leukocyte count, and erythrocyte sedimentation rate. An elevated leukocyte count, however, may be difficult to interpret in patients treated with corticosteroids. Other biochemical abnormalities may be present. Hypoalbuminemia is a sign of severe disease, usually of long duration. Electrolyte disorders, particularly hypokalemia, are seen with severe diarrhea.

The role of microbial agents in inducing exacerbations of IBD has been a somewhat controversial area. Intercurrent intestinal infections, either bacterial (*Clostridium difficile*, *Campylobacter* species, *Yersinia* species) or viral (cytomegalovirus), have been implicated in inducing exacerbations. Although one study reported high levels of recovery of *C. difficile* toxin from patients with symptomatic relapses, [111] other studies have reported low rates. [112] Cytomegalovirus causes gastrointestinal infection and is fairly common in the immunosuppressed host (e.g., patients taking immunomodulators). The typical presentation is abdominal pain and watery diarrhea. Endoscopic biopsies show cytomegalovirus vasculitis within the lamina propria. Typical intranuclear inclusions are seen in endothelial cells. If cytomegalovirus is found, corticosteroids and immunomodulators should be tapered and stopped if possible.

Natural History

Most commonly, ulcerative colitis follows a chronic intermittent course, marked by long periods of quiescence interspersed with acute attacks lasting weeks to months

(Table 83-2). [102] In a few patients diagnosed as having ulcerative colitis, there is a single acute attack of colitis with no recurrences. It seems likely, however, that in some of these patients the diagnosis is not correct. A small but significant percentage of patients suffer a chronic, continuous course with persistent symptoms and no complete remission. Patients who require continuous treatment with steroids to maintain remission are also part of this group. In drug studies in acute ulcerative colitis, the placebo remission rates average 10% and the placebo improvement rates average 30%. [113]

CLINICAL COURSE	NUMBER OF PATIENTS	PERCENTAGE
Acute fulminating	20	8.0
Chronic intermittent	161	64.4
Chronic continuous	18	7.2
One attack only	45	18.0
Total colectomy in first attack	2	0.8
Died in first attack of other causes	1	0.4
Unknown	2	0.8
Total	249	100.0

Adapted from ref. 102.

TABLE 83-2 Clinical Course of Ulcerative Colitis

The risk of relapse after the first attack of ulcerative colitis is a function of the patient's age at the time of the first attack. [105] Older patients are more likely than younger ones to go long periods without relapse. For patients younger than 50 years, the median time for relapse after the first attack is 2 to 3 years. Neither the severity of the first attack nor the extent of colonic involvement at the time of diagnosis has any effect on the frequency of recurrence; however, the severity and extent of the disease at initial presentation affect the likelihood and timing of subsequent colectomy. [105] For those with severe disease at first presentation, the rate of colectomy reaches 50% by 2 years after the initial attack. For patients with pancolitis, the rate of colectomy reaches 50% after 5 years. In contrast, fewer than 10% of patients who present with mild disease or with proctitis alone have undergone colectomy after 10 years. As with the risk of relapse, the cumulative resection rate among patients with ulcerative colitis is inversely proportional to age. Those in the oldest age group are the least likely to suffer relapse and the least likely to undergo resection.

No systematic studies of triggering events for relapses in ulcerative colitis have been undertaken. Among the potential triggering events that have been suggested are:

noncompliance with maintenance medications
NSAIDs
antibiotics given for problems unrelated to ulcerative colitis (e.g., sinusitis, pneumonia)
intercurrent colonic infections (e.g., *Shigella*, *Salmonella*, *C. difficile*)
cessation of smoking.

Antibiotics and intercurrent infections are thought to induce relapses by altering the colonic flora and thus altering the relationship between the mucosal immune system and the antigens in the lumen. For patients with ulcerative colitis with enteric infections, it is important to determine if the patient has only an enteric infection or an enteric infection plus a flare of ulcerative colitis.

Those who present initially with proctitis have a more benign course than those who present initially with more extensive disease. These patients are likely to respond to local therapy and thus are spared the side effects of systemic therapy. However, those who present with proctitis are at risk for extension of their disease; they have a 50% chance of extension and a 12% chance of colectomy within 25 years. Those with disease proximal to the sigmoid have a 9% chance of progression to pancolitis and 23% chance of colectomy. In contrast those who start with pancolitis have a 40% chance of colectomy. [114]

Mortality in patients with ulcerative colitis has decreased dramatically and now life expectancy is similar to that of the general population. Ulcerative colitis has a significant lifelong impact on a patient's quality of life. Most patients lead productive lives with 90% employed after treatment of the initial attack. [115] More patients have impairment of social and emotional functioning as manifested by worry about the need for surgery, the social problems associated with an ostomy, side effects of medication, and the uncertain course of the disease. These concerns are likely to be reduced if the physician is actively involved in teaching the patient about the natural history of the disease.

CROHN'S DISEASE: CLINICAL FINDINGS AND NATURAL HISTORY

Disease Location

Crohn's disease is a more complex and difficult clinical entity than ulcerative colitis, partially because of the diversity of anatomic locations in which it is detected and the effects of this diversity on presentation, clinical course, and therapeutic options. There are three major patterns of disease distribution: disease present in the ileum and cecum, a pattern seen in 40% of patients at presentation; disease confined to the small intestine, a pattern seen in 30% of patients at presentation; and disease confined to the colon, a pattern seen in 25% of patients at presentation. [116] Among those with colonic disease, most have pancolitis, but about a third have segmental disease. Much less commonly, Crohn's disease involves more proximal parts of the gastrointestinal tract—the mouth, the tongue, the esophagus, the stomach, and the duodenum.

Symptoms

The predominant symptoms in Crohn's disease are diarrhea, abdominal pain, and weight loss. [116] , [117] Any of these three symptoms may be most prominent, in contrast to ulcerative colitis, in which diarrhea is almost universally the most prominent complaint. The initial presentation of Crohn's disease may not be dramatic. Patients may complain for months or years of vague abdominal pain and intermittent diarrhea before the diagnosis of Crohn's disease is considered.

Diarrhea occurs in almost all persons with Crohn's disease, but the pattern varies with the anatomic location of the disease (Table 83-3). [116] In patients with colonic disease, especially with rectal involvement, diarrhea may be of small volume and associated with urgency and tenesmus. Inflammation in the rectum causes a loss of distensibility. The entry of even a small amount of stool into a nondistensible rectum causes an immediate and urgent need to defecate. Prolonged rectal inflammation and scarring in the rectum can leave it so rigid and nondistensible that the patient is incontinent. In disease confined to the small intestine, stools are of larger volume and are not associated with urgency or tenesmus. Patients with severe involvement of the terminal ileum and those who have had surgical resections of the terminal ileum may have elements of bile salt diarrhea or, in more severe cases, frank steatorrhea. [118] Strictures in the small intestine may lead to bacterial overgrowth with deconjugation of bile salts and fat malabsorption. If diarrhea is a product of fat malabsorption, the timing and severity of the diarrhea are functions of the pattern of fat ingestion. Finally, internal fistulae are common in Crohn's disease and can lead to diarrhea either by colonization of the small bowel with bacteria, as in enterocolonic fistulae, or through bypass of large segments of absorptive epithelium, as in enteroenteric or enterocolonic fistulae.

	DISEASE LOCATION (%)		
CLINICAL FEATURE	Ileitis (%)	Ileocolitis (%)	Colitis (%)
Diarrhea	~100	~100	~100
Abdominal pain	65	62	55
Bleeding	22	10	46
Weight loss	12	19	22
Perianal disease	14	38	36
Internal fistulae	17	34	16
Intestinal obstruction	35	44	17
Megacolon	0	2	11
Arthritis	4	4	16
Spondylitis	1	2	5

Adapted from ref. 116.

TABLE 83-3 Frequency of Clinical Features in Crohn's Disease

The location and pattern of pain in Crohn's disease often correlate with disease location. One common pain pattern is cramping right lower quadrant pain in patients with ileocolonic disease. [119] This pain usually occurs after eating and probably is related to partial intermittent obstruction of a narrowed intestinal lumen. Pain is caused by stretching of the wall in the dilated segment proximal to the obstruction and by powerful contractions of the small bowel musculature attempting to push intestinal contents through the obstructed segment. Abdominal distention, nausea, and vomiting may accompany pain in this circumstance. A second common pain pattern in Crohn's disease is visceral pain resulting from inflammation of the serosa, as seen in transmural Crohn's disease. The pathophysiologic basis of abdominal pain in nonobstructed or stable patients with Crohn's disease is less clear. Crohn's disease is associated with an increased risk of depression; pain management is more difficult in patients with depression.

Weight loss of some degree occurs in most patients with Crohn's disease, irrespective of anatomic location. Loss of more than 20% of body weight is less common, occurring in 10% to 20% of affected persons. Some weight loss is a product of malabsorption, but weight loss usually is a product of diminished intake. Patients, especially those with small bowel disease, may avoid food because eating brings on pain or diarrhea or, more commonly, because they are anorectic. Colonic disease is associated with a high incidence of rectal bleeding and perianal involvement but a low incidence of internal fistulae and obstruction (see Table 83-3). In contrast, disease confined to the small intestine is associated with a lower incidence of bleeding and perianal involvement but a higher incidence of obstruction.

Constitutional symptoms contribute significantly to the overall morbidity in Crohn's disease. Fever and chills often accompany Crohn's disease activity; a low-grade fever may be the patient's first warning sign of a flare of activity. Fatigue and malaise can reduce the ability to function markedly and may impact work performance negatively. Although they are more likely to complain of pain and diarrhea, patients may be more bothered by fatigue. In patients in whom fatigue is the dominant symptom, coexisting depression should be considered. Induction of remission by drugs or surgery invariably is associated with increased energy and a sense of well being.

The initial presentation of Crohn's disease can usually be characterized as either obstructing or fistulizing. Obstructive disease is the result of inflammation narrowing the intestinal lumen and obstructing the flow of intestinal contents. Over time, fibrosis and thickening of the intestinal wall also contribute to obstruction. Crampy abdominal pain, nausea, vomiting, and diarrhea are the major symptoms associated with obstructing disease. Fistulizing disease occurs when the inflammatory process extends completely through the intestinal wall. The escape of bacteria through these defects in the wall can result in abscesses. Extension of the inflammatory process into adjacent organs results in fistulae (enteroenteric, enterocutaneous, enterovesicular, etc.). Fistulizing disease can present with fever, leukocytosis, and evidence of fistulization (e.g., enterocutaneous fistulae). Obstruction and fistulization are not mutually exclusive, in fact the enteric end of a fistula is often found immediately upstream from a stricture.

Distinguishing the obstructive and fistulizing forms of Crohn's disease is important because the distinction affects therapy. For example, steroids are likely to be effective in obstructing disease but not in fistulizing disease. The distinction between obstructing and fistulizing disease also affects prognosis. Relapses in patients with a past history of fistulae are more likely to be characterized by fistulization and relapses in those with a past history of obstruction are more likely to be characterized by obstruction. Obstruction and fistulization are discussed in detail later in the chapter.

Physical and Laboratory Findings

Physical findings in Crohn's disease also vary with the distribution and severity of the disease. [120] When the disease is active, the patient looks pale, weak, and chronically ill. Aphthous ulcers in the mouth are common in active Crohn's disease. These are shallow ulcers covered by a grayish exudate and surrounded by an erythematous margin. These painful lesions can be found on the lips, gingiva, or buccal mucosa. Occasionally, oral lesions are the presenting problem (see Chapter 50). [121] Long-standing severe disease with malnutrition results in temporal and interosseous wasting. The abdomen may be tender, typically over the area of disease activity. Thickened bowel loops, thickened mesentery, or an abscess may cause a sense of fullness or a mass, often in the right lower quadrant. Rebound tenderness (most often referred) is often present. Fistulous openings, induration, redness, or tenderness near the anus suggest the presence of perianal Crohn's disease. The mucosa at the anal verge may appear purplish because of vascular engorgement. Fissures in the anal canal can occur; bleeding from these fissures can be confused with active colitis.

Laboratory findings in Crohn's disease are largely nonspecific. [122] The peripheral blood count may reveal anemia resulting from chronic disease, blood loss, or nutritional deficiencies (iron, folate, or vitamin B_{12}). A modestly elevated leukocyte count is indicative of active Crohn's disease, but a marked elevation suggests the presence of an abscess or other suppurative complication. Thrombocytosis may occur with active disease. Bleeding or thrombotic complications may occur secondary to thrombocytosis. The erythrocyte sedimentation rate has been used to monitor disease activity in Crohn's disease, and it tends to be higher in colonic disease than ileal disease. Hypoalbuminemia is a good indication of disease severity and malnutrition. Ileal disease or resection of more than 100 cm of ileum results in a diminished serum vitamin B_{12} level because of malabsorption.

Crohn's disease may rarely involve the stomach and duodenum. In these cases, more distal involvement, particularly of the ileum, is usually also present. Gastroduodenal Crohn's disease may present with epigastric pain similar to that of duodenal ulcer. Upper gastrointestinal series may show ulceration and narrowing of the antrum and duodenum (Fig. 83-2). Aphthous ulcers and linear ulcers in the gastric antrum may be seen on endoscopy. [123] Therapy is the same as for ileal Crohn's disease, although a trial of H_2-receptor antagonists is useful for those with ulcers. Duodenal Crohn's disease often leads to stenosis, obstruction, and postprandial vomiting. [124] Gastrojejunostomy without resection may be required to bypass the obstruction but should be avoided if possible.

Disease Activity Indices

It is often difficult to assess the course of disease activity in Crohn's disease, especially when fatigue or pain are prominent symptoms. Usually, a number of different disease manifestations (increased number of bowel movements, diminished general sense of well being, fistula formation, weight loss, decreased hematocrit, endoscopic appearance, histology, increased sedimentation rate, increased orosomucoid levels) occur and do not necessarily improve or worsen in parallel. This problem becomes particularly obvious in comparing medical therapies or in assessing the efficacy of new medical therapies. Many markers of disease activity can be monitored, and it is difficult to interpret studies in which some markers improve but others do not. Several attempts have been made to establish numerical systems for evaluating disease severity and response to therapy in Crohn's disease. [125], [126], [127], [128] and [129] The National Cooperative Crohn's Disease Study devised the Crohn's Disease Activity Index (CDAI) for evaluating response to therapy in that study. [124] The CDAI was calculated by assigning numerical scores to the number of diarrheal stools, abdominal pain, general well being, systemic manifestations, use of antidiarrheal agents, presence of abdominal mass, hematocrit, and body weight. Other groups have proposed and used alternative numerical indices to quantify Crohn's activity, but these indices, although promoted as simplified, are not especially easy to use, nor are they necessarily more valid than the CDAI. [122], [127], [128] and [129] Thus, the use of indices is not suggested for following disease activity in patients except in research studies.

Natural History

Crohn's disease, like ulcerative colitis, is a relapsing and remitting disease. About 30% of placebo-treated patients with Crohn's disease of mild to moderate activity go into remission within 4 months. [130], [131] Conversely, in a group of patients with Crohn's disease in remission and not receiving any type of therapy, about 70% remained in remission at 1 year and 50% at 2 years. Within 10 years of diagnosis, 60% of patients with Crohn's disease have surgery. Postoperatively, endoscopic signs of recurrence are seen in 70% of patients at 1 year and recurrence of symptoms is seen in 40% to 50% within 4 years. [132], [133] Of those patients who have one surgical resection for Crohn's disease, 45% eventually require reoperation. The younger the age at onset, the more likely the patient will have a complicated course and the more likely surgery will be required. [134]

Life expectancy in Crohn's disease patients is near normal but there is some increased mortality, especially among those who develop the disease before age 20. The increase in mortality is most prominent in the early years of the disease. [135], [136] Despite the low mortality, Crohn's disease can have a large negative impact on quality of life. Patients have problems with employment, social activities, and interpersonal relationships. The quality of life in Crohn's disease is, on average, less good than in ulcerative colitis. The majority of patients are employable; however half of them need to modify their employment as a result of their disease. These modifications include decreased hours, leaves of absence, and career changes. [137] Patients with Crohn's disease have concerns about the uncertain nature of their disease, decreased energy, medication side effects, and surgery, especially fear of an ostomy. [138] The high incidence of depression as a co-morbid condition also diminishes the quality of life for patients with Crohn's disease.

EXTRAINTESTINAL MANIFESTATIONS

Although ulcerative colitis and Crohn's disease primarily involve the bowel, both are associated with manifestations in other organ systems. For some patients, especially those with sclerosing cholangitis or ankylosing spondylitis, the extraintestinal manifestations may be more troublesome than the bowel disease. The extraintestinal manifestations can be divided into two major groups: those in which the clinical activity follows the activity of the bowel disease and those in which the clinical activity is unrelated to the clinical activity of the bowel disease. Most extraintestinal manifestations occur more commonly with ulcerative colitis or Crohn's colitis than with Crohn's disease confined to the small intestine.

Peripheral Arthritis

The most common extraintestinal manifestation of IBD is arthritis (Table 83-4). [139], [140] and [141] The two arthritic complications of IBD are colitic or peripheral arthritis and ankylosing spondylitis or axial arthritis. Colitic arthritis is a migratory arthritis or arthralgia that affects the large joints of the knees, hips, ankles, wrists, and elbows, in that frequency. Usually, fewer than six joints are involved and small joints of the hands are typically not involved. [139] Colitic arthritis is more common with Crohn's colitis than ulcerative colitis and is uncommon with Crohn's disease confined to the small intestine. Most arthritic flares last only a few weeks, though recurrences are common with renewed disease flares. Deformity with radiologic changes occurs in fewer than 25% of cases. The joint pain, swelling, and stiffness parallel the course of the bowel disease. Serology for rheumatoid factor is negative in these patients. Colitic arthritis, uveitis, and erythema nodosum often are seen together. Successful treatment of the intestinal inflammation results in improvement in the arthritis. Acetaminophen can be used for joint discomfort. NSAIDs are generally avoided as they often may induce a flare or worsening of the disease. Often, treatment of bowel disease with corticosteroids results in a dramatic improvement in the associated arthritis.

ORGAN INVOLVED	NUMBER OF PATIENTS	PERCENTAGE OF TOTAL
Joint	53	26
Polyarthralgia	27	13
Spine	8	4
Extremities	18	9
Skin	39	19
Erythema nodosum	9	4
Pyoderma gangrenosum	10	5

TABLE 83-4 Extraintestinal Manifestations in 202 Patients With Ulcerative Colitis

Axial Arthritis

Ankylosing spondylitis is seen in patients with IBD, but its activity does not follow that of the bowel disease, and treatment of the bowel disease does not affect the spondylitis. [140], [141] Ankylosing spondylitis presents with morning stiffness, low back pain, and stooped posture. Radiography of the spine in ankylosing spondylitis shows squaring of the vertebrae and straightening of the spine. Syndesmophytes appear along the lateral and anterior portions of the intervertebral discs, giving the picture of "bamboo spine" (Fig. 83-3).

FIGURE 83-3. (See Color Fig. 83-3.) Sacroiliitis and ankylosing spondylitis demonstrating obliteration of the sacroiliac joints (*large arrow*) and bamboo spine with syndesmophytes (*small arrow*). (Courtesy of Dennis Balfe, M.D., St. Louis, MO.)

Patients with ulcerative colitis have a 30-fold increase in the incidence of ankylosing spondylitis compared with the general population. Even though there is no increased incidence of HLA-B27 in ulcerative colitis, 80% of those with both ulcerative colitis and ankylosing spondylitis are B27-positive. [142] IBD-associated ankylosing spondylitis occurs frequently in females (perhaps up to 40%), whereas, ankylosing spondylitis unassociated with intestinal disease occurs at a male-to-female ratio of nearly 9:1. In contrast to colitic arthritis, which is episodic and usually nondeforming, ankylosing spondylitis can be relentlessly progressive and crippling. The results of medical management of ankylosing spondylitis in IBD are poor. Physical therapy plays a major role in maintaining function. Pain management is a problem, and narcotic addiction is common. NSAIDs, though they reduce inflammation and pain in spondylitis and in colitic arthritis, do not halt the progression of the disease and may exacerbate intestinal inflammation. Medical treatment of IBD and colectomy are not helpful in managing the ankylosing

spondylitis. A report of successful treatment with infliximab suggests a hopeful, possibly effective option. [143]

Sacroiliitis, inflammation of the joint between the sacrum and the ileum, can be seen in conjunction with ankylosing spondylitis but more often is seen alone. Over 20% of IBD patients, most of whom have no back pain, have radiographs consistent with sacroiliitis. [144], [149] Some will present with low back pain which can be slowly progressive, not related to intestinal inflammation. Radiographs of the pelvis reveal blurring of the margins of the sacroiliac joints, with patchy sclerosis.

Osteoporosis

Osteoporosis or osteopenia occurs in as many as half of patients with IBD. [145] In Crohn's disease osteopenia may be present at diagnosis. Numerous factors may contribute including malnutrition, malabsorption, and smoking. Persistent inflammation and steroid use may be the most important factors. Tumor necrosis factor enhances bone resorption. Although osteopenia may occur independent of steroid use, steroids can still worsen the problem. In ulcerative colitis, the loss of bone density occurs more directly as a result of steroid use. Patients with primary sclerosing cholangitis, particularly with longer standing disease, can have more severe osteoporosis. The therapeutic options of estrogen replacement therapy, raloxifene, and calcitonin have expanded considerably, with the addition of bisphosphonates-alendronate (Fosamax) and risedronate (Actonel) which can augment bone density considerably. Screening patients with dual photon absorptiometry is recommended. [146] Guidelines for the management of osteoporosis in IBD have been developed by the British Society of Gastroenterology. [147]

Renal Complications

The incidence of kidney stones in IBD patients, with estimates ranging between 1% to 25%, is several times that in the general population. [148] Calcium oxalate stones are seen in patients with small intestine Crohn's disease. Ileal resections or ileal disease can lead to fat malabsorption, and unabsorbed fatty acids bind calcium in the lumen. In healthy persons, oxalate in the lumen is bound to calcium. Calcium oxalate is poorly soluble and poorly absorbed. If calcium is bound to malabsorbed fatty acids, however, oxalate combines with sodium to form sodium oxalate, which is soluble and is absorbed in the colon. [149] The development of calcium oxalate stones in Crohn's disease requires an intact colon to absorb oxalate; patients with ileostomies do not develop calcium oxalate stones. However, the presence of an ileostomy predisposes to other kinds of kidney stones, particularly urate stones, because of the diminished urine volumes in patients with significant ileostomy volume losses. [150] Measurement of 24-hour urinary oxalate, uric acid, and citrate may be useful to guide therapy. Dietary restriction of oxalate and citrate supplementation can help prevent recurrence of oxalate stones.

Other urinary tract complications are associated specifically with Crohn's disease. Inflammation from the bowel extending into the retroperitoneal space can occlude the ureters, leading to obstruction and hydronephrosis. [151] This process most commonly extends from the area of the cecum and terminal ileum and involves the right ureter. Also in Crohn's disease, fistulae can form between an inflamed bowel and the urinary bladder, leading to urinary tract infections. [152] Amyloidosis is seen in patients with Crohn's disease and has caused death from renal insufficiency. [153] Renal amyloidosis does not respond to conventional medical therapy for Crohn's disease and, for the most part, does not improve after the inflamed section of intestine is resected.

Dermatological Manifestations (see Chapter 49)

The two common dermal complications of IBD are pyoderma gangrenosum and erythema nodosum. Pyoderma gangrenosum is seen with colitis and ileocolitis and is associated with extensive long-standing disease. The incidence of pyoderma in ulcerative colitis is low (1%–5%), and it is even lower in Crohn's disease; however, 36% to 50% of all patients with pyoderma gangrenosum have IBD. [154], [155] The typical lesion is a discrete ulcer with a necrotic base, usually found on the lower extremities (Fig. 83-4) but may occur elsewhere, particularly the face. Lesions often occur at the site of previous injury (pathergy). The ulcers may drain purulent material, but the drainage is sterile on culture. These ulcers can become large and deep, with destruction of surrounding soft tissues. Activity of pyoderma gangrenosum may or may not follow the activity of the bowel disease, but these lesions almost always develop during a bout of acute colitis. Usually, the lesions resolve with control of the colitis by use of oral corticosteroids. Alternatively, corticosteroids can be injected directly into the skin lesions. Therapies with Periactin, dapsone, and azathioprine have been reported, with cyclosporine increasingly recommended. [156], [157] and [158] Infliximab has also been reported to be dramatically effective in some cases. [159] Topical tacrolimus has also been effective. [160]

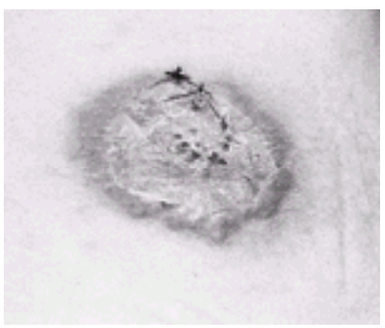

FIGURE 83-4. (See Color Fig. 83-4.) Pyoderma gangrenosum (with stitches after biopsy). (Courtesy of Ira Kodner, M.D., St. Louis, MO.)

Erythema nodosum is seen particularly in association with Crohn's disease in children. [161] The lesions are raised, tender nodules, usually found over the anterior surface of the tibia. Activity of erythema nodosum follows the activity of the bowel disease and responds to treatment of the bowel disease. Most patients have only a single episode of erythema nodosum. Sweet syndrome (acute febrile neutrophilic dermatosis), which has some similarity to erythema nodosum, is another dermatologic condition associated with IBD. [162]

Eye Complications

The ocular complications of IBD are uveitis and episcleritis. [163] Uveitis (iritis) is an inflammatory lesion of the anterior chamber, presenting with blurred vision, headache, eye pain, photophobia, and conjunctival injection. Diagnosis is made by slit-lamp examination, which demonstrates perilimbic edema and cells in the anterior chamber. Scarring and blindness can be prevented with local therapy of corticosteroids and atropine or other agents that dilate the pupil. Episcleritis is a less serious problem, presenting with burning eyes and scleral injection. Treatment with topical steroids is effective.

Thromboembolic Complications

Thromboembolic complications, with arterial as well as venous events, occur in about 1% to 2% of patients with ulcerative colitis and Crohn's disease. [164] Activation of clotting factors and thrombocytosis are common. [165] In patients with active disease, procoagulant factors tend to be increased and fibrolytic factors are decreased, potentially generating a hypercoaguable state. In both Crohn's disease and ulcerative colitis increased levels of factor V, factor VIII, and fibrinogen and decreased levels of antithrombin III have been demonstrated. [166], [167] Deep vein thrombosis and pulmonary emboli affect patients with active disease. Thromboembolic events in the eye and in intracranial vessels also have been described. [166], [168]

Hepatobiliary Complications

The hepatic complications of IBD include fatty liver, pericholangitis, chronic active hepatitis, and cirrhosis. The biliary tract complications are sclerosing cholangitis and gallstones. Cholesterol gallstones occur in patients with ileal disease or ileal resections owing to malabsorption of bile salts and the resultant decrease in the size of the bile salt pool. Pericholangitis is the most common hepatic complication of IBD, with prevalences as high as 50% to 80% reported. [169], [170] Patients with pericholangitis are usually asymptomatic. Elevations of alkaline phosphatase are seen frequently; elevations of bilirubin are less common. Histologically, there is inflammation of the portal tracts, with lymphocyte and eosinophil infiltrates and degenerative changes of the bile ductules. [171] In more advanced cases, progressive

fibrosis can develop. The relationship between pericholangitis and primary sclerosing cholangitis is uncertain. Some studies have suggested that pericholangitis may be a part of the spectrum of sclerosing cholangitis, and the histological manifestations of sclerosing cholangitis and pericholangitis on liver biopsy may be indistinguishable. [172] Patients diagnosed on liver biopsy as having pericholangitis may need to undergo endoscopic retrograde cholangiopancreatography (ERCP) to rule out sclerosing cholangitis. There is no effective therapy for pericholangitis.

Sclerosing cholangitis is a chronic cholestatic liver disease marked by fibrosing inflammation of the intrahepatic and extrahepatic bile ducts; it occurs in 1% to 4% of patients with ulcerative colitis and with lower frequency in Crohn's disease. [173], [174] Most patients with sclerosing cholangitis have IBD. The prevalence of IBD is so high in patients with sclerosing cholangitis that colonoscopy should be performed even on patients who are without intestinal symptoms. Endoscopic and histological evidence of IBD are commonly found in patients with sclerosing cholangitis without intestinal symptoms. Patients with ulcerative colitis and sclerosing cholangitis have a higher risk of colon cancer than those with ulcerative colitis alone and should undergo more intensive screening. [175] Sclerosing cholangitis can affect intrahepatic bile ducts, extrahepatic bile ducts, or both. In patients with IBD and sclerosing cholangitis, usually both intrahepatic and extrahepatic ducts are affected. Early in the disease, liver biopsy shows enlargement of the portal tracts, with edema and bile duct proliferation. Later, biopsies show extension of fibrosis out of the portal space, eventually leading to cirrhosis.

Bile duct strictures are the major clinical problem in sclerosing cholangitis; strictures can occur in both intrahepatic and extrahepatic bile ducts (Fig. 83-5). Patients may be asymptomatic until the disease is far advanced and then present with fever, right upper quadrant pain, and jaundice. More often, sclerosing cholangitis is first recognized in the evaluation of abnormal laboratory studies: elevated alkaline phosphatase, bilirubin, and transaminases. The differential diagnosis of sclerosing cholangitis includes biliary tumors and common duct gallstones; diagnosis is made by ERCP or transhepatic cholangiography. Sclerosing cholangitis progresses to cirrhosis, hepatic failure, and death in 5 to 10 years. [176] Clinical features at presentation associated with a poorer prognosis include hepatomegaly, splenomegaly, elevated serum alkaline phosphatase, advanced histological stage, and age. [177] Endoscopic balloon dilation or stenting of extrahepatic strictures may be palliative. Cholestyramine, a bile salt–binding resin, may help to relieve pruritus. Colectomy and medical therapy of the bowel disease are without benefit in the management of sclerosing cholangitis. Ursodeoxycholic acid can decrease alkaline phosphatase and transaminases but does not alter histological progression or influence the occurrence of clinically important events such as time to transplant or death. [178] Liver transplantation has been used with success, and sclerosing cholangitis is now one of the most common indications for liver transplantation in adults. Cholangiocarcinoma develops in 10% to 15% of IBD patients with long-standing sclerosing cholangitis. Differentiating cholangiocarcinoma from the benign strictures of sclerosing cholangitis is difficult. ERCP with brushing or cholangioscopy with biopsy may help to make this distinction.

FIGURE 83-5. (See Color Fig. 83-5.) Sclerosing cholangitis with segmental strictures (*arrows*) in common bile duct. There are also strictures in the intrahepatic bile ducts. (Courtesy of Dennis Balfe, M.D., St. Louis, MO.)

ENDOSCOPY AND RADIOLOGY

Endoscopy

Endoscopy and radiology serve complementary roles in the diagnosis and management of patients with IBD. Endoscopy serves to diagnose IBD, to distinguish between ulcerative colitis and Crohn's disease, to determine the extent and severity of disease, to assess response to treatment, and to screen for dysplasia. Due to its ability to visualize the mucosa directly and obtain biopsies, endoscopy has become established as the primary diagnostic tool. Differentiating between acute infectious colitis and an initial flare of ulcerative colitis or Crohn's disease by endoscopic findings may be difficult. The endoscopic findings in several varieties of infectious colitis are indistinguishable from those seen in IBD. [106], [179], [180] *Yersinia, Campylobacter, Shigella*, and cytomegalovirus infections all can have endoscopic pictures that do not differ from that of ulcerative colitis. They show mucosal edema, granularity, erythema, and easy friability. [179], [180] Pseudomembranous colitis in its later stages may produce diffuse mucosal changes like those of ulcerative colitis, but the characteristic raised, yellow, plaquelike pseudomembranes should be diagnostic. Amebiasis is the infectious disease most likely to result in discrete, punched-out ulcers with normal intervening mucosa, as seen in Crohn's colitis. [181], [182]

Over time, endoscopic diagnosis of IBD is more certain, and the distinction between ulcerative colitis and Crohn's disease can be made in most cases. The important distinguishing features of Crohn's disease include rectal sparing; areas of active disease interspersed with normal mucosa; sharp, punched-out ulcerations surrounded by normal mucosa; and "cobblestoning," or nodular mucosa often intersected by crossing linear ulcerations. The characteristic findings of ulcerative colitis are rectal involvement with a confluent distribution, friable mucosa, a blurred vascular pattern, and ulcerations in areas of active inflammation.

Endoscopy is more sensitive than radiographic contrast studies in defining the margins of inflammation. Contrast studies may be unable to detect endoscopically evident disease in up to 20% of cases. [183] Comparisons of double-contrast radiography with colonoscopy show that radiography underestimates the extent of colonic involvement in two thirds of cases. [184] However, as many as 65% of patients will have active disease in the ileum beyond the reach of the colonoscope, with 13% having a normal terminal ileum. [185] Colonoscopic assessment of the extent of inflammation is frequently part of preoperative evaluations, especially for Crohn's disease, to guide the surgeon on the extent of resection so that all the severely involved tissue is removed.

Endoscopy may be useful in following the course of disease. Arbitrary values of 0 to 4+ can be assigned to erythema, granularity, edema, and friability to yield an endoscopic severity score. These scores correlate reasonably well with the patient's clinical condition as assessed by symptoms in ulcerative colitis. In many cases, however, the colonoscopic picture is either much better or much worse than would be predicted by the patient's symptoms. In these cases, the usual approach is to base management decisions primarily on the patient's clinical presentation rather than on the endoscopic findings.

Similarly, in Crohn's disease, there can be a discrepancy between clinical symptoms and endoscopic findings. A randomized trial was performed to determine whether colonoscopy is useful in deciding how long to continue corticosteroid therapy in patients with Crohn's colitis. In this study, all patients were placed on steroids. In one group, steroid tapering was begun as soon as the patients achieved clinical remission; in the other group, endoscopy was used to guide the timing of the start of steroid withdrawal. [186] The two groups did equally well; suggesting that colonoscopy was not required to time the start of tapering a steroid. Endoscopy can be useful in guiding therapy; colonoscopy in the year after an ileal resection may help identify patients with progressive disease that might benefit from more aggressive therapy. Among patients free of lesions or with mild disease at 1 year, 80% remained quiescent for 3 years. In contrast, 92% of patients with more severe endoscopic findings worsened clinically during that time period. [187]

Strictures and mass lesions in the colon in patients with IBD are suspicious for carcinoma, especially if the disease has been present for longer than 10 years and particularly in ulcerative colitis. These lesions should be investigated colonoscopically and biopsied. [188] Carcinoma causing a stricture usually appears as an eccentric, friable mass. Malignant strictures have these endoscopic features: rigidity, nodules within the stricture or at its margins, an eccentric lumen, and a shelflike

margin. Sometimes in ulcerative colitis the bulk of the tumor may be submucosal, even though the tumor starts in the epithelium. In these cases, epithelial biopsies may be negative. Strictures that appear malignant by endoscopy probably should be resected regardless of the histological appearance on biopsy. Colonoscopy for dysplasia surveillance is discussed later in this chapter.

Colonoscopy also has therapeutic potential in IBD. Polypectomy is approached much the same way in patients with IBD as in the general population; however, pseudopolyps are not premalignant and do not need to be resected. However, adenomatous polyps removed endoscopically in patients with IBD raise the issue of dysplasia-associated lesions or masses (DALM). These lesions may be less of a herald of carcinoma than previously thought and some patients may be followed with conservative colonic screening after endoscopic removal of the lesion. [189] Biopsies around the polyp base and tattooing the area for later surveillance may be helpful. Pseudopolyps can be resected colonoscopically if they are bleeding or causing obstruction. Colonoscopic dilation of strictures is sometimes possible; dilation is performed with a balloon passed through the colonoscope. The best results have been achieved with short, un-inflamed strictures. Longer strictures are less likely to be dilated successfully and more likely to perforate during attempted dilation.

For the most part, the precautions to be taken in performing colonoscopy in patients with IBD are similar to those for the general population; however, some considerations are peculiar to IBD. [190] Perforation during colonoscopy is more likely; the bowel wall is inflamed, and its integrity may be weakened by penetrating ulcers and fistulae, particularly in Crohn's disease. Known or suspected severe inflammation with deep ulceration is a relative contraindication to colonoscopy. Similarly, toxic megacolon is an absolute contraindication to colonoscopy because of the paper-thin colonic wall. Scarring and fibrosis, often present in IBD, make the colon less elastic and distensible and more susceptible to perforation from pressure. Great care should be taken not to use excessive force *or air* in advancing the scope. The risk of perforation in severe ulcerative colitis makes it unwise to attempt a complete colonoscopy. Examination of the rectum with a flexible sigmoidoscope should yield enough information to confirm the diagnosis.

The earliest colonoscopic manifestation of ulcerative colitis is loss of the fine vascular pattern seen in the normal rectal mucosa and the development of diffuse erythema (Color Fig. 83-1). [106], [190] Erythema usually is accompanied by mucosal edema, which is manifested endoscopically by blunting of the rectal valves, loss of normal vasculature, and development of granular-appearing mucosa. In the normal colon, finely branching vessels are seen easily through the mucosa. In mild colitis, the vessels still are seen but may be tortuous *and less sharply defined*. As colitis becomes more severe, edema blunts the haustral pattern, and vessels cannot be seen at all (Color Fig. 83-2). Normal rectal mucosa is flat and smooth and reflects light in large patches. If the mucosa becomes edematous, small mounds of swollen tissue surround the crypts, creating an uneven surface (Color Fig. 83-3). Light reflects off the uneven surface as numerous small spots rather than large patches. This pattern of reflection is termed granularity (Table 83-5). Inflammation is associated with the presence of collections of yellowish exudate on the mucosa. The exudate is called mucopus, and the more active the disease, the larger the area of mucosa it covers. The inflamed mucosa bleeds easily if it is touched with the endoscope or a cotton swab. This easy bleeding is termed friability. In more severe disease, the mucosa bleeds spontaneously and small ulcerations appear. In the presence of inflammation and spasm, the rectum does not distend easily when insufflated with air. This is the equivalent of the loss of distensibility seen on radiography. An important aspect of the endoscopic findings in ulcerative colitis is their distribution. Inflammation begins in the rectum, extends proximally a certain distance, and then stops; all the mucosa proximal to that point is normal, and all the mucosa distal to it is abnormal (see Fig. 83-6). However, a modest amount of cecal inflammation may be noted in ulcerative colitis, particularly around the appendiceal orifice. Cecal inflammation does not indicate a skip lesion or suggest Crohn's disease as a more appropriate diagnosis. [191] As ulcerative colitis heals, residual mucosal edema, absent vasculature, and postinflammatory polyps in a tubular ahaustral lumen occur (Color Fig. 83-4). The ileum is uninvolved in ulcerative colitis but in 10% to 20% of patients with pancolitis, mild ileal inflammation with edema may be seen. This finding in ulcerative colitis is termed "backwash ileitis" but ulcers are not usually present and the endoscopic appearance is not particularly characteristic of Crohn's disease.

TABLE 83-5 Colonoscopic Mucosal Features and Their Diagnostic Specificity in Inflammatory Bowel Disease [a]

The earliest endoscopic manifestation of Crohn's disease is the aphthous ulcer (Color Fig. 83-5), a small discrete ulcer a few millimeters in diameter surrounded by a thin red halo of edematous tissue (see Table 83-5). [192], [193] Aphthous ulcers are usually multiple, and the intervening mucosa is normal. They can grow to form large stellate or linear ulcers. Ulcers may be rounded (Color Fig. 83-6) or long and serpiginous. Longitudinal and transverse ulcers may intersect to form a grid with intervening cobblestone-like areas of non- ulcerated mucosa. In Crohn's disease, large, deep penetrating ulcers can be surrounded by areas of normal-appearing mucosa. The diffuse mucosal irregularities of erythema, edema, and granularity, which are prominent in ulcerative colitis, occur less commonly and later in the course of Crohn's disease. The rectum may or may not be involved in Crohn's disease. Areas of involvement typically are interspersed with normal "skip areas." In a prospective endoscopic study of patients with Crohn's disease who were about to start a course of prednisone, the incidence of endoscopic findings was as follows: superficial erosions, 93%; deep erosions, 74%; mucosal edema, 48%; erythema, 44%; pseudopolyps, 41%; aphthous ulcers, 10%; ulcerated stenosis, 8%; and non-ulcerated stenosis, 2%. [194]

Radiology

Contrast radiology and computed tomography (CT) are both important in the management of IBD. They are more central to the management of Crohn's disease. In ulcerative colitis endoscopy is the preeminent diagnostic tool. The decision as to which radiologic modality to use is made on the basis of the question being addressed as they are complementary techniques with their own strengths and weaknesses. Air-contrast radiography is better for assessing mucosal detail, colonic distensibility, and the presence of strictures. In an acutely ill patient with Crohn's disease, a CT scan is often the preferred initial diagnostic test to answer urgent

clinical questions concerning the presence of abscesses or possible obstruction. Both techniques may be useful to detect the presence of fistulae. Radiography without contrast serves two functions in IBD: the assessment of colonic dilation in suspected toxic megacolon (Fig. 83-7) and the initial approach to the definition of the location and completeness of intestinal obstruction.

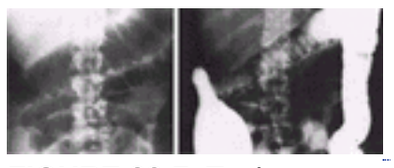

FIGURE 83-7. Toxic megacolon. **A:** Plain film radiograph shows colonic dilation. **B:** Contrast radiography reveals large ulcerations. (Courtesy of Dennis Balfe, M.D., St. Louis, MO.)

For the most part, air-contrast or double-contrast studies are preferred to single-contrast studies because they give much better definition of fine mucosal detail and even can assess the depth of ulcerations. [195] Single-contrast studies are more useful, however, for the definition of fistulae, strictures, and tumors. [196] Although contrast studies are usually well tolerated, some precautions should be observed. Barium enema is contraindicated in patients with severe colitis (either ulcerative colitis or Crohn's colitis) because injection of air and barium into the inflamed colon may precipitate toxic megacolon. Even patients with significant diarrhea usually need laxatives to clean the bowel in preparation for barium enema. Harsh, irritative laxatives should be avoided, but osmotic laxatives such as citrate of magnesia usually are tolerated. Oral contrast agents should be used with caution when obstruction may be present.

In both ulcerative colitis and Crohn's disease, radiographic findings may not correlate well with disease activity. [197] In particular, asymptomatic patients may have markedly abnormal radiographic studies because of fibrosis of the bowel wall with resultant loss of distensibility. A peroral pneumocolon, a regular air-contrast, small bowel follow-through in which air is insufflated in the colon, can assist in determining distensibility of the terminal ileum and can improve the visualization of the ileum. Air-contrast studies are frequently unhelpful in distinguishing whether a narrowed segment is due to fibrosis or inflammation. Air-contrast studies are also often inadequate to determine disease activity or to monitor the patient's response to medical management over relatively short periods. The patient's clinical response or endoscopic findings are more useful for these purposes.

In early ulcerative colitis, the barium enema may be normal. The most sensitive radiologic finding in ulcerative colitis is limited distensibility of the involved segment, resulting in a narrowed, shortened, tubular form of the lumen. The haustral markings disappear, and the normally tortuous appearance of the colon is straightened. Air-contrast examination reveals a fine granular appearance to the mucosa, with a slightly irregular surface (Fig. 83-8). In more severe disease, the granularity becomes coarser and eventually nodular. These changes may be more obvious on evacuation films. In addition to the granularity, small discrete ulcers surrounded by mounds of inflamed tissue may be seen. In more severe disease, ulcers penetrate through the mucosa and can be seen in profile as small, collar-button collections of barium extending beyond the colonic lumen (Fig. 83-9). Inflammatory polyps, either nodular or filiform, may be seen in either active or quiescent disease (Fig. 83-10). Inflammation and fibrosis in the rectum increase the presacral space, which is the distance from the sacrum to the rectal lumen, on lateral views. An enlarged presacral space (>2 cm) is consistent with severe rectal inflammation. In chronic ulcerative colitis, the colon becomes shortened and loses its haustral markings (Fig. 83-11 and Fig. 83-12). In cases of burnt-out ulcerative colitis, markedly abnormal radiographs may be seen in patients who are asymptomatic.

FIGURE 83-12. Air-contrast study of chronic ulcerative colitis with ahaustral colon. (Courtesy of Dennis Balfe, M.D., St. Louis, MO.)

In 15% to 20% of ulcerative colitis patients with pancolitis, the terminal ileum appears abnormal radiographically. The ileocecal valve is deformed and open, the terminal ileum is dilated, and the mucosa is irregular, but there are no ulcerations. This process, termed backwash ileitis, should be differentiated from terminal ileal involvement in Crohn's disease, which is marked by lumenal narrowing, wall thickening, ulceration, and fistula formation. [198]

Carcinoma in ulcerative colitis can appear as a mass protruding into the lumen, as it may in those without ulcerative colitis. However, ulcerative colitis carcinoma is more often an infiltrating process that appears on radiography either as a flattened, rigid area of bowel wall or, in more advanced cases, as a stricture. Radiologic methods fail to detect cancer in patients with ulcerative colitis about 15% of the time. [196], [199] Benign strictures may be indistinguishable from malignancy radiographically (Fig. 83-13). The presence of a flattened, rigid area or a stricture necessitates colonoscopy with biopsy. Because of the infiltrating nature of carcinoma in ulcerative colitis, colonic biopsies may be negative even if malignancy is present. If the radiograph is suggestive of carcinoma, surgery may be necessary despite a negative endoscopic biopsy.

FIGURE 83-13. Benign stricture in transverse colon of patient with chronic ulcerative colitis. This lesion is radiographically indistinguishable from a malignancy. (Courtesy of Dennis Balfe, M.D., St. Louis, MO.)

The earliest form of Crohn's disease detectable by air-contrast barium enema is marked by the presence of aphthous ulcers, which appear as small discrete collections of barium surrounded by radiolucent halos of inflammatory infiltrate (Fig. 83-14). These small ulcers are usually multiple, and the intervening mucosa is normal. Aphthous ulcers are not, however, unique to Crohn's disease; they are seen in amebiasis, Behçet syndrome, shigellosis, and other conditions. As Crohn's disease becomes more severe, the aphthous ulcers enlarge, deepen, and connect with one another to form stellate and linear ulcers; the intervening mucosa develops a nodular appearance on radiograph, a process termed cobblestoning.

FIGURE 83-14. Crohn’s colitis with numerous aphthous ulcers (*arrowhead*). (Courtesy of Dennis Balfe, M.D., St. Louis, MO.)

Progressive deepening of ulcers can lead to formation of abscesses or fistulization. Contrast studies are far more likely than endoscopic studies to identify fistulae. Transmural inflammation and fibrosis lead to limited distensibility, with decreased lumenal diameter. If transmural inflammation and fibrosis are circumferential, the result is stricture formation and possible obstruction. Like fistulae, strictures are appreciated more easily on radiographic studies than by endoscopy. Long areas of circumferential inflammation and fibrosis result in long areas of lumenal narrowing: if this process occurs in the ileum, the result is the “string sign.” Transmural inflammation and fibrosis result in thickening of the bowel wall, and as a result there are wide gaps between the barium-filled lumens of loops of inflamed small bowel (Fig. 83-15 and Fig. 83-16). The distribution of radiographic abnormalities can support the diagnosis of Crohn’s disease. Findings typical of diffuse colitis may be consistent with either Crohn’s disease or ulcerative colitis, but distal sparing is more consistent with Crohn’s disease. Thickening of the bowel wall and retraction and thickening of the mesentery make the bowel rigid, stiff, and immobile on fluoroscopy. Small bowel Crohn’s disease can be evaluated by small bowel follow-through or by enteroclysis. Comparison of the two techniques in patients with known small bowel Crohn’s disease suggested that small bowel follow-through gives better mucosal detail and identifies more fistulae and, thus, is the procedure of choice. [200]

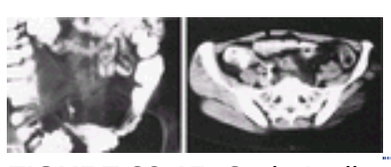

FIGURE 83-15. Crohn’s disease of the terminal ileum (*arrows*) on small bowel follow-through (**left**) and computed tomography (CT) scan (**right**) in the same patient. Thickening of the intestinal wall is easily appreciated on the CT scan. On small bowel follow-through, wall thickening is indicated by the separation of the columns of barium. (Courtesy of Dennis Balfe, M.D., St. Louis, MO.)

FIGURE 83-16. In Crohn’s ileitis with a long segment of involved ileum, the barium columns are widely separated as a result of wall thickening. (Courtesy of Dennis Balfe, M.D., St. Louis, MO.)

The CT scan, with its ability to assess wall thickening, inflammatory reaction in adjacent fat, and extralumenal complications allows for a rapid assessment of a patient with Crohn’s disease and helps guide therapy. While these issues may be considered for ulcerative colitis as well, CT is less central to the management of patients with ulcerative colitis. A CT scan may be the diagnostic test that first suggests the diagnosis of IBD in a patient who presents with abdominal pain and has signs and symptoms suggesting a structural lesion. Thickened bowel wall, which is appreciated on barium studies as separation of the columns of barium, is easily seen on CT scan (see Fig. 83-15). The presence of isolated right colon involvement, mesenteric fibrofatty proliferation, or intra-abdominal abscess are all significantly more common in Crohn’s disease, whereas submucosal fat is more common in ulcerative colitis. [201], [202] Fat surrounding bowel loops, seen in surgery as “creeping” fat, can be suggestive of Crohn’s disease, particularly of more chronic disease. Stranding in the adjacent fat indicates areas of active inflammatory disease.

CT is particularly critical in evaluating a patient for intestinal complications of Crohn’s disease, most notably fistulae, abscesses, and obstruction. While barium studies may be superior in demonstrating most fistulae, CT is better in visualizing the associated inflammatory response and thus may allow for the detection of a fistula only intermittently open and not apparent on barium study. The iodinated contrast used in CT scans is safer in the presence of an intestinal obstruction than barium. In addition, extraintestinal manifestations of Crohn’s disease (including hydronephrosis, sacroiliitis, gallstones, and renal calculi) can be identified by CT. CT also can be used to direct percutaneous drainage of abscesses.

Other imaging modalities occasionally may have a role in IBD, including radionuclide studies, ultrasonography, and magnetic resonance imaging (MRI). In IBD, there is a markedly increased migration of neutrophils into the inflamed tissue and then out into the intestinal lumen. This process can be followed by harvesting a patient’s peripheral blood neutrophils, labeling them in vitro with indium 111 (^{111}In) or technetium 99 (^{99}Tc), and then injecting them intravenously into the patient. [82], [203] The radiolabeled neutrophils are carried by the bloodstream to the bowel, where they migrate into the inflamed tissue. A gamma camera then can be used to identify the sites of inflammation. This method not only allows the definition of the anatomic extent of inflammation but also allows an assessment of the severity of the inflammatory response by defining the number of neutrophils leaving the circulation and entering the bowel wall. MRI may also have a role in defining perianal disease and associated fistulae.

PATHOLOGY

Ulcerative colitis and Crohn’s disease each have a characteristic pathological appearance, but in any given case the pathological picture may not be specific enough to distinguish between them or to differentiate them from other diseases such as infectious colitis or ischemic colitis. In both ulcerative colitis and Crohn’s disease, the pathological picture is influenced by the degree of disease activity; the pathological assessment of disease activity may or may not correlate with the clinical and endoscopic assessments.

Macroscopic features of pathological specimens in ulcerative colitis depend on the severity and duration of the disease. In severe disease, the mucosa is edematous and deep purple owing to congestion with blood (see Fig. 83-6). The distribution of the involved mucosa is also characteristic of ulcerative colitis. The inflammation begins in the rectum, extends proximally a certain distance, and then abruptly stops, with a clear demarcation between involved and uninvolved mucosa (see Fig. 83-6). In mild disease there are superficial erosions or only mild erythema, with blurring of the vascular pattern as the initial, subtle findings. In severe disease there may be large ulcers or areas where the mucosa is denuded completely. In chronic disease, the mucosa loses its normal folds and becomes flat. Inflammatory polyps or pseudopolyps may be present; rarely, these polyps may be long (filiform polyps) and occur in groups (Fig. 83-17).

FIGURE 83-17. Filiform pseudopolyps. (Courtesy of Ira Kodner, M.D., St. Louis, MO.)

Most of the pathological findings in ulcerative colitis are limited to the mucosa and submucosa (Fig. 83-18); the muscularis propria is affected only in fulminant disease. Active ulcerative colitis is marked by an intense infiltrate, with neutrophils in the mucosa and submucosa and clumps of neutrophils in crypt lumens (crypt abscesses) (Fig. 83-19). Although characteristic of active ulcerative colitis, the presence of a neutrophil infiltrate with crypt abscesses also may be seen in Crohn's disease and infectious colitis. In active ulcerative colitis, mucus depletion and mucosal edema are seen; vascular congestion with focal hemorrhage is seen in more severe cases. Ulcers, if present, are superficial, only penetrating the muscularis mucosae in severe disease. In addition to signs of acute activity, there are usually also signs of chronicity, with lymphoid aggregates, plasma cells, mast cells, and eosinophils in the lamina propria. In quiescent ulcerative colitis, the inflammatory infiltrate is less intense than in active disease, but the mucosa is usually architecturally abnormal. The number of crypts is reduced and often branched. Shortening and branching of the crypts are typical of ulcerative colitis, although they also may be seen in Crohn's disease. In quiescent disease, goblet cell mucin content is restored to normal.

Histological evaluation of rectal biopsy may be helpful in differentiating ulcerative colitis from acute self-limited colitis and from Crohn's disease (Table 83-6). [204] Distorted crypt architecture, mixed acute and chronic inflammation in the lamina propria, a villous mucosa, and crypt atrophy are all far more common in ulcerative colitis than in acute self-limited colitis. The best histological distinction between Crohn's colitis and ulcerative colitis is the presence of granulomas, which, in one series, was seen in 16 of 26 patients with Crohn's colitis but in only 3 of 56 patients with ulcerative colitis. Endoscopic skip lesions, or uninvolved areas, should be biopsied and may be histologically normal in Crohn's disease but histologically active in ulcerative colitis. Crypt atrophy, polymorphonuclear leukocytes in the epithelium, and surface erosions are each more common in ulcerative colitis than Crohn's colitis. Despite these distinctions, ulcerative colitis and Crohn's disease cannot be distinguished histologically in 15% to 25% of cases. [205]

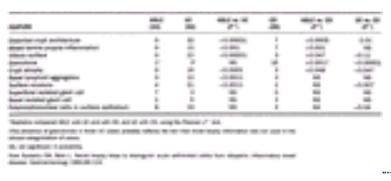

TABLE 83-6 Histological Features That Allow the Physician to Distinguish Among Acute Self-Limited Colitis (ASLC), Ulcerative Colitis (UC), and Crohn's Disease (CD)*

Gross examination of the intestine in Crohn's disease shows the bowel wall to be thickened and stiff. The mesentery is thickened and edematous and may be contracted, which fixes the intestine in one position. Adipose tissue extends from the mesentery and "creeps" over the serosal surface of the intestine. Transmural inflammation may cause loops of intestine to be matted together. All layers of the intestine are thickened, and the lumen is narrowed (Fig. 83-20). Deep linear ulcers with intervening normal mucosa give the mucosal surface the appearance of having been clawed (Fig. 83-21). The distribution of inflammation in the gross specimen may suggest the diagnosis of Crohn's disease. Colonic inflammation with rectal sparing is more consistent with Crohn's disease than with ulcerative colitis.

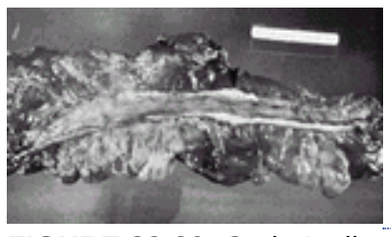

FIGURE 83-20. Crohn's disease of the small intestine showing lumenal narrowing and thickening of the intestinal wall (*arrow*). There is also a large amount of fat on the serosa. (Courtesy of Ira Kodner, M.D., St. Louis, MO.)

FIGURE 83-21. Crohn's colitis colectomy specimen shows deep, clawed linear ulcers in the transverse and descending colon. (Courtesy of Ira Kodner, M.D., St. Louis, MO.)

The earliest lesion of Crohn's disease is the aphthous ulcer. In the small intestine, aphthous ulcers typically occur over Peyer patches and in the colon over lymphoid aggregates. Aphthous ulcers can occur anywhere in the epithelium, however, even where there is no lymphoid tissue. As the disease progresses, aphthous ulcers enlarge and become stellate. Eventually, the stellate ulcers coalesce to form longitudinal and transverse linear ulcers. The remaining islands of non-ulcerated mucosa give a cobblestone appearance. Fissures develop from the base of aphthous ulcers, extending down through the muscularis to the serosa. Free perforation is uncommon because serositis induces the adherence of other bowel loops into which the fissure extends.

Transmural inflammation is the histological hallmark of Crohn's disease (Fig. 83-22). [206] Lymphoid aggregates are found in the submucosa and external to the muscularis propria. Occasional lymphoid aggregates in the muscularis propria complete the transmural pattern. Granulomas are found in most surgical resections for Crohn's disease (Fig. 83-23), but the exact percentage of positive specimens is not clear. The likelihood of finding granulomas in biopsies is a function of the number of biopsies taken, the number of sections examined, and the definition of a granuloma. [207] Granulomas occur more commonly in the submucosa than in the mucosa and therefore are found more easily in surgical specimens than in mucosal biopsies. Granulomas also can be found in lymph nodes, mesentery, peritoneum, and liver. In most cases, clinical, endoscopic, and pathological characteristics allow the diagnosis of Crohn's disease, even if no granulomas are found. Intestinal granulomas can be found in a number of infectious diseases, including tuberculosis, fungal infections, yersiniosis, and chlamydial infections. They also are seen in sarcoidosis and foreign body reactions. Granulomas in Crohn's disease resemble those in sarcoidosis and lack the caseating necrosis seen in tuberculosis. Granulomas are less commonly part of the pathological picture in ulcerative colitis. If pathological findings are used to differentiate ulcerative colitis from Crohn's colitis, the presence of granulomas suggests Crohn's colitis, but the absence of granulomas is not helpful. One pathological finding thought to be characteristic of Crohn's disease is the presence of axonal necrosis of autonomic nerves. [208]

DIFFERENTIAL DIAGNOSIS

Crohn's Disease and Ulcerative Colitis

For many therapeutic decisions, it is not critical to know whether the patient has ulcerative colitis or Crohn's disease. In some circumstances, however, the distinction is important. For example, an ileoanal anastomosis could be recommended with much more enthusiasm if the physician were confident that the patient had ulcerative colitis rather than Crohn's colitis. Similarly, colectomy could be recommended more confidently as a curative procedure if it were certain that the patient had ulcerative colitis. As unequivocal genetic or other serologic markers do not yet exist for either disease, the diagnoses rest on clinical evaluation. If a patient appears in all other ways to have ulcerative colitis, but is found to have a feature usually seen in Crohn's disease, such as a fistula or a granuloma, it is a diagnostic dilemma to determine whether the patient should be considered to have ulcerative colitis, Crohn's disease, or indeterminate colitis. In as many as 5% of cases when ulcerative colitis is confidently diagnosed and a colectomy with an ileoanal anastomosis performed, Crohn's disease is eventually diagnosed, though at times many years later.

The clinical presentation of ulcerative colitis resembles that of Crohn's disease, especially Crohn's colitis. [209], [210] Diarrhea may be the most prominent symptom in both diseases, although it is more likely to be bloody in ulcerative colitis. The presence of pain as a prominent symptom is more suggestive of Crohn's disease, although patients with severe ulcerative colitis also may have significant pain, usually in the rectum. Systemic features such as malaise, fever, and weight loss are more common with Crohn's disease. The presence of a right lower quadrant mass and tenderness directs the diagnosis toward Crohn's disease. Certain complications are far more common in Crohn's disease than in ulcerative colitis; among these are fistulae (enteroenteric, enterocutaneous, enterovesicular, enterovaginal), intraabdominal abscesses, strictures, and malabsorption. Extensive perianal involvement with fistulae and abscesses point to Crohn's disease as the diagnosis. The patient who smokes cigarettes is more likely to have Crohn's disease and a nonsmoker, or a former smoker, is more likely to have ulcerative colitis.

The serologic markers being advanced to diagnose and differentiate ulcerative colitis and Crohn's disease may have an adjunctive role in diagnosis but are not yet proven in their utility. The marker associated with approximately 60% of patients with ulcerative colitis, perinuclear antineutrophil cytoplasmic antibodies (pANCA), is also found in approximately 10% of patients with Crohn's disease. The pANCA-positive patients with Crohn's disease appear to be a subtype with an ulcerative colitis-like left-sided, often hemorrhagic, colitis. Anti- *Saccharomyces cerevisiae* antibody (ASCA) found in approximately 60% of patients with Crohn's disease and about 10% of patients with ulcerative colitis appears highly specific for Crohn's disease if IgA and IgG are both positive. Further studies with these markers will determine their use in diagnosing and differentiating ulcerative colitis and Crohn's disease. [211], [212] and [213]

Usually, ulcerative colitis and Crohn's disease can be differentiated endoscopically (see Table 83-5). [106], [214] The anatomic distribution of the inflammatory response is suggestive of the diagnosis. In ulcerative colitis, inflammation is seen in the rectum and extends proximally for some distance; in extensive disease, inflammation extends to the cecum. Although ulcerative colitis does not involve the small intestine, a few centimeters of inflamed mucosa without ulceration may be present in the terminal ileum. If the rectum is spared or if there are areas of un-inflamed mucosa (skip areas) between areas of inflamed mucosa, Crohn's colitis is more likely. Ulcerative colitis is not only continuous along the longitudinal axis of the colon, but the degree of inflammation is also consistent and circumferentially symmetric at any level. In contrast, in Crohn's colitis, areas of normal mucosa may separate deep linear ulcers. Involvement of more than a few centimeters of the terminal ileum or ulceration in the terminal ileum is also indicative of Crohn's disease. In addition to the presence of skip areas and asymmetric involvement, other endoscopic findings also suggest Crohn's colitis. Ulcers are more likely to be large and deep and to have discrete margins in Crohn's colitis than in ulcerative colitis. Aphthous ulcers occur commonly in Crohn's disease but infrequently, if at all, in ulcerative colitis.

The pathological changes seen in Crohn's disease and ulcerative colitis are discussed elsewhere in this chapter (see Table 83-6). A major distinguishing mark in favor of Crohn's disease is the presence of transmural inflammatory changes; in ulcerative colitis, inflammation is confined to the mucosa and submucosa. The presence of noncaseating granulomas suggests Crohn's disease, but even in Crohn's disease, most patients have no granulomas on biopsy.

Despite all these differences, a small but significant number of patients with IBD cannot be assigned with confidence to one disease category or the other. [215] These patients are considered to have indeterminate colitis. As for patients who seem to fall definitively into one category or the other, it is important to keep an open mind about the diagnosis. Later developments may require that it be reconsidered. Usually these cases present as ulcerative colitis but ultimately develop signs of Crohn's disease rather than the reverse.

Inflammatory Bowel Disease Versus Other Diseases

Much has been written about the necessity for differentiating the initial episode of ileocolonic Crohn's disease from acute appendicitis; however, in practice, this distinction is seldom a major problem. [216] Patients with Crohn's disease usually give a history of diarrhea of significant duration before the episode of severe pain. More severe pain, guarding, and a more rapid course is indicative of appendicitis. A CT scan is likely to help sort out this dilemma preoperatively. If the surgeon operates and finds ileocolic Crohn's disease rather than appendicitis, a decision must be made as to whether to resect the inflamed intestine. If there is no compelling reason for resection, medical management of the condition should be attempted. Another consideration in this differential diagnosis is acute ileitis caused by *Yersinia* infection. [217] *Yersinia* infection may present with a clinical picture resembling appendicitis or the initial onset of Crohn's disease. At laparotomy, the acute *Yersinia* ileitis may be indistinguishable from Crohn's ileitis. The diagnosis of this infection is made by stool culture, and antibiotic therapy is curative. The possibility of *Yersinia* infection is another reason to avoid hasty resections for what is thought to be the acute onset of Crohn's ileitis.

The most common problem in the differential diagnosis of the recent onset of IBD is ruling out infectious colitis (see Chapter 88 and Chapter 125). [218] Infections with *Shigella,* amoeba, *Giardia, Escherichia coli* O157:H7, and *Campylobacter* organisms all cause symptoms similar to those of ulcerative colitis. Moreover, the endoscopic picture of infections with *Shigella* or *Campylobacter* organisms can be identical to that seen in ulcerative colitis. The endoscopic picture of amebiasis also may resemble that of ulcerative colitis, but in amebiasis there are usually scattered ulcers, 5 to 15 mm in diameter, covered with a yellow exudate that contains organisms. These ulcers may occur anywhere in the colon but are most common in the cecum and ascending colon. An important distinction between these infectious diseases (excepting amebiasis) and IBD is that the diarrhea in the infectious diseases tends to be limited to a period of days to a few weeks, whereas the diarrhea of IBD is typically of longer duration. Stool cultures for bacterial pathogens and serologic tests for amebiasis help to distinguish infectious diarrhea from IBD. In patients who present with prolonged diarrhea, the diagnosis of other protozoal diseases, such as giardiasis, must be considered. Giardiasis, like Crohn's disease, can present with cramping abdominal pain, weight loss, and lactose intolerance.

Sexual transmission of enteric pathogens by anal intercourse in homosexual men can lead to proctitis resembling ulcerative proctitis. [219] *Neisseria gonorrhoeae,* chlamydia organisms, herpes simplex, and *Treponema pallidum* can all cause proctitis. Chlamydial infections of the lymphogranuloma venereum immunotype can result in diffuse rectal ulceration that is difficult to distinguish from Crohn's colitis. The increased prevalence of the human immunodeficiency virus (HIV) has broadened the number of potential enteric pathogens to include *Cryptosporidium* and *Isospora* species, *Mycobacterium avium* complex, and cytomegalovirus. In patients without risk factors for HIV infection, the only diagnostic studies needed to rule out infectious colitis are routine stool cultures, examination of stool for ova and parasites (on three separate days), and sigmoidoscopy. Patients who are at risk for HIV infection require a more elaborate evaluation. Viral culture and

histological examination of biopsy specimens will identify cytomegalovirus and herpesvirus. Cytomegalovirus can complicate IBD, particularly when immunosupressive medication is being used. Serology and culture are diagnostic for chlamydial infections. Intestinal involvement in HIV infection is discussed more fully in Chapter 124.

Intestinal tuberculosis resembles Crohn's disease both clinically and pathologically (see Chapter 75). [220] The areas most commonly involved with intestinal tuberculosis are the cecum and the ileum. If pulmonary tuberculosis is also present, the diagnosis of intestinal tuberculosis is not difficult, but intestinal tuberculosis can occur without pulmonary involvement. It is important not to mistake tuberculosis for IBD because steroid treatment exacerbates tuberculosis. Although Crohn's disease may be increasing in the developing world, intestinal tuberculosis remains a higher diagnostic probability among recent emigrants from Third World countries and should be ruled out among this population before a presumptive diagnosis of Crohn's disease is made.

Intestinal lymphoma can produce symptoms similar to those of Crohn's disease—fever, weight loss, diarrhea, and abdominal pain. Small bowel radiographs in lymphoma may show diffuse involvement with masses in the bowel wall, but in Crohn's disease there is usually more localized involvement of the ileum, with ulceration and narrowing of the lumen.

Collagenous or lymphocytic colitis is a chronic inflammatory disease marked pathologically by the presence of a thick collagen deposition in the subepithelial layer of the colonic mucosa, lymphocyte infiltration, or both. [221] The typical clinical presentation is chronic watery diarrhea in a middle-aged woman who smokes and uses NSAIDs. Endoscopically, the mucosa appears mildly inflamed or, more commonly, absolutely normal. The histological picture provides the diagnosis. Collagenous colitis is discussed more fully in Chapter 85.

Ischemic colitis is part of the differential diagnosis of the initial bout of IBD and should be considered in older adults or others at particular risk for ischemic disease. [222] Bloody diarrhea and abdominal pain are common with ischemic colitis. Colonoscopy reveals mucosal edema and erythema, and there may be discrete ulcers similar to those seen in Crohn's colitis. Usually, ischemic colitis spares the rectum because of its extensive collateral circulation. Differentiation of ischemic colitis from IBD, especially Crohn's colitis, may be impossible on clinical, histological, or endoscopic grounds. In contrast to IBD, ischemic colitis usually resolves spontaneously over a few weeks. However, as many as 10% of patients with acute ischemic disease can continue into a chronic picture resembling Crohn's disease, distinguished only in its failure to respond to treatment. If the mesenteric vasculature is involved, systemic vasculitis can have small intestinal manifestations similar to Crohn's disease. Small intestinal ulcerations, perforation, and hemorrhage are seen in systemic lupus erythematosus, polyarteritis nodosa, rheumatoid arthritis, and dermatomyositis. [223]

Henoch-Schónlein purpura presents with rectal bleeding and abdominal pain before the development of the characteristic rash on the legs and buttocks. Behçet syndrome is marked by oral and genital ulcers with uveitis. There is an associated inflammation of the ileocecal area with aphthous ulcers and a lymphocytic infiltrate; these lesions can resemble Crohn's disease. Moreover, Behçet syndrome and Crohn's disease share a number of extraintestinal manifestations, including arthritis, erythema nodosum, and iridocyclitis.

Diverticulitis may be difficult to separate from acute Crohn's colitis, especially in older adult patients. [224] Both diseases can present with abdominal pain, fever, diarrhea, and rectal bleeding. Endoscopically, the presence of inflammation over a long segment of colon or in the rectum, where there are no diverticula, suggests Crohn's disease, as does the presence of perianal disease or extracolonic disease. Involvement of the pericolonic fat, which can be detected by CT is more consistent with Crohn's disease. Diverticulitis, like ischemic colitis, tends to be an acute problem and does not lead to a chronic inflammatory state as does IBD. However, patients with focal Crohn-like changes complicating diverticulitis have been described. [225] Diverticulosis can be associated with rectal bleeding, but the bouts of bleeding are abrupt in onset and blood loss is great, whereas in ulcerative colitis or Crohn's colitis, blood loss is usually chronic and small in volume.

Pseudomembranous colitis presents with profuse watery diarrhea and may last from a few days to 2 months (see Chapter 88). [226] The presence of small membranous plaques adherent to the mucosa on sigmoidoscopy is pathognomonic. Not all patients with pseudomembranous colitis however have the characteristic sigmoidoscopic picture. As part of the initial evaluation of patients with acute presentation of IBD, it is appropriate to check the stool for *C. difficile* toxin, especially if there has been recent antibiotic exposure.

Mild ulcerative colitis or proctitis in which rectal bleeding is the primary manifestation can be confused with hemorrhoids or anal fissures. The presence of urgency or diarrhea is more consistent with ulcerative colitis or proctitis. Sigmoidoscopy should easily differentiate ulcerative colitis from these perianal problems.

If IBD, especially Crohn's disease of the small intestine, has a long, indolent course with relatively mild symptoms, it may be difficult to differentiate from irritable bowel syndrome. [227] It should be easy to distinguish between irritable bowel syndrome and ulcerative colitis by proctoscopy, which is normal in irritable bowel syndrome. Chronic, cramping abdominal pain and diarrhea are typical of both irritable bowel syndrome and Crohn's disease. The presence of fever, abdominal tenderness, and weight loss all suggest Crohn's disease. This differential diagnosis may be particularly troublesome in that some patients with Crohn's disease also have irritable bowel syndrome. Making the diagnosis of irritable bowel syndrome in a patient with coexisting IBD is difficult because of the overlapping symptoms and the absence of any definitive histological or biochemical marker for either IBD or irritable bowel syndrome. For many patients with IBD, there are symptoms, typically pain and diarrhea, that appear not to correlate with disease activity as assessed endoscopically or histologically. Whether these symptoms are products of undetected disease activity, "functional" symptoms of IBD, or signs of irritable bowel syndrome is difficult to establish. A confounding issue is the high incidence of depression in both irritable bowel syndrome and Crohn's disease and the influence of depression on the patient's symptoms. The coexistence of these diseases is important not only in making the diagnosis but also in following therapy. Patients who have both Crohn's disease and irritable bowel syndrome have been treated aggressively (and unsuccessfully) with corticosteroids for abdominal pain and diarrhea that were, in fact, products of irritable bowel syndrome.

Diversion colitis is a nonspecific inflammation of segments of colon excluded from the fecal stream. It sometimes occurs in patients who have had surgery for Crohn's colitis with creation of a Hartmann pouch. In these cases, diversion colitis may be difficult to differentiate from recurrence of Crohn's disease in the excluded segment. Many patients with diversion colitis have severe endoscopic findings with minimal symptoms. A clinical response to antibiotics or to enemas of short-chain fatty acids should differentiate diversion colitis from active Crohn's disease. [228]

NUTRITIONAL MANAGEMENT

Malnutrition is an important clinical problem in IBD, particularly in Crohn's disease. At diagnosis, most patients with Crohn's disease have lost weight. Hypoalbuminemia, anemia, and vitamin D deficiency all can result from malnutrition in Crohn's disease.

Five factors lead to malnutrition in Crohn's disease. The first, diminished oral intake primarily as a result of loss of appetite, is the most important cause of malnutrition in patients with Crohn's disease. [229] Anorexia may result from inflammation, depression, or the side effects of medication. Even in the absence of anorexia, many patients diminish their food intake because eating causes pain, cramps, and diarrhea; this problem is seen particularly in patients with small bowel obstruction. The second factor is the increase in caloric requirements because of the catabolism associated with fever and inflammation; however, this factor makes a relatively minor contribution to malnutrition in Crohn's disease. [230] The third factor is malabsorption of nutrients as a result of a reduction in the absorptive area by extensive surgical resections or involvement of large areas of small bowel with inflammation. Rarely, fistulae can result in malabsorption as a result of nutrients bypassing absorptive epithelium. The nutrients most likely to be affected are calcium, magnesium, fats and fat-soluble vitamins, and vitamin B_{12}. Bile salts and vitamin B_{12} are selectively absorbed in the distal ileum, the area of the small intestine most commonly involved in Crohn's disease and the area most commonly resected. Malabsorption of bile salts leads to a decrease in the total bile salt pool and thus to fat malabsorption. Bacterial overgrowth in the small intestine proximal to strictures leads to deconjugation of bile salts by bacteria. The deconjugated bile salts are absorbed passively and thus are not retained in the lumen to participate in the absorption of fat and fat-soluble vitamins. The fourth factor is the loss of proteins and electrolytes in the intestinal lumen in areas of inflammation. Bleeding into the intestinal lumen results in iron deficiency. Magnesium and zinc can be depleted by losses into the intestine. The fifth and last factor is drug therapy. Sulfasalazine impairs folate absorption but uncommonly leads to anemia. Corticosteroids induce negative nitrogen balance and decrease intestinal calcium absorption.

For most patients with IBD, the only nutritional therapy required is the instruction to eat adequate amounts of a well-balanced diet. Patients look for a nutritional basis to their disease and for nutritionally based therapy. These expectations lead many to decide that exacerbations of pain or diarrhea were caused by the foods they ate before the exacerbation. They exclude from their diets a lengthy list of foods that were associated temporally with an exacerbation of disease. As a result, these patients place themselves on a diet that has limited variety and is likely to be nutritionally unbalanced. Foods should be eliminated from the diet only if they consistently and reproducibly result in symptoms. Some patients have lactose intolerance and should avoid dairy products or use lactase-containing products, such as Lactaid. Patients with strictures should avoid fibrous, high-residue foods such as nuts, popcorn, bean sprouts, and celery.

More involved nutritional therapy in Crohn's disease can be directed toward one of two goals: treating nutritional deficiencies or reducing inflammation. Deficiencies of specific nutrients usually can be managed by supplementation. Oral or parenteral iron supplementation may be necessary in patients with significant intestinal bleeding. Specific supplementation with calcium, magnesium, zinc, vitamin B_{12}, vitamin D, and vitamin K may be required if clinical or biochemical manifestations of deficiency occur (see Chapter 53). These nutrients may be malabsorbed if there is extensive involvement of the small bowel mucosa. Bone densitometry will reveal evidence of calcium loss from bone caused by calcium malabsorption or steroid therapy. Even in the absence of clinical or biochemical evidence of micronutrient deficiency, it is reasonable to give multivitamin supplements to patients with small bowel Crohn's disease. Extensive (>100 cm) resections of the terminal ileum or lesser resections combined with active disease or scarring in the remaining ileum lead to vitamin B_{12} malabsorption. Some clinicians evaluate patients with serum vitamin B_{12} levels, but others empirically treat all patients with significant ileal resections with parenteral vitamin B_{12} (1000 µg once a month). Ileal resection and ileal disease also lead to malabsorption of bile salt and fat. Diarrhea induced by bile salts can be managed with cholestyramine, a resin that binds bile salts and prevents them from inducing water and electrolyte secretion from the colonic mucosa. Cholestyramine therapy, however, further depletes the bile salt pool and can worsen fat malabsorption. Unabsorbed fatty acids entering the colon are hydroxylated by bacteria. This leads to fat malabsorption that induces diarrhea because the hydroxylated fatty acids induce colonic water and electrolyte secretion. Fatty acid–induced diarrhea is managed by reducing the fat content of the diet. Caloric deficiencies are made up by increasing the intake of complex carbohydrates. Alternatively, medium-chain triglycerides, which do not require bile salts for absorption, can be substituted for part of the conventional long-chain triglycerides in the diet. The dose of medium-chain triglycerides is limited to about 3 tablespoons per day (300 kcal) because larger amounts cause diarrhea.

Anorexia leads to inadequate nutritional intake and malnutrition in many patients with IBD, even if absorptive function is normal. Supplementation of the patient's oral intake with defined-formula diets can prevent or reverse malnutrition. Defined formula diets can be taken orally or administered by nasogastric tube, gastrostomy tube, or jejunostomy tube (see Chapter 53). Most IBD patients who require nutritional supplementation can be managed with enteral therapy. In some cases, however, parenteral nutrition is required: in the presence of chronic small intestine obstruction that is not amenable to surgical resection; after massive small bowel resection, especially if the amount of remaining small intestine is insufficient for absorption of daily caloric needs; or if enteral nutrition results in severe, uncontrollable diarrhea.

The use of total parenteral nutrition (TPN) or the enteral administration of an elemental diet as specific therapy in IBD is controversial (see Chapter 53). Elemental diets consist of amino acids, monosaccharides, vitamins, minerals, and essential fatty acids. The results of controlled trials comparing elemental diets with drug therapy have been inconsistent. [231], [232], [233] and [234] In Crohn's disease, elemental diets have been used more extensively in children than adults. Providing adequate nutrients can reverse growth failure in Crohn's disease. Elemental diets taken orally or by nasogastric tube enhance linear growth in children with Crohn's disease. [235] In these studies, enteral nutrition was superior to steroids in promoting growth.

Malnutrition is less commonly troublesome in ulcerative colitis than in Crohn's disease, in part because malabsorption of nutrients is not a problem in ulcerative colitis. Diminished food intake, however, can be a problem in ulcerative colitis. Because of loss of appetite and because eating worsens their diarrhea, patients with ulcerative colitis reduce their calorie intake. Nutritional requirements are increased in severe ulcerative colitis because of the catabolism associated with fever and inflammation. TPN has been used to improve the nutritional status and reduce the symptoms of patients with severe ulcerative colitis. [236] This approach has been especially successful in improving the nutritional status of patients before colectomy is undertaken. Improved nutritional status decreases the likelihood of complications for surgical procedures in general and, presumably, for IBD surgery in particular. No evidence has been found that TPN reduces the necessity for colectomy or that it is effective primary therapy for the disease. Two studies compared the rates of colectomy in ulcerative colitis patients receiving TPN with those on regular hospital food. In both studies, the rates for colectomy were the same in the two groups. [237], [238]

Dietary supplementation with fish oil may have antiinflammatory activity because the n-3 fatty acids in fish oil compete in the substrate pool for the enzymes that synthesize prostaglandins and leukotrienes. Supplementation with high-dose fish oil over a period of months reduced steroid requirements in ulcerative colitis. [239] Fish oil supplementation was tested in placebo-controlled trials as maintenance therapy in Crohn's disease. In one trial it was effective, [240] but in the other it was not. [241]

DRUGS USED IN INFLAMMATORY BOWEL DISEASE

General Supportive Therapy

Drugs (antidiarrheal agents, antispasmodics, analgesics) that reduce the patient's symptoms without affecting the level of disease activity have a role in the management of IBD. The use of these drugs should not be a matter of routine for all patients; rather, their use should be individualized. Moreover, they should supplement antiinflammatory drugs, not substitute for them.

Antidiarrheal agents, usually loperamide or diphenoxylate, are useful in patients with mild disease activity to reduce the number of bowel movements and to relieve rectal urgency. In addition to controlling disease-related diarrhea, these agents can control diarrhea caused by bile salt and fat malabsorption, as seen in patients with surgical resections of the terminal ileum. Antidiarrheal agents can be given on a regular schedule or on an as-needed basis. Antidiarrheal agents may allow reduction of steroid dosage in patients with chronic steroid requirements. In patients with severe colitis, antidiarrheal agents are contraindicated because they predispose to the development of toxic megacolon. For patients who have undergone ileocolic resections and do not have fatty acid–induced diarrhea, treatment with cholestyramine (up to six scoops per day) may be particularly useful. Cholestyramine is a resin that binds bile salts in the lumen and prevents bile salt–induced colonic secretion. If the gallbladder is present, most of the dose should be given in the morning to take advantage of the concentrated bile emptied into the lumen with breakfast. Much more commonly, fatty acid–induced diarrhea will be present in patients with ileal resections; these patients will respond better to a low fat diet without the addition of cholestyramine.

Abdominal cramping is often a prominent complaint in IBD. Anticholinergics (tincture of belladonna, clidinium, propantheline bromide, dicyclomine hydrochloride) may reduce cramps, pain, and rectal urgency. They are best given before meals to depress peristalsis brought on by eating. An especially effective combination of an antidiarrheal and an antispasmodic is powdered opium (25 mg) and belladonna (15 mg). This formulation is not widely available and must be specially prepared. Opium and belladonna can be associated with drowsiness and confusion. Diarrhea that is not controlled with loperamide or diphenoxylate often responds to opium and belladonna. As with antidiarrheal agents, antispasmodics are contraindicated in severe colitis because of the risk of precipitating toxic megacolon. Antispasmodics also should be avoided if obstruction is present. Analgesia can be a difficult problem in IBD. In general, the best approach to pain management is control of disease activity. Sometimes tricyclic antidepressants can be helpful, even in the absence of clinical depression, as an adjunct for chronic pain management. Narcotics can cause dependency and, by reducing bowel motility, induce toxic megacolon. They should be avoided, especially as IBD patients with pain, but without obstruction or acute inflammation, seem especially susceptible to opiate dependency.

Anemia associated with IBD usually is due to iron deficiency or, less commonly, vitamin B_{12} or folate deficiency. Oral iron and folate or parental vitamin B_{12} should be given as indicated by laboratory studies. Parenteral iron is indicated if oral iron is not absorbed or causes gastrointestinal upset. Recombinant erythropoietin may be indicated in IBD for patients in whom anemia does not respond to iron and vitamins. [242] Folate supplementation has been suggested for patients with ulcerative colitis or extensive Crohn's colitis as a possible means for decreasing the risk of colon cancer. [243]

5-Aminosalicylic Acid Compounds

Sulfasalazine consists of 5-aminosalicylic acid (5-ASA) connected to sulfapyridine by a diazo bond. In the colon the diazo bond is cleaved by bacteria, yielding free 5-ASA and sulfapyridine. Free 5-ASA is the active agent in the treatment of ulcerative colitis; it appears to act from the lumen since little 5-ASA is absorbed into the systemic circulation from the colon. Free 5-ASA given orally is rapidly absorbed from the small intestine into the systemic circulation and has no therapeutic efficacy in ulcerative colitis. Sulfapyridine is absorbed after release in the colon and is responsible for most of the side effects associated with sulfasalazine including headache, nausea, and abdominal discomfort.

A variety of approaches have been taken to deliver 5-ASA to the colonic lumen without exposing the patient to sulfapyridine (Table 83-7). One approach was to formulate free 5-ASA into suppositories and enemas for treatment of colitis confined to the rectum and the left colon, respectively. Another approach has been to formulate oral 5-ASA to yield high colonic luminal concentrations with little systemic absorption. In olsalazine, one 5-ASA is bound covalently through an azo linkage to another 5-ASA. Like sulfasalazine this compound releases its 5-ASA in the colon when bacteria cleave the azo bond. Olsalazine causes chloride secretion in the small intestine, resulting in watery diarrhea in 5% to 10% of treated patients. [244] Formulation of 5-ASA in coated granules results in pH-dependent release (Pentasa, Asacol). Asacol, 5-ASA coated with Eudragit-S, dissolves a pH 7 or above and releases 5-ASA primarily in the colon and terminal ileum. Pentasa, 5-ASA in a semipermeable membrane, releases 5-ASA at pH6 and above. Pentasa releases 35% of its 5-ASA in the small intestine and may be useful for small intestine Crohn's

disease. Although Pentasa is widely thought of as a treatment for Crohn's disease, the FDA has not approved its use for this purpose. A controlled study of Asacol suggests it may be useful in Crohn's disease. [245] In addition, as with Pentasa, the pharmacokinetics of Asacol suggest that it may be effective in small intestinal Crohn's disease, especially when disease is confined to the distal ileum. Release in the small intestine results in increased absorption, however, and therefore increased risk of toxicity. High doses of oral 5-ASA are nephrotoxic in rats, but this has not been a major problem in human clinical studies with 5-ASA preparations. [246] The newest oral 5-ASA formulation is balsalazide (Colazide), in which 5-ASA is linked via a diazo bond to 4-aminobenzoyl-ß-alanine, an inert carrier. [247] Balsalazide releases 5-ASA in the colon.

TABLE 83-7 5-Aminosalicylate (5-ASA Preparations)

The exact role of the newer 5-ASA preparations, both rectal and oral, in the management of IBD remains to be seen. The incidence of side effects is lower with these compounds than with sulfasalazine. The increased level of tolerability allows patients to achieve higher colonic luminal concentrations of 5-ASA with these preparations than with sulfasalazine and thus increases the likelihood of a clinical response. These compounds are useful as substitutes for sulfasalazine in patients with known adverse reactions to sulfapyridine. In addition, they may have a broader therapeutic role in circumstances in which increased local concentrations of 5-ASA or an increased area of distribution are important. Pentasa and Asacol may have a place in the management of small intestinal Crohn's disease where sulfasalazine does not.

A large number of pharmacological effects have been described for sulfasalazine and 5-ASA; however, which, if any, of these pharmacological effects accounts for its efficacy in IBD is unknown. Sulfasalazine and 5-ASA inhibit 5-lipoxygenase and thus the synthesis of leukotrienes in both peripheral blood neutrophils and in IBD mucosa. [248], [249] 5-ASA acts as a free-radical scavenger and thus inactivates the products of the neutrophil respiratory burst, which are important in the microbicidal properties of neutrophils and may also be important in neutrophil-induced epithelial damage in IBD. [250] Nuclear factor-?N (NF-?B) is a transcription factor critical to the expression of multiple genes involved in the inflammatory response including cytokines and adhesion molecules. Sulfasalazine inhibits NF-?B activation by a number of activating agents including TNF-a and lipopolysaccharide. In contrast, 5-ASA does not block NF-?B activation. [251]

Two groups of side effects are associated with sulfasalazine: dose-related toxic effects thought to be related to serum sulfapyridine levels, and hypersensitivity reactions not related to serum sulfapyridine levels. The dose-related toxic effects include nausea, vomiting, headache, abdominal discomfort, and low-grade hemolysis. Sulfapyridine is metabolized by acetylation; slow acetylators have high serum levels of free sulfapyridine and low levels of acetylated sulfapyridine; whereas, fast acetylators have low levels of free sulfapyridine and high levels of acetylated sulfapyridine. The dose-related side effects are more common in slow acetylators. Most of the dose-related side effects of sulfasalazine develop in the first few weeks of therapy and resolve with discontinuation of the drug. The incidence of dose-related side effects increases at doses of 4 g/day or more. Most patients can avoid these side effects if given a dose that is sufficiently low. For patients whose only side effect is dyspepsia, relief may be obtained by taking the drug with meals or by using the enteric-coated preparation. [252] The second group of side effects, hypersensitivity reactions, includes fever, aplastic anemia, pancreatitis, lupuslike rash, nephrotoxicity, hepatitis, agranulocytosis, and autoimmune hemolysis. These effects are not related to the dose of sulfasalazine, acetylator status, or serum sulfapyridine concentrations. Nephrotoxicity can be seen with any 5-ASA compound. Caution should be exercised when using these drugs in patients with known renal dysfunction or a history of kidney disease. Hypersensitivity reactions occur less commonly than toxic reactions, but tend to occur with greater severity. Myeloblastic anemia, presumably a result of folate deficiency, has been reported with sulfasalazine but is much less common than a reduction in the serum folate concentration. [253] Malabsorption of folic acid and reduced serum folate levels are seen with sulfasalazine therapy; some clinicians recommend folic acid supplementation of 1 to 2 mg/day for patients treated with sulfasalazine. This is not necessary for the other mesalamine preparations. Although uncommon, agranulocytosis with a mortality rate of 35% reported in one series, is probably the most common fatal side effect. A small number of patients can develop a hypersensitivity reaction that can worsen colitis. It is particularly important to recognize this complication and withdraw the medication rather than treat the patient for refractory disease.

Sulfasalazine commonly causes changes in sperm morphology and decreases sperm count, leading to infertility. [254], [255] The incidence of abnormalities in sperm morphology and number appears to be higher in slow acetylators. These effects are reversible with 3 months of sulfasalazine withdrawal. The effects of sulfasalazine on sperm may relate to its antifolate activity.

5-ASA compounds have been used successfully as single agents in mild to moderate acute attacks of ulcerative colitis with favorable responses of 64% to 80% in patients treated with sulfasalazine compared to 35% to 40% favorable response in placebo-treated controls. [256], [257] and [258] In these series, the patients were treated with sulfasalazine at doses of 4 to 6 g/day. Success rates with sulfasalazine and acute ulcerative colitis are dose-related. Most clinicians do not use dosages above 4 g/day; however, several studies demonstrate better success rates with 6 g or more per day. The incidence of side effects increases with the dosage; however, if a patient tolerates 4 g/day and has not fully responded clinically, there is no reason not to push the dose higher. To lessen the side effects, sulfasalazine is given in gradually increasing doses, beginning at 500 mg twice a day and increasing to 1 g four times a day over the course of about a week. Taking sulfasalazine with food in four divided doses lessens gastric symptoms in most patients, but if the patient tolerates the drug the schedule can be changed to 2 g twice a day. Patients who respond to sulfasalazine usually do so in 2 to 3 weeks although some take 4 weeks or longer.

5-ASA preparations are as effective as sulfasalazine, although not superior to sulfasalazine, in the management of acute exacerbations in ulcerative colitis. [259], [260] and [261] Steroids induce remission in severe ulcerative colitis in a higher percentage of the patients than 5-ASA compounds and induce them more quickly. [262], [263] For this reason corticosteroids, either alone or in combination with 5-ASA compounds, are the treatment of choice in moderate to severe attacks. There is no evidence to suggest that the combination is better than corticosteroids alone. One advantage of combined therapy is that when the time comes to taper steroids the patient is already on a 5-ASA compound. If patients on combined therapy go into remission the usual approach is to taper and stop steroids and continue the 5-ASA compound.

The efficacy of 5-ASA compounds in preventing relapse in ulcerative colitis is well established. [264] In maintenance therapy, as in acute therapy, the higher the dose of sulfasalazine the greater the likelihood of success. When maintenance doses of 1, 2, and 4 g of sulfasalazine per day were compared the recurrence rates were 33%, 14%, and 9%, respectively (Fig. 83-24). These findings indicate a dose-response effect to the prevention of relapse by sulfasalazine. Some clinicians use sulfasalazine at a dose of 2 g per day for maintenance therapy because more patients tolerate 2 g/day than 4 g/day. However, if patients tolerate higher doses of sulfasalazine the higher doses should be used for maintenance therapy. The oral formulations of 5-ASA are also effective in the maintenance of remission in both ulcerative colitis and Crohn's disease. Both olsalazine and Pentasa are as effective as sulfasalazine in the maintenance of remission in ulcerative colitis. [265], [266] The risks of long-term maintenance therapy with sulfasalazine and 5-ASA compounds are modest. There are no definitive guidelines for the duration of maintenance therapy; the usual approach has been to continue therapy for several years in patients who have had a single attack of mild to moderate severity and to continue maintenance therapy indefinitely in patients with multiple relapses.

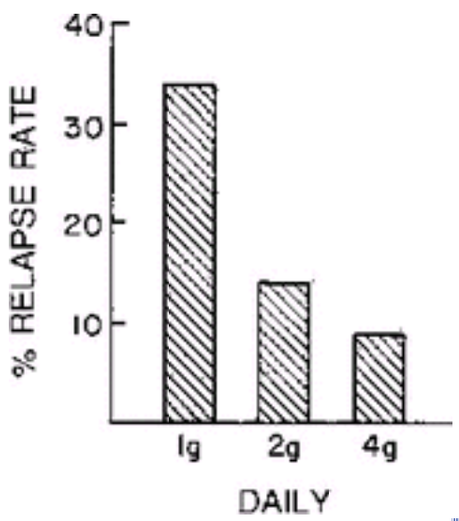

FIGURE 83-24. Relapse rate with maintenance sulfasalazine. (From ref. [352].)

5-ASA compounds are also useful in acute attacks of Crohn's colitis. In the National Cooperative Crohn's Disease Study, sulfasalazine at a dose of 1 g per 15 kg of body weight per day for 17 weeks was superior to placebo, inducing symptomatic improvement for patients with colonic involvement whether or not the small bowel was involved. [267] Sulfasalazine was not effective against disease confined to the small bowel, however, and patients were less likely to respond to sulfasalazine if they had been on prednisone before being randomized to sulfasalazine. The European Cooperative Crohn's Disease Study also found sulfasalazine therapy to be beneficial for patients with active colonic disease. [268] In that study, treatment with sulfasalazine (3 g/day) resulted in a modest but statistically significant improvement in the CDAI. Asacol is as effective as corticosteroids in the treatment of active Crohn's ileitis. [269]

Several studies investigated the usefulness of 5-ASA compounds in preventing relapse in patients with Crohn's disease. The National Cooperative Crohn's Disease Study examined the effects of sulfasalazine in patients who achieved remission during the initial study. [267] Most patients in both the sulfasalazine- and placebo-treated groups remained in remission, with no significant differences between the groups. Similarly, the European Cooperative Crohn's Disease Study showed no benefit of sulfasalazine treatment for patients with quiescent disease at entry into the study. [268] Despite the lack of support in the literature, many physicians use sulfasalazine as maintenance therapy in Crohn's disease, especially for patients with Crohn's colitis in whom acute disease responded to sulfasalazine. One study did suggest a modest benefit of Pentasa at 4 g/day in Crohn's disease. [245] Asacol was also superior to placebo in the maintenance of remission in patients with Crohn's disease, particularly in patients with ileitis. [270], [271]

A number of studies have investigated the effects of 5-ASA compounds on infants in utero and on nursing children. No evidence of harmful effects has been found, and the usual recommendation is that the drug can be used safely either in acute or maintenance therapy in pregnant and lactating women. [272], [273] Folate supplementation in early pregnancy reduces the risk of neural tube defects. The antifolate properties of sulfasalazine suggest that dietary folate supplements may be especially important in women taking sulfasalazine who are pregnant or contemplating pregnancy. Children can be treated safely with sulfasalazine. For acute disease in children older than 2 years, the initial dosage is 25 to 40 mg/kg daily in three to six doses; this dosage can be increased gradually to 75 mg/kg daily. [274] For maintenance therapy in children older than 2 years, the dosage is 20 mg/kg daily in divided doses. An oral suspension is available.

Corticosteroids

Steroids are highly effective in bringing about remission in patients with ulcerative colitis and Crohn's disease. The clinical benefits are counterbalanced by their predictable and considerable side effects. In addition, although clinically beneficial, corticosteroids do not often bring about mucosal healing in Crohn's disease. The hazards of steroids as well as their questionable benefit in mucosal healing and a high rate of steroid dependence has brought about a reevaluation of their role in IBD. Attempts to substitute other medications for steroids at an earlier time point or to avoid steroids all together, particularly in Crohn's disease, are increasingly advocated by some gastroenterologists.

Corticosteroids prevent or suppress inflammation induced by chemical, mechanical, infectious, and immunologic agents. Corticosteroids block the early manifestations of inflammation: enhanced vascular permeability, vasodilation, and neutrophil infiltration. They also block the later stages of the inflammatory process: vascular proliferation, fibroblast activation, and collagen deposition. Corticosteroids have in vitro effects on immunologic events, such as T-cell response to antigens, as well as on inflammatory events, such as neutrophil migration and mediator production.

In 1955, Truelove [101] compared patients with ulcerative colitis treated with cortisone (100 mg/day) with subjects treated with placebo for 6 weeks. Cortisone was superior to placebo in patients with disease ranging in severity from mild to severe; the difference was less striking in the more severely ill patients. Corticosteroids are effective in ulcerative colitis given either orally or parenterally; oral steroid therapy is effective in most patients with mild to moderate disease. [262] Few studies have assessed the relative value of various dosage regimens of oral corticosteroids. In one study (Fig. 83-25), two thirds of outpatients treated with 40 to 60 mg of prednisolone per day improved over a period of 3 weeks compared with just one third of those receiving 20 mg/day. [275] Most responders improved within 2 weeks. As a result of this study, 40 mg/day has been widely recommended as an initial dosage of prednisone for patients with moderately severe ulcerative colitis (prednisone and prednisolone are effectively equal in antiinflammatory potency). Some practitioners give an inadequate dose of prednisone because of the fear of side effects. This approach markedly reduces the likelihood of a positive response. For most patients, administration of oral prednisone in a single morning dose is as effective as divided doses; [276] however, use of divided doses may be appropriate in selected patients. Administration of prednisone as a single dose in the early morning may cause less suppression of endogenous steroid production.

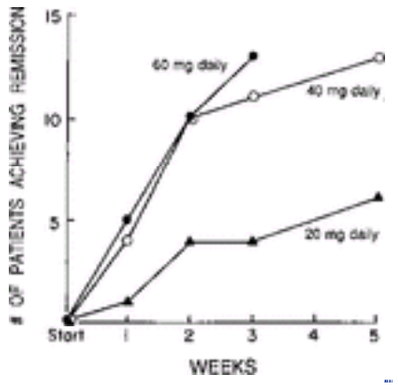

FIGURE 83-25. The number of patients with active ulcerative colitis achieving remission over a 5-week period with increasing doses of prednisolone. (From ref. [275].)

Corticosteroid enemas are useful in left-sided colitis. [277], [278] In most patients, a 100-mL corticosteroid enema reaches the mid-descending colon, although in some the enema reaches the midtransverse colon. About 80% of patients with proctitis obtain a remission or significant improvement with one enema per night for 2 to 3 weeks. The extent of systemic absorption varies with the corticosteroid preparation and the severity of inflammation. In general, systemic absorption is much less than that with orally administered steroids; however, in some cases, as much as 75% of the dose administered rectally is absorbed. [279], [280] In addition to enema preparations, corticosteroids are also available in foam suspension. Because proximal penetration with foam is not as great as with enemas, foam can be used only for disease confined to the rectum; however, foam preparations are less bothersome for the patient than enemas.

The National Cooperative Crohn's Disease Study found that a 17-week course of prednisone (0.25–0.75 mg/kg daily) was more effective than placebo in Crohn's

disease of the small bowel. [267] Sixty percent of prednisone-treated patients achieved remission compared with 30% of those receiving placebo. The European Cooperative Crohn's Disease Study found similar benefits with oral corticosteroids in Crohn's disease. [268] In a large series of 142 patients with active Crohn's disease, treatment with prednisolone (1 mg/kg daily) resulted in clinical remission in 92% of patients within 7 weeks, although the rate of endoscopic remission was much lower. [194] Considering the prominent role that corticosteroids have played in the management of Crohn's disease, few studies have addressed the issues of optimal doses, duration of therapy, and parameters for adjusting dosages. The physician must ensure that there is no abscess present if the use of corticosteroids is being considered. An abscess requires surgical drainage and antibiotics, and the use of corticosteroids in a patient with an undrained abscess may lead to uncontrolled sepsis. In addition, the physician also must be certain that the patient's symptoms relate to inflammation and not to a stricture or other fibrotic process that will not respond to steroids. The usual starting oral dosage is 40 mg of prednisone per day; starting with lower doses diminishes the likelihood of a positive response. These dosage recommendations should be adjusted if the patient's response to steroids is known from past experience. Corticosteroids can be given parenterally if the patient cannot tolerate oral medication. The patient is left on high doses of corticosteroids until symptoms begin to diminish, after which the dose is reduced gradually.

Maintenance therapy with corticosteroids for the prevention of recurrences in patients in clinical remission has been demonstrated to be ineffective in both ulcerative colitis and Crohn's disease. [267] In both diseases, however, some patients have continuously active disease that responds to corticosteroids but flares up if the dose of steroids is reduced.

The many side effects of corticosteroids are the major factor limiting their use in IBD. [268], [281] Although the side effects of corticosteroids are dose-dependent, there is a wide range of patient susceptibility to these side effects. Some patients tolerate prolonged courses of high-dose corticosteroid therapy without ill effects, but others develop devastating side effects with short courses of low-dose therapy. The range of patient susceptibility to developing corticosteroid side effects is a function of differences in plasma protein binding (with hypoalbuminemic patients being at risk) and of variations in rates of metabolism and clearance of synthetic steroids. The major differences between the manifestations of iatrogenic steroid administration and the manifestations of spontaneous Cushing syndrome are related to the increased levels of androgens and mineralocorticoids in spontaneous Cushing syndrome. [282] Features more common in spontaneous Cushing syndrome include hypertension, virilism, striae, and purpura. Features more common in iatrogenic steroid administration include posterior subcapsular cataracts, avascular necrosis of bone, osteoporosis, and glaucoma. Although there is much individual variability in response, patients taking 10 mg or more of prednisone daily for longer than 3 weeks should be viewed as having a suppressed hypothalamic-pituitary-adrenal axis for 1 year after cessation of therapy and should receive supplemental glucocorticoids for surgery or severe illness. Patients should be instructed about adrenal suppression and the need for glucocorticoid supplementation for surgery and severe illness even after cessation of therapy.

Patients also need to be educated about the benefits and toxicities of glucocorticoids. In particular, they should understand the more predictable side effects of osteoporosis and cataract formation and the necessity of observing for their occurrence. Common predictable side effects include increased appetite, centripetal obesity, moon facies, acne, insomnia, increased risk of infection, and, in children, growth arrest. Less common problems for which the patient should be monitored include hypertension and glucose intolerance. Steroid-induced glucose intolerance may require treatment with insulin or oral hypoglycemic agents. In patients with diabetes, steroids may make blood-sugar control more difficult. Psychiatric problems occur, including depression and psychosis. Avascular bone necrosis, particularly of the femoral heads, occurs and can result in permanent disability.

Osteoporosis is a common and potentially devastating side effect of corticosteroid therapy. Every patient treated with glucocorticoids develops negative calcium balance. The effects of corticosteroids on bone include both enhanced bone resorption and diminished bone formation. [282] Steroid-induced bone loss is a particular problem in small intestine Crohn's disease, in which malabsorption of vitamin D and calcium also can accelerate calcium loss from bone. Bone loss characteristically involves trabecular bone in ribs, vertebrae, and distal radius. Rib fractures and vertebral compression fractures are common. The incidence of symptomatic bone loss is higher in children and postmenopausal women. Data are conflicting on the effects of low-dose corticosteroids on bone loss. Dykman and colleagues [283] reported significant bone loss with dosages as low as 8 to 10 mg of prednisone per day, but Sambrook and associates [284] reported no increase in bone loss over a period of 7 years using an equivalent dosage of prednisolone. To minimize bone loss, the management of patients on corticosteroids should include the following [147]:

use of the lowest possible dose of corticosteroids
smoking cessation, limitation of alcohol consumption, and 30 to 60 minutes of weight-bearing exercise per day
history, physical examination, and laboratory evaluation, including bone mineral densitometry
dietary or supplemental calcium (1500 mg/day)
vitamin D (50,000 IU 1–3 times/week) or calcitriol (0.5 µg/day)
hormone (estrogen) replacement therapy where appropriate.

Posterior subcapsular cataracts occur frequently with corticosteroid therapy, and their incidence correlates with dose and duration of therapy. [285] Of patients receiving 15 mg of prednisone for 1 year, 25% developed lenticular changes. Glucocorticoids also increase intraocular pressure in up to 40% of patients. Irreversible glaucoma and blindness can occur in susceptible persons. Referral to an ophthalmologist for baseline measurement of intraocular pressure and slit-lamp examination should be considered if long-term corticosteroid management is expected. Periodic examinations should be performed if therapy is continued.

The high level of efficacy of systemic corticosteroids in IBD combined with a high level of undesirable side effects has led to attempts to develop new corticosteroids with the same level of efficacy but diminished toxicity compared with currently available drugs. Budesonide is a potent corticosteroid whose systemic toxicity is diminished by rapid first-pass metabolism in the liver. It was formulated with a Eudragit-S coating to direct its delivery to the terminal ileum and proximal colon, areas likely to affected by Crohn's disease. In theory, this formulation would allow the absorption of budesonide in the area of active inflammation in Crohn's disease. The absorbed budesonide then would travel through the portal circulation to the liver, where it would be metabolized; relatively little unmetabolized budesonide would escape from the liver to cause the systemic side effects associated with conventional corticosteroids. This formulation was used in an 8-week, placebo-controlled Crohn's disease trial; budesonide was effective in inducing remission, but the doses of budesonide that induced remission also suppressed plasma cortisol levels. [286] Budesonide is more effective than mesalamine [287] and as effective, or almost as effective, as prednisone in inducing remission in Crohn's disease. [288], [289] The suppression of serum cortisol with budesonide is appreciable but less than that seen with prednisone. Oral budesonide at 3 or 6 mg daily was compared with placebo as maintenance therapy in Crohn's disease. [290] Mean time to relapse was 124 days and 168 days in those receiving 3 and 6 mg of budesonide, respectively. In comparison, the mean time to relapse was 39 days in those receiving placebo. However, at 1 year the rate of relapse was similar in all three groups. In a study of the prevention of recurrence after surgery in Crohn's disease, budesonide was found to decrease the rate of recurrence in those who had undergone resection for disease activity but not in those who had resections for fibrostenotic disease. [291] All available studies are of relatively short duration; a comparison of the side effects of budesonide and prednisone in a long-term study is needed to confirm any relative clinical advantage for budesonide.

Immunomodulators

Immunomodulators are a loosely defined group of drugs that act by blocking lymphocyte proliferation, activation, or effector mechanisms. There is fairly extensive experience in the use of two immunomodulators, azathioprine and its metabolite, 6-mercaptopurine (6-MP), in the treatment of IBD and lesser experience with other immunomodulators, including cyclosporine and methotrexate (reviewed by Sandborn). [292] The mechanisms of action for these compounds in IBD are not completely understood.

Azathioprine is a prodrug that is non-enzymatically converted to 6-MP. The role of these immunomodulators in Crohn's disease therapy has been controversial. The National Cooperative Crohn's Disease Study found that azathioprine was no more effective than placebo in a 17-week trial. [267] The therapeutic effects of azathioprine and 6-MP are not seen until after 3, 4, or more months of therapy, and the 17-week treatment period in this study was too short to demonstrate the maximal effect. The use of azathioprine and 6-MP in the treatment of Crohn's disease is no longer a source of controversy because several studies have shown these drugs to be efficacious. [293], [294], [295], [296] and [297] In one placebo-controlled study, 67% of the 6-MP-treated patients improved, compared with 8% of those receiving placebo. [293] In another study, patients with active Crohn's disease were randomized to prednisone or prednisone plus azathioprine; 38% of those receiving prednisone alone achieved remission, compared with 70% of those receiving both drugs. [298] A metaanalysis of the use of azathioprine and 6-MP in Crohn's disease led to the conclusion that these drugs are effective both in treating active disease and in maintaining remission. [299] In earlier studies, azathioprine and 6-MP were used at relatively low doses to minimize toxicity. More recently somewhat higher doses have been used, and typical initial doses are 1 to 1.5 mg/kg for 6-MP and 2.0 to 2.5 mg/kg for azathioprine. Many patients who fail to respond to lower doses will respond to higher doses; if there are no adverse effects it is reasonable to push the dose higher.

Azathioprine and 6-MP induce leukopenia in a dose-dependent manner; some investigators suggest that leukopenia and efficacy are related. In one retrospective

study, patients who became leukopenic were more likely to go into remission and to do so sooner. [300] One problem with the use of 6-MP and azathioprine is the long delay between the initiation of therapy and the clinical response. This delay is typically 3 or 4 months. In one open-labeled study, the administration of an intravenous loading dose of azathioprine reduced the time to response; [301] however, a subsequent placebo-controlled trial could not confirm this effect. [302]

Both the therapeutic efficacy and the adverse events associated with azathioprine and 6-MP are related to their metabolism and the serum levels of their active metabolites. [303], [304] 6-MP can be metabolized intracellularly by thiopurine methyltransferase (TPMT) to an inactive metabolite, 6-methylmercaptopurine (6-MMP), or anabolized to the active metabolites, 6-thioguanine (6-TG) nucleotides and 6-methylmercaptopurine ribonucleotides (6-MMPRs) (Fig. 83-26). Both the therapeutic efficacy and the hematologic toxicity of 6-MP are positively related to the serum levels of 6-TG. There is an established genetic polymorphism for TPMT, which results in significant interindividual variation in its activity. One in 300 (0.3%) individuals have low to absent TMPT activity, whereas 11% have intermediate activity and 89% have normal to high levels of activity. Low levels of TMPT activity have been associated with high levels of 6-TG and, as a consequence, with high levels of both therapeutic efficacy and bone marrow suppression. Either TPMT genotyping or measurement of 6-TG levels may assist clinicians in optimizing the therapeutic response to azathioprine and 6-MP and in identifying individuals at increased risk for drug-induced toxicity. [303], [304] Allopurinol reduces the metabolism of azathioprine and 6-MP; coadministration of allopurinol requires a reduction in dose.

FIGURE 83-26. Metabolism of azathioprine and 6-mercaptopurine.

Although most investigators and clinicians agree that these drugs have an important role in the management of Crohn's disease, opinions differ as to what that role should be. Their use is widely accepted in patients who have active disease that is unresponsive to steroids (steroid-refractory patients) and by those with active disease that is controlled by steroids but in whom steroids cannot be withdrawn (steroid-dependent patients). In these patients, 6-MP or azathioprine is added to steroid therapy; after 3 or 4 months, when the 6-MP and azathioprine are likely to have taken effect, the dose of steroids is gradually tapered. The patient is considered to be in remission induced by 6-MP or azathioprine if the activity of the disease does not flare as steroids are withdrawn. If the activity flares as steroids are withdrawn, the patient is considered to have failed to respond to 6-MP or azathioprine and the drug is withdrawn. Some clinicians use 6-MP and azathioprine as first-line therapy in Crohn's disease, although most reserve these drugs for steroid-refractory or steroid-dependent patients. These drugs also have been promoted as primary therapy for fistulae in Crohn's disease. [293] Although many fistulae heal, the fistulae tend to recur after the drugs are stopped. Azathioprine and 6-MP also are useful as maintenance therapy in Crohn's disease. Three placebo-controlled trials of 6-MP or azathioprine in the maintenance of remission have been done in patients who were brought into remission by these drugs. [305], [306] and [307] In these trials, the relapse rate of patients on placebo was 2.5 to 8 times the relapse rate on active drugs. The duration of maintenance therapy with 6-MP and azathioprine has evolved over time. Previously clinicians would discontinue these drugs after a few years of maintenance therapy; however, patients relapsed within a few months after these drugs were withdrawn. [308] Now most clinicians continue these drugs indefinitely after remission is achieved.

The major limiting factor in the use of 6-MP and azathioprine is their toxicity. [309] They commonly cause leukopenia, and the leukocyte count of patients receiving them must be monitored carefully. [310] There is no universally accepted timetable for monitoring blood counts. Monitoring every week or two at the start of therapy and then every 1 to 3 months is reasonable. These drugs should be tried only in patients who are likely to be compliant with the required laboratory monitoring. Pancreatitis is a common side effect, but withdrawal of the drug usually leads to prompt resolution. The largest review of the toxicity of 6-MP in IBD cataloged experience with 396 patients with an average follow-up of 60 months. [311] Significant but reversible morbidity included pancreatitis (3.3%), bone marrow depression (2%), and allergic reactions (2%). Infectious complications were seen in 7%, including one case of herpes zoster encephalitis. There were 12 neoplasms, but probably only one, a diffuse histiocytic lymphoma of the brain, was associated with the drug. Another retrospective study reviewed the incidence of cancer in a group of 755 patients who had received azathioprine for IBD. [312] The average dose was 2 mg/kg and the median follow-up was 9 years. No increase occurred in the incidence of lymphoma or in total cancer cases in the azathioprine-treated patients. An analysis of the effect of azathioprine on life expectancy in Crohn's disease revealed that the enhanced life expectancy due to successful treatment of Crohn's disease exceeded any decrease in life expectancy due to the increased risk of lymphoma. [313]

The roles of 6-MP and azathioprine in ulcerative colitis are less clear than in Crohn's disease. Controlled trials demonstrated the efficacy of azathioprine (1.5–2.5 mg/kg daily) as a steroid-sparing agent in ulcerative colitis. [314], [315] As in Crohn's disease, 6-MP and azathioprine are effective in maintaining remission in ulcerative colitis in patients brought into remission with these drugs. [316]

Methotrexate is another immunomodulator that has been used in IBD, [317] although experience with this drug is much less than with 6-MP and azathioprine. It is a folate antagonist that has been widely used in other chronic inflammatory diseases, including psoriasis and rheumatoid arthritis. Three placebo-controlled trials of methotrexate in Crohn's disease have been reported. [318], [319] and [320] In one study, methotrexate was given intramuscularly (25 mg once a week) for 16 weeks. The remission rate in the placebo group was 19% and in the methotrexate group 39%. [318] In the second study, methotrexate was given orally (5 mg three times a week) for a year to steroid-dependent patients. Patients receiving methotrexate were more likely to be able to withdraw from steroids. [319] In the third study, methotrexate was given orally 15 mg/week. There was a trend for fewer flares in the Crohn's disease group but this did not reach statistical significance. [320] Patients who enter remission on methotrexate are likely to remain in remission if a low dose (25 mg IM once a week) of methotrexate is continued. [321]

Methotrexate has a high incidence of side effects, including nausea, bone marrow suppression, and hepatic toxicity. Elevated transaminases are common in patients with IBD treated with methotrexate. The incidence of methotrexate-associated fibrosis/cirrhosis is high in psoriasis and low in rheumatoid arthritis, although the reasons for this distinction are not clear. There is not enough experience with methotrexate in IBD to predict the incidence of fibrosis/cirrhosis. Monitoring for both hepatic injury and bone marrow suppression is required with methotrexate therapy. Methotrexate induces abortions and should not be used in pregnant women or those considering pregnancy. Folic acid (1 mg/day) reduces the bone marrow suppression seen with methotrexate. The risk of bone marrow suppression with methotrexate is increased in renal disease and with simultaneous use of trimethoprim/sulfamethoxazole.

The exact place of methotrexate in the management of Crohn's disease is not clear. In general, the same steroid-dependent and steroid-refractory patients who are candidates for 6-MP or azathioprine could be candidates for methotrexate. The larger experience with 6-MP and azathioprine would make them the more likely choice. There is no basis in the literature for treating ulcerative colitis with methotrexate. The only placebo-controlled trial found no benefit for methotrexate in steroid-dependent ulcerative colitis. [322]

Cyclosporine is a powerful immunomodulator that is widely used to prevent rejection in transplant patients; there is increasing experience with the use of cyclosporine (parenteral, oral, enema formulations) in IBD. [323] One clear advantage of cyclosporine over azathioprine and 6-MP is that the onset of action is seen in a few days rather than several months. There is some experience with the use of intravenous cyclosporine in ulcerative colitis. Here, the major indication is an attempt to avoid colectomy in severe disease that is unresponsive to intravenous corticosteroids. In one series 36 of 42 patients with severe ulcerative colitis, 62%, avoided colectomy. [324] Those who received 6-MP or azathioprine in addition to cyclosporine did better. In another series, patients who failed to respond to 7 to 10 days of intravenous corticosteroids were given placebo or cyclosporine at a daily dose of 4 mg/kg by continuous infusion. Nine of 11 patients who received cyclosporine responded, but none of the nine placebo-treated patients responded. [325] The approach to the use of cyclosporine in ulcerative colitis is to control disease activity with 1 to 2 weeks of parenteral cyclosporine and then switch to oral cyclosporine for 3 months. During that time, the patient is begun on 6-MP with the hope that after 3 months the cyclosporine can be stopped and the 6-MP continued. How many cyclosporine-treated patients remain under control after being switched to oral cyclosporine is not known, and the long-term success rate with this approach is not established. Anecdotal reports suggest that many patients treated this way come to colectomy within a few months despite cyclosporine therapy. Nonetheless, if there is a role for cyclosporine in IBD, it is in patients with severe ulcerative colitis for whom colectomy is being considered. Cyclosporine has been tested in four double-blind studies in chronic Crohn's disease. In one study, patients were treated for 3 months with a high dose (5–7.5 mg/kg daily) of oral cyclosporine. [326] Cyclosporine was superior to placebo in achieving treatment goals designated for each patient but was not superior

to placebo in reducing the CDAI. Moreover, the benefits did not persist when cyclosporine was withdrawn. In three other placebo-controlled trials of lower dose oral cyclosporine in Crohn's disease, no benefit was seen with the drug. [327], [328] and [329] All three of the negative studies had much larger numbers of patients than the single positive study.

Side effects are a major issue with cyclosporine therapy. Renal toxicity is the greatest concern. Cyclosporine causes a 20% decrease in glomerular filtration rate. This decrease was thought to be entirely reversible, but it is now clear that many patients suffer irreversible renal damage with cyclosporine. Risk factors include increased initial creatinine, increased age, and high cyclosporine blood levels. Other side effects with cyclosporine include hypertension, paresthesias, tremor, and headache.

Antibiotics

Except in cases of overt sepsis, antibiotics have been thought to have only a limited role in the management of ulcerative colitis. Antibiotics do not affect the remission rate, [330] and a trial of metronidazole in ulcerative proctitis showed it to be ineffective. [331] Moreover, the risk of inducing antibiotic-associated pseudomembranous colitis must be considered. However, one blinded study demonstrated that long-term (6 months) treatment with ciprofloxacin improved the results of conventional therapy with mesalamine and prednisone in the induction and maintenance of remission. [332]

Antibiotics have a larger role in the management of Crohn's disease where they are important in the treatment of the suppurative complications, especially abscess formation and perianal disease, although surgical drainage is the primary therapy for abscesses. In addition, antibiotics are used to treat the diarrhea caused by overgrowth of bacteria in the small bowel. This problem usually occurs because of stasis behind a stricture. If the stricture is not amenable to surgical or endoscopic management, the symptoms of pain, gaseousness, and diarrhea can be managed with courses of broad-spectrum antibiotics, such as tetracycline.

Metronidazole has been the most extensively studied antibiotic in the management of Crohn's disease. The efficacy of metronidazole has been demonstrated in perianal Crohn's disease and in colonic Crohn's disease. A Swedish trial compared metronidazole (800 mg/day) and sulfasalazine (3 g/day) in patients with Crohn's disease. [333] The two drugs were equally effective, and both were more effective in disease confined to the colon. A second study compared metronidazole at 10 mg/kg and 20 mg/kg with placebo in Crohn's disease and found dose-related improvements in disease activity, but the incidence of side effects was high, and only half the patients completed the study. [334] The mechanism of action of metronidazole in Crohn's colitis is not known. An important side effect of metronidazole is neurotoxicity resulting in numbness and burning in the feet.

Ciprofloxacin is another antibiotic that is used with some frequency in Crohn's disease. A typical dosing schedule is 500 mg twice a day for a few weeks. In a randomized comparison of ciprofloxacin 500 mg bid and Pentasa 2 g bid for 6 weeks in patients with mildly to moderately active Crohn's disease, the rates of remission and the rates of improvement were the same in the two groups. A controlled trial of steroids versus combined treatment with ciprofloxacin and metronidazole demonstrated an equivalency between the two treatment arms. [335] Antibiotics are generally more useful in Crohn's colitis than in ileal disease.

Infliximab

Infliximab, a mouse-human chimeric monoclonal IgG1 antibody directed against TNF, is approved by the FDA for treatment of Crohn's disease and rheumatoid arthritis. The mechanism of action of infliximab is not clear. One possibility is that it neutralizes free TNF; another possibility is that, as an IgG1 antibody, it lyses lymphocytes that express TNF on their surface through complement fixation or antibody-dependent cell-mediated cytotoxicity.

After a promising open label study in Crohn's disease, [336] a randomized placebo-controlled trial of infliximab was performed in patients with moderate to severely active disease. [67] Single infusions of infliximab (5, 10, or 20 mg/kg) resulted in a decrease of 70 points or more in the CDAI in 65% of treated patients at 4 weeks. In comparison, 17% of patients treated with placebo responded. The response rate was somewhat better in patients receiving 5 mg/kg than in those receiving 10 or 20 mg/kg. Patients who continued to respond were re-randomized at week 12 to receive either placebo or infliximab at 10 mg/kg every 8 weeks for an additional four infusions. Although there were no statistically significant differences in the response rate after repeated dosing there was a trend toward a higher response rate in patients treated with infliximab at week 44, 8 weeks after the last infusion. There was a significant difference in the rate of remission at week 44 with 52.9% of patients treated with infliximab in remission compared with 20% of patients given placebo.

Infliximab is also useful in closing fistulae in Crohn's disease. [337] In a randomized controlled trial, patients with enterocutaneous fistulae were randomized to infusions of placebo or infliximab at 5 or 10 mg/kg at weeks 0, 2, and 6. Success was defined as closure of 50% or more of the fistulae at two visits one month apart. The success rate was 68% in patients receiving 5 mg/kg of infliximab and 56% for those receiving 10 mg/kg compared with 26% in the placebo-treated group. These results were statistically significant. In the infliximab-treated group the medium duration of response was 3 months.

The short-term toxicity after a single dose of infliximab appears to be modest but toxicity increases with repeated dosing. It is a chimeric antibody, part human and part mouse, and is associated with both acute and delayed hypersensitivity reactions. [338] Some patients develop high titers of human antichimeric antibodies. Retreatment is associated with delayed hypersensitivity reactions marked by rash, fevers, arthralgias, and myalgias; these typically occur 3 to 10 days after retreatment. Infliximab has been associated with the development of a number of infections including varicella zoster, *Candida* esophagitis, and tuberculosis. TNF is an important regulator of the immune response to infectious agents; thus, it is not surprising that an antibody to TNF would be associated with infectious complications. At least six cases of lymphoma have been seen in patients receiving infliximab; four of these occurred in patients with rheumatoid arthritis, one in a patient with Crohn's disease, and one in a patient with acquired immunodeficiency syndrome (AIDS). [339] Both rheumatoid arthritis and Crohn's disease are themselves associated with an increased incidence of lymphoma, thus it is difficult to establish a causal relationship for infliximab and lymphoma in these cases. An interesting and unexpected complication associated with infliximab therapy has been the development of strictures in the gastrointestinal tract associated with the rapid healing of ulcers. Some of these strictures have required dilation.

The fast-track approval of infliximab by the FDA resulted in its release at a time when there was little experience with either repeated dosing or combination therapy with other agents. Moreover, the rapid approval resulted in its release at a time when little safety data were available. This has created problems for clinicians in deciding on which patients to treat with this drug. Although there is some evidence for the efficacy of repeated dosing [340] the general impression has been that both the strength and duration of the response declines with each additional infusion. Moreover, the incidence of adverse events increases with subsequent infusions. Therefore, it would seem reasonable to combine infliximab with an immunomodulator such as azathioprine or 6-MP with the hope that a short course of infliximab would control disease activity until the efficacy of azathioprine or 6-MP was established 3 or 4 months after the initiation of therapy. There are, as yet, no large-scale controlled studies investigating this approach.

Future Therapy

A large number of new therapeutic approaches are under investigation for the management of IBD, most of them directed at Crohn's disease. Several of these therapeutic approaches involve either treatment with recombinant cytokines or treatment with antibodies to cytokines.

Recombinant human IL-10 has been tested in the treatment of Crohn's disease. The rationale for IL-10 therapy is relatively straightforward: Crohn's disease is mediated by Th1 lymphocytes and IL-10 suppresses production of IL-2 and IFN-? by Th1 lymphocytes. There have been three controlled trials of IL-10 in Crohn's disease. [341] On the whole, the results of these studies have been disappointing and it is not clear that IL-10 as monotherapy will have a role to play in the management of Crohn's disease. In a single study 37 adults with moderate to severely active Crohn's disease were randomized to 4 months of self-administered injections of growth hormone (loading dose 5 mg/day subcutaneously for one week, followed by a maintenance dose of 1.5 mg/day) or placebo. [342] At 4 months the decrease in the CDAI in the treated group was significantly greater than in the control group.

CDP571 is a humanized IgG4 antibody against TNF-a. In a randomized placebo-controlled trial of patients with mild to moderately active Crohn's disease CDP571 was significantly better than placebo. [343] CDP571 has two characteristics that distinguish it from infliximab. One distinction is that CDP571 is a humanized antibody, whereas, infliximab is a mouse-human chimeric antibody; this distinction may account for the superior safety profile of CDP571 compared with infliximab. In particular, CDP571 was associated with fewer infusion reactions. The second distinction is that CDP571 is an IgG4 antibody, which does not bind complement and cannot mediate antibody-dependent cell-mediated cytotoxicity; whereas, infliximab is an IgG1 antibody which can bind complement and which can mediate antibody-dependent cell-mediated cytotoxicity. It is possible that the improved efficacy of infliximab in comparison with CDP571 may be due to its ability to bind

complement and thus to lyse lymphocytes that express TNF-a on their surface.

A central role of the intestinal flora has been proposed for both Crohn's disease and ulcerative colitis. One approach to altering the intestinal floral involves the use of probiotics, the administration of live bacteria as a therapeutic agent. A nonpathogenic strain of *E. coli*, Nissle 1917, has been evaluated in ulcerative colitis for induction of remission as well as maintenance of remission. In a two-part study, initial treatment for active colitis and then maintenance, the *E. coli* strain appeared as effective as mesalamine for attaining remission (75% patients in the mesalamine group attained remission compared with 68% in the *E. coli* group). [344] The successful use of probiotics was demonstrated in a placebo-controlled trial for the maintenance of remission in chronic pouchitis. [345] The probiotic used in this study, VSL#3, is composed of eight strains of bacteria including lactobacilli, *Bifidobacterium*, and *Streptococcus* at a dose of 1.8 × 10 [12], a much higher dose than studied in other probiotic studies. Only 2 of 20 patients relapsed after 9 months of treatment with probiotics in contrast to 100% of the 20 patients receiving the placebo. These products are being studied for use in ulcerative colitis and Crohn's disease. A variation of these approaches is the use of a parasite, *Trichuris suis*. Infection with helminths modulates the Th1 response and it was thought that this modulation might be therapeutic in Crohn's disease. After positive pilot studies, placebo-controlled trials are testing *T. suis* in both Crohn's disease and ulcerative colitis. [346]

An alternate approach of immune stimulation in Crohn's disease relies on genetic immune deficiency syndromes, such as chronic granulomatous disease and glycogen storage disease type Ib, as models to understand the pathophysiology of Crohn's disease. Crohn's disease or a Crohn-like intestinal disease is highly associated with these genetic diseases which have a defect of innate immunity. These immunodeficiency syndromes suggest that the characteristic inflammatory response of Crohn's disease may be a secondary compensatory response to a primary deficiency of innate immunity. Focused immune stimulation has been proposed as an alternate therapeutic paradigm. [347] Immune stimulation with G-CSF and GM-CSF was effective in pilot trials and further studies are anticipated.

Heparin emerged as a potential therapeutic agent from serendipitous observations of improvement of ulcerative colitis for patients being treated with heparin for thromboembolic disease. [348] Heparin has been proposed to be beneficial as an anticoagulant, helping reverse microvascular thrombotic disease responsible for an element of the pathophysiology of IBD. However, heparin also acts as an antiinflammatory agent as well as a potentiator of cellular repair. Controlled trials have demonstrated some conflicting data using standard heparin in ulcerative colitis. Lidocaine enemas appear beneficial in distal ulcerative colitis, studied in large open-labeled trials which have not yet been validated with placebo-controlled trials. [349] This approach suggests that manipulation of neural input may influence the inflammatory process and enable resolution of colitis. Rosiglitazone emerged as a potential therapy in ulcerative colitis through another serendipitous observation. Pilot studies suggested a positive therapeutic effect, presumably acting through the PPAR? pathway. [350]

MEDICAL MANAGEMENT OF ULCERATIVE COLITIS

Active Proctitis

Several reasonable approaches to the initial treatment of active ulcerative proctitis can be undertaken. [351] One relatively effective and rapidly acting approach is the nightly administration of 5-ASA (Rowasa) retention enemas or suppositories. If the patient responds, the frequency of the enemas or suppositories can be reduced from nightly to every other night after 2 to 3 weeks. 5-ASA enemas often are supplemented with oral sulfasalazine or an oral 5-ASA preparation. An acceptable alternative is the use of local corticosteroids in the form of retention enemas (Cortenema) or, for more limited disease rectal foam (Cortifoam or Proctofoam-HC) administered at bedtime for 2 to 3 weeks. If there is a good clinical response, this therapy is continued for another few weeks every other night. Either 5-ASA suppositories or corticosteroid foam is appropriate for disease involving up to 20 cm of distal colon; 5-ASA or corticosteroid retention enemas can be used for active disease involving up to 60 cm of distal colon. A third acceptable initial therapeutic approach to proctitis or distal colitis is an oral 5-ASA preparation. The response to sulfasalazine or other oral 5-ASA compounds may not be seen for 3 to 4 weeks, which is slower than the response to corticosteroid or 5-ASA enemas. Sulfasalazine is begun at a dose of 500 mg twice daily and is increased gradually every few days until a daily dose of 3 to 4 g is reached. Mesalamine (Asacol) and olsalazine (Dipentum) can be used instead of sulfasalazine, although Dipentum is not approved by the FDA for acute disease. The initial dose of Asacol is 800 mg three times a day; this dose can be increased up to 4.8 g/day if necessary. A metaanalysis suggests that mesalamine enemas are superior to steroid enemas or oral 5-ASA products in the management of left-sided colitis. The same metaanalysis found that mesalamine suppositories were superior to topical steroids in ulcerative proctitis. [351]

The patient with proctitis who does not respond to corticosteroid enemas can be given 5-ASA enemas, oral sulfasalazine, or oral 5-ASA. Conversely, patients who are not responsive to these therapies can be given corticosteroid enemas. Patients not responding to any of these modalities should be given oral corticosteroids; treatment with prednisone can be started with a dose of 40 mg/day. If there is a response, the dose is gradually tapered over 3 months. Patients who do not respond to oral corticosteroids (steroid-refractory) or who cannot be weaned off corticosteroids (steroid-dependent) can be given azathioprine or 6-MP, although there is usually a delay of several months before a clinical response is seen with either of these drugs.

For the patient who does not respond to corticosteroids or immunomodulators, surgery becomes a consideration. Loop ileostomies and temporary colostomies have been tried to give the colon a chance to heal. Whether a diverting ileostomy or colostomy has the potential to affect the course of the disease is not clear; however, diverting procedures do eliminate the diarrhea, urgency, and incontinence associated with proctitis. Some patients eventually require colectomy and an ileoanal anastomosis for proctitis, although this step is unusual. The creation of a diverting ostomy prior to a proctectomy reduces inflammation and thus reduces the technical difficulty of the proctectomy.

For patients with mild disease activity, whether with proctitis or more extensive disease, there is likely to be a role for symptomatic antidiarrheal therapy, usually with loperamide or diphenoxylate or opium and belladonna. They can be used to reduce the number of bowel movements or to reduce rectal urgency. Most patients use them on an as-needed basis after diarrheal stools, but some find it useful to take them with meals to reduce food-stimulated diarrhea.

After the proctitis is in remission, maintenance therapy should be considered. There is no compelling evidence that patients with a single, easily managed bout of proctitis need maintenance therapy; however, patients who have disease that is difficult to manage or with frequent or early relapses should have chronic maintenance therapy. The greatest experience with maintenance therapy is with sulfasalazine. The usual maintenance dose of sulfasalazine is 2 g/day; however, there is convincing evidence that maintenance with 4 g/day is more effective. [352] For patients who have undesirable side effects with sulfasalazine, maintenance therapy with olsalazine (1 g/day) or other oral 5-ASA formulations should be considered. If active disease is controlled with 5-ASA enemas, maintenance therapy with the same enemas may be appropriate. [353] Typically, maintenance therapy with 5-ASA enemas is given every other day or every third day. Because of the expense and inconvenience, maintenance therapy with 5-ASA enemas is reasonable only in patients who have failed maintenance therapy with sulfasalazine and other oral 5-ASA compounds.

Active Extensive Colitis

For patients with colitis of mild to moderate activity and extension proximal to the sigmoid colon, the initial drug of choice is either sulfasalazine or an oral 5-ASA compound. Typical doses are sulfasalazine 4 g/day, Asacol 2.4 g/day, and Pentasa 3 g/day. The efficacy of 5-ASA therapy increases with the dose, and it is reasonable to try doses higher than those typically used. Many patients tolerate gradual increases in sulfasalazine to a dose of 8 g/day or Asacol to a dose of 4.8 g/day. Not every patient responds to sulfasalazine or other 5-ASA formulations, however, and the response, if it occurs, may take 3 or 4 weeks. For patients with more active disease (more than five or six bowel movements per day) or in whom a therapeutic response is desired in less than 3 to 4 weeks, the initial treatment of choice is oral prednisone. This is also the drug of choice for those who have not respon- ded to 3 to 4 weeks of therapy with oral 5-ASA preparations. The typical starting dose of prednisone is 40 mg/day. Because of the side effects associated with high-dose prednisone there is a temptation to start therapy at a lower dose. This should be avoided as lower doses are associated with lower response rates. Most patients respond to oral corticosteroids within a few days to 3 weeks. After the symptoms are controlled, the dose of prednisone can be reduced gradually. One standard approach is to cut the daily dose by 5 to 10 mg every 1 to 2 weeks. It is usually relatively easy to reduce the corticosteroid dose to 20 mg/day, but the disease is more likely to flare as the dose is reduced further. It may be necessary to taper the dose more slowly below 20 mg/day or to use alternate-day dosing as part of the tapering protocol. Patients who respond to oral prednisone and who can be fully withdrawn from prednisone should be maintained on sulfasalazine or an oral 5-ASA preparation, these maintenance drugs should be started at least 3 to 4 weeks before prednisone is discontinued.

Severely Active Colitis

Some patients develop incapacitating disease that requires hospitalization. [101] The most common reason for hospitalization is intractable diarrhea, although blood loss is also a common problem. Incapacitating symptoms may develop acutely over a period of a few days or insidiously over weeks to months. Management with oral

corticosteroids usually has been tried before admission. Patients with severe active ulcerative colitis should be evaluated for toxic megacolon, the management of which is discussed in a subsequent section of this chapter. Anticholinergics and antidiarrheal agents are contraindicated in severe ulcerative colitis because of the risk of precipitating toxic megacolon. The mainstays of therapy for severe ulcerative colitis are bed rest, rehydration with intravenous fluids, and intravenous steroids (hydrocortisone 300 mg/day, prednisolone 60–80 mg/day, or methylprednisolone 48–60 mg/day). Patients with significant anemia should be transfused, and those with peritoneal signs or signs of systemic infection should be treated with parenteral antibiotics. Because active ulcerative colitis often is associated with a moderate leukocytosis and a low-grade fever, it may be difficult to identify those who have bacterial infection in addition to ulcerative colitis. If there is any doubt, cultures should be obtained, and the patient should be given broad-spectrum antibiotics such as ampicillin, metronidazole, and an aminoglycoside. Dehydration with or without hypokalemia occurs in those with severe diarrhea. Fluids should be administered aggressively to replenish water and electrolytes. The patient is given nothing by mouth, and nasogastric suction is used if there is an ileus or colonic dilation.

Maintaining adequate nutrition is often a major problem in severe active ulcerative colitis. Patients whose disease has been active for a considerable time may enter the hospital malnourished; these patients and those who are likely to be unable to take adequate oral nutrition for an extended period should be placed on TPN. If the bout of acute colitis has been of short duration, the patient's current nutritional status is good, and the history of previous exacerbations suggests that this one will be of short duration, then TPN is probably unnecessary. Patients with severe active ulcerative colitis should be given a trial of bed rest, TPN, and intravenous steroids for 7 to 10 days. Patients who do not improve during this period should be considered for either colectomy or a trial of intravenous cyclosporine, which is given at a dose of 4 mg/kg daily by continuous infusion, aiming for therapeutic serum levels. [325] For patients who do respond to cyclosporine, the average time to response is 7 days. If therapeutic success is achieved with intravenous cyclosporine, the patient is switched to oral cyclosporine (8 mg/kg daily).

Steroid-Refractory and Steroid-Dependent Disease

A small but troublesome group of ulcerative colitis patients includes those who do not respond to corticosteroids (steroid-refractory patients) and those who do respond but whose disease flares whenever the corticosteroids are withdrawn (steroid-dependent patients). In these cases, the clinician is faced with three potential courses of action: a trial of an immunomodulator; colectomy; and, if the patient has responded but cannot be withdrawn from corticosteroids, indefinite continuation of corticosteroids. The option of continued chronic corticosteroid therapy is frequently the least appealing of the three options because of the long-term side effects, including osteoporosis and cataract formation. Continuation of high-dose corticosteroid therapy for too long is the most common serious error in the management of ulcerative colitis. If the patient is on a substantial dose (>15 mg of prednisone per day) for longer than 6 months, a trial of an immunomodulator or surgery should be given serious consideration. The use of immunomodulators, usually 6-MP or azathioprine, is worth considering in many cases. For patients who have been on high-dose steroid therapy, the steroids are continued, and 6-MP (1–1.5 mg/kg daily) or azathioprine (2–2.5 mg/kg daily) is added. The combination of an immunomodulator plus steroids is continued for 3 to 4 months, and then the steroids are tapered gradually. If the steroids cannot be tapered after 6 months on immunomodulator therapy, the immunomodulator should be stopped. For patients who respond to an immunomodulator in this circumstance, the next question is how long they should be maintained on the drug and what happens if it is withdrawn. Although some clinicians attempt to withdraw the patient from immunomodulators after 1 to 3 years of therapy, most patients will have their disease flare within a few months of withdrawal. For this reason it is probably best to continue the immunomodulator indefinitely. The other option is colectomy. Given the risks of malignancy associated with long-standing ulcerative colitis and the risks associated with long-term immunomodulator therapy, the prospect of colectomy, especially if the creation of an ileoanal anastomosis is possible, should be offered as a realistic alternative rather than as an enforced consequence of failed medical management.

Maintenance Therapy

There is compelling evidence that oral 5-ASA preparations can reduce the incidence of recurrences in patients with ulcerative colitis. Most patients with ulcerative colitis should be viewed as candidates for chronic maintenance therapy. For the patient with a single episode of easily managed ulcerative colitis, it may be difficult to justify long-term maintenance therapy. In this case, the usual course is to have the patient on maintenance therapy for 1 year and then discontinue it. For patients who have difficulty controlling the disease or who have multiple recurrences, it is reasonable to recommend lifetime maintenance therapy. Sulfasalazine and other oral 5-ASA agents are probably equally effective. The efficacy of sulfasalazine as maintenance therapy in ulcerative colitis is a function of the dose; the efficacy of 3 to 4 g/day is greater than the efficacy of 2 g daily, even though 2 g daily is the usual recommended maintenance dose. [352] The dose of sulfasalazine should be pushed to the higher levels in patients who tolerate higher doses. Other oral 5-ASA agents can achieve higher lumenal concentrations of 5-ASA than usually are achieved with sulfasalazine and, on that basis, may be more effective as maintenance therapy. Asacol at 2.4 g/day is commonly used for maintenance therapy but higher doses may be more effective. Corticosteroids are not effective as maintenance therapy and should not be used. Most of the experience with 6-MP as maintenance therapy in ulcerative colitis is in patients whose acute disease has been brought under control with 6-MP; withdrawal of 6-MP from these patients has resulted in a high incidence of exacerbation.

COMPLICATIONS OF ULCERATIVE COLITIS

Perforation

Free perforation of the colon commonly complicates toxic megacolon but can occur in severe ulcerative colitis even without toxic megacolon. Perforation occurs more often during first episodes of colitis, perhaps because of lack of fibrosis and scarring from previous attacks. Most perforations occur in the left colon, particularly the sigmoid. Steroid therapy has been suggested to be a risk factor for colonic perforation, but some investigators have not found this to be the case.

Stricture

Clinically important strictures are relatively uncommon in ulcerative colitis, but some degree of narrowing may be seen in as many as 12% of surgical specimens. [354] Careful histological examination of strictures demonstrates hypertrophy and thickening of the muscularis mucosae without fibrosis. Strictures most often occur in patients with extensive disease and continuous symptoms without remission. They tend to appear later in the course of the disease, typically between 5 and 25 years after onset, most commonly in the sigmoid and rectum. Most strictures are short, typically 2 to 3 cm long, but they may be much longer. Symptoms associated with strictures include an increase in diarrhea and fecal incontinence. Strictures often are associated with malignancy in ulcerative colitis and should be viewed as potentially malignant lesions. Unfortunately, biopsy of strictures containing malignancy does not always yield malignant tissue. Development of a stricture in a patient with long-standing ulcerative colitis should be a source of concern and may necessitate resection because of the risk of malignancy.

Toxic Megacolon

If the inflammatory process extends beyond the submucosa into the muscularis, the colon loses its ability to contract and as a result becomes dilated. Dilation of the colon is associated with a worsening of the patient's clinical condition and the development of fever and prostration. A colonic diameter larger than 6 cm is sufficient to raise the possibility of toxic megacolon. Criteria for the clinical diagnosis of toxic megacolon, [109] include radiographic evidence of colonic distention (see Fig. 83-7) in addition to at least three of the four following conditions: fever higher than 38.6°C; heart rate greater than 120 beats per minute; neutrophil leukocytosis greater than 10,500 cells/mm ^{3}; or anemia. At least one sign of toxicity—dehydration, mental changes, electrolyte disturbance, or hypotension—also must be present. Physical examination of the patient with toxic megacolon reveals fever and postural hypotension. The abdomen is tender over the distribution of the colon, and there may be rebound tenderness. Colonic dilation causes abdominal distention. Bowel sounds are markedly hypoactive or absent because of loss of colonic motility.

Toxic megacolon usually occurs in patients with pancolitis but has been reported in patients with more limited disease. Patients are at greatest risk for developing toxic megacolon early in the course of their disease, and it can even occur as the initial presentation. In one series of 55 patients who developed toxic megacolon, 23 developed it within 3 months of the initial presentation of ulcerative colitis. [109]

Pharmacological agents that impair colonic motility are likely to initiate or exacerbate toxic megacolon. [355] Anticholinergic drugs diminish muscular tone in the colon and inhibit motility. Narcotic analgesics and antidiarrheals also inhibit the propulsive activity of the colonic musculature. Many cases of toxic megacolon are temporally associated with the initiation of therapy with anticholinergics or opiates or with increases in the doses of those drugs. [355], [356] For this reason, anticholinergic agents and antidiarrheals are contraindicated in patients with severe ulcerative colitis. Even in disease of moderate activity, these drugs should be used with caution, and the patient should be instructed to discontinue them if symptoms worsen. Toxic megacolon also has been temporally associated with barium enema examination and with colonoscopy. [357] Barium enema and colonoscopic examination are contraindicated in patients with severe ulcerative colitis; however, the patient can be examined safely by rigid proctoscopy or by limited flexible sigmoidoscopy as long as the physician takes care not to insufflate air into the already dilated colon.

Radiographic examinations are useful both for establishing the diagnosis and for following the course of toxic megacolon. X-ray films of the abdomen reveal colonic dilation, usually maximal in the transverse colon, which exceeds 6 cm in diameter. Although the transverse colon may not be the site of the most severe disease, it is usually the most dilated segment, because colonic gas tends to accumulate in the highest portion of the colon, and the transverse colon is the highest portion when the patient is supine. Serial flat-plate films of the abdomen taken at 12- to 24-hour intervals are useful in following the clinical course.

Although laboratory findings are not diagnostic in toxic megacolon, a pattern of laboratory abnormalities is commonly seen. Patients with toxic megacolon may be anemic because of blood loss, and there is usually a leukocytosis with predominance of neutrophils. Hypokalemia and hypoalbuminemia as a result of losses from diarrhea also are seen.

Medical therapy is designed to reduce the likelihood of perforation and to return the colon to normal motor activity as rapidly as possible. The patient is given nothing by mouth, and a nasogastric tube is placed in the stomach. Some clinicians use a longer tube, such as a Miller-Abbott or Cantor tube, but there is no evidence to suggest that these tubes are more efficacious than a nasogastric tube. Intravenous fluids should be administered to replace water and electrolytes. [358] Fluid and electrolyte disorders impair the normal motility of the colon and increase the risk of perforation from toxic megacolon. Frequently, large deficits of water, sodium, chloride, and, especially, potassium occur. Patients with toxic megacolon often receive broad-spectrum antibiotics in anticipation of peritonitis resulting from perforation. The value of corticosteroids in the treatment of toxic megacolon has not been established in controlled studies; however, most clinicians treat patients who have the condition with parenteral corticosteroids at a dose equivalent to more than 40 mg of prednisone per day. [359], [360] Medical therapy for toxic megacolon is most likely to be successful if the condition is recognized early and appropriate steps are taken. The patient should be monitored carefully. Signs of improvement include a decrease in abdominal girth and the return of bowel sounds. Deterioration is marked by the development of rebound tenderness, increasing abdominal girth, and cardiovascular collapse.

If medical therapy is successful during the first 24 to 48 hours, both an improvement in the signs of clinical toxicity and a decrease in the diameter of the dilated colon on radiographic examination should be seen. Persistence of fever after 48 hours on high-dose steroids suggests perforation or abscess. If the patient does not begin to show signs of clinical improvement during the first 24 to 48 hours of medical therapy, the risk of perforation increases markedly, and surgical intervention is indicated. [361] The most common procedure is colonic resection with creation of an ileostomy. The rectum may be left in place and removed at a later date; however, single-stage proctocolectomy is done more commonly. The key steps in management are early recognition of the condition and identification of patients who do not respond to medical therapy. Surgical therapy after perforation is likely to have a poor outcome. [362] Mortality in that group is 44%, compared with 2% in those who were operated on before perforation. Among patients with toxic megacolon, many who are successfully treated medically are likely to undergo colonic resection for intractable disease within a year. Toxic megacolon is a sign of severe disease that may not respond to medical therapy over a long period. One study followed the clinical course of 38 patients who had been successfully treated medically for toxic megacolon; 18 eventually underwent colectomy. [363]

MEDICAL MANAGEMENT OF CROHN'S DISEASE

General Approach

It is more difficult to develop generally applicable guidelines for the management of Crohn's disease compared with ulcerative colitis. Crohn's disease involves a greater variety of anatomic locations and has more varied clinical presentations, more gastrointestinal complications, such as fistulae, abscesses, strictures, and perforations, more insidious onset and recovery from attacks; and frequently lacks definable therapeutic end points. The guidelines given here are for active disease without complications; management of specific complications is discussed separately. Adequate rest is essential, and a few days of enforced rest (or a few hours of additional rest each day) may speed up the resolution of a flare. Patients with Crohn's disease who smoke should be strongly encouraged to stop. Many practitioners believe continued smoking reduces the likelihood of response to medical management.

Symptomatic therapy plays an important role in the management of mild Crohn's disease. Antidiarrheal agents can reduce the number of bowel movements in patients with mild disease activity or in those with diarrhea secondary to surgical resections, bile salt malabsorption, or fat malabsorption. Loperamide and diphenoxylate are the antidiarrheal agents most commonly prescribed; however, opium and belladonna should be considered if loperamide and diphenoxylate are ineffective. Antispasmodics can reduce the pain associated with Crohn's disease but are contraindicated in patients with obstruction or near obstruction. Appropriate symptomatic therapy can reduce steroid requirements; however, antispasmodics and antidiarrheal agents should be used with caution in patients with severe disease because of the risk of precipitating toxic megacolon. Psychotropic drugs, particularly tricyclic antidepressants, can be useful adjunctive therapy in Crohn's disease. The incidence of depression is high among patients with Crohn's disease, and the manifestations of depression can make management of Crohn's disease more difficult. A trial of a tricyclic antidepressant or a selective serotonin reuptake inhibitor (SSRI) is indicated in patients who have clinical manifestations of significant depression.

A common problem in the management of Crohn's disease is a marked discrepancy between the severity of the patient's symptoms and the objective signs of disease. Patients with severe pain and diarrhea may have minimal findings on endoscopy or radiographic studies. In these cases, several possible explanations may need to be considered. Patients who have undergone ileal resections may have significant diarrhea on the basis of their surgery alone. Removal of the ileocecal valve speeds transit and can increase the number of bowel movements. Surgical removal of the distal ileum can result in failure to reabsorb bile acids, which induce colonic chloride secretion, leading to diarrhea. More extensive ileal resections may result in enough bile salt malabsorption to decrease the size of the bile salt pool, resulting in fat malabsorption. Malabsorbed fatty acids can be hydroxylated by colonic bacteria; hydroxyfatty acids also induce colonic chloride secretion and contribute to diarrhea. Crohn's disease patients with a history of ileal resection who present with diarrhea should have a trial of a low-fat diet (75 g/day or less) to determine how much of their diarrhea is a product of their surgery rather than a product of active Crohn's disease. A few patients with bile salt–induced diarrhea also may need cholestyramine.

For medical therapy, response is monitored by empiric clinical assessment directed at the problem that is most troublesome for the patient. If the major complaint is pain, the success of therapy is assessed by the severity of pain; if diarrhea is the major problem, success is measured by the frequency of diarrhea. In assessing the patient's response to drug therapy, it is important to understand the basis of the chief complaint. If abdominal pain is a result of obstruction behind a fibrotic stricture, it is not reasonable to expect corticosteroids to relieve the pain. Similarly, if diarrhea is caused by small bowel overgrowth behind a stricture, it is unlikely that corticosteroids will improve the diarrhea.

Mildly to Moderately Active Disease

For colonic or ileocolic Crohn's disease with mild to moderate activity, an oral 5-ASA formulation is a reasonable first approach to therapy. The dosage and treatment schedules are the same as those described for ulcerative proctitis or ulcerative colitis of mild to moderate activity (see Table 83-7). Pentasa, an oral 5-ASA preparation with greater availability of 5-ASA in the ileum than sulfasalazine, may be a better choice for patients with ileitis or ileocolitis. In a controlled trial, Asacol was as effective as methylprednisolone in the treatment of active Crohn's ileitis. [364] An alternative to 5-ASA preparations is treatment with antibiotics. Ciprofloxacin (500 mg bid) and/or metronidazole (10–20 mg/kg day) can be used a first-line therapy. A disadvantage of the 5-ASA preparations and antibiotics is that a clinical response may not be seen for 3 to 4 weeks.

Oral prednisone may be used as first-line therapy for patients with ileal disease or for patients with colonic or ileocolic disease with higher levels of disease activity. Prednisone is also the drug of choice for patients who have failed to respond to 5-ASA preparations or antibiotics. The response to prednisone is usually seen in a few days, which is more rapid than that to 5-ASA formulations or antibiotics. In a patient with Crohn's disease with abdominal pain, fever, and a high leukocyte count, an abdominal CT scan should be obtained to rule out the presence of an abscess before corticosteroids are given. Corticosteroid therapy in a patient with Crohn's disease with an abscess, especially in the absence of antibiotic therapy, can lead to serious septic complications. The most common clinical indication for the use of prednisone in Crohn's disease is the presence of an ileal narrowing caused by mucosal inflammation. If the patient's ileum is only partially obstructed, he or she is managed as an outpatient with bed rest, a low-residue diet, and oral prednisone at dose of 40 mg/day. If the symptoms come under control, the dose of prednisone is tapered as described in previous sections. If disease activity flares as the dose of prednisone is tapered, the possibility of surgery or a trial of immunosuppressives should be considered.

A frequently troublesome area is management of the patient who has been brought into clinical remission on steroids. The general goal is to taper and discontinue the steroids without inducing a flare of activity. The rate at which the steroid dose is tapered is arbitrary, and no studies have attempted to define optimal tapering schedules. The rate of taper is influenced by the patient's response to steroid tapers in the past and by the side effects of the steroids. Those who have tolerated rapid tapers in the past are likely to tolerate rapid tapers again. Many patients have side effects with high doses (40 mg/day) of prednisone. These side effects, which include insomnia, agitation, and blurred vision, may necessitate more rapid tapering. Usually the prednisone dose can be tapered from 40 mg daily to 20 mg daily

relatively rapidly (a 5–10 mg reduction every 1 to 2 weeks) without inducing a flare of disease activity. Among patients with Crohn's disease receiving their first course of steroids, 20% do not respond (steroid-resistant), 36% respond but cannot be withdrawn from therapy (steroid-dependent), and 44% respond and remain in a prolonged response after steroids are withdrawn. [365] There is a clinical pattern to patients likely to become steroid-dependent. They are more likely to have a younger age at diagnosis, to be smokers, to have colonic disease, and to have inflammatory rather than fibrostenotic disease. [366]

If the patient has not been on a 5-ASA preparation, one should be added to increase the likelihood of a successful steroid withdrawal. The 5-ASA preparation should be added by the time the prednisone dose is reduced to 20 mg/day. Pentasa (3 g/day) for ileal disease or Asacol (2.4 g/day) for colonic or ileocolic disease is appropriate for maintenance therapy. Metronidazole or ciprofloxacin can be added to enhance the likelihood of a successful steroid taper, especially if the patient has a history of responding to antibiotics in the past.

Once the dose of prednisone has reached 20 mg per day, the taper is slowed to 5 mg every 10 to 14 days. Symptoms often flare as the prednisone dose is tapered; these flares usually are due to a continued high level of intestinal inflammation that persists despite apparent clinical remission. When symptoms flare, the dose of prednisone is increased. At this point, several approaches are possible. Continuing steroid therapy indefinitely is the least desirable approach; the long-term side effects of even modest doses of steroids are likely to be significant. For a few patients, surgery is a reasonable approach at this point. It is a more attractive option if the area of involvement is small or if there are features (e.g., strictures) that increase the appropriateness of a surgical approach. For most patients, the best approach at this point is a trial of an immunomodulator, either 6-MP (1–1.5 mg/kg daily) or azathioprine (2–2.5 mg/kg daily). Treatment with the immunomodulator is initiated and steroid therapy continued for 3 to 4 months, and then the dose of steroids is tapered gradually. About 60% of steroid-dependent patients will be able to withdraw from steroids using this approach. If steroid withdrawal is tolerated, the patient is continued on the immunomodulator indefinitely. If the clinical activity flares when the dose of steroids is tapered in patients receiving 6-MP or azathioprine, the dose of the immunomodulator should be increased. Blood counts need to be monitored carefully as the risk of leukopenia increases with increasing doses of 6-MP or azathioprine. An alternative to increasing the dose of 6-MP or azathioprine would be to substitute methotrexate (25 mg parenterally once a week). Although there are data to support the use of methotrexate as a steroid-sparing agent in Crohn's disease, there is much less experience than with 6-MP or azathioprine. For patients who fail to respond to immunomodulators, the options are surgery or long-term steroids. A significant number of patients have allergic or idiosyncratic reactions to immunomodulators. Those who have had an idiosyncratic reaction, such as pancreatitis, or an allergic reaction to either 6-MP or azathioprine should not be tried again on either drug but could be given methotrexate.

Another therapeutic approach is the use of infliximab although there is considerable uncertainty as to the circumstances in which it is best used. In patients who are steroid-resistant or steroid-dependent it may be reasonable to use infliximab and start therapy with 6-MP or azathioprine at the same time. The expectation would be that the response to one or two infusions of infliximab would keep the disease under control until the response to 6-MP or azathioprine was established at 3 or 4 months. Infliximab can also be used in patients who are steroid-resistant or steroid-dependent and who have had an adverse reaction to 6-MP or azathioprine. If these patients respond to infliximab, the next question is how many times can infliximab be infused before either the efficacy is lost or adverse reactions develop? Although there is little experience with the long-term use of infliximab some patients have received five infusions over 36 weeks and stayed in remission. [340] The safety and efficacy of repeated infusions of infliximab will need to be addressed in future long-term studies. Similarly the safety and efficacy of the combination of infliximab with 6-MP and azathioprine or with corticosteroids will need to be addressed.

Severely Active Disease

Severe disease refers to patients who have persisting symptoms despite the introduction of oral corticosteroids or patients presenting with abscess, obstruction, high fever, vomiting, rebound tenderness, or cachexia. The approach to severe Crohn's disease is similar to the approach to severe ulcerative colitis. The patient is hospitalized, given nothing by mouth, rehydrated with intravenous fluids, and given parenteral steroids in the dosages listed in the previous section. Patients who respond to parenteral corticosteroids are switched to oral corticosteroids (prednisone 40 mg/day), and the dose is gradually reduced. For patients who require moderate to high doses of corticosteroids for a long time (15 mg of prednisone per day for 3 to 6 months) to control disease activity, a trial of immunosuppressives may be indicated. Patients with severe Crohn's disease who do not respond to parenteral steroids within a week should be considered for surgery. Particular efforts should be made to avoid surgery if possible in patients with previous extensive small bowel resections to avoid the risk of short bowel syndrome. A course of TPN may be useful as adjunctive therapy.

Maintenance Therapy

Therapy in IBD traditionally has been divided into therapy for active disease and maintenance therapy. The suggestion is that patients on maintenance therapy are in remission and do not have active disease. For Crohn's disease and, to a lesser extent, ulcerative colitis, the distinction between therapy for active disease and maintenance therapy is false. It is more reasonable to consider that all patients with Crohn's disease have active disease; that is, patients in clinical remission have activity even though it is not clinically apparent.

Patients with Crohn's disease who are in clinical remission tend to relapse over time. There have been at least a dozen trials of 5-ASA preparations for the maintenance of remission of Crohn's disease. [367], [368], [369], [370] and [371] Most of these trials have demonstrated positive results and metaanalysis has demonstrated efficacy. However, one large (318 patients) prospective randomized double-blind trial failed to find any benefit of 4 g of mesalamine compared with placebo in preventing relapse after surgical treatment of Crohn's disease. [372] In the studies that found 5-ASA compounds to be effective in maintaining remission, there were approximately 50% reductions in the rate of relapse over the course of the studies, which typically lasted 1 or 2 years. The efficacy of 5-ASA compounds for maintaining remission in Crohn's disease over longer times has not been addressed. Data are not available to make firm recommendations about the choice of preparation and doses for maintenance. The dose needed presumably will be proportional to the degree of continued inflammation present in patients in clinical remission. The trials suggested that 5-ASA maintenance therapy was more effective in patients with ileitis alone and more effective in patients whose remission was achieved surgically rather than medically. As in the treatment of active disease with 5-ASA compounds, higher doses of 5-ASA appeared to be more effective in maintaining remission. Pentasa (3 g/day) for patients with ileitis and Asacol (2.4 g/day) for patients with colonic or ileocolic disease are reasonable choices for maintenance therapy. There are some practical problems in using 5-ASA preparations for maintenance in Crohn's disease. The 5-ASA preparations, as a group, are expensive and require multiple dosing; moreover, the benefits of maintenance therapy in Crohn's disease are modest. For these reasons, some patients may not be motivated to participate in a 5-ASA maintenance program.

Although it is commonly stated that there is no role for corticosteroids in maintenance therapy in Crohn's disease, patients we categorize as steroid-dependent are being maintained in clinical remission with steroids. It may be more useful to state that there is no role for long-term, high-dose steroids in the management of Crohn's disease and that patients who require long-term steroids to keep their disease clinically inactive should be offered other therapies.

Many patients who are brought into remission with immunomodulatory agents, particularly azathioprine and 6-MP, are maintained on these drugs for years. For patients who have been brought into remission with azathioprine or 6-MP, and who tolerate those drugs, maintenance therapy is justified.

There is limited experience with antibiotics or fish oil as maintenance therapy in Crohn's disease. One study demonstrated a benefit of 3 months of metronidazole immediately after a surgical resection in preventing recurrence. [373] Two studies investigated the use of fish oil supplementation for maintenance of remission in Crohn's disease. One study demonstrated efficacy, [240] and the other did not. [241]

In brief, maintenance with 5-ASA preparations is recommended for those brought into remission on steroids or with surgery, though the benefit is limited. Maintenance with 6-MP or azathioprine is recommended for patients brought into remission on those drugs or who were steroid-dependent and could be converted to those drugs. Maintenance therapy may have increased importance in patients who have a history of multiple surgical resections or particularly short periods of remission.

COMPLICATIONS OF CROHN'S DISEASE

Abscesses and Fistulae

Abscesses and fistulae are both products of the extension of a mucosal fissure or ulcer through the intestinal wall and into extraintestinal tissue. Leakage of intestinal contents through a fissure into the peritoneal cavity results in an abscess. Extension of the inflammatory process through the wall of adjacent viscera or through the abdominal wall to the exterior results in a fistula.

Abscesses occur in 15% to 20% of patients with Crohn's disease. [374] They can arise from any affected area, but the terminal ileum is an especially likely point of

origin. If confined to the abdominal cavity, abscesses form between loops of intestine within the mesentery or between the intestine and the parietal peritoneum. Abscesses also extend into the iliopsoas and retroperitoneal regions. One pattern is extension of an abscess from the terminal ileum to the right iliopsoas; such a lesion presents as pain on flexion of the right hip, which can be mistaken for sciatica. [375] Hepatic and splenic abscesses also occur. Abscesses may develop postoperatively at the site of an anastomosis after resection. Development of an abscess soon after resection usually results from an anastomotic leak, whereas development of an abscess several months after surgical resection is a result of disease recurrence. [376] The typical clinical presentation of intra-abdominal abscess associated with Crohn's disease is fever and abdominal pain. The location and quality of the pain are determined by the location of the abscess. Tenderness and abdominal mass may accompany the pain and fever. Leukocytosis is the most common laboratory abnormality. Spontaneous rupture of an abscess through the abdominal wall can occur and results in an enterocutaneous fistula.

Abdominal abscess is most often diagnosed by CT scan, but barium enema, ultrasonography, and radionucleotide scanning with gallium 67 (^{67}Ga) are also useful. [377] , [378] and [379] The frequently encountered organisms in Crohn's abdominal abscesses are *E. coli, Bacteroides fragilis,* enterococcus, and hemolytic *Streptococcus* species. [378] Many different organisms may be found in a single abscess. Broad-spectrum antibiotic therapy, including anaerobic coverage, is indicated. Antibiotic coverage should be adjusted on the basis of results of culture of blood and abscess contents. Corticosteroids are not effective in the treatment of these abscesses and may impair the host response to infection. If the patient has not been taking steroids, they should not be started until the infection has been brought under control with drainage and antibiotics. If the patient has been taking steroids and the dose is being tapered, higher doses may be required to deal with the stress of infection.

Simple drainage of abscesses in patients with Crohn's disease may not provide adequate therapy because of persistent communication between the abscess cavity and the intestinal lumen. In fact, drainage in such circumstances commonly results in the formation of an enterocutaneous fistula. Resection of the portion of involved intestine containing the communication usually is required for definitive therapy. First, the abscess is drained percutaneously under guidance by ultrasound or CT scan. After the abscess is adequately drained and inflammation is reduced, the involved segment of bowel is resected. The site of communication is not always obvious and radiographic examination after oral administration of contrast material or injection of contrast into the abscess cavity may help in its identification.

The prevalence of fistulae is 20% to 40% in Crohn's disease. [374] Most fistulae are enteroenteric or enterocutaneous, with smaller numbers that are enterovesical or enterovaginal. Irrespective of the location, the mechanism of fistula formation appears to be the same. A deep abscess penetrates through the intestinal wall and into an adjacent organ or the skin. Enteroenteric fistulae develop either between a loop of involved bowel and a loop of uninvolved bowel or between two loops of involved bowel. The terminal ileum is the segment most commonly involved; fistulae from the terminal ileum may extend to other loops of small intestine or to the sigmoid. Fistulae develop when the disease is active but frequently persist even after the disease is no longer active. Enteroenteric fistulae by themselves seldom cause significant symptoms and often are found incidentally by barium contrast studies. [380] Most enteroenteric fistulae are of small diameter and do not have significant flow rates; however, those of larger diameter may allow a flow great enough to cause malabsorption, diarrhea, and weight loss.

Pain and diarrhea in patients with enteroenteric fistulae usually are caused by active Crohn's inflammation and not by the mere presence of the fistula. The treatment of fistulae in Crohn's disease has been reviewed. [381] Patients should be treated as they would be in the absence of a fistula; asymptomatic fistulae require no treatment. If an enteroenteric fistula is thought to be responsible for significant symptoms, administration of TPN or immunomodulator therapy may induce fistula closure; [382] , [383] however, fistulae often recur after the TPN or immunomodulator is stopped. Korelitz and Present [382] performed a double-blind, placebo-controlled study using 6-MP at a dose of 1.5 mg/kg/day to close fistulae. Of the 29 patients who received 6-MP, 9 completely healed their fistulae, compared with 1 of 17 in the placebo group. The mean time required for healing with 6-MP was 3 months; the fistulae reopened after 6-MP was stopped. Corticosteroids are not effective in closing fistulae. Infliximab is effective in closing enterocutaneous fistulae. Three doses (0, 2, and 6 weeks) of infliximab at 5 mg/kg resulted in the closing of most fistulae in 68% of patients and of all fistulae in 55%. [337] The median duration of closure was 3 months. Whether fistulae closed on treatment with infliximab would stay closed if the patient were treated indefinitely with azathioprine or 6-MP has not been tested. Although nutritional and medical therapy may play a role in the management of some fistulae in Crohn's disease, the problem of recurrence with the discontinuation of these treatments leaves surgery as the major therapeutic modality. [384] , [385] and [386] Surgical therapy includes resection of the segment involved with active disease. If both loops are involved, both need to be resected; if only one is involved, it should be resected and the other oversewn. Fistulae commonly develop in the high-pressure zone proximal to a stricture. Successful management of the fistula and prevention of recurrence are more likely if the stricture is resected with elimination of the high-pressure zone.

Enterocutaneous fistulae are more often troublesome than enteroenteric fistulae. They commonly occur as a result of anastomotic leaks after resections for active disease. [387] In these cases, the cutaneous end of the fistula is in the scar, and the enteric end is at the anastomosis. Enterocutaneous fistulae also occur spontaneously in the absence of previous surgery. Although the presence of an enterocutaneous fistula does not constitute an absolute indication for surgery, most patients find significant persistent drainage through the abdominal wall to be intolerable. The decision in favor of surgical therapy depends on the amount of drainage, the extent of disease activity, and the patient's nutritional status. More than one cutaneous opening may be present, but usually the enteric ends of the fistulae are close together, and the amount of bowel requiring resection may be no more than if only one cutaneous opening were present.

Rectovaginal fistulae are seen most commonly in active rectal Crohn's disease. [388] Smaller fistulae cause only a foul vaginal discharge, but larger fistulae result in the passage of gas and stool through the vagina. Rectovaginal fistulae usually can be identified by proctoscopy or by speculum examination of the vagina; however, some fistulae are apparent only on barium enema. If the symptoms are minimal, no therapy is necessary. Metronidazole leads to healing in some patients; [389] , [390] however, definitive therapy usually requires surgical intervention. [391] Primary closure has been successful in some patients, whereas diverting colostomy or abdominal perineal resection has been necessary in others. Enterovesicular fistulae usually involve diseased segments of ileum or sigmoid. [152] Signs include gas in the urine (pneumaturia) and recurrent urinary tract infections. Diagnosis may be made by barium enema, upper gastrointestinal series with small bowel follow-through, cystoscopy, or intravenous pyelogram. Definitive surgical management is usually recommended, especially if there are recurrent urinary tract infections, because of the risk of irreversible kidney damage. Surgical therapy includes resection of the involved segment of bowel. The bladder defect may be closed primarily or, more rarely, resected.

Obstruction

Obstruction is a common complication of Crohn's disease, particularly in the small intestine, and is a leading indication for surgery. [116] , [392] Small bowel obstruction in Crohn's disease may be caused by mucosal thickening from acute inflammation, by muscular hyperplasia and scarring as a result of previous inflammation, or by adhesions. Obstruction also may occur because of impaction of a bolus of particularly fibrous material in a stable, long-standing stricture. Obstruction presents with cramping abdominal pain and diarrhea that worsen after meals and resolve with fasting. Symptoms worsen as the obstruction tightens. A common history is that of intermittent episodes of mild cramps and diarrhea, followed by prolonged episodes of severe pain and diarrhea accompanied by nausea and vomiting. The prolonged episodes of symptoms may be brought on by fibrous meals. It is important to distinguish obstruction caused primarily by mucosal inflammation and edema from obstruction caused primarily by scarring because medical therapy may benefit inflammation but will have no effect on scarring. Such a distinction is often difficult, as both processes are usually present, and response to therapy will be determined by whichever effect is predominant. Patients with obstruction caused by inflammation usually have a prolonged course of gradually worsening symptoms: although the symptoms may vary in severity over time, they do not resolve entirely. In contrast, the patient with obstruction caused by scarring may feel well except when totally obstructed. Depending on the anatomic location, strictures may be evaluated by oral contrast studies, barium enema, or colonoscopy. Evaluation of strictures includes assessment of location, length, and lumenal diameter. Dilation of the intestine proximal to the stricture suggests chronicity. There is often an apparent discrepancy between the tightness of the stricture as assessed radiographically and the severity of the patient's complaints. Some patients have minimal complaints with near-obstructing strictures, but others have severe complaints with only modest narrowing. Lesions that block the passage of food particles may allow liquid contrast agents to pass freely; as a result functionally significant strictures and adhesions may be completely missed by radiographic studies.

Initial therapy is to give nothing by mouth, to apply nasogastric suction, and to give intravenous fluids. Anticholinergics should not be used in patients with obstruction. If acute inflammation is an important component of the obstructive process, parenteral corticosteroids may help; however, corticosteroids are not useful in the management of fibrotic strictures. A common error in the management of Crohn's disease is to treat patients with obstructive symptoms from fixed anatomic lesions with long courses of corticosteroids. If the obstruction does not resolve with nasogastric suction and corticosteroids, dilation or surgery is necessary. If the fibrotic stricture is short and accessible, endoscopic balloon dilation can be attempted; more likely, surgical intervention, either resection or stricturoplasty, will be required. [393]

Perianal Disease

Perianal disease is an especially difficult complication of Crohn's disease. [394] , [395] Patients with IBD are subject to the same perianal problems as the general

population, primarily hemorrhoids and anal fissures. Patients with Crohn's disease also may have perianal disease that is specifically associated with Crohn's disease. Although perianal disease can be seen with Crohn's disease anywhere in the gastrointestinal tract, it is seen more commonly in association with colonic disease. Patients with Crohn's disease also develop a complex of problems marked by ulcers in the anal canal which result in perirectal abscesses or fistulae that extend from the ulcers. The fistulous openings are most commonly in the perianal skin but can be in the groin, the vulva, or the scrotum. A single rectal ulcer can give rise to a fistulous tract with multiple openings. The mucosal ends of fistulae often arise from anorectal glands. There are 10 to 12 anorectal glands at the level of the dentate line (see Chapter 92) that extend through the internal sphincter to the intermuscular plane. Two of these glands, one in the anterior midline and one in the posterior midline, are the source of most fistulae and rectal abscesses. These fistulae extend into the intersphincteric space and from there can extend in a variety of directions following tissue planes (Fig. 83-27).

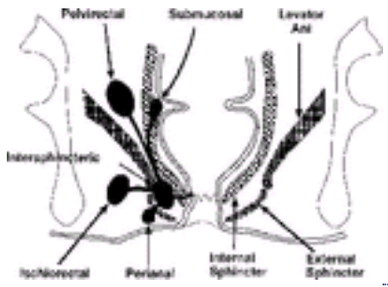

FIGURE 83-27. In Crohn's disease perirectal abscesses develop from fistulous tracts that begin in rectal ulcers of anorectal glands. These fistulae extend into the intersphincteric space and then follow tissue planes to a variety of pelvic locations where abscesses may form.

Fistulae present with drainage of serous or mucous material. If the fistula does not drain freely, there is local accumulation of pus and abscess formation with redness, pain, and induration. Perianal abscesses present with pain that is exacerbated by defecation, sitting, or walking. The typical presentation of abscess is redness and pain in the perianal region with tenderness on digital examination; however, supralevator and pelvirectal abscesses may present with rectal pain or have no local manifestations and may present with fever alone. Usually, perirectal fistulae and abscesses are seen in conjunction with disease activity, but they may occur in the absence of other symptoms and may be the initial presentation of the disease.

Adequate assessment of perianal disease usually requires proctoscopic examination under anesthesia. Barium enema may reveal the course of fistulae. CT scans are useful in defining the presence and extent of perianal abscesses. Endoscopic ultrasound [396] and MRI [397] may be useful in characterizing fistulae. Defining the extent of perianal disease is important for therapy and prognosis. Simple fistulae are low lying and have one external opening. Simple fistulae frequently heal with minimal surgical intervention. Typically, the only surgery required with simple fistulae is a fistulotomy. More complex fistulae and rectovaginal fistulae may require more extensive surgical intervention and have a worse prognosis. Persistent severe perianal Crohn's disease can result in destruction of the anal sphincter and fecal incontinence.

The wide variety of presentations and locations of perianal disease requires individualized therapy. For complex disease, surgical and medical therapy must be combined and coordinated. The goals of therapy in perianal disease are relief of local symptoms and preservation of the sphincter. Abscesses must be surgically drained. The mere presence of a fistula does not require therapy; if it is not causing problems, it does not need to be treated. The aggressiveness of therapy is determined by the severity of the perianal disease. Careful local cleansing with sitz baths is an important first step in management. Limited disease can be approached with sitz baths and antibiotics, but in most cases, adequate external drainage is also required. Setons or drains in the fistulous tracts allow for continuing drainage. Optimal management of perianal complications includes control of disease activity, which reduces the amount of diarrhea passing through the perianal area. Control of disease activity is a more important issue when both perianal disease and rectal disease are present. When active rectal disease is present, effort should be made to minimize disease activity with medical management before any consideration is given to further surgical intervention for perianal disease.

Metronidazole plays a role in the management of perianal disease. Bernstein and colleagues [389], [390] treated perianal Crohn's disease with metronidazole at a dosage of 20 mg/kg/day in divided doses; complete healing occurred in 45% of patients and improvement without complete healing in another 23%. Other investigators also have had success with metronidazole but with a lower response rate. [398] Prolonged therapy at this dosage is associated with a high rate of side effects, of which peripheral neuropathy is the most troublesome. Numbness and tingling in the feet are seen in as many as 75% of patients after 3 months of therapy. [398], [399] Paresthesias usually resolve if the dose is reduced or the drug discontinued. To minimize side effects, particularly paresthesias, initiate therapy at a lower dosage (250 mg four times daily). Discontinuation of metronidazole therapy results in recurrence of perianal disease in most patients, even if complete healing has been achieved. Despite these problems, a trial of metronidazole is recommended if the patient still has significant symptoms after adequate surgical drainage of perianal disease. The experience with ciprofloxacin is less than with metronidazole, but one small series reported success with 1000 to 1500 mg/day for 3 to 12 months. [400] If the response to antibiotics is inadequate, azathioprine or 6-MP can be tried. There is a high rate of success in closing fistulae with these immunomodulators [401] although the time to response is long. Fistulae can also be closed with infliximab. [337] Fistulae recur when the drugs are stopped, and the results of long-term therapy are unknown.

If simple drainage is unsuccessful, there are a number of possible surgical approaches to perianal disease. Many patients respond well to careful surgical drainage and placement of setons and mushroom catheters, which can be left in place for months as the perianal disease slowly heals. Partial internal anal sphincterotomy can be used to remove the cryptoglandular epithelium from which the fistulae arise. [402] An alternative approach is to marsupialize all the fistulous tracts and lay open the crypt of origin. Fecal diversion by colostomy has also been used; however, the general experience is that fecal diversion does not lead to healing of perianal disease. [403], [404]

SURGICAL MANAGEMENT (see also Chapter 84)

Ulcerative Colitis

About 20% to 25% of patients with extensive ulcerative colitis eventually undergo colectomy, usually because their disease has not responded adequately to medical therapy. [405], [406] For some, the indications for colectomy are urgent and compelling, but more commonly the decision for or against colectomy is made at a time when the disease is active but stable. The decision between surgery and continued medical therapy is often not clear, and in many cases arguments can be made for either course. It is important in these cases to attempt to balance the risks and benefits of the two approaches. Excessive enthusiasm for or avoidance of operative therapy are both inconsistent with the patient's best interests. At the time of first diagnosis, the patient may reject even the consideration of eventual colectomy. However, a single prolonged episode of severe colitis or multiple recurrent episodes of more moderate severity increase the patient's desire to eliminate this debilitating disease with its restrictions on activity, and the prospect of colectomy becomes less intolerable.

In ulcerative colitis, colectomy is a curative procedure, in contrast to the situation in Crohn's disease, in which there is a significant likelihood of recurrence sometime after colectomy. [407] The assurance of a permanent cure increases the appeal of colectomy in ulcerative colitis. The development of the ileoanal anastomosis, eliminating the need for an ostomy, has made the idea of colectomy more tolerable for many patients. The patient's age, social circumstances, and duration of disease all influence the decision for or against colectomy. The morbidity of severe ulcerative colitis in childhood and the morbidity of corticosteroids in childhood combine to lead to the early consideration of colectomy as definitive therapy. For young adults with moderately severe disease, colectomy may be more acceptable for those in stable marriages than for those who are single. The risk of developing malignancy enters into the equation when considering colectomy in those with long-standing ulcerative colitis; if the other indications are equivocal, the risk of malignancy may tilt the balance in favor of colectomy.

Emergency colectomy may be required in toxic megacolon or in a severe fulminating attack without toxic megacolon. [408] Although colectomy for acute attacks of ulcerative colitis is more commonly associated with toxic megacolon, it is clear that acute fulminating ulcerative colitis in the absence of colonic dilation also can proceed to perforation. The goal is to recognize the necessity for surgical intervention before perforation occurs. If perforation does occur, it is an absolute indication for surgery. Perforation in this circumstance is a medical disaster, with a 40% mortality rate. [409] For fulminant colitis, in the absence of toxic megacolon, the general indications for operation are similar. Before the patient undergoes colectomy for intractable ulcerative colitis, it is important to rule out complicating conditions that can

be treated. The possibilities of infection with *Giardia* organisms, amoebae, *C. difficile,* and cytomegalovirus should be considered and, if indicated, testing for these organisms should be done. The presence of worsening colitis and especially worsening systemic signs (e.g., fever, prostration, tachycardia, hypotension) in the face of aggressive medical therapy is a sign that surgical intervention may be indicated. Severe hemorrhage is another indication for emergency colectomy.

The failure of medical therapy to control the activity of ulcerative colitis, resulting in an unacceptable lifestyle, is the most common indication for colectomy in ulcerative colitis. There are several varieties of intractability. In one variety, the disease enters a chronic continuous phase in which the patient no longer achieves remission even with maximal medical therapy, and chronic diarrhea is severe enough that the quality of life is severely compromised. Frequent bowel movements prevent the patient from moving far from a bathroom and do not allow normal travel or employment. In some cases, the patient's or the physician's aversion to colectomy results in months or years of functional disability far worse than would have existed if a colectomy had been performed. Another type of intractability occurs when adequate control of the patient's symptoms requires high doses of corticosteroids over a long period. It is appropriate to attempt to reduce steroid requirements by administering azathioprine or 6-MP. The side effects of corticosteroids are dose- and time-dependent and vary considerably from patient to patient. Unacceptable side effects (e.g., psychosis, accelerated hypertension) occur in some patients even with modest doses given over a short period. In these cases, the decision for surgery is clear.

A more difficult and more common problem is the patient who requires moderate to high doses of corticosteroids to control disease activity but who has had no specific problem with the corticosteroid treatment. Although this is a decision in which factors specific to the individual patient play a large role, some general guidelines may be useful. In patients who have taken large doses of prednisone (>15 mg/day) for more than 6 months, even if no specific corticosteroid side effects are present, the morbidity of continued steroid therapy must be weighed against the morbidity of surgery. Ophthalmologic examination for cataract and bone densitometry may help to identify patients with clinically silent corticosteroid side effects. The identification of asymptomatic but clinically important corticosteroid side effects may make the decision for colectomy easier. Growth failure in children is another form of intractability. Adequate nutritional support helps in most young patients, but some require colectomy. Surgical intervention should be strongly considered if growth retardation persists despite maximal nutritional and medical therapy. [410] In such a case, it is important to initiate therapy before puberty and the closing of epiphyses.

Surgery plays a relatively small role in the management of extraintestinal manifestation in ulcerative colitis. Uveitis, pyoderma gangrenosum, and arthritis usually resolve with colectomy. Some other extraintestinal manifestations, including ankylosing spondylitis and sclerosing cholangitis, do not. The extraintestinal manifestations that respond to colectomy usually respond to medical management as well. Extraintestinal manifestations are an infrequent indication for colectomy.

The standard operation for ulcerative colitis is a proctocolectomy and Brooke ileostomy. The use of newer procedures is measured against this standard. Proctocolectomy and ileostomy can be performed in one or two stages. Both have a number of advantages: the procedure is definitive and curative, and additional surgery is seldom required; the patient's functional status with the operation can be predicted with confidence; most patients make a remarkably good adjustment to the ileostomy and lead full, useful lives; many surgeons can perform this procedure successfully.

The major disadvantage of the proctocolectomy and ileostomy is that the patient has an ostomy and is totally incontinent of gas and stool; an appliance must be worn at all times. The most popular alternative operation is ileoanal anastomosis. [411], [412] In this procedure, the colon is removed completely, but the mucosa and submucosa of the rectum are dissected from the muscularis; the mucosa and submucosa are removed and the muscularis, including the internal and external sphincters, is left in place. A pouch is constructed from the terminal 30 cm of ileum. The distal end of the pouch is pulled through the anal canal, and the ileal mucosa is sewed to the dentate line. The advantage of the ileoanal anastomosis is that the patient has no ostomy and no appliance; however, a proximal temporary diverting loop ileostomy commonly is used to protect the ileoanal anastomosis until it heals. For several months after the creation of an ileoanal anastomosis, the patient has numerous bowel movements. [413] The number gradually declines so that, at 12 months, most patients are having five or six bowel movements per day. Twelve months after operation, 75% of patients have complete daytime continence, 23% have daytime seepage (minor staining of underclothes), and 2% have daytime incontinence. [414] Twelve months after the operation, 48% of patients are completely continent at night, 47% have nighttime seepage, and 5% have nighttime incontinence. Results are better for patients younger than 50 years than for older patients. An in-depth discussion of these surgical alternatives is presented in Chapter 84.

Crohn's Disease

Within 10 years of diagnosis, about 60% of patients with Crohn's disease undergo surgery for their disease. [415] The surgical approach to Crohn's disease differs markedly from the approach to ulcerative colitis. Surgical resection is not curative in Crohn's disease as colectomy is in ulcerative colitis. As a consequence, there has been a more conservative approach to the amount of tissue removed, in the knowledge that recurrences are likely and additional surgical resections in the future may be necessary. A controlled trial comparing limited resection (narrow margins) and extended resection (wide margins) found no difference in the incidence of recurrence. [416] Intractability, or failure of medical management, is a common cause for resection in Crohn's disease, as it is in ulcerative colitis, but complications (e.g., obstruction, fistula, abscess) are often indications for resection in Crohn's disease. The line between failure of medical management and a more defined complication, such as obstruction, is often not distinct. If a patient with a radiographically identifiable stricture has symptoms consistent with intermittent partial obstruction (i.e., diarrhea and pain brought on by eating) and does not respond to medical management, it is difficult to say whether the indication for surgery is obstruction or failure of medical management. Indications for surgery have been used for defining two subsets of patients with Crohn's disease, those with perforating indications (perforation or fistula) and those with nonperforating indications (obstruction or stricture). [417] If a patient's initial surgery was for a perforating indication, it is likely that subsequent surgeries also will be for perforating indications; similar results are seen with surgery for nonperforating indications.

Defining the point at which medical management has failed in Crohn's disease is somewhat more involved than in ulcerative colitis, because in Crohn's disease symptoms may not be caused by disease activity. Diarrhea and weight loss may be results of fatty-acid malabsorption, bile salt–induced colonic secretion, or small bowel bacterial overgrowth. Pain may not be due to obstruction. Optimal medical management requires recognition and treatment of these disorders. If these problems are not identified, patients may be subjected to unnecessary surgery.

As in ulcerative colitis, surgery for failure of medical management in Crohn's disease falls into two groups. In the first group, surgery is required because the progression of the disease has led the patient to a condition of unacceptable disability and invalidism despite optimal medical management. Whereas in ulcerative colitis the major source of disability is diarrhea, in Crohn's disease there is more commonly a combination of diarrhea, pain, weight loss, and malnutrition. In evaluating the possibility of surgical intervention in ulcerative colitis, the patient's current morbidity from disease activity is balanced against the relatively predictable morbidity of a colectomy. In Crohn's disease, however, the current morbidity must be balanced against the less well-defined morbidity of more limited surgery and also against the projected long-term morbidity as the disease progresses. Another distinction between surgical therapy in ulcerative colitis and Crohn's disease is that surgery for ulcerative colitis is almost always performed to remove actively inflamed tissue, but surgery for Crohn's disease may be required to remove actively inflamed tissue or to remove the sequelae of inflammation. For example, strictures requiring surgical intervention may occur in Crohn's disease at the site of a surgical anastomosis where there is considerable scarring with only a modest amount of active inflammation. This distinction is important because there is no point in treating a stricture with a therapeutic trial of steroids if scarring and fibrosis has caused the stricture. In addition, if the problem is known to be largely scar tissue and fibrosis, a stricturoplasty can be done or the extent of the surgical resection can be limited to the area of narrowing without worry about maintaining adequate uninflamed margins.

The second group of patients who undergo surgery for failure of medical management in Crohn's disease are those suffering side effects from drugs, usually corticosteroids. The guidelines for surgical intervention in patients with Crohn's disease with complications of medical therapy are exactly the same as for patients with ulcerative colitis. A problem frequently faced by physicians treating Crohn's disease is the patient whose disease is controlled with corticosteroids but flares if the dose of corticosteroids is reduced below a certain level. The level varies from patient to patient, but one study put the average at 0.15 mg of prednisone per kilogram per day. [418] Several options are available in this circumstance. One approach is to maintain the patient at a steroid dose above the critical level and to monitor the patient carefully for manifestations of steroid toxicity. This follow-up includes bone densitometry and ophthalmologic examinations. A second approach, not exclusive of the first, is the use of immunomodulators to achieve a steroid-sparing effect. This approach trades potential complications of corticosteroids for those of immunomodulators. A third approach is to resect the involved segment, knowing that the chance of eventual recurrence is high. Each of these approaches has advantages and disadvantages, all of which should be explained to the patient before a decision is made.

The incidence of recurrence after ileal resection for ileitis or ileocolic resection for ileocolic disease is about 50% after 10 years and 75% after 15 years as assessed by rates of reoperation. [419] If the presence of recurrence is assessed endoscopically, it is clear that recurrence after resection occurs more rapidly than previously appreciated. [132] Routine colonoscopic surveillance 1 year after ileocolic resections revealed a 72% incidence of recurrence, as manifested by the presence of aphthous ulcers on the ileal side of the ileocolic anastomosis. [419]

A surgical alternative to resection for small intestine strictures, termed stricturoplasty, involves longitudinal incision of the strictured segment, followed by transverse closure. [420], [421] This method preserves bowel and has a low rate of complications. [422], [423]

Surgical approaches to Crohn's colitis include segmental resection, subtotal colectomy with ileoproctostomy, and total colectomy with ileostomy. Segmental resection of Crohn's colitis is appropriate if a relatively short segment of colon is involved. Recurrence rates are high, approximating those described for ileal and ileocolic disease. Subtotal colectomy with ileoproctostomy should be considered only in a patient with an absolutely normal rectum. [424] Even in selected patients, the recurrence rate after this procedure is high, about 75% at 10 years. [425] For patients with extensive disease including the rectum, the procedure of choice is total proctocolectomy with a Brooke ileostomy. Total colectomy with ileoanal anastomosis is not appropriate in Crohn's colitis because recurrence of Crohn's disease in the ileal segment forming the new pouch would require a repeat operation and loss of a long segment of ileum.

COLON CANCER, DYSPLASIA, AND COLONOSCOPIC SURVEILLANCE

Patients with extensive ulcerative colitis have a markedly increased risk for colon cancer compared with the general population. The magnitude of this risk is uncertain. Early reports of extremely high incidences of colon cancer among patients with ulcerative colitis (50% cumulative risk at 30 years) were biased by the use of referral-based populations that were not representative of the general population. [426] A report of the experience of a private gastroenterology practice in New York probably comes closer to the experience in the general population. In this practice, the probability that colon cancer would develop in patients with extensive colitis was 11.7% at 26 years. [427] Retrospective studies reveal cumulative risks as high as 34% at 25 years in Sweden and as low as 1.4% at 18 years in Denmark. Several series have put the lifetime risk of cancer in ulcerative colitis patients in the 3% to 5% range. [428], [429] and [430] The identified risk factors for colon cancer in patients with ulcerative colitis include duration and extent of disease, primary sclerosing cholangitis, and the presence of backwash ileitis. A family history of colorectal cancer is an independent risk factor as well. The risk of developing cancer becomes appreciable 8 to 10 years after diagnosis and increases with time. Age of onset of ulcerative colitis seems to have little impact on the annual incidence of colon cancer. The risk of malignancy, however, is a larger issue for those who develop ulcerative colitis earlier in life because they have a longer period in which they are at risk and thus a higher cumulative incidence of cancer. Recent studies have suggested that among patients developing ulcerative colitis after the age of 45, the risk of cancer might increase in less than 8 to 10 years. Colon cancer in the general population is a disease of late middle and older age, but in ulcerative colitis, colon cancer occurs earlier and is commonly seen in the fourth decade of life. The risk of malignancy is also a function of the anatomic extent of the disease; the risk is much greater with pancolitis than with left-sided disease. Those with pancolitis and backwash ileitis are at greater risk than those with pancolitis alone. [431] Patients with long-standing ulcerative colitis are at risk for developing cancer even if their symptoms have been relatively mild. [426], [432] Patients are seen with colon cancer whose ulcerative colitis has been quiescent for 10 to 15 years.

The response of the medical community to the risk of colon cancer in ulcerative colitis has been that the increased risk is too high to ignore but not high enough to recommend prophylactic colectomy at some arbitrary time after diagnosis. These circumstances led to a desire to be able to identify patients at special risk for colon cancer so that they can be offered a colectomy before the development of malignancy or after malignancy has developed but curative resection is still possible. Examination of stool for occult blood is a widely used screening test for colon cancer in the general population, but it is useless in ulcerative colitis because of colitis-induced bleeding. Even overt symptoms are of less use in identifying colon cancer in ulcerative colitis than in the general population. Rectal bleeding, a symptom associated with left-sided colon cancers in the general population, is a common feature of ulcerative colitis and thus is not a reliable marker for the presence of malignancy.

Surveillance colonoscopy is used in patients with long-standing ulcerative colitis to search for malignancies and to obtain random mucosal biopsies to be examined for dysplasia. In patients with ulcerative colitis, colon cancers are often submucosal and may be easily missed at colonoscopy. Dysplasia, if present, does not occur universally throughout the colon but only in certain areas, and cannot be identified by visual inspection but only by microscopic examination of biopsies.

The pathology of colon cancers in ulcerative colitis also differs from that in the general population. Multicentric tumors account for only 2% to 3% of all colon cancers in the general population, but for up to 26% of colon cancers in patients with ulcerative colitis. [428], [433], [434] Cancers in ulcerative colitis are more likely to be largely submucosal. The tumor may be indistinguishable from the surrounding mucosa; it may appear as a flat, plaquelike lesion, or it may present as a stricture. The large exophytic masses with sharp margins seen in colon cancer in the general population are less common in ulcerative colitis.

Dysplasia is an unequivocal neoplastic transformation in the epithelium without penetration to the lamina propria. It is marked by nuclear stratification, loss of nuclear polarity, and nuclear and cellular pleomorphism (Fig. 83-28). In 1967, Morson and Pang [435] reported a group of nine patients with ulcerative colitis who were found to have dysplasia on rectal biopsy and underwent colectomy. Of these nine patients, five were found to have malignancies elsewhere in the colon. The investigators then reviewed 23 colon specimens removed for cancer in patients with ulcerative colitis and found that all of them had areas of dysplasia. Other groups confirmed these observations, and it is now clear that about 88% of colons resected for malignancy in ulcerative colitis have dysplasia somewhere in the specimen. These findings suggest that dysplasia may precede the development of carcinoma and that dysplasia may be a marker to identify patients with ulcerative colitis who have developed or are at risk of developing carcinoma. [436] Dysplasia should therefore be viewed as not a marker for future cancer but indicative of a high risk of concurrent cancer in the colon at that point in time. This finding, in turn, led to the suggestion that patients with long-standing ulcerative colitis undergo periodic colonoscopy with biopsies and, if the biopsies show dysplasia, prophylactic colectomy.

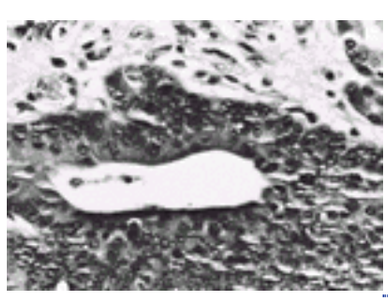

FIGURE 83-28. High-grade dysplasia with nuclear stratification, nuclear and cellular pleomorphism, and loss of nuclear polarity. Compare with Figure 83-19, in which nuclear polarity is clearly preserved despite the presence of inflammation. (Courtesy of David Lacey, M.D., St. Louis, MO.)

This plan of action, however, has several problems. The first is that dysplasia is not easy to read on colonic biopsy, and interobserver variation is considerable. A group of pathologists developed a classification for dysplasia that should help to resolve this problem. [437] This classification divides biopsies into negative, indefinite, and positive groups; the positive group is further divided into those of high-grade and low-grade dysplasia. Even in major academic centers, considerable interobserver variation occurs in diagnosing low-grade dysplasia. A second problem is that the presence of inflammation often makes it effectively impossible to decide whether dysplasia is present. A third problem is that, although dysplasia may be extensive, it is more often patchy and can be missed entirely if blind biopsies are taken at 10-cm intervals through the colon. In some cases, dysplasia exists only in small patches in the immediate vicinity of the tumor. Although 88% of carcinomas are associated with dysplasia elsewhere in the specimen, this does not mean that colonoscopy with biopsies will always find the dysplastic area.

In one group of patients the finding of dysplasia appears to have special meaning: those in whom dysplasia is found in the vicinity of a suspicious lesion or mass. [438], [439] This condition is called DALM (dysplasia-associated lesions or masses). Preliminary figures suggest that if an endoscopically visible lesion and low-grade dysplasia are present together on a first colonoscopy, there is a 40% chance the lesion will be carcinoma; if high-grade dysplasia and an endoscopically visible lesion are present, the incidence of colon cancer increases to 60%. However, recent studies have suggested that not every polyp needs to be considered a DALM. [440] Some patients with ulcerative colitis can be followed safely after polypectomy without colectomy, though with conservative surveillance. [441] Polypectomy with biopsy around the base is recommended to determine if the adenoma arose from a fat lesion. This approach to polypectomies is recommended for patients with ulcerative colitis, particularly for those in whom an adenoma developed in mucosa proximal to the extent of colitis or in those whose polyp did not arise from a dysplastic, flat lesion.

The association of dysplasia and colon cancer in ulcerative colitis is firmly established, but the benefits of surveillance for dysplasia are less clear. [442], [443], [444] and [445]

The usual approach to surveillance has been to perform a screening colonoscopy with biopsy in patients with pancolitis of 7 to 10 years' duration. The value of this screening examination is well established. What is less clear is the value of surveillance colonoscopy with multiple biopsies done every 1 to 2 years later.

After the pathological diagnosis of either high-grade or low-grade dysplasia has been made, the next step is to decide on management. A wide range of approaches to management can be found in the literature. If the diagnosis of high-grade dysplasia is made and confirmed by an experienced pathologist, the patient should have a colectomy. The approach to low-grade dysplasia probably should be the same as the approach to high-grade dysplasia. Some authors have recommended that if the diagnosis of low-grade dysplasia is made, the colonoscopy and biopsy should be repeated and the patient should have a colectomy if the diagnosis is confirmed. Low-grade dysplasia is a neoplastic lesion, however, and is usually patchy so that repeat endoscopy with biopsy may miss the dysplastic area. In one series of patients undergoing colectomy for low-grade dysplasia, 19% were found to have colorectal cancer. [446], [447] In addition, surveillance of patients with low-grade dysplasia eventually found high-grade dysplasia in a high percentage of cases. [448] On this basis, some recommend colectomy on a single firm diagnosis of low- grade dysplasia. Repeat biopsies should be reserved for a reading of indefinite dysplasia.

Table 83-8 shows the results of four large studies of surveillance in ulcerative colitis. [438], [448], [449], [450], [451], [452] and [453] These results are difficult to interpret. The most obvious success is identification of seven patients with Dukes stage A carcinoma. How does one interpret the 46 patients who, as a result of surveillance studies, had colectomies that contained dysplasia but no carcinoma? Some would declare all these to be surveillance successes, but we do not know how many of these patients would have developed carcinoma if untreated. We know that there is a high incidence of dysplasia in patients with ulcerative colitis whose colons were resected for carcinoma. However, both the *sensitivity* (how many patients with ulcerative colitis with early cancer will have biopsies positive for dysplasia) and the *specificity* (how many people who test positive for dysplasia will go on to develop cancer) for dysplasia surveillance are unknown. Thus, despite huge amounts of effort over a long period, we do not have the information to make clear recommendations about the usefulness or the timing of surveillance. Developing guidelines for surveillance would be much easier if we had a clearer idea of the magnitude of the risk of developing carcinoma in ulcerative colitis. It would be easier to be enthusiastic about a program that called for prophylactic colectomy in patients with ulcerative colitis with dysplasia if the cumulative lifetime risk of patients with ulcerative colitis developing colon cancer were 25% than if it were 2%.

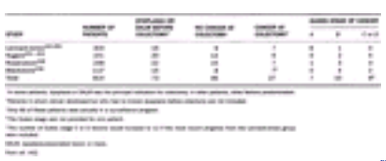

TABLE 83-8 Summary of Four Surveillance Studies in Patients With Ulcerative Colitis

The present system of surveillance is not ideal, but no more definitive or more useful alternative markers of malignancy in ulcerative colitis have been identified. There is also no clear evidence that surveillance improves survival. How should the practitioner deal with the issue of surveillance in the face of inadequate data? The first step is to inform the patient of the risks of malignancy. Patients with long-standing quiescent disease need this information as much as those with active disease because they too are at increased risk. Similarly, patients with subtotal colectomies and retained rectums need to know that they are at risk. The second step is to explain the purpose of surveillance. If the patient would refuse colectomy even if high-grade dysplasia were found, there is no purpose in initiating surveillance. Conversely, knowledge of the increased risk of malignancy may drive the patient to seek a prophylactic colectomy, especially if he or she has already suffered severe problems from disease activity. Another consideration is the availability of a pathologist competent to evaluate dysplasia. Many pathologists have little or no experience in identifying and grading dysplasia in ulcerative colitis.

If the patient is willing to undergo surveillance and competent pathology support is available, the next question is the design of the surveillance protocol. Most protocols involve taking three or four biopsies every 10 cm throughout the colon. It is important that the entire colon be examined. Biopsies should be taken from uninflamed areas. [437] The colon also should be examined for masses, strictures, and plaquelike lesions, and biopsies be performed on any that are found. Additionally the colon should be examined for polyps, which should be removed. Pseudopolyps are not premalignant lesions and need not be removed. Surveillance should begin about 8 to 10 years after the start of pancolitis and can be delayed longer than that for left-sided disease. Some protocols call for colonoscopy every year, but that is probably excessive. One group calculated the optimal screening interval on a cost-benefit basis and suggested surveillance every 3 years initially and then more frequently as the duration of the disease and the risk of malignancy increase. [454] The algorithms for most surveillance programs are similar, and the specifics of one are given in Figure 83-29. High-grade dysplasia associated with a mass or lesion is a strong indication for colectomy. High-grade dysplasia, even without an associated lesion, is also reason for colectomy. Low-grade dysplasia is viewed by some as an adequate indication for colectomy. Despite the absence of evidence for increased survival, most clinicians use a surveillance program for patients with long-standing extensive disease. Although most gastroenterologists use some surveillance protocol, it would be difficult to fault one who, because of the absence of a well-documented benefit to surveillance, did not engage in any surveillance program. In addition, administration of folic acid at 1 mg daily has been advocated to reduce the risk of colorectal cancer. Although hardly conclusive, the data suggest that low red cell folate levels correlate with a greater risk of cancer. [243] But as controlled trials are likely never to be done, given the benign nature of folic acid supplementation and the supportive evidence for a role in decreasing the risk of colon cancer in individuals without ulcerative colitis, many recommend daily folate supplementation for their patients.

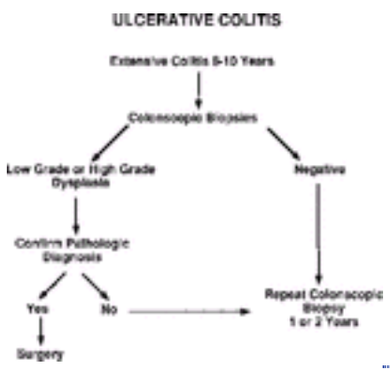

FIGURE 83-29. A proposed system of surveillance for cancer in patients with ulcerative colitis using colonoscopy and biopsy.

Much less information is available on cancer in Crohn's disease than in ulcerative colitis. [455] For those with Crohn's colitis, the incidence of colon cancer is higher than in the general population; the risk of colorectal cancer in extensive Crohn's colitis appears to be similar to that of ulcerative colitis. [441], [456], [457] As with ulcerative colitis, the incidence of colon cancer in Crohn's colitis increases with the duration of the disease and is associated with dysplasia. Also, as in ulcerative colitis, colon cancers occur in patients with Crohn's disease at a younger age than in the general population. A similar surveillance strategy has been suggested with extensive Crohn's colitis as with ulcerative colitis. [457]

An association between small intestine Crohn's disease and adenocarcinoma of the small intestine has been found. [458] Most adenocarcinomas occur in areas of the small intestine actively involved with Crohn's disease. Adenocarcinoma of the small intestine occurs at an earlier age in patients with Crohn's disease than in the general population. There is also an association of small intestine adenocarcinoma with surgically bypassed loops of small bowel. It is not clear whether the high incidence of cancer in bypassed bowel is a product of the bypass procedure or merely reflects the long duration of the disease.

PREGNANCY AND INFLAMMATORY BOWEL DISEASE

Because IBD affects many women in early adulthood, the effect of IBD on pregnancy is an important clinical issue. Fertility in women with IBD is normal or only

minimally impaired. [459], [460] Fertility in men taking sulfasalazine is diminished but returns to normal a few months after cessation of the drug. [255], [461]

Most pregnancies in women with IBD produce healthy babies. The incidences of prematurity, stillbirth, and developmental defects are similar to those of the general population. [273] The incidence of spontaneous abortion is slightly higher in women with IBD (12.2%) than in the general population (9.9%). There is some suggestion that the incidence of fetal complications is somewhat higher in cases in which the mother's disease is clinically active, irrespective of drug therapy. [273] The incidences of prematurity and spontaneous abortion are both higher in patients with more active disease. Previous proctocolectomy or the presence of an ileostomy is not an impediment to the successful completion of a pregnancy. [462]

Many women with IBD take medication on a chronic basis, and the possibility of the fetus suffering undesirable effects from the drugs is a matter of concern. [463], [464] Many women have taken sulfasalazine throughout the course of pregnancy, and there is no evidence for its causing harm to the fetus or newborn. In one series of 174 patients, sulfasalazine had no effect on spontaneous abortion, prematurity, or fetal weight. [272] Pregnant women have an increased requirement for folic acid, and sulfasalazine interferes with folate absorption. Women taking sulfasalazine who are pregnant or considering pregnancy should receive folate supplementation (1 mg twice daily) to ensure that the fetus receives amounts adequate for normal development. Up to 1 mg daily of folate supplementation is now recommended for all pregnant women to prevent congenital neural tube malformations. It seems reasonable, therefore, that all women taking sulfasalazine who are pregnant or contemplating pregnancy should take 2 mg of folate daily to ensure absorption of adequate amounts, as the period surrounding conception is the most critical for neural tube development. The use of corticosteroids by pregnant women with IBD is not associated with an increased rate of fetal complications. [272] In general, it appears that the risks to the pregnancy of treatment with sulfasalazine or corticosteroids are less than the risks of allowing disease activity to go untreated. Nonetheless, it is advisable for pregnant women to minimize their exposure to drugs, and sulfasalazine and corticosteroids should be withdrawn if possible. Even better, the patient should delay becoming pregnant, if possible, until her disease is quiescent and drugs can be withdrawn.

Most data on azathioprine and 6-MP in pregnancy come from the transplant literature and involve higher doses than are commonly used in IBD. Reported fetal effects in the transplant population include congenital malformations, immunosuppression, prematurity, and growth retardation. Risks in the IBD population are not known. It may be reasonable for a patient to continue maintenance therapy through pregnancy if the potential risks to the fetus are explained. Breast-feeding is not recommended for women taking these drugs. Methotrexate induces abortions and should not be used in women at risk for pregnancy. Metronidazole, in the short courses used to treat trichomoniasis, appears to be safe in pregnancy, although there are no data with the longer courses commonly used in IBD.

A number of studies have assessed the effects of pregnancy on disease activity in IBD. If the patient's disease is inactive at the time of conception, it is likely that it will remain inactive during the course of the pregnancy. [465], [466] If the disease is active at the time of conception, the course is harder to predict. Ulcerative colitis that is active at the time of conception tends to worsen. In two thirds of Crohn's disease cases that are active at conception, the degree of activity remains the same; among the other third, some improve clinically and others deteriorate.

INFLAMMATORY BOWEL DISEASE IN CHILDHOOD AND ADOLESCENCE

Although the peak incidence of IBD is in young adulthood, 15% of patients with ulcerative colitis and 25% to 33% of patients with Crohn's disease present before 20 years of age. For the most part, IBD presenting in childhood is similar to the disease in adults. The clinical presentation of ulcerative colitis in childhood, as in adulthood, is marked by diarrhea and rectal bleeding. The clinical presentation of Crohn's disease, however, is somewhat different in childhood. [467] Abdominal pain, weight loss, and diarrhea are common in both adults and children, but extraintestinal manifestations (e.g., arthritis, iridocyclitis, clubbing, erythema nodosum) are more likely to be major components of the initial clinical presentation in children than in adults. Abdominal pain in Crohn's disease tends to be periumbilical and colicky and is confused with the pain of functional disease.

Growth failure is a major presenting complaint in 30% of children with Crohn's disease. [467], [468] and [469] In mild disease of short duration, growth failure manifests itself as reduced weight for height; but, in long-standing disease, linear growth may be markedly retarded. Retarded bone development and delayed sexual maturation also may be manifestations of growth failure. In one third of children with impaired growth and Crohn's disease, the failure of linear growth antedates the onset of intestinal symptoms. Malnutrition appears to be the major cause of growth retardation. Poor oral intake and malabsorption both contribute to malnutrition. Poor oral intake results from anorexia and food avoidance as a result of pain and diarrhea associated with eating. Hypoalbuminemia is common, as is anemia, which may result from blood loss or from diminished intake of iron and folate. In addition to malnutrition, the presence of inflammation may contribute to growth failure. Extensive inflammation increases caloric requirements. Whether cytokines and other factors produced during inflammation contribute to growth retardation is unknown. Corticosteroid therapy also may contribute to growth failure. Growth retardation is less common in children with ulcerative colitis than in those with Crohn's disease.

Diagnosis of Crohn's disease in children is commonly delayed. The prominence of extraintestinal manifestations and growth retardation and the lesser role of intestinal symptoms contributes to the delay in the consideration of Crohn's disease as a diagnosis. Recurrent abdominal pain with or without diarrhea is a common complaint in childhood and usually reflects no significant pathology. In Crohn's disease, however, pain and diarrhea are seldom the only presenting symptoms. [467] Urgency, rectal bleeding, fever, and weight loss are signs that the child's abdominal pain is not on a functional basis and suggest that evaluation for IBD is indicated. Findings of perianal disease, uveitis, clubbing, or arthritis should suggest the possibility of Crohn's disease.

Nutritional supplementation plays a major role in the management of IBD, particularly Crohn's disease, in childhood. Children have smaller nutritional reserves and higher nutritional requirements per kilogram than adults. Moreover, nutritional deficiencies are a major source of growth retardation in childhood IBD. Oral supplementation with liquid formulas, [470] continuous supplementation by nasogastric tube, [471] and TPN all have been successful in reducing symptoms and reversing growth retardation. Irrespective of the method of delivering nutrition, all programs attempt to administer a number of calories in excess of the number recommended for healthy children, because the children with Crohn's disease have lost weight. Calorie intake on the various regimens ranges from 50 to 93 kcal/kg daily and protein intake ranges from 1.6 to 3.5 g/kg daily.

Medical management of IBD in childhood (reviewed by Winter and Grand [472]) is largely the same as in adulthood. All the major controlled studies of therapy in IBD purposefully excluded children. Treatment in children is extrapolated from those studies. The indications for sulfasalazine therapy in children are the same as in adults. In children, sulfasalazine is begun at 25 to 40 mg/kg daily and increased to 75 mg/kg daily. The indications for corticosteroid therapy are also the same as for adults with IBD. Typical starting doses for moderate to severe disease would be 1 to 2 mg of prednisone per kilogram per day. Continuous therapy with prednisone in doses as low as 10 mg/day can inhibit normal growth. After acute symptoms are under control, an attempt should be made to convert the patient to an every-other-day prednisone regimen. [473] If prednisone is given as a single dose every other day, the side effects are markedly reduced. In particular, prednisone at doses as high as 40 to 50 mg every other morning allows normal growth in some children, although lower doses (10–20 mg every other day) are more likely to be compatible with normal growth. [474] Not all patients can be converted to an alternate-day regimen, however. In some patients, the disease flares on the day off prednisone.

Immunomodulators, specifically 6-MP and azathioprine, have been used in childhood Crohn's disease much as they have been used in the adult disease. [474], [475] and [476] Reservations about side effects are, if anything, greater if these drugs are used in children. The possibility of malignancy is particularly worrisome in children, who have the potential for longer exposure. Nonetheless, the problems with steroid therapy in children are so great that a trial of 6-MP or azathioprine is probably justified in steroid-dependent children.

Indications for colectomy in ulcerative colitis in childhood are the same as for adults, with the addition of growth failure as an indication. Growth failure may be the result of either disease activity or corticosteroid administration. Surgical resection of localized areas of disease activity may be useful in children with Crohn's disease; however, the success of surgical resections in reversing growth retardation has been disappointing. CHAPTER 84

Alessandro Fichera and Fabrizio Michelassi

SURGICAL TREATMENT OF INFLAMMATORY BOWEL DISEASE

Crohn's disease, ulcerative colitis, and the rare forms of true indeterminate colitis represent a disease spectrum with protean manifestation and complications. Although as many as half of the patients with inflammatory bowel disease require at least one surgical procedure during their lifetime, the decision to operate is rarely an easy one. Such a decision should be the result of a thorough collaboration between the gastroenterologist and the surgeon, assisted by the radiologist and the pathologist. Factors to take into consideration are the age and the general conditions of the patient; the extent of the disease; the duration of the disease and the treatment offered to that point; and the specific complication in regard to the available treatment options. Once the need for surgical intervention has been established, other factors, specific to each individual presentation, must be considered in order to choose the most appropriate surgical procedure. This chapter addresses surgical options and their results in view of the different indications for surgical treatment of inflammatory bowel disease. Emphasis is given to new options offered by advances in laparoscopic surgery.

CROHN'S DISEASE

Crohn's disease is a heterogeneous entity, which requires individual approaches for management due to the variety of intestinal segments affected and the different clinical manifestations of the disease. The first attempt to classify patients with Crohn's disease was based on the anatomic locations of the disease. [1] Subsequently Greenstein and Greenstein [2] proposed that perforating and nonperforating presentations might separate patients into two different clinical forms of Crohn's disease. Indeed recurrent postoperative disease usually follows the pattern of the initial presentation. [2], [3] The more recent Vienna Classification divides patients with Crohn's disease into groups based on age at diagnosis, location of involved segment, and clinical behavior (nonstricturing and nonpenetrating, stricturing and penetrating). [4] These distinctions have proven implications with respect to medical therapy, indication for surgery, and risk of postoperative recurrence.

The majority of patients presenting with uncomplicated active disease are initially treated with medical therapy. Although medical therapy has become more sophisticated with the adoption of new biologic agents, it still fails to significantly change the natural history of the disease. [5], [6] Patients still tend to require surgery as time progresses: after 20 and 30 years of symptoms, 78% and 90% of patients, respectively, require surgery. [7]

Indications for Surgery in Crohn's Disease

The chronic, unrelenting, and recurrent nature of Crohn's disease brings these patients to the attention of the gastroenterologist during the early phases of the disease. [1] In the absence of complications, the initial management is medical, until the treatment fails or a complication ensues. Table 84-1 lists the indications to surgical treatment.

Sepsis
Inflammatory masses or abscesses
Fistulae
Perforation
Failure of medical therapy
Obstruction
Hemorrhage
Cancer
Fulminant colitis with or without toxic megacolon

TABLE 84-1 Indications for Surgery in Crohn's Disease

A significant number of patients with perforating Crohn's disease present with septic complications as the first presentation or recurrence. [2] Not all the septic complications are an absolute indication for surgery, rather they are a marker of a severe and aggressive form of the disease. Fistulae are identified in one third of patients with Crohn's disease, [8] but they are rarely the primary indication for surgery. Specific indications for surgical treatment include enterocutaneous and enterovaginal fistulae, where the enteric drainage becomes a matter of personal embarrassment for the patient; [9] enterovesical or colovesical fistulae, where the connection of the intestine to the genitourinary system causes repeated urinary tract infections and eventually impairment of renal function; [10] and those enteroenteric fistulae that produce functional and anatomic bypass of a major segment of intestine with consequent malabsorption and/or profuse diarrhea. Inflammatory masses and abscesses occur in as many as 20% of patients. [8], [11] These patients should be treated with antibiotics, the abscesses drained percutaneously, if feasible, and surgery should be postponed until a definitive procedure can be safely performed. Primary free perforation is a very unusual complication of Crohn's disease: usually the severity of the transmural inflammation leads to the formation of adhesions, which wall-off the perforation resulting in an abscess. The secondary rupture of an abscess into the abdominal cavity requires prompt surgical intervention.

Medical treatment has failed and surgery is necessary (a) when maximal medical therapy proves inadequate; (b) for those patients who may be asymptomatic while on maximal medical therapy, but develop recurrence of symptoms with tapering of the medications; (c) when the disease progresses with worsening symptoms or a complication arises while the patient is receiving maximal medical therapy; and (d) in the presence of significant treatment-related complications, including steroid-induced Cushingoid features, cataracts, glaucoma, hypertension, aseptic necrosis of the head of the femur, myopathy, vertebral body fractures, myelosuppression, anaphylactic reaction, or growth retardation in children. [12] In our series, failure of medical therapy was the primary indication for surgery in 33.6% of patients. [8]

As many as 22% of patients present to the surgeon with worsening obstipation. [8] Symptoms are caused by a single or multiple strictures or a lengthy diseased segment and differ depending on the location of the disease in the gastrointestinal tract: delayed gastric emptying in gastroduodenal disease; postprandial cramps in

jejunoileitis; distention, pain, and diarrhea in colonic disease; laborious defecation in perianal Crohn's disease. Intestinal obstruction, even when complete, is rarely an indication for urgent surgery. In general, it is advisable to let the obstruction, even if complete, resolve with nasogastric decompression, intravenous hydration, and medical therapy and to postpone surgery after resolution of the obstruction to allow for a definitive procedure (i.e., strictureplasty or resection).

Other less frequent complications requiring surgical treatment include gastrointestinal hemorrhage, cancer, and toxic megacolon. Massive hemorrhage is an extremely rare complication occurring in less than 1% of patients. [1], [13] Preoperative localization studies are mandatory to minimize the length of intestine resected. Cancer has been described in the small bowel [14] and the colon [15] and in a previous strictureplasty site. [16] The risk of cancer correlates with duration of the disease and may be higher in bypassed loops. Surgery for cancer in patients with Crohn's disease follows the same oncologic principles as for sporadic cancers. Fulminant colitis with or without toxic megacolon is a known entity in inflammatory bowel disease. [17], [18] The surgical treatment of this complication will be discussed in more detail in the ulcerative colitis section of this chapter.

Crohn's Diseases of the Stomach and Duodenum

Crohn's disease may involve any portion of the gastrointestinal tract, from the mouth to the anus. About 2% to 4% of patients with Crohn's disease present with involvement of the stomach or duodenum. [19] The most common indications for surgical treatment include hemorrhage and obstruction [20] (Fig. 84-1). Indeed, in a recent review of 108 patients, 83% underwent surgery for this complication. [21] Multiple surgical procedures have been advocated for the treatment of gastroduodenal Crohn's disease. Resectional antiulcer procedures have been performed mostly in situations in which an ulcer was misdiagnosed, and they have been associated with high morbidity and mortality rates. [19] Bypass procedures, such as gastrojejunostomy with or without vagotomy, have been the procedures most often advocated. Based on the location of the disease, gastroduodenostomy or duodenojejunostomy have also been advocated. These procedures are associated with good short-term outcome and acceptable morbidity rates, although delayed gastric emptying occurs in up to 24% of patients, [22] occasionally requiring reoperation. [23] Strictureplasty has been advocated as an alternative to bypass procedures in selected patients. Only two retrospective reports are available that compare strictureplasty with bypass surgery for treatment of gastroduodenal Crohn's disease. [22], [23] With a follow-up between 42 and 192 months the strictureplasty-treated group had a lesser rate of delayed gastric emptying (15% vs. 24%), but suffered more anastomotic dehiscences (12% vs. 6%) and had a higher rate of repeated surgical interventions: 11 of 26 patients (42%) required a second operation after strictureplasty, 9 of them due to recurrent Crohn's disease, compared with 24% in the bypass-treated group. [22], [23] Based upon these limited data, both bypass and strictureplasty procedures appear to offer merit in appropriately selected patients.

FIGURE 84-1. Upper gastrointestinal barium study showing Crohn's disease of the third and fourth portions of the duodenum. (From Block GE, Michelassi F, Tanaka M, et al. Crohn's disease. Curr Probl Surg 1993;30:173.)

Crohn's Disease of the Small Bowel

The jejunum and ileum, not including the terminal ileum, are affected by Crohn's disease in 3% to 10% of patients. [8], [24] The two most common indications for surgical treatment are obstruction and sepsis; massive hemorrhage and carcinoma are much less common. Chronic, high-grade small bowel obstruction may be caused by single or multiple, short or long strictures. These patients present with postprandial abdominal pain, nausea, and vomiting and often progress to a high-grade obstruction. When multiple tight strictures are present, the small bowel is transformed into a sequence of dilated saccular segments separated by tight, ringlike strictures (Fig. 84-2). The dilated segments, which contain partially digested food particles, become the ideal environment for bacterial overgrowth. Because of bacterial overgrowth and stagnation, patients report symptoms of occasional diarrhea, malabsorption, and vitamin B_{12} deficiency.

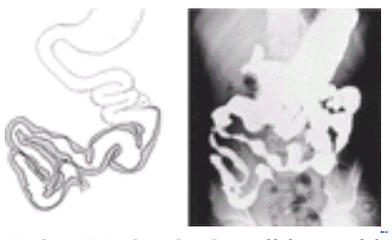

FIGURE 84-2. Small bowel barium study showing extensive jejunoileal disease with strictures and saccular dilations. (From Block GE, Michelassi F, Tanaka M, et al. Crohn's disease. Curr Probl Surg 1993;30:173.)

With this clinical picture, patients have traditionally undergone resection of long segments of small bowel. Considering that Crohn's disease is a recurrent disease and up to 30% of patients require a second operation, [25] short bowel syndrome may eventually be precipitated in 1.5% to 12.6% of cases. [26], [27] In an attempt to preserve bowel length, Lee and Papaioannou in 1982 [28] and subsequently Alexander-Williams and Haynes in 1985 [29] described the use of strictureplasty, which had been previously described in India to correct tubercular stricture of the terminal ileum and cecum. [30]

Many different strictureplasty techniques have been described. The most popular are the Heineke-Mikulicz, the Finney, and the side-to-side isoperistaltic strictureplasties. [31], [32], [33], [34], [35], [36], [37], [38] and [39] Generally for short strictures, less than 10 to 12 cm in length, a Heineke-Mikulicz strictureplasty is performed (Fig. 84-3); for longer strictures either a Finney type (Fig. 84-4) or a side-to-side isoperistaltic strictureplasty (Fig. 84-5) is indicated. Prior to performing a strictureplasty, it is advisable to perform biopsy on all suspicious areas to rule out the presence of malignancy. Strictureplasty is contraindicated in the presence of active sepsis (peritonitis, abscess, or acute fistula), when the bowel wall is thickened and unyielding, when the stricture has undergone malignant degeneration, or in patients with severe weight loss and marked hypoalbuminemia. [40]

FIGURE 84-3. Heineke-Mikulicz strictureplasty for short stenosis (up to 7 cm). (From Fazio VW, Galandiuk S, Jagelman DG, et al. Strictureplasty in Crohn's disease. Ann Surg 1989;210:621.)

FIGURE 84-4. Finney strictureplasty for single stenosis longer than 7 cm. (From Shahrif H, Alexander-Williams J. The role of strictureplasty in Crohn's disease. Int Surg 1992;77:15.)

FIGURE 84-5. Isoperistaltic side-to-side strictureplasty for multiple sequential strictures and extensive jejunoileitis. **A:** The mesentery of the diseased loop is divided at its midpoint, and the small bowel is severed between atraumatic intestinal clamps. The proximal intestinal loop is moved over the distal one in a side-to-side fashion. **B:** The two loops are approximated by a layer of interrupted seromuscular Cushing stitches using nonabsorbable sutures. **C:** A longitudinal enterotomy is performed on both loops and the intestinal ends are spatulated to avoid blind stumps (*inset*) **D:** Both outer and inner suture lines are continued and finished anteriorly. The completed side-to-side isoperistaltic strictureplasty is shown in the *inset*. (From Michelassi F, Hurst RD, Melis M, et al. Side-to-side isoperistaltic strictureplasty in extensive Crohn's disease. Ann Surg 2000;232:401.)

The Cleveland Clinic group reviewed their experience of 1124 strictureplasties in 314 patients with a median follow-up of 7.5 years. [40] The overall morbidity rate was 18% including 2% anastomotic dehiscence rate and 7% postoperative bleeding from the suture line requiring transfusion. [41] These investigators reported 34% surgical recurrence rate, which compares favorably with the results of resective surgery. [42] The authors identified age and weight loss as the only factors associated with postoperative morbidity and younger age at diagnosis as the primary factor associated with early recurrence. [40] These results confirm the safety and efficacy of strictureplasty in selected patients. Yet, as a word of caution, one of their patients developed adenocarcinoma at the strictureplasty site 7 years after the index operation. Negative results of biopsies of the stricture had been obtained at the time of the strictureplasty. [43]

Septic complications, such as an inflammatory mass, an abscess and, occasionally, a fistula, are also considered indications for surgical treatment of small bowel Crohn's disease. As already discussed, fistulae usually reflect severe disease rather than an absolute indication for surgical treatment. Septic complications will be discussed in further detail in the section on Crohn's disease of the terminal ileum.

The first case of a carcinoma of the small bowel in Crohn's disease was described by Leon Ginzburg in 1956 in a case of stricturing small bowel Crohn's disease. [44] Since then there have been more than 100 cases described in the literature. [16], [43], [44], [45], [46], [47], [48], [49], [50] and [51] Most cancers are adenocarcinomas, [46] but they differ from de novo cancers in many respects: they present at a younger age, are more common in the distal small bowel, and may be multifocal or diffuse. [47]

Cancer may occur in association with chronic perineal fistulae and excluded loops of small bowel. Several cases of small bowel adenocarcinoma in bypassed loops have been reported. [47], [48], [49] and [50] The increased risk of cancer development in a bypassed loop and the inability to image such a loop has deterred surgeons from performing intestinal bypass or allowed them to consider leaving excluded intestinal segments in situ for a long time.

The surgical treatment of small bowel carcinomas in Crohn's disease is segmental radical resection, when feasible. The prognosis is poor, with survival rates reported between 23% at 3 years [49] and 5% at 5 years. [51] The patients with cancers in a bypassed loop usually do not survive longer than 18 months. [49]

Crohn's Disease of the Terminal Ileum

The terminal ileum is the most common gastrointestinal location requiring surgery in Crohn's disease and accounts for approximately 40% of patients with Crohn's disease referred to the surgeon. [1] Classically, patients present with obstructive symptoms or with septic features suggesting either a contained perforation or an abscess with or without a fistula. Cancer and hemorrhage are infrequent indications to surgical resection.

For obstructive disease of the terminal ileum secondary to strictures (Fig. 84-6) or an inflammatory mass (Fig. 84-7), resection is the treatment of choice. An ileocecectomy usually suffices; if the disease extends in the colon, an ileocolectomy may be necessary.

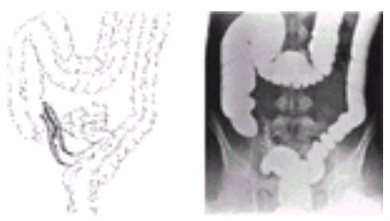

FIGURE 84-6. Barium enema with reflux in the terminal ileum showing long stenosis, referred to as the "string sign." (From Michelassi F. Crohn's disease. In Bell RH Jr, Rikkers LF, Mulholland MW, eds. Digestive tract surgery: a text and atlas. Philadelphia: Lippincott-Raven, 1996:1201.)

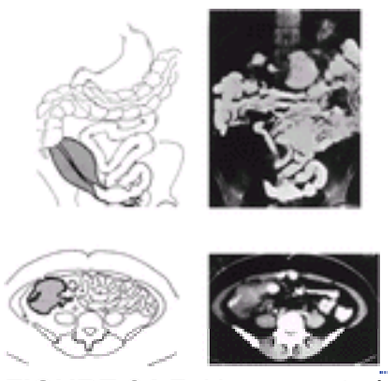

FIGURE 84-7. Upper gastrointestinal series and computed axial tomography showing a large right lower quadrant inflammatory mass in a patient with disease confined to the terminal ileum. Note the displacement of several loops of small bowel in the right lower quadrant. (From Michelassi F, Balestracci T, Chappell R, et al. Primary and recurrent Crohn's disease. Experience with 1379 patients. Ann Surg 1991;214:230.)

Abscesses (Fig. 84-8) and fistulae are two relatively common complications of Crohn's disease of the terminal ileum. Their occurrence may influence the timing of surgery and significantly increase its complexity. When feasible, these patients should be managed with image-guided drainage and antibiotics with elective resection at a later time. This approach is feasible in approximately 50% of patients. [52] If percutaneous drainage is not successful or in the presence of a secondary free rupture of the abscess in the peritoneal cavity, open surgical exploration is necessary. The procedure should aim at draining the abscess, clearing the sepsis, and resecting the diseased intestinal segment. A primary anastomosis can then be fashioned if the patient's hemodynamic and nutritional conditions allow it and if the final suture line can be placed away from the abscess cavity. It is also advisable to lay an omental flap on the residual wall of the abscess cavity to quarantine any residual infection from the abdominal cavity and the anastomosis. If a primary anastomosis is not advisable, a stoma needs to be brought out as a temporary end ileostomy. When the extent of the inflammatory reaction is massive and involves several adjacent loops of bowel, the procedure should be limited to drain the abscess and place a proximal diverting stoma. In due time, after most of the acute inflammatory reaction has subsided, a limited resection of the diseased bowel can be performed, saving a significant amount of bowel that otherwise would have been resected at the time of the first exploration.

FIGURE 84-8. Computed axial tomography showing a right lower quadrant abscess originating from Crohn's disease of the terminal ileum and perforated through the abdominal wall into the subcut. Air fluid level is evident. (From Michelassi F, Balestracci T, Chappell R, et al. Primary and recurrent Crohn's disease. Experience with 1379 patients. Ann Surg 1991;214:230.)

Psoas abscess occurs as a result of a retroperitoneal perforation of the ileocecal region. Clinical manifestations vary from mild sepsis to severe psoas spasm with hip pain, flexion, and external rotation of the thigh associated with an abdominal mass. The retroperitoneal process can compress the ureter and cause right hydronephrosis (Fig. 84-9). Resection of the inflammatory mass and drainage of the abscess usually relieves the compression on the ureter and cures the hydronephrosis.

FIGURE 84-9. Complete right ureteral obstruction with hydronephrosis. (From Michelassi F, Balestracci T, Chappell R, et al. Primary and recurrent Crohn's disease. Experience with 1379 patients. Ann Surg 1991;214:230.)

Fistulae are common in Crohn's disease of the terminal ileum, but they rarely represent the only indication for surgical treatment. In our series of 639 patients undergoing surgery for Crohn's disease, 331 patients had disease in the terminal ileum. Of these, 217 patients (65.6%) were found to harbor 285 intra-abdominal fistulae; yet these fistulae represented the primary indication for surgical treatment in only 6.3% of our patients. [53] Enteroduodenal, enteroenteric, and enterocolic fistulae usually are asymptomatic and often discovered only during a careful abdominal exploration or at inspection of the resected specimen. [54] We consider these fistulae the indication to surgical treatment only if they cause massive diarrhea because of the bypass of a sizable length of intestine.

Enterocutaneous fistulae usually drain through a previous abdominal scar or through the umbilicus. [55] At times, they result from surgical incision and drainage of a subcutaneous abscess complicating severe intra-abdominal disease or from percutaneous drainage of an abdominal abscess. [52] The presence of an enterocutaneous fistula does not necessarily dictate the need for immediate surgical intervention. [9], [56] Patients may be reluctant to undergo surgical treatment when the enterocutaneous fistula has a minimal output and the underlying disease is under satisfactory control. However, in most cases the difficulty in maintaining personal hygiene, the fear of social embarrassment, the bothersome symptoms associated with the severely diseased segment that led to the formation of the fistula, and the skin excoriation, which invariably forms around the cutaneous opening of the fistula, become factors in indicating the need for surgical treatment.

Enterovesical fistulae occur in 2% to 5% of patients with Crohn's disease. [57], [58] Some controversy exists regarding the timing of surgical intervention in the presence of these fistulae. Nevertheless, most surgeons and gastroenterologists agree that the consequences of chronic urinary tract infections on renal function, in addition to the symptoms affecting the intestinal tract itself, represent an indication for operation. Enterovaginal fistulae are rare complications of Crohn's disease and most often occur in women who have undergone a previous hysterectomy. The vaginal discharge is cause for discomfort, social and sexual embarrassment, and difficulty in maintaining personal hygiene. Most patients readily accept surgical intervention.

Massive intestinal hemorrhage is a rare complication of terminal ileitis. [59] Because the hemorrhage originates from active disease, patients with Crohn's disease are likely to have repeated episodes ultimately requiring surgical intervention. If the extent of the disease is limited, as assessed by contrast radiography, an elective resection should be considered after two episodes of self-limited hemorrhage. In the presence of an ongoing, unrelenting hemorrhage, an angiogram should be obtained to localize the source of bleeding, especially in the presence of multiple sites of disease involvement. [13] The possibility of a life-threatening hemorrhage in patients with Crohn's disease should not be underestimated. Five cases of exsanguinating gastrointestinal hemorrhage have been reported in the literature. [60]

Malignant transformation of the terminal ileum is fortunately rare. Its treatment is based on oncologic principles and it has been described in the previous section.

Controversies still persist about the timing of the operation. In view of the fact that 70% to 90% of these patients require a resection in their lifetime, [61], [62] some authors have advocated early resection to avoid possible septic complication associated with recurrent attacks and the side effects of aggressive medical treatment. [63], [64] On the other hand, in general, most physicians and surgeons recommend a resection only after medical treatment has failed or a complication of the disease has arisen.

Overall the results of resection are excellent. Large series have reported a surgical recurrence rate between 31% and 36% at 10 years with 69% of patients requiring only one resection. [61], [63] Several disease-related and patient-related factors associated with high risk of recurrence have been identified. The presence of perianal disease, extensive ileal involvement, and cigarette smoking seem to be significantly associated with high recurrence rate after ileocolic resection. [61], [65], [66] When Crohn's disease recurs, it usually involves the ileum just proximal to the anastomosis; less frequently the colon just distal to the anastomosis or the anastomosis exclusively are involved. Strictureplasty has been used for the treatment of anastomotic stricture secondary to recurrent Crohn's disease after ileocolic resection with excellent results. [67], [68]

Crohn's Colitis

The colon is affected by Crohn's disease in up to 30% of patients. [1], [8], [69] The involvement can be limited to a segment or extend to the entire colon and rectum; furthermore, patients may present with associated anorectal or small bowel disease. In the presence of pancolitis without perineal or small bowel manifestations of the disease, the differential diagnosis between Crohn's disease and ulcerative colitis may be difficult and many patients end up carrying a diagnosis of indeterminate colitis as a result of diagnostic uncertainty [70] or with the wrong diagnosis. [71], [72], [73] and [74] With the advent of ileoanal pouch procedures this differentiation has become crucial since pouch reconstruction in patients with Crohn's disease is contraindicated, with a pouch failure rate up to 40%. [71], [72], [73] and [74]

The most common indication for surgery in patients with disease localized primarily to the colon is failure of medical therapy. [8], [75] These patients present with persistent and often bloody diarrhea and abdominal pain not responding to medical therapy. With worsening conditions, toxic colitis with or without megacolon may develop. This complication is less frequently associated with Crohn's disease than ulcerative colitis, but it carries similar mortality rates (14%–16%) in both conditions. Factors affecting mortality include age (30% for patients older than 40 years old, vs. 5% for those younger than 40), gender (21% in women vs. 13% in men), and the occurrence of colonic perforation (44% for cases with perforation vs. only 2% in those without perforation). [18] In the absence of overt perforation, initial therapy consists of high-dose steroids, bowel rest, and antibiotics. Lack of improvement over a short period of time or any signs of worsening condition are indications for an urgent operation to avoid colonic perforation.

The risk of colorectal cancer is increased in Crohn's colitis between 4-fold and 20-fold, [76], [77] with an incidence between 1.4% and 1.8%. [15], [44], [45] and [46], [78], [79] Carcinoma can arise in a long-standing benign stricture, probably due to chronic inflammation. [80]

Routine surveillance colonoscopy should be considered after 7 to 10 years of disease duration, with the recommendation to proceed with resection in the presence of dysplasia. Prophylactic colectomies should be performed for tight strictures not allowing passage of the endoscope and, therefore, interfering with a complete colonoscopy; a stricture difficult to survey; multiple pseudopolyps rendering surveillance difficult; and, as mentioned earlier, the presence of an excluded intestinal segment (retained rectal stump). Surgery for adenocarcinoma in Crohn's colitis should be based on oncologic principles and on the extent of the lumenal disease.

Septic complications occur in the form of inflammatory masses or, more infrequently, fistulae or abscesses. Inflammatory masses can be found in any segment of the colon and rectum with equal frequency. Transverse colon disease occasionally fistulizes into the stomach. A common location for abscesses to occur is the descending colon at the junction with the sigmoid colon. These abscesses, which form in the left parietocolic gutter and lay over the psoas muscle, may be confused with a complication of diverticular disease. Usually, the age of the patient and other manifestations of Crohn's disease help in arriving at the correct diagnosis.

Several different surgical approaches are available for the treatment of patients with Crohn's colitis. The surgical plan depends on the location of the disease, the urgency of intervention, the presence of complications, and the general condition of the patient. In Crohn's colitis the need to preserve bowel length is less pressing than in small bowel Crohn's disease, but still the extent of surgery should be carefully planned by the surgeon in conjunction with the gastroenterologist, the pathologist, the radiologist and, foremost, the patient.

Surgery for Crohn's disease of the colon must encompass the entire gross disease. In patients with disease limited to the right colon, a right hemicolectomy will suffice (Fig. 84-10); if the disease extends beyond the midtransverse colon, an extended right hemicolectomy may be necessary; for patients with disease involving the entire abdominal colon (Fig. 84-11), an abdominal colectomy will be needed. All these procedures can be performed in one stage. In the past, a diverting ileostomy was widely used as the sole initial step in patients too ill to tolerate definitive surgery. [81], [82], [83], [84] and [85] A more current approach consists of the appropriate colon resection with an end ileostomy and delayed reconstruction of the gastrointestinal continuity. This procedure is also indicated in patients with a diagnosis of indeterminate colitis to preserve the option of an ileal pouch procedure if the diagnosis of ulcerative colitis is later confirmed or established.

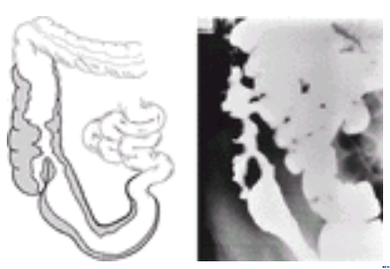

FIGURE 84-10. Small bowel follow-through series showing Crohn's disease of the ileal cecal valve and right colon. (From Michelassi F. Crohn's disease. In Bell RH Jr, Rikkers LF, Mulholland MW, eds. Digestive tract surgery: a text and atlas. Philadelphia: Lippincott-Raven, 1996:1201.)

FIGURE 84-11. Barium enema showing Crohn's colitis with sparing of the rectum and rectosigmoid. (From Michelassi F. Crohn's disease. In Bell RH Jr, Rikkers LF, Mulholland MW, eds. Digestive tract surgery: a text and atlas. Philadelphia: Lippincott-Raven, 1996:1201.)

Abdominal colectomy and ileorectal anastomosis, in one or two stages, is ideally suited for young patients with no sigmoid or rectal involvement and normal anal sphincter function. [86] In older adult patients, the decision in favor of an abdominal colectomy with ileorectal anastomosis is a difficult one and needs to carefully consider the degree of anal sphincter function and the possible debilitating high fecal frequency.

Total proctocolectomy and end ileostomy, in one or two stages, has been and still is the surgical therapy of choice in patients with Crohn's pancolitis or in Crohn's colitis with extensive anorectal involvement or anal incontinence. [87] Recurrence of Crohn's disease in the small bowel after total proctocolectomy has been reported in 3% to 46% of patients [88], [89] and it involves the distal 25 cm of ileum in up to 90% of patients. [90] If Crohn's disease is limited to the rectum (Fig. 84-12) or the patient is affected by severe anorectal disease or incontinence, an abdominoperineal resection with a left-end colostomy is the procedure of choice.

FIGURE 84-12. Barium enema showing Crohn's proctitis with loss of the rectal ampulla, several rectosigmoid fistulae, and an intervening perirectal abscess. (From Michelassi F. Crohn's disease. In Bell RH Jr, Rikkers LF, Mulholland MW, eds. Digestive tract surgery: a text and atlas. Philadelphia: Lippincott-Raven, 1996:1201.)

In the presence of severe perineal sepsis, patients undergoing a proctocolectomy or an abdominoperineal resection are at risk of developing perineal wound problems. Large series have reported up to 34.4% of nonhealing perineal wounds after proctectomy in Crohn's disease. [90], [91] and [92] A subtotal colectomy or an abdominal proctectomy with colostomy may be indicated as the first step to allow for appropriate drainage and healing of the perineal sepsis. A perineal proctectomy at a later time is still necessary to avoid the risks of a retained rectal stump. The use of myocutaneous flaps may further decrease the incidence of nonhealing perineal wounds. [93]

For left-sided Crohn's colitis (Fig. 84-13), segmental resection is a valuable alternative. It allows for restoration of bowel continuity and maintenance of the absorptive mucosa of the right colon, but patients are at risk of recurrence and additional surgery. [94] Small series have reported a recurrence rate of 62% at 5.5 years, requiring further surgery, [95] but up to 86% of patients maintaining bowel continuity at 14 years. [96]

FIGURE 84-13. Barium enema showing Crohn's colitis limited to the proximal portion of the descending colon. (From Michelassi F. Crohn's disease. In Bell RH Jr, Rikkers LF, Mulholland MW, eds. Digestive tract surgery: a text and atlas. Philadelphia: Lippincott-Raven, 1996:1201.)

Ileal pouch surgery is contraindicated for patients with Crohn's colitis. [72], [74] Despite the effort to correctly diagnose patients before surgery, some patients undergo surgery with a preoperative diagnosis of indeterminate colitis or ulcerative colitis and are found to have Crohn's disease on final pathological evaluation of the specimen. [97] Sagar and colleagues [98] and Deustch and associates, [71] in two separate unselected series, reported a pouch failure rate of 45% at 10 years in a total of 46 surgical patients with a preoperative diagnosis of mucosal ulcerative colitis who were subsequently proven to have Crohn's disease. Hyman and colleagues [73] analyzed the outcome of this procedure on 25 patients: 16 patients, at a mean follow-up of 38 months, had a functioning pouch, 7 had required pouch excision, 1 had a diverting stoma, and 1 had died. Only 1 of 9 patients with preoperative clinical features suggestive of Crohn's disease had a functioning pouch, with complications uniformly occurring within months of ileostomy closure. In contrast, 15 of 16 patients with out preoperative features of Crohn's disease had maintained their pouch, generally with good results. These studies suggest that pelvic pouch procedure should not be performed in patients with clinical features of Crohn's disease because of the high associated complication rate. Yet, there may be a subgroup of patients with Crohn's colitis who may ultimately be recognized as possible candidates for an ileal pouch procedure. To this extent Panis and colleagues [99] reported a series of 31 patients with Crohn's disease with no evidence of perineal or small bowel disease. These patients were specifically selected for ileoanal pouch as an alternative to ileostomy. Their results were compared with those obtained from patients with ulcerative colitis undergoing the same procedure. Of the 31 patients with Crohn's disease, six (19%) experienced specific complications 9 months to 6 years after surgery: three had pouch-perineal fistulae, which required pouch excision in two cases. At the 5-year follow-up, there was no significant difference between patients with Crohn's disease and patients with ulcerative colitis with a functioning pouch in stool frequency, continence, gas/stool discrimination, leak or need for protective pads, and sexual activity. It is probable that in the future more sophisticated diagnostic tests may allow selection of a subgroup of patients with Crohn's disease appropriate for ileal pouch procedures.

Perianal Crohn's Disease

Anorectal Crohn's disease may manifest with edematous skin tags, fissures, ulcers, abscesses, fistulae, strictures and, as a complication of chronic, long-standing inflammation, anal cancer. The reported incidence of perianal Crohn's disease requiring surgery varies between 25% and 34%. [93], [100] Crohn's colitis is much more frequently associated with anal lesions than Crohn's disease of the small bowel (52 % vs. 14 %). When an anal lesion is the manifesting sign, Crohn's disease will soon develop elsewhere in the intestine. [100] Since these lesions frequently herald the onset of intestinal Crohn's disease, the physician must always be aware of the possibility of inflammatory bowel disease when dealing with a suspicious anal lesion.

Skin tags, fissures, and ulcers rarely require surgical treatment. The most common indications for surgery in perianal Crohn's disease are septic in nature. For these complications the treatment plan should be based on the patient's general condition, anal continence, and degree of colorectal involvement. In patients with a grossly normal rectal mucosa, the anal stenosis can be dilated, ischiorectal abscesses can be drained, appropriate fistulectomies can be performed, and repair of complex fistulae or low rectovaginal fistulae can be attempted with every expectation of successful outcome. In patients with mild to moderate involvement of the rectal mucosa, treatment of the rectal disease with topical antiinflammatory agents may occasionally effect dramatic improvement. If the improvement persists, surgical repair of even complicated defects may result in complete healing and normal function. In patients with severe perineal disease or incontinence, only a proctectomy with a permanent stoma may be expected to bring relief. Extensive perineal disease, while not a sole indication for proctectomy, usually is associated with destruction of the sphincter mechanism and incontinence, often dictating a resection with a permanent stoma.

Patients presenting with an ischiorectal abscess require prompt incision and drainage. In the majority of patients, the incision will heal by secondary intention without any need for further intervention. In 35% of patients, a fistula-in-ano will develop. [93]

Many surgeons mistakenly believe that perineal wounds do not heal in patients with Crohn's disease and therefore have adopted a philosophy of therapeutic nihilism even in the presence of simple fistulae-in-ano. [101], [102], [103], [104] and [105] This attitude may result in the patient's continued suffering and may lead to the development of new abscesses and fistulae, progression to a "watering-pot" perineum, and destruction of the sphincter mechanism. Patients with Crohn's disease with symptomatic low anal fistula involving minimum sphincter musculature can be treated safely with fistulotomy [106] with healing rates up to 85%. [107], [108] In patients with horseshoe abscesses and high fistulae, aggressive local surgical intervention aimed at drainage of sepsis and appropriate usage of setons permit preservation of the sphincter and good postoperative function. [106], [107], [109], [110]

Rectovaginal fistulae occur as a complication of anorectal Crohn's disease in about 10% of patients [111], [112] and require special mention. Most fistulae are truly anovaginal, with the internal opening located at the dentate line. These fistulae result from deep anterior anal ulceration and less commonly from a crypto-glandular source. These patients may be treated with a mucosal advancement flap. [113], [114] and [115] This procedure entails performing a semicircular incision at the dentate line, with the internal opening of the fistula at its center (Fig. 84-14). A 3- to 4-cm flap of mucosa, submucosa, and smooth muscle is elevated in a proximal direction. The tract is curetted and closed and the flap is advanced to the anoderm and sutured without tension. Several variations have been proposed when the rectal mucosa is significantly diseased, including performing the repair from the vaginal side [116], [117] and using an anocutaneous flap from the perianal skin. [118] Success rates with this approach have been reported around 70% to 75% in relatively small series. [113], [114] and [115] In the event of a failure, the advancement can be repeated as reported by Joo and colleagues. [115] In their series, four of five patients who did not heal with the first procedure were successfully closed after a second attempt.

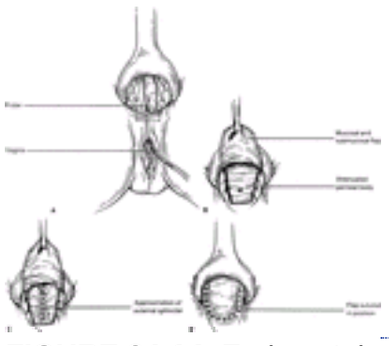

FIGURE 84-14. Endorectal advancement flap for low rectovaginal fistula. **A:** The patient is in the jack-knife prone position and the probe identifies the rectovaginal fistula. **B:** The rectal wall is elevated from the external sphincter, starting at the dentate line. **C:** Plication of the external sphincter with closure of fistula. **D:** The rectal wall flap is advanced over the plicated external sphincter; the tip of the flap with the fistula opening is excised; the flap is then sutured in position with interrupted sutures. (From Michelassi F. Crohn's disease. In Bell RH Jr, Rikkers LF, Mulholland MW, eds. Digestive tract surgery: a text and atlas. Philadelphia: Lippincott-Raven, 1996:1201.)

Anorectal complications also include stenosis and cancer. In the absence of severe rectal disease, anal stenosis can be dilated to achieve prolonged symptomatic relief. Cancer may develop from the diseased anorectal mucosa, a chronic fistula-in-ano, or a retained rectal stump. In all cases, an oncologic resection needs to be carried out. In the presence of a resulting large soft tissue and cutaneous perianal defect, the use of myocutaneous flaps may be the only way to achieve primary closure of the perineal wound (Fig. 84-15).

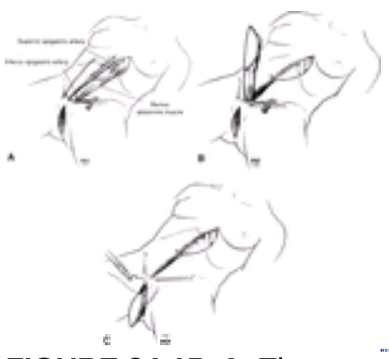

FIGURE 84-15. A: The superior epigastric vessels supply the rectus abdominis myocutaneous flap. **B:** The flap includes skin, anterior fascia, and the rectus muscle. **C:** The flap is delivered through the pelvis to the perineal defect. (From Hurst RD, Gottlieb LJ, Crucitti P et al. Primary closure of complicated perineal wounds with myocutaneous and fascia cutaneous flaps after proctectomy for Crohn's disease. Primary myocutaneous flap closure following resection of locally advanced pelvic malignancies. Surgery 2001;130:767; originally from Radice E, Nelson H, Mercill S, et al, Br J Surg 1999;86:349, with permission of the Mayo Foundation.)

All told, an aggressive surgical approach should allow healing of the Crohn's disease perineal septic complication with sphincter preservation in 62% to 86% of patients. [112], [119] In our series of 224 consecutive patients, the reasons for proctectomy in 85 patients included aggressive disease nonresponding to conservative measures in 66 patients, extensive fistular disease in 15 patients, fecal incontinence in 2 patients, and tight anal stenosis in 2 patients. We found that patients with rectal disease had a significantly higher rate of proctectomy than patients with rectal sparing (77.6% vs. 13.6%), and that in the absence of rectal involvement, patients with multiple complications had a significantly higher rate of proctectomy than patients with single complications (23% vs. 10%). [119]

Laparoscopic Surgery for Crohn's Disease

Although laparoscopic techniques have become standard approaches to the treatment of several upper abdominal pathologies (i.e., gallbladder disease and reflux esophagitis) and benign colorectal conditions (i.e., diverticulitis, limited colectomies for benign polyps, endometriosis involving the intestine), the use of laparoscopy in Crohn's disease is still debated. On the one hand, surgery for Crohn's disease can be quite challenging even with a conventional approach. Many of the unique features of Crohn's disease, such as the intense inflammation, thickened mesentery, enteric fistulae, inflammatory masses or abscesses, and the multiplicity of areas of intestinal involvement, have deterred many surgeons from even considering a laparoscopic approach. On the other hand, the natural history of the disease may lead to the need for repeated operations and a less "invasive" approach would indeed be appealing. Additionally, patients are generally young and interested in undergoing procedures that involve minimal scarring and prompt recovery.

Although a number of clinical reports have described that laparoscopic-assisted ileocolic resections are feasible and safe in the treatment of Crohn's disease, these series have been uncontrolled and nonrandomized. [120], [121], [122], [123] and [124] Additionally, several reports question whether or not any advantages at all support the use of laparoscopic methods compared to conventional methods in Crohn's disease. [124], [125]

Two prospective and controlled studies have shown several advantages of the laparoscopic-assisted approach over the conventional open approach. Bemelman and associates [126] compared 48 open ileocolic resections with 30 laparoscopic-assisted resections. They showed that laparoscopic ileocolic resection for Crohn's disease is associated with similar morbidity rates, a shorter hospital stay, and improved cosmetic results. Alabaz and colleagues [127] compared 48 open ileocolic resections with 26 laparoscopic-assisted resections. Patients in the laparoscopic-assisted group returned to work more quickly, had better cosmetic results, and were more likely to have improved social and sexual lives.

A prospective randomized trial comparing open and laparoscopic-assisted ileocolic resections in 60 patients [128] showed a faster postoperative recovery of respiratory function (measured as recovery of 80% of forced expiratory volume and forced vital capacity), a lower incidence of minor complications, and the need for a shorter abdominal incision in the laparoscopic-limited group. With a follow-up of 20 months there were no recurrences in either group. This limited single-surgeon experience needs to be validated by others and needs to be extended to a longer follow-up to see whether the purported advantages for patients who may need repeated surgical procedures are indeed validated.

The indication for laparoscopic surgery in Crohn's disease should not differ from the indications for conventional open surgery. Contraindications to a laparoscopic approach include patients who are critically ill and unable to tolerate the pneumoperitoneum due to hypotension or hypercarbia, patients with dense adhesions or extensive intra-abdominal sepsis (abscess, free perforation, complex fistulae), and the inability to clearly identify the anatomy (previous surgery, obesity, adhesions). [129]

Laparoscopic assisted ileocolic resection (Fig. 84-16) is currently the most commonly performed laparoscopic procedure for Crohn's disease. [120], [130] Laparoscopic fecal diversion and closure of stomas may obviate a laparotomy and allow for a full evaluation of the gastrointestinal tract. Laparoscopic-assisted small bowel resection or strictureplasty may be performed as the index procedure or when associated with another bowel resection, usually an ileocolic resection. The diseased area or areas can be marked with intracorporeal stitches, exteriorized through a small abdominal incision needed for removal of the resected specimen, and the strictureplasty performed extracorporeally in a standard fashion.

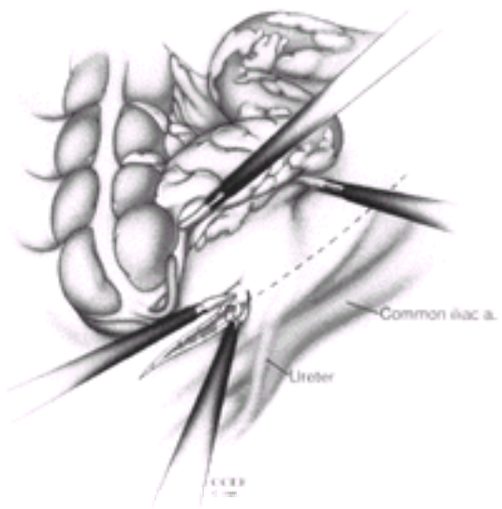

FIGURE 84-16. Laparoscopic ileocecectomy (From Kim SH, Milsom JW. Laparoscopy in inflammatory bowel disease. In: Michelassi F, Milsom JW, eds. Operative strategies in inflammatory bowel disease. New York: Springer-Verlag, 1999:326.)

Segmental or total colectomies with or without anastomosis are can be performed by the laparoscopic-assisted method. Due to their complexity these procedures are still controversial. [131] A few series have reported a small number of cases; [124], [130], [132], [133] and [134] some authors do not consider laparoscopic colon resection for Crohn's disease advantageous. [135]

In summary, laparoscopy in Crohn's disease may allow for faster recovery and reduced surgical trauma; morbidity, in experienced hands, compares favorably with the conventional open approach. With the continuous improvement of laparoscopic instruments and the refinement of laparoscopic surgical techniques, this approach in the near future may also be offered to patients with more challenging and extensive complications of Crohn's disease.

ULCERATIVE COLITIS

There is a major difference between the management of ulcerative colitis and Crohn's disease. In Crohn's disease the surgical approach is palliative, with the more limited objective of relieving the complications of the disease to improve the patient's clinical status and preserving bowel length. In ulcerative colitis, removal of the colon and rectum eliminates and cures the disease.

Ulcerative colitis is a disease confined to the colon and rectum and the presence of intestinal involvement outside these boundaries must be ruled out to confirm the diagnosis. Anamnestic evidence of recurrent episodes of perianal sepsis or bowel obstruction should suggest the possibility of Crohn's disease. On physical examination, the presence of active perianal sepsis and fistulae, healed scars, or anal stenosis should raise doubts about the diagnosis of ulcerative colitis. A complete preoperative evaluation should include: stool cultures to rule out an infectious etiology; small bowel x-ray series to exclude involvement of the small intestine; colonoscopy to evaluate the extension of the disease, rule out the presence of malignancy, and obtain histological confirmation.

The majority of patients with ulcerative colitis present with bloody diarrhea, urgency, and fatigue; during an acute flare, they may present with fever and, possibly, abdominal distention. In absence of absolute indications for immediate surgery, such as perforation or carcinoma, the patient is treated initially with medical therapy. [136], [137] and [138] However, a definitive treatment plan should be formulated after complete diagnostic evaluation, taking into account the extent and duration of the disease, the presence of dysplasia or cancer, medical therapy used, presence of side effects due to the medical treatment, and the patient's general condition and expectations. As in Crohn's disease an optimal treatment plan requires input from the patient as well as the surgeon and the gastroenterologist, assisted by the radiologist and pathologist.

Indications for Surgery

The most common indication for surgical treatment of ulcerative colitis in our experience is the failure of medical therapy. [139] This constitutes the following scenarios: when maximum medical therapy proves inadequate; for those patients who may be asymptomatic while on maximum medical therapy, but develop recurrence of symptoms with tapering of the medications; when the disease progresses with worsening symptoms while the patient is receiving maximum medical therapy; and when the patient develops significant treatment-related complications.

Other indications for surgical treatment include the presence of a mass at colonoscopy, dysplasia on colonic biopsy, and dysplasia-associated lesions or masses (DALM). Colonoscopic detection of mucosal dysplasia is considered the best available surveillance tool for the detection of cancer. The presence of dysplasia has been reported in a much higher percentage of specimens of ulcerative colitis complicated by cancer than in ulcerative colitis without malignant transformation. Because the correlation between dysplasia and cancer is not constant, when dysplasia is found on surveillance colonoscopy, some suggest immediate colectomy, whereas others opt for continued surveillance. Gorfine and colleagues [140] reviewed the pathology reports of 590 patients who underwent total proctocolectomy or restorative proctocolectomy for ulcerative colitis and found that cancers were significantly more common among specimens with dysplastic changes. Specimens with dysplasia of any grade were 36 times more likely to harbor invasive carcinoma. Stage III disease was found in association with indefinite or low-grade dysplasia in 19.2% of cases. More important, tumor stage did not correlate with dysplasia grade. These investigators concluded that even though dysplasia is an unreliable marker for the detection of synchronous carcinoma, when dysplasia of any grade is discovered at colonoscopy, the probability of a coexistent carcinoma is high. We believe that a histopathological diagnosis of dysplasia is an indication for colectomy.

Carcinoma was the indication for surgery in 2% of our series. [139] Patients with ulcerative colitis are known to have an increased risk of colorectal cancer. [141], [142] The risk of cancer increases with the extent and the duration of the colitis. Gyde and associates [143] reported an overall 8-fold increase in the risk of cancer in these patients, with a 4-fold increase in the left-sided colitis and proctitis group and a 19-fold increase in the pancolitis group. In addition, the pancolitis group had a cumulative risk of 7.2% at 20 years and 16.5% at 30 years from diagnosis.

Acute fulminant colitis with or without an acute abdomen develops in about 13% of patients. [139] About 60% of these patients fail to respond to medical therapy [136], [144] or develop persistent abdominal pain, distention, diffuse abdominal tenderness, rebound, tachycardia, and fever, suggesting an acute abdomen. The acute abdomen may be due to the development of a toxic megacolon or a walled-off or free perforation. These patients should undergo emergency surgical intervention after appropriate volume resuscitation.

Massive hemorrhage is also another indication for urgent surgery. Persistent hemorrhage despite maximal medical treatment is a manifestation of severe disease. The hemorrhage originates from extensive mucosal ulcerations, rather than a definite arterial source. As such, an abdominal colectomy is necessary to remove the majority of the bleeding surface. A primary anastomosis should be avoided in favor of an ileostomy and closure of the rectal stump. With fecal diversion obtained by placing the ileostomy, postoperative rectal bleeding is rare. When it happens it usually responds to increased doses of systemic steroids, or administration of topical steroids or intrarectal tamponade with gauzes soaked in a diluted epinephrine solution. Retention of the rectal stump maintains the option of a subsequent restorative procedure.

Proctocolectomy With Brooke Ileostomy

Proctocolectomy with Brooke ileostomy was the gold standard for the treatment of ulcerative colitis until the early 1980s when Utsonomiya popularized the ileo pouch–anal anastomosis. [145] Since then its role in the surgical treatment of ulcerative colitis has become more limited, although it is still valuable in selected patients. [146] By removing all diseased epithelium, a proctocolectomy cures patients of the disease, eradicates the risk of malignancy associated with it, and eliminates the need for costly medications and time-consuming lifelong follow-up. The disadvantages of this operation include the presence of a permanent ileostomy, the potential for nerve injury during pelvic dissection, and the risk of perineal wound healing problems, even if significantly less than in Crohn's disease.

A proctocolectomy is indicated in patients who are not candidates for an ileal pouch–anal anastomosis or a Kock pouch, either because of older age, the presence of

poor anal sphincter function, or obesity. The operation may also be indicated if other medical problems make a more complex, longer operation too risky [147] or in the presence of a low rectal cancer in need of resection of the anal sphincter or postoperative adjuvant radiotherapy. Finally, proctocolectomy should be considered in patients who desire a single operation for cure or whose work makes it easier to handle an appliance rather than frequent bowel movements. There are no absolute contraindications to this procedure, although, in the emergent setting, it is advisable to stage the procedure with an initial abdominal colectomy. This strategy avoids the morbidity associated with the rectal dissection, which can be potentially difficult and time consuming in an unstable patient, and maintains the option of an ileal pouch–anal anastomosis as a second stage.

Preoperatively, the surgeon is well advised to have a thorough discussion with the patient for a complete understanding of this procedure and its implications on body image and self-perception. In addition, a stoma therapist, in charge of the postoperative care of the stoma, should mark the abdominal site for the ileostomy (Fig. 84-17). The appropriate site is the least inconvenient for the patient and usually it is away from bony prominences, previous scars, and does not interfere with the patient's clothing. The site is usually just lateral and inferior to the umbilicus midway between the midline and the right anterior iliac spine.

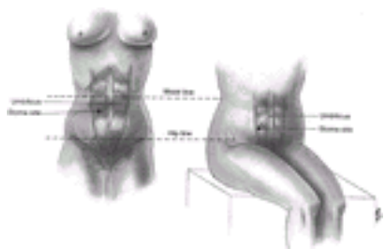

FIGURE 84-17. The stoma site is marked prior to surgery. The ileostomy should be located over the right rectus abdominus muscle on a flat area away from skin folds and bony prominences. (From Hurst R. Proctocolectomy with ileostomy, abdominal colectomy with ileostomy, and abdominal colectomy with ileoproctostomy. In: Michelassi F, Milsom JW, eds. Operative strategies in inflammatory bowel disease. New York: Springer-Verlag, 1999:157.)

The proctocolectomy is associated with very low postoperative morbidity. Delayed healing or nonhealing of the perineal wound is rare if the perineal dissection is performed in the intersphincteric plane, between the internal and external anal sphincter. Primary closure is associated with an 80% to 90% success rate. [148], [149] and [150] In the event of perineal wound infection, drainage of the wound abscess and debridement usually are sufficient for secondary healing. Rarely, myocutaneous flaps or skin grafts are necessary to achieve closure of the perineal wound. Impotence is reported in 2% to 3% of male patients after proctectomy for benign disease. [150], [151] Impotence is secondary to injury of the autonomic nerves during pelvic dissection and its occurrence is minimized by keeping the dissection close to the rectum and by choosing an intersphincteric plane for the most distal anorectal resection. In women, dyspareunia may occur due to the posterior displacement of the vagina. Fortunately, it is usually temporary. [150], [151]

Late complications are largely related to the stoma and include retraction, prolapse, parastomal hernia, bleeding, stenosis, and varices. They usually require surgical revision. Other late complications are intestinal obstruction, urinary stone formation, and gallstone formation.

Restorative Proctocolectomy With Ileal Pouch–Anal Anastomosis

Most patients with ulcerative colitis who are candidates for elective operation are suitable for proctocolectomy with ileal pouch–anal anastomosis. Exceptions include patients with low rectal cancers, patients with fecal incontinence, or patients who, for work-related issues or personal reasons, prefer not to have a pouch. [147]

Obesity is considered a relative contraindication. A fatty ileal mesentery may cause the pouch to be rather bulky and ill fitting in a narrow pelvis; furthermore, the ileal pouch may not reach the upper anal canal despite operative techniques designed to lengthen the ileal mesentery. [152] A stapled ileoanal anastomosis, as described later in the chapter, offers advantages over a conventional hand-sewn anastomosis in these challenging patients. Alternatively, patients may need to undergo an initial colectomy with ileostomy to allow for cessation of steroid therapy and a successful weight reduction program.

The presence of cancer of the colon or proximal rectum does not rule out the possibility of an ileal pouch–anal anastomosis, provided that the cancer can be completely resected during the operation. [153], [154], [155] and [156] In the presence of metastatic cancer and a short life expectancy, less extensive procedures, such as colectomy and ileorectal anastomosis or Brooke ileostomy should be considered. The Mayo Clinic group presented their experience with 77 patients with carcinoma complicating ulcerative colitis. Although pouch failure was more common in patients with cancer than in the overall registry (16% vs. 7%), there were no differences between cancer and noncancer groups in operative complications, median stool frequency, incontinence, pad usage, or pouchitis. [153] A study from Toronto that reviewed function and quality of life after ileal pouch–anal anastomosis for colitis-associated neoplasia confirmed the functional results reported by the Mayo Group and showed that quality of life of these patients is excellent and equal to that of patients who have a pouch for failure of medical therapy. [154]

Patients with sclerosing cholangitis and cirrhosis are at increased risk of chronic pouchitis and pouch loss after an ileal pouch–anal anastomosis, but the operation usually can be performed successfully and with morbidity rates similar to that in patients without hepatobiliary complications of ulcerative colitis.

In the past, if a patient was older than 50 years, this was considered a contraindication to the procedure. However, this is no longer true. The clinical results in fit patients over the age of 50 are similar to those in younger patients. [157], [158], [159], [160] and [161] Takao and colleagues [160] have shown that there are no significant differences among age groups relative to manometric results, frequency of bowel movements, incontinence scores, or overall patient satisfaction. The same results were confirmed by others. [157], [159] Jorge and associates [158] showed that the effect of ileoanal reservoir on anal sphincter function in patients older than 50 years is similar to that in younger patients. Even though impairment of internal anal sphincter function is more pronounced after ileoanal reservoir in older patients, this appears to be transient, as it is in younger patients.

Although there are small series showing that an ileal pouch–anal anastomosis is feasible in fulminant ulcerative colitis, [162] most patients with emergent indications to surgical treatment should undergo an initial colectomy with ileostomy followed by ileal pouch–anal anastomosis [163] several months later.

The ileal pouch–anal anastomosis is most commonly performed in two stages. The colon and the rectum are excised to the pelvic floor, an ileal pouch is constructed with the terminal ileum (Fig. 84-18), an ileal pouch–anal anastomosis is constructed, and a diverting loop ileostomy is fashioned. The loop ileostomy is closed at a second operation about 3 months later. The operation, or portions of it, can be accomplished by using laparoscopic techniques.

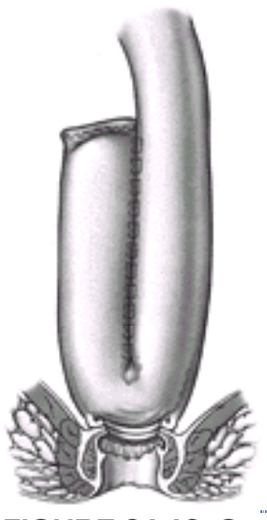

FIGURE 84-18. Stapled J-pouch ileoanal anastomosis. (From Michelassi F, Takanishi D, McLeod RS, et al. Ileal reservoirs. In: Michelassi F, Milsom JW, eds. Operative strategies in inflammatory bowel disease. New York: Springer-Verlag, 1999:186.)

Occasionally a diverting ileostomy can be omitted after construction of the ileal pouch. Omitting this transforms an elective ileal pouch–anal anastomosis into a single-stage procedure and avoids the need for a third stage in those patients who underwent an initial colectomy and ileostomy in the emergent setting or in elective circumstances (indeterminate colitis, obesity).

Several large series examining complications and long-term outcome have been published. [164], [165], [166] and [167] The Cleveland Clinic group reported their experience with 1005 ileal pouch–anal anastomoses, 858 of which had been performed for ulcerative colitis. [165] One death (0.1%) related to pouch necrosis and sepsis was reported. The overall morbidity rate was high, with 630 patients (62.7%) suffering 1218 complications. Septic complications and reoperation occurred in 6.8% and 24%, respectively. The ileal pouch was removed in 34 patients (3.4%) overall, but in only 15 patients (1.8%) with ulcerative colitis. Approximately 25% of patients developed pouchitis. Functional results and quality of life were good to excellent in 93% of patients. The Mayo Clinic series [164], [167] of more than 1300 patients showed similar results. Three patients died as a consequence of the procedure. Postoperative pelvic sepsis rates decreased from 7% in the 1981 to 1985 period to 3% in the 1991 to 1994 period. After mean follow-up of 6.5 years, the mean number of stools was five during daytime and one at nighttime. Frequent daytime and nighttime incontinence occurred in 7% and 12% of patients, respectively, and did not change over a 10-year period. The cumulative probability of suffering at least one episode of clinical pouchitis was 18% and 48% at 1 and 10 years, respectively, and the cumulative probability of pouch failure at 1 and 10 years was 2% and 9%, respectively. [167] The most common early postoperative complications were bowel obstructions (13%), pelvic (5%) and wound sepsis (3%), transient urinary dysfunction (7%), and large enteric losses from the temporary loop ileostomy. Postoperative impotence and retrograde ejaculation was noted in up to 3% of men; transient dyspareunia occurred in 11% of patients after operation. [164] Pregnancy and delivery are well tolerated by women with a pouch. [164]

Late complications of the procedure include: anal fistulae and abscesses, which may need drainage and possibly temporary fecal diversion; stricture of the anastomosis, which can be repeatedly dilated or treated with pouch advancement in presence of dense scar tissue or inflammation of the mucosal cuff; and pouchitis, which is the most frequent late complication. Patients with pouchitis present with abdominal cramps, frequent watery stools, urgency, incontinence, malaise, and fever. Of 120 patients who underwent ileal pouch–anal anastomosis for ulcerative colitis at the University of Chicago, 50 patients suffered at least one episode of pouchitis. Two thirds of patients had multiple episodes. Chronic pouchitis occurred in 6 patients, necessitating pouch removal in 2. [168] In a prospective evaluation of 149 patients in Sweden, [169] the risk of pouchitis was highest during the initial 6 postoperative months. The cumulative risk leveled off after 2 years but was substantial (51%) at 4 years. Similar to our data and that of the Mayo Clinic, fewer than 10% of the Swedish patients had severe chronic pouchitis, and only 2 patients (1.3%) had their pouch removed because of pouchitis.

The etiology of pouchitis remains unknown. It may be due to bacterial overgrowth secondary to poor pouch emptying, or to an immunologic reaction to bacterial products or a chemical injury; ischemia and reperfusion injury has also been postulated; or it may be a novel manifestation of inflammatory bowel disease. Patients who are positive for antineutrophil cytoplasmic antibody (ANCA) are more likely to develop pouchitis than those who are not; [170] also, patients with primary sclerosing cholangitis and extraintestinal manifestation of ulcerative colitis are at a higher risk to develop pouchitis, especially of the chronic type. [171] Backwash ileitis, on the other hand, does not predispose to pouchitis. Pouchitis is rare in patients who have undergone ileal pouch–anal anastomosis for familial polyposis, an observation which seems to suggest that whatever causes colitis may predispose to pouchitis.

The activity of pouchitis can be scored using a Pouchitis Activity Index, [172] which uses clinical, histological, and endoscopic criteria. The activity index may help with the medical treatment of pouchitis, which is based on oral antibiotics (metronidazole and ciprofloxacin) in the majority of cases. Interestingly, smoking seems to prevent pouchitis. [173]

The risk of cancer in the ileal pouch is, to date, unknown. Although, no reports have appeared describing the development of carcinoma in the mucosa of a pelvic pouch, the pouch mucosa undergoes structural transformation: initially the mucosa appears normal or with mild villous atrophy and, possibly, mild inflammation. Then the mucosa shows transient atrophy with temporary moderate inflammation followed by normalization of architecture. Finally it develops a pattern of persistent atrophy with severe inflammation. [174] These changes can progress to dysplasia. [175], [176] The continual contact with a noxious medium and changes in bacterial flora are hypothesized as causes of these phenomena. The large number of proliferating cells and the frequent presence of inflammation provide fertile ground for carcinogenesis. Pouch surveillance is probably indicated, as the natural history of the pouch mucosal change is not known at this point.

Controversies in Ileal Reservoir Surgery

The technique of restorative proctocolectomy and ileal pouch–anal anastomosis for adult patients was originally described by Parks and Nicholls [177] and Utsunomiya and colleagues. [145] Since these initial descriptions several modifications have been introduced into clinical practice: they mainly involve the configuration of the pouch and the method of anastomosing the pouch to the anal canal (Table 84-2).

Mucosectomy and hand-sewn pouch–anal canal anastomosis
Stapled pouch–distal rectal anastomosis
Diverting loop ileostomy
One-stage procedure
Multiple-stage procedure

TABLE 84-2 Controversies in Pouch Surgery

In the initial description by Parks and Nicholls [177], the ileal reservoir was fashioned as a triple loop S-pouch (Fig. 84-19), with a 5-cm-long exit conduit, which created problems with evacuation. Subsequently the limb was shortened to less than 2 cm with significant functional improvement. [178] The two other pouch designs that are currently in use are the double loop J-pouch [145] and the quadruple loop W-pouch. [179], [180] The lateral isoperistaltic H-pouch (Fig. 84-20) is no longer used and it is now of historical interest only. [181] Each pouch design has its own advantages and currently there is not a single configuration ideal for every patient. The S-pouch with the long exit limb allows for further reach in tall male patients with short mesentery. [182] The W-pouch (Fig. 84-21) has larger capacity and better compliance [179] and is ideal when part of the terminal ileum has been or needs to be resected. The J-pouch is technically easier and faster to perform. [183], [184] When comparing the W-pouch with either the S-pouch [182] or the J-pouch, [180], [185], [186] patients with the W-pouch have significantly fewer bowel movements compared to the S-pouch or J-pouch group during the first 6 to 12 months after closure of the ileostomy. However, Keighley and colleagues, [187] comparing the J-pouch to the W-pouch in a randomized

prospective trial, did not confirm those findings and Johnston and colleagues [188] showed that both types of pouches conferred the same functional results at one year.

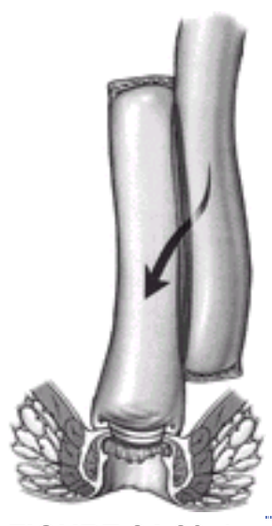

FIGURE 84-20. Isoperistaltic H-pouch. (From Michelassi F, Takanishi D, McLeod RS, et al. Ileal reservoirs. In: Michelassi F, Milsom JW, eds. Operative strategies in inflammatory bowel disease. New York: Springer-Verlag, 1999:186.)

FIGURE 84-21. Quadruple loop W-pouch. (From Michelassi F, Takanishi D, McLeod RS, et al. Ileal reservoirs. In: Michelassi F, Milsom JW, eds. Operative strategies in inflammatory bowel disease. New York: Springer-Verlag, 1999:186.)

We elect to perform a J-pouch for the vast majority of our patients because of the lower complication rate and the excellent functional results experienced. [139], [168], [183], [184], [189] We reserve the S-pouch for patients in whom we suspect a difficult “reach” to the anal canal and the W-pouch for patients in whom a substantial portion of terminal ileum has been or needs to be sacrificed.

Controversy still exists on whether the ileoanal anastomosis should be stapled or hand sewn. The initial descriptions of ileal pouch–anal anastomosis included a mucosectomy to the dentate line. [145], [177], [190] The anal dilation necessary for a complete mucosectomy [191] or the eversion of the anorectum advocated by some authors [192], [193] caused significant decrease in the maximum resting pressure [191] and increase of the threshold sensation, which correlated with increased number of episodes of incontinence. [192], [193] Furthermore removal of the most distal lower rectal–upper canal epithelium, the anal transitional zone (ATZ), results in the loss of the anoderm sensory capacity, which together with the rectoanal inhibitory reflex allows for sampling of rectal contents and contributes to continence. [194] The technique of stapled ileal–pouch anal anastomosis was introduced to address some of the shortcomings of the hand-sewn technique. The potential advantages of the stapled technique include less tension on the anastomosis, ease of construction, preservation of the lower rectal–upper anal canal and less trauma to the sphincter mechanism. These advantages translate to a shorter operation with fewer anastomotic complications and, potentially, better long-term functional results.

Several comparative long-term studies have reported better functional results for the stapled ileal pouch–anal anastomosis. [195], [196], [197], [198] and [199] Gemlo and associates [195] evaluated 235 patients with a mean follow-up of 70 months and found that elimination of a mucosectomy dramatically reduced nocturnal minor and major incontinence, daytime minor incontinence, and daytime protective pad use. Sagar and colleagues [199] studied anal physiological results in 20 patients up to 12 months after stapled ileal pouch–anal anastomosis. Resting anal pressure, which decreased immediately after the surgical procedure, was almost back to normal 12 months later, the rectoanal inhibitory reflex was present in 19 patients and sampling was observed in 17 patients. Ability to discriminate flatus from feces was associated with return of the rectoanal reflex and sampling. The functional results obtained following a stapled or hand-sewn ileal pouch anal anastomosis were evaluated by several prospective randomized studies. [200], [201] and [202] No statistically significant differences were detected, although the validity of the results of these studies is compromised by their small size and by the short follow-up.

Several studies have looked at the rate of anastomotic complications after mucosectomy and hand-sewn ileal pouch–anal anastomosis. Preserving a short rectal cuff with the stapled technique lessens the tension on the anastomosis and reduces anastomotic complications. In a retrospective study, the Cleveland Clinic group

evaluated 692 patients, 238 with hand-sewn and 454 with stapled ileal pouch–anal anastomosis. In the hand-sewn ileal pouch–anal anastomosis group, 25 patients (10.5%) had 32 septic complications, and 24 required 89 reoperations. In 7 patients, the pouch was excised. In the stapled ileal pouch anal anastomosis group, 21 patients (4.6%) had 23 septic complications, and 14 required 40 reoperations. One patient needed pouch excision. Patients with hand-sewn anastomosis experienced more early septic complications and more pouch excisions related to these complications than patients with stapled ileal pouch anal anastomosis. [203] Yet, when these complications were evaluated in prospective randomized studies, no difference was noted. [200], [201] and [202]

The potential disadvantages associated with preserving the ATZ include persistence of ulcerative proctitis symptoms and risk of malignant degeneration. The Cleveland Clinic [204], [205] noticed that symptomatic inflammation of the retained mucosa occurred in 14.7% of their patients; 4.1% of patients had inflammation of the anal canal alone, and 10.6% had pouchitis in addition. The need for surgical treatment occurred in 12.9% of the total patients with anal canal inflammation and 10.6% with anal canal inflammation plus pouchitis. [204], [205] These patients are usually treated with topical steroids or 5-aminosalicylate (5-ASA), and when that fails and surgical treatment is needed, a transanal mucosectomy with ileal pouch advancement is performed with excellent results. [205]

Advocates of the mucosectomy argue that the entire diseased anorectal mucosa, including the ATZ, must be removed to eliminate the risk for future dysplasia and cancer. To determine the long-term risk of dysplasia and cancer in the retained mucosal cuff after stapled ileal pouch–anal anastomosis the Cleveland Clinic group published their series of 210 patients with at least 5 years (median 77 months) of follow-up. [206] Dysplasia developed in 7 patients (3.3%) at a median of 11 months postoperatively. Patients with history of cancer or dysplasia in the colon or rectum were at a higher risk of developing dysplasia. Two patients, each with low-grade dysplasia detected on three separate occasions, underwent mucosectomy 29 and 38 months after detection of low-grade dysplasia and, fortunately no cancer was found. The 5 other patients with dysplasia on one or two occasions were treated expectantly and were apparently dysplasia-free for a median of 72 months. More important, preservation of the ATZ did not lead to the development of cancer after 5 to 10 years of follow-up. The authors recommend long-term surveillance to monitor dysplasia and, if repeat biopsy confirms persistent dysplasia, mucosectomy with pouch advancement. [206]

The actual extent of the ATZ is highly variable and mucosectomy does not assure its complete removal. Fenger, [207] using Alcian blue staining, found that the mean span of the ATZ was 8.9 mm (range 0 to 20 mm), starting up to 6 mm below the dentate line. On the other hand, Thompson-Fawcett and colleagues [208] measured the ATZ by two techniques: whole-mount Alcian blue staining and a computer map of the histological findings based on longitudinal sections taken every 3 mm. They found that the Alcian blue technique overestimates the length of the ATZ, which usually commences just above the dentate line. The median length of the ATZ measured from computer maps of the histology was only 4.5 mm. Due to this variability, mucosectomy does not reliably remove completely the entire rectal mucosa. [209] Small islets of residual rectal mucosa have been identified in up to 14% of patients; in 7% at the ileo anal anastomosis. [209]

This probably explains why, currently in the literature, the reported cases of cancer after a pouch procedure are all in patients who had a mucosectomy, [210], [211] and [212] except in one case, where the cancer was detected 16 months after stapled ileal pouch–anal anastomosis following long-standing ulcerative colitis complicated by a cancer in the upper rectum. [213] It is likely that this cancer represents a local recurrence rather than a metachronous cancer originated in the ATZ.

No hard data exist to support the superiority of one technique over the other and we believe that there is a role for both procedures in clinical practice. [139], [183] We preserve the ATZ in older patients with borderline sphincter function and in tall or obese patients to decrease tension on the anastomosis. Mucosectomy is otherwise advised in presence of dysplasia or cancer in the colon or rectum in the pediatric population [214] and in patients with primary sclerosis cholangitis, known to have a high risk of dysplasia and cancer. [215] If the ATZ is preserved, surveillance anoscopies with biopsies are performed on an annual basis to detect dysplasia and indicate the need for a completion mucosectomy.

With the perception that anastomotic complications are reduced by the stapled ileal pouch–anal anastomosis technique, some authors have questioned the need for a diverting ileostomy. [216] The Medical College of Virginia group started to perform stapled ileal pouch–anal anastomosis without diverting ileostomy in the early 1980s. [217], [218] Their series of 193 patients who underwent a stapled ileal pouch–anal anastomosis as a one-stage procedure without ileostomy, was reported with a mean follow-up of 5.1 years. [218] They noticed an anastomotic leak rate of 12% (23 patients), with 5% (9 patients) requiring a diverting ileostomy; ileal pouch–anal anastomosis function was excellent in 19 of these patients, although 2 required permanent ileostomies. Daytime stool control was 95% and nighttime control was 90%. In patients taking steroids, there was no significant difference in complication rate.

Similar results were reported by Mowschenson and colleagues. [219] In 102 patients they reported a 9.8% anastomotic leak and subsequent diverting ileostomy rate. Overall 74.8% of their patients reported total satisfaction, and 84.7% regarded themselves as being in perfect health. Once again patients on steroids did not experience a higher complication rate. These results are in contrast with several studies where patients on steroids either had a higher incidence of anastomotic complication, [220], [221] and [222] or were not even considered candidates for a one-stage procedure. [223]

The Mayo Clinic group [164], [220] and the Cleveland Clinic group [165], [221] are strong advocates of a two- or three-stage operation, especially in patients on more than 20 mg of prednisone. When comparing the two procedures these studies reported septic complications in up to 22% of the nondiverted group [220] and it was noted that half of the nondiverted patients with septic complications required relaparotomy for diversion and drainage, whereas none of the patients in the diverted group with septic complications required surgery of any kind. [221] We believe that a very select group of patients may benefit from the avoidance of a temporary stoma and its associated complications. [223] Healthy, young patients, not on immunosuppressants or steroids, whose surgery was uneventful and who show minimal tension on the anastomosis, are better served by a one-stage procedure. We usually leave a rectal tube in these patients for few days to avoid pouch distention and perianal skin irritation due to the initial diarrhea.

Proctocolectomy With Continent Ileostomy

The proctocolectomy with continent ileostomy, or Kock pouch, offers an alternative to an ileal pouch–anal anastomosis for few and selected patients with ulcerative colitis. Specifically, this operation should be offered in specialized centers to patients with a locally advanced low rectal cancer that will need adjuvant therapy postoperatively. Patients who already have a Brooke ileostomy, after proctocolectomy, and wish to have a continent ileostomy; patients not candidate to an ileal pouch–anal anastomosis because of poor sphincter function; patients who prefer a continent ileostomy to an ileal pouch–anal anastomosis as a personal choice; and patients who have failed an ileal pouch–anal anastomosis but prefer a continence-preserving procedure to a Brooke ileostomy are all candidates. [224], [225] Contraindications to this procedure include older age, Crohn's disease, obesity, patients who are critically ill, and those who are deemed psychologically unfit. This procedure has also been performed in the pediatric population with satisfactory results. [226], [227]

The distal 30 cm of the terminal ileum are used to form the internal Kock pouch. Intussuscepting the terminal ileum backward into the pouch and anchoring the intussusceptum in place with staples creates a valve that prevents distal outflow from the pouch. The end of the terminal ileum is brought to the skin surface as a flash stoma (Fig. 84-22). The patient empties the pouch intermittently by passing a catheter through the stoma and valve into the pouch. Between intubations, the pouch is continent to both gas and stool.

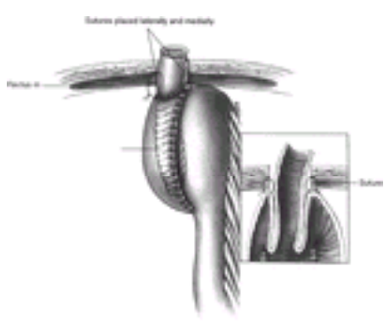

FIGURE 84-22. Kock pouch. (From Cohen Z, McLeod RS. Proctocolectomy with Kock pouch. In: Michelassi F, Milsom JW, eds. Operative strategies in inflammatory bowel disease. New York: Springer-Verlag, 1999:215.)

Kock pouch procedures have fallen out of favor in recent times, as the majority of patients with ulcerative colitis undergo an ileal pouch–anal anastomosis. The largest series reporting on the Kock pouch were published in the late 1970s. [224], [228], [229] Overall long-term follow-up showed excellent results, between 70% and 89% continence for gas and stool, with 95% of these patients free from wearing an appliance. [224], [228], [229] The two main long-term problems with continent ileostomy are malfunction of the valve and pouchitis. Malfunction of the valve causes incontinence and difficult intubation of the pouch, resulting in reoperation. Between 11% and 20% of patients developed this problem, [224], [228], [229] precipitating the need for valve revision. The incidence of pouchitis is nearly identical to that after ileal pouch anal anastomosis, and management is similar.

Kohler and colleagues [230] evaluated quality of life in 406 patients with Brooke ileostomy, 313 with Kock pouches, and 298 with ileal pouch–anal anastomosis. They found that patients with ileal pouch–anal anastomosis had fewer restrictions in sports and sexual activity than the Koch pouch group, which in turn had fewer restrictions in these activities, but more travel restrictions than patients with Brooke ileostomy. Overall as far as social life, recreation, work, and family activities there was no difference between those groups and more than 90% of patients in each group were satisfied with the results. [230]

Total Abdominal Colectomy With Brooke Ileostomy

In patients who are too ill to withstand a definitive procedure for ulcerative colitis, a total abdominal colectomy with end ileostomy is warranted. [231], [232], [233] and [234] Acute toxic colitis nonresponsive to medical therapy [232] with or without megacolon or perforation or hemorrhage is the primary indication for a total abdominal colectomy, end ileostomy, and either a rectal or rectosigmoid Hartmann stump or mucous fistula. This procedure eradicates the disease, requires no bowel anastomosis or pelvic dissection, and allows the patients to be weaned off medications.

Patients who are potential candidates for a total abdominal colectomy are those who carry a diagnosis of indeterminate colitis. This preliminary step allows the pathologist to obtain a final diagnosis after reviewing the resected colon, thus avoiding performance of an ileal pouch–anal anastomosis in a patient with Crohn's disease. As mentioned earlier, this procedure may also be indicated in the obese patient as a first step toward an ileal pouch–anal anastomosis. In these patients, a total abdominal colectomy with Brooke ileostomy eradicates most of the active disease, allows for decrease and eventual cessation of any steroid therapy, and for the possibility of successful weight reduction.

The abdominal colectomy with ileostomy entails resection of the entire colon with exteriorization of the terminal ileum as an end ileostomy. Distally the colon is usually transected at the level of the distal sigmoid or upper rectum, based on the surgeon preference. Controversy persists regarding the management of the rectal stump. Some authors prefer to place it as a closed rectal stump into the subcutaneous tissue of the midline abdominal incision, others leave it as an open mucous fistula through a separate abdominal wound; [233] the majority prefer closure of the intestinal stump and intrapelvic placement (Hartmann pouch). [232], [233] Only small comparative studies have examined this issue. Carter and associates [231] suggested that exteriorization of the closed rectal stump following total abdominal colectomy is associated with fewer pelvic septic complications and minimal local morbidity, facilitates subsequent pelvic dissection, and is not associated with increased disease activity in the retained rectum. Yet, the increased incidence of wound infections mitigates against this strategy as routine. A surgeon will be well served by choosing appropriately, using the different options after having evaluated the patient's general condition, the presence or absence of generalized peritonitis, and the local status of the rectosigmoid.

The removal of the vast majority of the diseased intestine and the diversion of the fecal stream from the residual disease allow these patients to recover from the debilitating effects of high-dose medications, [232] malnutrition, and sepsis. Delaying the ileal pouch–anal anastomosis does not affect postoperative functional results. [234]

Colectomy With Ileorectal Anastomosis

Colectomy with ileorectal anastomosis is only performed in few selected patients. The obvious advantages of this procedure are its relative simplicity, the preservation of the anal route of defecation, and the maintenance of fecal continence in all but the most debilitated patient. In addition, the risk of pelvic nerve dysfunction and perineal wound problems is virtually eliminated. Yet, this operation does not excise the diseased rectum, which maintains a risk of neoplastic transformation and may continue to cause symptoms. Indications for this conservative approach include patients with relative rectal sparing at high medical risk or older patients who are not good candidates for ileal pouch–anal anastomosis; in addition, patients with metastatic colon carcinoma in ulcerative colitis are good candidates due to their limited life expectancy. [86]

Contraindications include severely diseased rectum, dysplasia or nonmetastatic rectal carcinoma, and poor sphincter function; noncompliant patients are subject to lifelong surveillance. [147]

Based on the patient's medical condition and presentation, colectomy and ileorectal anastomosis may be performed as a one-stage procedure or as a two-stage procedure in those requiring emergency surgery. This operation can also be done by laparoscopic techniques.

The presence of pelvic anastomosis puts these patients at risk of septic complications due to an anastomotic leak, which occurs in about 4% of patients. [86] Dehiscences can manifest themselves in the immediate postoperative period as diffuse peritonitis or later, as abscess or fistula. When diffuse peritonitis occurs, patients need to be emergently reexplored, drained, and diverted; if the dehiscence manifests itself as a pelvic abscess, this can be treated by percutaneous, transrectal, transvaginal, transabdominal, or transperineal drainage, depending on its location, and, possibly, proximal fecal diversion. Patients who have suffered an anastomotic dehiscence have worse functional results with more than eight stools per day, continued need for steroids, and incontinence. Eventually, between 12% and 56% of these patients require proctectomy within a few years. [86], [235], [236]

Long-term poor function can also be due to recurrent or worsening proctitis. Endoscopy and biopsy can guide in the diagnosis and treatment. Persistent disease requires either topical or systemic therapy and, ultimately, proctectomy may be necessary. [147]

The risk of cancer in the rectal remnant has been reported to be 15.3% at 12 years, [86] but it varies considerably between series [235], [236] due to the difference in follow-up rates. The risk, however, is major, considering that most of these patients are relatively young.

More than 90% of patients with a functioning ileorectal anastomosis considered their health status to be better than before surgery. [86] Comparative studies, however, have shown no major benefit of colectomy and ileorectal anastomosis over ileal pouch–anal anastomosis in terms of postoperative morbidity, mortality, and long-term function. [237], [238]

Laparoscopic Surgery for Ulcerative Colitis

Skepticism still exists regarding laparoscopic management of patients with ulcerative colitis. Several authors believe that laparoscopic total colectomy is associated with higher morbidity than the open approach [132] and that restorative proctocolectomy does not have the same short-term benefits as seen in other laparoscopic colorectal procedures. [135] Critics of laparoscopic colorectal surgery cite a few early, small studies which suggest that laparoscopy offers no advantages compared with open surgery in terms of return of bowel function or length of hospital stay in ulcerative colitis. [132], [239], [240], [241] and [242] They furthermore claim that laparoscopy increases operative time and cost, and may even have a higher complication rate.

However, as experience in laparoscopy has increased, both technique and instrumentation have improved. Laparoscopic-assisted restorative proctocolectomy has been shown to be technically safe and feasible by various authors. [243], [244] In a case-matched series comparing laparoscopic and open restorative proctocolectomy procedures, Marcello and colleagues [244] have shown that return of intestinal function and length of hospital stay are reduced in the laparoscopic group without increase of morbidity or mortality.

Different techniques have been proposed for laparoscopic-assisted restorative proctocolectomy. [242], [244] Usually the entire colon is mobilized intracorporeally; the vessels are divided either intracorporeally or extracorporeally through a Pfannenstiel incision, based on surgeon preference and skills. The rectal dissection can be

accomplished intracorporeally, but some authors argue that, since a Pfannenstiel incision is needed to extract the specimen, the dissection should be safely and expeditiously performed through that approach. [243] Once the specimen has been delivered through the incision, the rectum is divided at the top of the anal canal using a linear stapler and an ileal pouch is constructed. A double-stapled anastomosis is then fashioned in a standard procedure. The use of a diverting loop has been advocated after laparoscopic-assisted ileal pouch–anal anastomosis. [239], [242], [244] Given that techniques in laparoscopic large bowel surgery are evolving rapidly, the role of this operation in the surgical treatment of patients with ulcerative colitis is likely to expand in the future.

INDETERMINATE COLITIS

A definitive pathological diagnosis is not feasible in 5% to 20% of patients with pancolitis as the only manifestation of inflammatory bowel disease, even after the entire proctocolectomy specimen has been analyzed. [70], [245], [246], [247] and [248] This group of patients has been classified as having indeterminate colitis. The fear that many of these patients with indeterminate colitis may actually harbor Crohn's disease [249] has created uneasiness in the ultimate treatment recommendation. [70] The largest series of patients with indeterminate colitis with a long-term follow-up after ileal pouch–anal anastomosis is from the Mayo Clinic. [248] The authors evaluated 82 patients with indeterminate colitis with a median follow-up of 83 months. They noticed that 15% of patients with indeterminate colitis and only 2% of patients with ulcerative colitis, as a control group, had their original diagnosis changed to Crohn's disease. At 10 years, patients with indeterminate colitis had significantly more episodes of pelvic sepsis, pouch fistula, and pouch failure (27%) than patients with ulcerative colitis. [248] Marcello and colleagues [245] also reported a 13% incidence of Crohn's disease in patients with an initial diagnosis of indeterminate colitis and a 37% pouch failure rate in this group.

Considering that approximately 15% of patients with indeterminate colitis will develop Crohn's disease over time, Bodzin and colleagues [250] advocated ileorectal over ileal pouch–anal anastomosis in patients with indeterminate colitis. Yet, as approximately 85% of patients with indeterminate colitis will remain free of Crohn's disease, we believe that, unless there are preoperative signs suggestive of Crohn's disease, [97] ileal pouch–anal anastomosis, rather than ileorectal anastomosis, should be considered as an option in the treatment of these patients. Patients should be informed preoperatively that they face a higher risk of development of Crohn's disease, but should also be reassured that, after ileal pouch–anal anastomosis, they will experience long-term outcomes identical to those of patients with ulcerative colitis, [248] in the absence of development of Crohn's features.

CHAPTER 85

R. Balfour Sartor, Mark E. Murphy, and Edward Rydzak

MISCELLANEOUS INFLAMMATORY AND STRUCTURAL DISORDERS OF THE COLON

A spectrum of colonic inflammatory conditions can be distinguished from ulcerative colitis and Crohn's disease by clinical, endoscopic, and histological characteristics, although there is some overlap due to the limited repertoire of pathological and physiological responses to injury (Table 85-1). This chapter discusses conditions distinct from idiopathic inflammatory bowel diseases (IBD), explores radiation, ischemic, and infectious enterocolitis and provides distinguishing characteristics to aid in their differential diagnosis and treatment, and emphasizes pathophysiology and etiologic theories.

TABLE 85-1 Clinical and Pathological Characterization of Inflammatory Disorders of the Colon*

COLLAGENOUS AND LYMPHOCYTIC COLITIS

Clinical Features

Collagenous and lymphocytic colitis are characterized by chronic watery diarrhea with normal endoscopic and radiographic evaluations but histological evidence of chronic mucosal inflammation. These disorders represent two extremes of the spectrum of “microscopic colitis.” Collagenous colitis is diagnosed by increased subepithelial collagen deposition and chronic mucosal inflammation while the only histological abnormality of microscopic colitis is increased numbers of mucosal mononuclear cells. [1], [2], [3] and [4] The term lymphocytic colitis was proposed by Lazenby and colleagues [6] to distinguish microscopic colitis from mild IBD and infectious colitis. Although these disorders share certain epidemiologic features (Table 85-2) and 35% to 40% have associated arthritis, autoimmune disorders, and celiac disease, [4], [5], [7] collagenous colitis tends to have a slightly higher age of onset, female predominance, and influence of smoking. [7], [8] and [9] Collagenous and lymphocytic colitis can occur in children [10] and [11] and at least 25% of cases are diagnosed before the age of 45. The predominant symptom is chronic nonbloody diarrhea, 300 to 1700 g/24 hours, [12] with 50% of patients having more than five stools per day. Nocturnal stools are common, and patients report occasional fecal incontinence and decreased stool volume with fasting. Associated symptoms include mild crampy abdominal pain, nausea, mild weight loss, and abdominal distention. [7] Fever and visible rectal bleeding are unusual. The diarrhea usually has an insidious onset and is persistent, between 2 months and 20 years in duration, with a fluctuating clinical course marked by spontaneous relapses and remissions in 90% of patients. [7], [8] Despite increased use of colonoscopic biopsies to evaluate patients with chronic diarrhea, these disorders remain relatively unusual with an incidence of 1 to 3 per 100,000 population. Routine laboratory tests are usually normal, although patients may occasionally exhibit mild anemia, hypoalbuminemia, increased sedimentation rate and, rarely, steatorrhea. Fecal leukocytes are present in approximately half of patients with collagenous colitis [13] although stool lactoferrin is rarely increased.

	COLLAGENOUS COLITIS	LYMPHOCYTIC COLITIS
Incidence (per 100,000 population)	1.0–2.3	3.1
Gender: male:female	1:3–1:10	1:1–1:2
Mean age of onset	55–65 y	51–63 y
Smoking: active	25%	14%
former	8%	23%

TABLE 85-2 Epidemiologic Features of Collagenous and Lymphocytic Colitis

Pathology

Collagenous and lymphocytic colitis are both characterized by moderate numbers of mononuclear cells (lymphocytes, plasma cells, and macrophages) infiltrating the mucosa, with epithelial cell damage and preservation of the crypt architecture (Fig. 85-1). Intraepithelial lymphocytes are increased five- to tenfold (20–25 lymphocytes/100 epithelial cells). [6] Flattened surface epithelial cells, occasionally with a syncytial appearance, decreased numbers of goblet cells, Paneth cell hyperplasia, and increased epithelial mitoses are common histological features. [6], [13] In some studies, eosinophils and mast cells are increased [14], [15] with eosinophilic cationic protein in the lumen, [16] although neutrophils, cryptitis, and crypt distortion are rarely present. Collagenous colitis is histologically differentiated from lymphocytic colitis by a linear subepithelial collagen layer (Fig. 85-1A) which is greater than 10 µm thick and can extend to 100 µm. [1], [17] The normal basement membrane is less than 4 µm thick. The thickened collagen layer is most prominent beneath the surface epithelium between crypts and is frequently penetrated by capillaries. Linearly arranged type IV collagen constitutes the basement membrane in normal subjects. The composition of the thickened band in collagenous colitis is controversial; in one study types I and III collagen and fibronectin predominated [18] but in another report type IV collagen and tenascin were more prevalent. [19] Although cellular infiltration in both disorders is pancolonic, distribution of the thickened collagen table is spotty, being most prevalent in the cecum (82% of cases) and transverse colon (83% of cases) and least likely to be detected in the rectum (72% of cases). [17] Marked variability in simultaneous samples from the same patient and regional distribution of lesions suggest that reports of resolution and development of collagenous colitis over time with serial biopsies [20], [21] could reflect sampling error.

FIGURE 85-1. Histological comparison of lymphocytic and collagenous colitis. **A:** Collagenous colitis is characterized by a thickened subepithelial collagen layer as well as the inflammatory features of increased plasma cells in the lamina propria and a damaged surface epithelium with increased epithelial lymphocytes. **B:** Lymphocytic colitis shows all the inflammatory features of collagenous colitis but lacks the subepithelial collagen layer. (Hematoxylin and eosin stains; original magnification ×225. Courtesy of Audrey Lazenby, M.D., Baltimore, MD.)

Etiology and Pathogenesis

These disorders remain idiopathic, but seem to have an immune-mediated basis by virtue of infiltrating $CD8^+$ T-cell receptor a///ß intraepithelial lymphocytes and $CD4^+$ lamina propria T lymphocytes. The antigens stimulating these T cells are unknown, but are presumably luminal in origin, since diverting the fecal stream decreases inflammation. [22] Inflammation is diffuse and superficial, and 60% of patients respond to antibiotics. [7] Infections with *Clostridium difficile* toxin or *Campylobacter jejuni* have been postulated as environmental triggers initiating this process, possibly accounting for the abrupt onset seen in a minority of cases, and direct toxic effects of bacterial products must be considered to explain therapeutic responses to bismuth subsalicylate. [23] The usual benign prognosis with eventual resolution of symptoms [7], [8] raises the possibility of a protracted postinfectious injury.

The relationship of these disorders to celiac disease remains unresolved. Patients with celiac disease whose diarrhea does not respond to a gluten-free diet have a high incidence (approximately 75%) of lymphocytic colitis. [24], [25] However mild colonic inflammation is less common in untreated, unselected patients with celiac disease (20%), [24], [25] the majority of patients with microscopic colitis do not exhibit malabsorption, and no clinical improvement is noted with a gluten-free diet in the majority of patients with microscopic colitis. However, patients with collagenous/microscopic colitis have similar human leukocyte antigen (HLA) class II haplotypes as celiac disease and have a relatively high frequency of small bowel inflammation and celiac disease serology. [26], [27]

An autoimmune etiology is suggested by the frequent association of arthritis, thyroid abnormalities, asthma and diabetes, [7] perinuclear antineutrophil cytoplasmic antibodies (pANCA) in 20% of cases, [28] and a slightly increased frequency of antinuclear antibodies. [29] Patients with diabetes seem to be at particular risk, with thickening of the subepithelial collagen plate even in the absence of diarrhea. [30] A minority of patients appear to have extracolonic abnormalities of fibrogenesis, with reports of collagenous gastritis [31] and fibrosis in salivary glands leading to the sicca syndrome. [32] In situ hybridization and enzymatic studies show no increased collagen production by subepithelial myofibroblasts, decreased metalloproteinases, and increased inhibitors of metalloproteinases, suggesting defective collagen remodeling rather than enhanced synthesis. [19], [33]

The strong association of arthritis with these disorders raises the possibility that nonsteroidal antiinflammatory drugs (NSAIDs) may play an etiologic role. In a well-controlled study, significantly more patients with collagenous colitis (61%) had used NSAIDs for more than 6 months than age- and gender-matched controls (13%; $P < 0.02$). [34] In uncontrolled studies, up to one third of patients in two collagenous colitis registries had used NSAIDs. [7], [35] NSAIDs can cause gastric, small bowel, and colonic inflammation in humans and experimental animals. [36] Given the high frequency of NSAID use in a 60-year-old population and the relative rarity of collagenous colitis and lymphocytic colitis, other factors must be important. The possibility of genetically determined host susceptibility factors was raised by reports of familial associations of microscopic colitis [37], [38] and of differential susceptibility of inbred rat strains to indomethacin-induced enterocolitis. [39] Of interest, collagenous and lymphocytic colitis can occur in the same family. [37], [38]

The possibility that luminal bile acids injure colonic epithelia in these disorders is raised by clinical responses to cholestyramine and the demonstration of bile salt malabsorption in 60% of patients with lymphocytic colitis and 27% to 42% of those with collagenous colitis. [40], [41] Finally, the ability of ingested substances to injure the colon is illustrated by clinical and experimental inflammation induced by L-tryptophan. [42] Future studies must concentrate on the role of environmental agents, especially NSAIDs, and host genetic factors in the etiology of these disorders.

Diarrhea in microscopic colitis is caused by defective active and passive absorption of sodium and chloride and reduced chloride-bicarbonate exchange in the colon with coexisting abnormal small intestine fluid and electrolyte absorption in one-third of patients. [2] Active colonic chloride secretion associated with increased luminal prostaglandin E_2 and nitric oxide concentrations [43], [44] and prevention of diarrhea by an H_1 antagonist in a patient with increased numbers of mast cells [14] suggest that soluble mediators produced by activated immune and mesenchymal cells mediate epithelial cell absorptive dysfunction. This hypothesis is supported by correlation of diarrhea with increased numbers of mucosal inflammatory cells rather than thickness of the collagen table. [45] The latter observation refutes the theory that subepithelial collagen blocks electrolyte and water absorption.

Diagnosis and Differential Diagnosis

In patients with chronic watery diarrhea whose endoscopic, radiographic, microbial, and endocrine evaluations are normal, lymphocytic and collagenous colitis are diagnosed by characteristic histological features. A minority (29%) of patients with collagenous colitis have nonspecific endoscopic abnormalities including erythema, edema, or abnormal vasculature. [7] Multiple biopsies must be taken from different colonic segments to reliably diagnose collagenous colitis. [13], [17] Biopsy of multiple segments demonstrated a single positive site in 5 of 17 patients and a greater than 50% variability of collagen thickness in multiple samples taken simultaneously. [17]

Biopsies on flexible sigmoidoscopy are usually sufficient to make the diagnosis, but random biopsies from the right and transverse colons will increase the yield by 5% to 10%. Proper orientation of the specimen is essential to prevent tangential sectioning leading to artifactual thickening of the subepithelial basement membrane; the presence of associated lamina propria inflammation is an important co-diagnostic feature of collagenous colitis. [46]

Ulcerative colitis and Crohn's disease can be differentiated from microscopic colitis by diagnostic colonoscopy, radiography, and histological features. Infectious agents must be excluded by stool ova and parasite examinations, standard fecal bacterial cultures, and *C. difficile* toxin assays. In addition, *Giardia* infestation and small bowel bacterial overgrowth can be evaluated by jejunal aspirates which may be taken at the time of small bowel biopsies performed to rule out celiac disease and Whipple disease. Although not a characteristic feature of lymphocytic colitis and collagenous colitis, malabsorption may be present. Hormone-producing tumors, laxative abuse, ischemic colitis, amyloidosis, and hyperthyroidism must be considered in the differential diagnosis. Irritable bowel syndrome can be differentiated by normal stool volume and colonic biopsies.

Several disorders resembling lymphocytic colitis and collagenous colitis can be differentiated by careful histological analysis. [46] Acute infectious colitis is identified by mucosal edema, neutrophilic infiltration, and a paucity of intraepithelial lymphocytes. Ulcerative colitis and Crohn's disease biopsies have crypt abscesses, neutrophils, and possible granulomas with few intraepithelial lymphocytes. Pericrypt eosinophilic enterocolitis shares the characteristics of chronic watery diarrhea and normal endoscopy but lacks increased intraepithelial and superficial lamina propria lymphocytes and is associated with eosinophilic infiltration, crypt foreshortening, and inflammation in the deep lamina propria and muscularis mucosa. [47] Ischemic colitis, radiation colitis, and solitary rectal ulcer syndrome (SRUS) have diffuse fibrosis in the lamina propria, and colonic collagen deposition in progressive systemic sclerosis occurs along all basement membranes and may be transmural. Similarly, amyloid deposits, which have a characteristic histochemical staining pattern, occur diffusely along the basement membrane of the crypts, blood vessels, and surface epithelium.

Treatment

A variety of medical therapies have been used in collagenous and lymphocytic colitis with reported benefit, [7], [48] although only prednisone [49] and bismuth subsalicylate [23], [50] have been subjected to placebo-controlled trials due to the small number of cases at any single institution. Because the course of these disorders is usually benign, it is prudent to start with the least toxic interventions prior to sequentially progressing to more toxic drugs such as prednisone and immunosuppressive agents. Bohr and colleagues [7] have demonstrated that prednisolone had a somewhat higher response rate in patients with collagenous colitis than 5-aminosalicylate (5-ASA) products and antibiotics (82% vs. 50%–67%), but most patients responding to steroids had recurrence of symptoms immediately after stopping treatment. Some studies have suggested excellent responses to relatively nontoxic bismuth subsalicylate [23], [50] and oral budesonide, [7], [51], [52] and [53] as well as to 6-mercaptopurine and azathioprine, [54] although larger trials must be conducted before widespread use of these agents. Ung and associates [41] demonstrated an excellent clinical response to cholestyramine in unselected patients, and a response rate of 92% in those patients with documented bile acid malabsorption. Given the chronic, slowly progressive nature of these disorders, a progressive approach beginning with the least toxic agents is suggested (Table 85-3).

TABLE 85-3 Sequential Approach to Treating Microscopic Colitis

Prognosis

Although chronic, symptoms tend to spontaneously wax and wane. The prognosis is excellent, with the majority of patients responding to treatment, although it appears that collagenous colitis is somewhat more resistant to therapy than is lymphocytic colitis. [8], [48], [55], [56] and [57] The presence of Paneth cell hyperplasia has been postulated as a marker of refractory disease. In contrast to ulcerative colitis and Crohn's disease, Chan and colleagues [58] reported that microscopic colitis is not associated with colonic adenocarcinoma, although the mean follow-up of 7 years may not be adequate for full expression of cancer risk. However, there is no rationale for periodic colonoscopic surveillance for dysplasia in lymphocytic or collagenous colitis.

Overlap or Distinct Diseases?

It is unclear whether lymphocytic and collagenous colitis are two separate but similar diseases or different presentations of a single disorder. [45] These syndromes share similar clinical, demographic, and histological characteristics and differ primarily by the presence or absence of a thickened subepithelial collagen plate. Serial biopsies show resolution or development of this collagen band with time [20], [21]; however, the spotty nature and segmental distribution of the collagen plate [17], [45] make it doubtful that lymphocytic colitis can develop into collagenous colitis. The thickness of the collagen table follows a multimodal distribution and does not increase with age or with duration of symptoms [45] suggesting that collagen deposition is not merely a consequence of active inflammation and the natural progression of long-standing lymphocytic colitis. Moreover, in small studies, the HLA associations of lymphocytic colitis (HLA-A1) and collagenous colitis (HLA-A2) are distinct, [59] and a higher female:male gender ratio and smoking history is present in collagenous colitis. [7], [8] This controversy can only be resolved by more complete understanding of the origin, pathogenesis, and natural history of these disorders.

DIVERSION COLITIS

Clinical Features and Natural History

Inflammation insidiously develops in the distal bypassed colon within Hartmann pouches or mucus fistulae after exclusion of the fecal stream. Most patients with proximal colostomies or ileostomies created for treatment of cancer, diverticulitis, Crohn's disease, ulcerative colitis, Hirschsprung's disease, or trauma have no symptoms from their bypassed colonic segment. However, approximately one third of patients develop frequent mucoid discharges which may progress to rectal bleeding and pain 1 to 9 months after fecal diversion. [60], [61] Symptoms are more prevalent in patients operated on for IBD than for carcinoma or other indications. [62] Histological abnormalities are apparent in almost all bypassed segments. [60], [61], [62], [63], [64] and [65] In a prospective study, endoscopic evidence of inflammation was found in 91% of patients. [63] Colitis was mild in 52% of cases, moderate in 44%, and severe in only 4%, although symptoms were present in only 6% of patients. Endoscopic features include diffuse erythema, granularity, friability, aphthous ulcers, and exudates, with nodularity and diffuse ulceration in more advanced cases. Clinical, endoscopic, and histological abnormalities appear to be progressive, with mild changes at 3 months [64] and more severe findings by 6 to 9 months after proximal fecal diversion. [60] Most patients, however, particularly those without preoperative Crohn's disease, do not develop debilitating symptoms. Anal sphincter function remains normal, although rectal volume diminishes by 3 months postoperatively. [64] Usually the inflammatory process completely resolves soon after restoration of the fecal stream.

Pathology

A histological spectrum of inflammation is present, ranging from mild follicular hyperplasia and lymphoplasmacytic infiltrates to severe inflammation. Diffuse follicular lymphoid hyperplasia with frequent germinal centers is a characteristic feature of all stages of diversion colitis. [63], [65], [66] and [67] Early inflammatory changes consist of mucosal infiltration by lymphocytes, plasma cells and neutrophils, aphthous ulcers overlying lymphoid aggregates, and reactive epithelial cells. Immunohistochemical studies show increased numbers of B and T lymphocytes within lymphoid follicles and in the lamina propria, but no increase of macrophages and plasma cells. [66] More advanced lesions consist of crypt abscesses, relatively mild crypt architectural changes, and Paneth cell metaplasia. Mucin granulomas are present in a minority of cases. In severely involved resected tissues, gross abnormalities include diffuse nodularity and minute ulcerations with exudate. [66] Large ulcers and transmural changes are not typically present. These features are recapitulated in distal colons in rats with fecal diversion. [68]

Pathogenesis

Considerable clinical and experimental evidence incriminates luminal nutrient deficiency as the cause of diversion colitis. Roediger and colleagues [69], [70] have demonstrated that lumenal short-chain fatty acids (SCFAs), metabolic products of carbohydrate and peptide fermentation by anaerobic bacteria, are the principal fuels for the distal colonocyte. Butyrate provides the majority of oxidative energy for the rectal epithelial cell; acetate, ketone bodies, and glutamine are alternative sources. Harig and colleagues [71] demonstrated that excluded colonic segments contained negligible concentrations of SCFAs and that infused carbohydrates were not metabolized to SCFAs. Moreover, instillation of SCFA enemas twice daily induced clinical, endoscopic, and histological remissions in four patients with diversion colitis. Butyrate has multiple effects on cultured colonic epithelial cell lines, including accelerated differentiation, increased constitutive expression of secretory component and HLA class I antigens, and down-regulation of tumor necrosis factor (TNF) and interleukin-1 (IL-1)-induced cytokine expression. [72] Although this theory has achieved widespread acceptance [73] and is supported by the observations that colonic epithelia in ulcerative colitis exhibit aberrant SCFA metabolism and respond to SCFA enemas, [74] it should be noted that SCFA therapy of diversion colitis is not always successful. [75] In addition, factors other than SCFAs may be involved in the pathogenesis of diversion colitis. Mucosal atrophy, rather than inflammation, occurs in germ-free rodents and rats receiving long-term parenteral nutrition or elemental diets [76] and urinary colon conduits (ureterosigmoidostomies) that are not in continuity with the fecal stream, [77] conditions in which lumenal SCFAs would be predicted to be quite low. The fact that diversion colitis rapidly resolves after reanastomosis to restore bowel continuity suggests that lumenal factors provide protection from inflammation. Alternatives to the SCFA hypothesis are that lumenal growth factors, dietary constituents, or other bacterial metabolic products are necessary to maintain optimal colonocyte function, or that post-exclusion alterations in bacterial profiles (dysbiosis) induce damage. In support of dysbiosis, normal anaerobic bacterial concentrations are significantly diminished, certain enterobacterial strains proliferate in the excluded colon, [78] and aerobic nitrate-reducing bacteria increase in frequency. [79] Colonic diversion in rats resulted in crypt atrophy, epithelial erosions, and mucosal inflammation associated with qualitative and quantitative changes of enteric bacteria and alterations in distribution and expression of sulfomucins and sialomucins [68] These observations raise the possibility that mucosal barrier function is diminished, leading to enhanced uptake of lumenal bacterial antigens which activate T and B lymphocytes and innate immune cells. [66]

Diagnosis and Differential Diagnosis

Evaluation of inflammation in the diverted colon is relatively straightforward in the patient who had no preoperative intestinal inflammation. Flexible sigmoidoscopy with biopsies and examination of luminal aspirates for ova and parasites, bacterial culture, and *C. difficile* toxin are usually adequate to establish the diagnosis and evaluate activity of inflammation. Radiographic contrast studies can be performed but add little additional information unless a fistula or abscess is suspected, in which case a computed tomography (CT) scan may be helpful. Visualization of the bypassed colonic segment must be included as part of periodic screening after resection of colonic adenocarcinomas, because recurrent cancers and polyps can cause bleeding in the excluded bowel. [62] Radiation or ischemic colitis must be considered in appropriate clinical situations.

The major diagnostic challenge is to differentiate recurrent Crohn's disease from severe diversion colitis, which is an important distinction if reanastomosis is being considered. Advanced diversion colitis has focal ulceration and a nodular appearance because of lymphoid follicular hyperplasia, which can mimic Crohn's disease. [65] Endoscopic features favoring recurrent Crohn's disease are longitudinal ulcers and possibly strictures, because mucosal ulcers are usually quite small, even in advanced diversion colitis. [66] Aphthous ulcers occur in both entities. CT scanning and endoscopic ultrasonography to measure rectal wall thickness has not yet been investigated in this setting. Histological features suggesting Crohn's disease are transmural inflammation, marked crypt architectural changes, and epithelioid granulomas. Granulomas can occur in diversion colitis but are usually mucinous. Lymphoid hyperplasia occurs in both disorders but is particularly prominent in diversion colitis. [80] The absence of preoperative rectal involvement in the patient with Crohn's disease can also be useful information; all four patients in the study by Korelitz and colleagues [81] regained their normal rectal appearance after reanastomosis, which is safe with mild to moderately active diversion colitis. [81], [82]

Treatment

Because most patients are asymptomatic or have only mild mucus discharge, therapy is rarely indicated. Although SCFA enemas (60 mmol/L acetate, 30 mmol/L propionate, and 40 mmol/L butyrate) induce a remission in some patients, [71], [83] SCFA enemas have not been beneficial in other studies, [75] are not yet commercially available in the United States, and have an unpleasant, odor-limiting compliance in some patients. Hydrocortisone enemas are usually not successful. [81], [75] 5-ASA enemas have induced an endoscopic and histological remission in one patient [84] and have been successful in our practices.

ENDOMETRIOSIS

Endometriosis, defined as the presence of endometrial glands and stroma outside the uterine cavity and musculature (myometrium), is a common disorder, occurring usually without symptoms in approximately 15% of menstruating women. [85] Approximately one third of patients who undergo surgical exploration for endometriosis have intestinal implants, usually in the rectosigmoid (95%), appendix (10%), and ileum (5%), with proximal colon locations uncommon. [86] Meyer [87] described the first case of rectal endometriosis in 1909.

Clinical Features

Most patients with serosal endometrial implants in the rectosigmoid have no specific intestinal symptoms apart from those symptoms typically experienced with pelvic endometriosis. Most patients with intestinal endometriosis have associated implants on their ovaries, anterior and posterior cul-de-sacs, uterus, and uterine ligaments. [85] Pelvic symptoms of dysmenorrhea, dyspareunia, infertility, and dysfunctional uterine bleeding almost always accompany and frequently overshadow intestinal symptoms. Patients with rectal serosal implants may have localized tenderness and palpable nodules on rectovaginal examination. Penetration of endometriomas into the bowel wall and adhesions can lead to symptoms of partial obstruction, including intermittent abdominal pain and constipation. [88], [89] and [90] Partial obstruction caused by compression of the lumen by submucosal endometriomas, fibrosis, and contraction of the mesentery usually occurs in the rectosigmoid area but may involve the ileum. Diarrhea and rectal bleeding have variable incidences, with grossly evident hematochezia present in 3% to 33% of patients who undergo surgical bowel resection. [88], [89] and [90] Bleeding is a rare event in nonoperative series. In a recent surgical series, presenting complaints in order of frequency included abdominal pain, mass, obstruction, rectal bleeding, infertility, diarrhea, and increasing urinary frequency. [90] Cyclic episodes of intestinal symptoms corresponding with menses occur in less than half of patients, although the vast majority (80%) of patients with intestinal endometriosis have associated gynecological symptoms. [91] There have been reports of acute appendicitis caused by intussusception or obstruction by an endometrioma. [92]

The average age of women undergoing surgical resection for intestinal endometriosis is 32 to 44 years, but ages range from 16 to 60 years. [88], [89] and [90] Endometriosis is found almost exclusively in women of reproductive age, with mean age of diagnosis at 25 to 29 years. [85] The somewhat older age of patients undergoing bowel resection probably is related to the chronic nature of the inflammation, which progresses to obstructive complications. Although it is unusual, postmenopausal women can develop symptomatic colonic obstruction, especially if they are treated with estrogen replacement or even tamoxifen. [93] Intestinal symptoms can persist after hysterectomy and oophorectomy if partially obstructing lesions are not resected at the time of initial surgical treatment. [92], [94]

Pathology

Serosal implants are common but usually do not produce specific symptoms unless they invade the intestinal wall. Peritoneal or serosal implants are classically described as bluish-gray nodules ranging from 2 mm to 2 cm in diameter, [85] although mural masses on resected tissue are larger, averaging 2.6 cm. [90] Secretory glands lined by cuboidal endometrial epithelial cells are surrounded by endometrial stroma embedded in fibrotic tissue. These glands can become cystic or be filled with blood. Endometrial deposits invading the bowel wall usually do not involve the mucosa but are associated with localized muscular hypertrophy and fibrosis (Fig. 85-2) [95] which may lead to strictures or asymmetric kinking of the bowel. Histological mucosal abnormalities are confined to the region of invading endometrial nodules and range from mild crypt distortion to active inflammation with crypt abscesses. [95] Mucosal ulceration and polypoid masses, which resemble primary intestinal inflammation or neoplasms, occur in 23% of resected tissues. [90]

FIGURE 85-2. A: Air-contrast barium enema shows an intramural filling defect in the sigmoid colon (*arrows*) which produced stenosis of the lumen. **B:** Operative specimen of the sigmoid colon demonstrates an intramural endometrium. The mucosa is intact but thinned, and the muscle layer is dramatically thickened. (From Croom RD, Donovan ML, Schweisinger WH. Intestinal endometriosis. Am J Surg 1984;148:660.)

Intestinal neoplasms can arise from endometrial implants, even after hysterectomy, particularly in the setting of unopposed estrogen therapy. [96], [97] At least 70% of these tumors involve the rectosigmoid region, but some arise from the ileum, paralleling locations of endometrial serosal implants. The most common type of malignancy is endometrial adenocarcinoma, followed by müllerian adenosarcoma and endometrial stromal sarcomas. [96], [97] These tumors arise from the serosal implants, but may extend into the mucosa.

Pathophysiology

Three theories of the genesis of endometriosis have clinical and experimental support. [98], [99] The *transplantation theory* suggests that dissemination of viable uterine epithelial and stromal cells by retrograde menstruation, vascular, lymphatic, or iatrogenic spread leads to implantation of cells in ectopic locations. Epithelial and stromal cells then proliferate under hormonal stimulation to form invasive nodules. Retrograde menstruation is an almost universal occurrence and the frequency of endometrial implants in the ovaries and dependent areas of the pelvis support dissemination by this route. The *coelomic metaplasia theory* suggests that peritoneal cells undergo metaplastic transformation to endometrial epithelial cells under estrogen stimulation. Although endometrial and peritoneal cells are derived from the coelomic-wall epithelium, the rarity of endometriosis in anovulatory women with persistently elevated estrogen levels and the low frequency of endometrial nodules within the thoracic cavity, which has a similar embryonic derivation, make this theory unlikely. The *induction theory* a combination of the first two theories, states that unknown secreted factors within the shed endometrium induce endometrial metaplasia. Evidence of endometrial-like glands adjacent to micropore filter chambers containing endometrial cells in rodents supports this theory, although the bulk of evidence supports the transplantation theory.

Regardless of which theory is correct, proliferation of endometrial glands and stroma is under hormonal influence. Estrogen stimulates growth, and progesterone inhibits it. A large variety of growth factors such as hepatocyte growth factor and transforming growth factor ß modulate hormonal influences, providing a mechanism by which local inflammatory and stromal cells can regulate growth of implanted tissues. [98], [100] Progressive invasion of intestinal muscle and submucosal layers leads to muscular hypertrophy and fibrosis resulting in segmental narrowing of the adjacent intestinal lumen and secondary obstructive symptoms. Smooth muscle hyperplasia, hypertrophy, and collagen deposition are almost certainly the result of stimulation by the same growth factors that regulate endometrial proliferation. Increased expression of IL-1a, IL-6, and IL-10 by ectopic endometrial tissue and the presence of microscopic inflammation [90], [101] support the concept of activated macrophages in the pathogenesis of this disorder. [98] Integrins such as the $a_V ß_3$ vitronectin receptor appear to be important in implantation. [102] Genetic predisposition is strongly suggested by increased familial incidence and dramatically increased concordance of endometriosis in monozygotic siblings compared with dizygotic sisters. [103]

Diagnosis

Clinical diagnosis of intestinal endometriosis can be difficult because of nonspecific symptoms. The classic presentation is partial obstruction of the colon in an infertile woman of reproductive age with progressive dysmenorrhea and dyspareunia. Cyclical symptoms associated with menses are suggestive but are present in less than half of patients. Most patients have symptoms of pelvic endometriosis. Tender nodules palpable in the rectovaginal septum (posterior cul-de-sac) on rectovaginal examination are highly suggestive of endometriosis, but fixation of the rectum is nonspecific. Radiographic and endoscopic examination are normal in the presence of noninvasive serosal implants. Most patients with obstructing endometriosis have extrinsic compression or smooth strictures with normal mucosa [104] (see Fig. 85-2A) and normal biopsy specimens. If rectal bleeding is present, endoscopic evaluation with biopsies has been reported to be diagnostic in four of six patients with histological confirmation in five. [105] CT and magnetic resonance imaging scans are usually nonspecific because of the small size of implants and cannot exclude carcinoma or lymphoma. [96] Endorectal ultrasonography can detect intestinal wall invasion by endometrial implants and distinguish these lesions from mucosal processes. [105], [106]

Definitive diagnosis is made by surgical exploration, either by laparoscopy or by celiotomy, and by tissue histological diagnosis. [88], [89] and [90] The vast majority of patients with intestinal endometriosis have multiple associated serosal implants on pelvic organs and the intestine.

Differential Diagnosis

Intestinal endometriosis with altered bowel habits is difficult to differentiate from irritable bowel syndrome, Crohn's disease, and invasive adenocarcinoma. [89], [90] The distinction can be suggested by associated infertility, dysmenorrhea and dyspareunia, presence of tender nodules on rectovaginal examination, and evidence of extrinsic rectosigmoid compression on flexible sigmoidoscopy or barium-contrast examinations. Laparoscopy or even surgical resection is usually necessary to establish the diagnosis. Strictures secondary to Crohn's colitis usually have associated mucosal ulceration and histological evidence of inflammation; these findings are rare in endometriosis. Of interest, ileal endometriosis has been reported to complicate established Crohn's disease. [107] Primary colonic carcinoma or lymphoma must be considered in all cases of bowel stricture regardless of age. Endoscopic and radiologic features favoring adenocarcinoma include mucosal ulceration and sharp margins; endometriosis is usually submucosal. [90] Additional clinical features suggesting carcinoma are advanced age (postmenopausal), hematochezia, multiparity, and lack of dysmenorrhea and tenderness. However, none of these features is absolute, particularly since carcinoma can arise from endometriosis even in postmenopausal with estrogen replacement, [96], [97] and resection with transmural histological examination is the only way to definitively rule out carcinoma. Rarely, mucosal involvement by endometriosis can simulate adenomatous polyps. [97] Long, smooth ischemic strictures are usually in the descending colon, whereas shorter eccentric endometrial strictures occur more distally in the rectosigmoid region. Diverticular masses and radiation-induced strictures occur in older age groups and can usually be differentiated on clinical grounds.

Treatment

Hormonal therapy or nonresective surgery can be used to treat superficial serosal implants without stricture. Current medical therapeutic options diminish estrogen stimulation by inducing pseudopregnancy, pseudomenopause, or chronic anovulation. Danazol, a 17a-ethinyltestosterone derivative, medroxy-progesterone, and gonadotropin-releasing hormone analogs are clinically comparable and superior to placebo in diminishing pain and size of pelvic endometrial nodules. [108], [109] Although Fedele and colleagues [110] reported excellent results in intestinal endometriosis with a 6-month course of luprolide, a gonadal-releasing hormone, all patients relapsed and these investigators suggested definitive surgical treatment. Ablation of infiltrating endometrial implants on the anterior rectum and rectovaginal septum can be safely accomplished with a laparoscopic carbon dioxide laser, [111] but most authors advocate segmental resection of partially obstructed colons because of poor results with medical therapy or superficial ablation and the inability to exclude carcinomas associated with endometriosis by clinical assessment. [91], [94], [97], [112], [113] Laparoscopic versus open explorative approaches to resection depend on the individual case and experience of the surgeon. [112], [114], [115] In postmenopausal women and those who do not desire pregnancy, hysterectomy and bilateral oophorectomy should be performed at the time of intestinal resection to treat associated pelvic endometriosis and to minimize the risk of recurrent disease. Patients who desire to preserve fertility should have excision or laser ablation of associated endometriosis in the pelvic organs in conjunction with bowel resection. Reports of successful pregnancies after surgical treatment vary, but results seem to be superior to those achieved with medical therapy. [85] However, recurrence of symptoms of endometriosis with preservation of ovarian function is substantial, and patients may subsequently develop obstructive intestinal symptoms despite medical therapy. [116]

DRUG- AND CHEMICAL-INDUCED COLONIC INJURY

Toxic colitis has been associated with numerous orally and rectally administered agents; in addition, certain drugs cause ischemic colitis, melanosis coli, and cathartic colon (Table 85-4). This section reviews the various types of chemical- and drug-induced colonic injury, with an emphasis on clinical findings and pathogenesis.

Enemas: soap, water-soluble contrast media (e.g., Gastrografin), hydrogen peroxide
Laxatives: melanosis coli, cathartic colon
Agents inducing ischemia: oral contraceptives, vasopressin, ergotamine, alosetron, cocaine, dextroamphetamine, neuroleptics, digitalis
Miscellaneous: nonsteroidal antiinflammatory drugs, selective cyclooxygenase X 2 inhibitors, penicillamine, gold, isotretinoin, antibiotics, chemotherapy, methyldopa, flucytosine, glutaraldehyde

TABLE 85-4 Colonic Injury Induced by Therapeutic Agents

Syndromes Associated With Enema Use

Colitis with a broad spectrum of clinical and endoscopic findings may result from rectal administration of various chemicals. High-risk groups for toxic colitis include patients with a history of self-mutilation or of self-medication for constipation, members of certain African tribes who ritualistically use herbal enemas, and those receiving soap enemas or water-soluble contrast media. Individuals with chemical colitis usually present with abdominal pain, bloody or nonbloody diarrhea, tenesmus, fever, and leukocytosis; rectal and abdominal tenderness, with or without peritoneal signs, may be seen on physical examination. [117], [118] and [119] Nonspecific endoscopic findings range from friable, granular mucosa to frank ulceration, with or without pseudomembrane formation. One endoscopic clue to toxin-induced colitis is the association of perianal excoriation with a predominantly distal colitis. [117] Treatment is primarily supportive, with intravenous fluids, bowel rest, and, if clinically indicated, broad-spectrum antibiotics. However, surgery may be necessary in some cases. [117], [119], [120]

Soap Colitis Syndromes of soap-induced colitis range from mild inflammation with increased stool frequency to severe acute co-litis with bloody diarrhea resembling idiopathic ulcerative colitis. [118] Acute colitis may heal with scarring and colonic cicatrization [120] or may progress to transmural necrosis and perforation. [121], [122] Endoscopic findings range from mucosal edema (with loss of normal vascular pattern) to mucosal sloughing and ulceration. [118] The pathophysiology of soap-induced colonic injury centers on its detergent effects on the colonic mucosa. Detergent enemas in animals caused acute liquefaction necrosis which resembled alkaline-induced corrosive esophagitis, with an acute necrotic phase (days 1–4), an ulceration/granulation phase (days 3–5), and a cicatrization phase (beginning in weeks 3–4). [120] The severity of damage in soap-induced colitis is related to both the soap concentration and the duration of mucosal contact. [118] Based on these well-described toxicities, there is no clinical role for soap enemas.

Water-Soluble Contrast Media Mild focal inflammation ranging to severe colitis with necrosis and perforation may be associated with several hyperosmolar water-soluble contrast media, including Gastrografin, Hypaque, and Renografin. [123] These agents are used to opacify partially obstructed colons and avoid the potential complications of barium with extraluminal leakage. Gastrografin is also used to treat meconium ileus in neonates with cystic fibrosis and severe fecal impactions in adults; its hypertonicity and the presence of the detergent Tween 80 are thought to facilitate stool passage by drawing fluid into the gut lumen. Gastrografin had a greater propensity for inducing colitis in animals than Hypaque, Renografin-76, or barium. [123] Tween 80 may damage the gut mucosa in a manner similar to soap enemas. Enemas containing Tween 80 in addition to Hypaque sodium 25%—which by itself did not cause substantial inflammation—increased the incidence and severity of colonic inflammation in rats. [123] These results, however, were not borne out in later animal studies. Animals without lumenal distention suffered no ill effects regardless of the medium used to fill the colon, causing Wood and colleagues [124] to postulate the pathogenetic importance of compromised mucosal blood flow in the distended gut. In humans, damage almost always occurs proximal to obstructing lesions, mainly in the cecum and ascending colon, [119], [125] raising the possibility that prolonged mucosal exposure and preexisting mucosal injury may be contributing factors.

Hydrogen Peroxide Hydrogen peroxide enemas used in the disintegration of impacted feces, treatment of meconium ileus, and removal of intestinal gas in preparation for radiologic study have been associated with bloody diarrhea, pneumatosis coli, colonic perforation, sepsis, and death. [126] The colitis may be caused by ischemia as a result of the entrance of gas into the loose connective tissues of the mucosa and submucosa and, eventually, into the vasculature, resulting in abolition of mucosal blood flow. In animal models hydrogen peroxide enemas resulted in the rapid formation of gas cysts in the mucosa, submucosa, and serosa, with subsequent absorption of the gas into the local circulation and eventual mucosal ischemia. [127], [128] Oxygen free radicals released by hydrogen peroxide may also contribute to mucosal damage.

Other Miscellaneous Substances Inadvertent ethanol enema administration has been reported to cause an acute hemorrhagic colitis with associated lower abdominal pain. [129] Self-administration of a hydrofluoric acid enema resulted in rectal pain and bloody diarrhea necessitating segmental resection of a necrotic, ulcerated sigmoid colon. [117] The ritual use of enemas by South African tribesmen —traditionally involving roots, herbs, tree bark, and other natural constituents—has been adapted to more modern agents, including vinegar, potassium dichromate, potassium permanganate, copper sulfate, unknown herbal medicines, and chloroxylenol (Dettol), which induced colitis ranging from mild rectal inflammation to transmural coagulative necrosis. [130] The vinegar enema induced extensive bowel infarction with destruction of the rectovaginal septum.

Syndromes Associated With Laxatives

Melanosis Coli Melanosis coli is a dark pigmentation of the colonic mucosa seen in 73% of patients who use anthraquinone laxatives (cascara sagrada, aloe, rhubarb, senna, and frangula), although the relationship is not exclusive. [131] Its gross appearance is a reticulated pattern of striations and spots that resembles alligator skin (Fig. 85-3; see Color Fig. 85-3). [132], [133] Melanosis can appear as rapidly as 4 months after the initiation of anthraquinone laxatives, with an average time to appearance of 9 months. Withdrawal of anthraquinones results in resolution of pigment changes in an average of 9 months. [132] Melanosis has also been described in patients with IBD. [134] The incidence of melanosis coli in endoscopy and autopsy series ranges from 0.25% to 23.6%, with an increased frequency in women and among those older than 40 years of age. [133] Melanosis coli is found mainly in the cecum and the rectum, although it may involve the entire colon, and may be detected in biopsy specimens even when not grossly visible. [114]

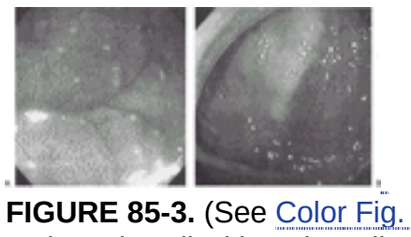

FIGURE 85-3. (See Color Fig. 85-3.) Endoscopic photographs of melanosis coli. **A:** The reticulated, alligator-skin appearance is characteristic of this condition. **B:** Melanosis coli with a sharp line of demarcation at the small bowel–colonic anastomosis.

Histologically, melanosis coli is associated with the deposition of a brown, granular pigment within lamina propria macrophages (Fig. 85-4). The number and size of mucosal macrophages are increased, and they are situated between the colonic crypts. Two distinct groups of macrophages are evident; those nearest the lumen have the least pigment, and those furthest from the lumen have the most pigment. [135] The colonic epithelial cells are normal by light microscopic examination. However, electron microscopy has revealed decreased numbers of microvilli, vacuolization of the apical cellular surface, lipid droplets near the basal membrane, and small vesicles near the lateral cell membrane. [136] The source of the pigment in melanosis coli is unclear. Its biochemical features of lipofuscin, ceroids, and melanin suggest a derivation from apoptotic epithelial cells. [137] Other suggested origins include degenerating mitochondria or lysosomes [135] and absorbed pigments derived from anthraquinone laxatives. [132] Guinea pigs fed danthron, an anthraquinone laxative, developed transient large-scale apoptosis of colonic surface epithelial cells. [138] Cellular debris phagocytosed by macrophages and carried into the lamina propria was transformed into the typical lipofuscin-like pigment seen in melanosis coli. These experimental results agree with dramatically increased apoptosis of colonic epithelial cells in patients with melanosis coli. [137], [138] and [139] The clinical significance of melanosis coli, apart from its association with anthracene laxative abuse, is uncertain; however, there is universal agreement that it is a benign condition. Colonic adenomas in patients with melanosis coli are not pigmented, and neoplastic tissues lack pigment-laden macrophages. [140] Biopsy of islands of unpigmented tissue in patients with background melanosis is therefore advised. Deposition of pigment proximal to carcinoma of the colon has led to speculation that

colonic stasis may be a contributing factor. [133] However, no correlation is found between the presence of melanosis and colorectal transit. [131] The risk of colonic neoplasia with melanosis coli is the subject of controversy. Siegers and colleagues [141] reported a relative risk of 3 for colorectal cancer with chronic anthranoid use, but Nusko and colleagues [142] found no increased risk of cancer with melanosis coli.

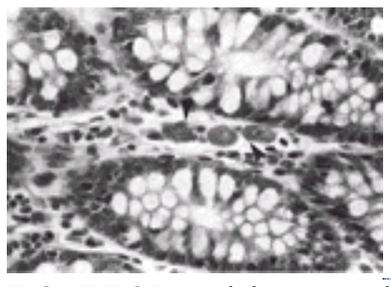

FIGURE 85-4. High-power photomicrograph demonstrates lipofuscin-like pigment within macrophages (*arrows*) in the lamina propria of a rectal biopsy specimen from a patient with melanosis coli.

Cathartic Colon The incidence of cathartic colon has dramatically decreased since its initial description in 1943. [143], [144] Most patients are women who have abused laxatives, either overtly or surreptitiously, for 15 or more years who develop bloating, abdominal fullness, and vague lower abdominal pain. [145] Symptoms of incomplete evacuation without laxatives lead to escalating doses of laxatives until these patients cannot defecate normally without cathartic use. [146] Ninety percent of surreptitious laxative abusers are women; many are emotionally disturbed. [146] These patients frequently undergo multiple diagnostic evaluations to evaluate complaints of chronic diarrhea, vague abdominal discomfort, thirst, and weakness. [147] Electrolyte and fluid abnormalities, particularly hypokalemia and hypovolemia, and steatorrhea have been reported. Heizer and colleagues [148] detailed two cases of protein-losing enteropathy with hypoalbuminemia which resolved after cessation of cathartic abuse. The most striking abnormalities in cathartic colon are seen on contrast radiographs (Fig. 85-5). Mild cases have findings limited to a foreshortened, conical cecum and loss of the typical beaklike appearance of the ileocecal valve. More severe cases are characterized by a dilated, tubular colon distal to the cecum, with loss of haustral markings; segments of bowel may appear narrowed, but these pseudostrictures are transient in nature. [145] The radiographic appearance of cathartic colon resembles that of long-standing ulcerative colitis but can be differentiated by the distensibility of the bowel in cathartic colon, the lack of mucosal inflammation and sparing of the rectosigmoid region. [143], [145] Complete resolution of these abnormalities within 4 months of cessation of laxative use has been reported. [149]

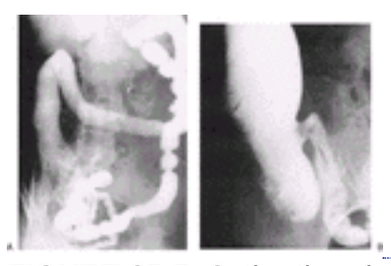

FIGURE 85-5. Cathartic colon. **A:** Barium enema study reveals that the right and transverse colon are devoid of haustrations. No ulcerations are seen. **B:** Detail of the cecum and proximal ascending colon reveals a gaping ileocecal valve. The lack of haustration in the right colon is striking. (From Campbell WL. Cathartic colon: reversibility of roentgen changes. Dis Colon Rectum 1983;26:445–448.)

Cathartic colon is related to chronic use of irritant laxatives (primarily anthraquinones); however, the precise mechanism is unknown. Anthraquinones are potent cellular toxins; for example, intravenous or oral administration of syrup of senna to mice causes damage to the myenteric plexus. [150] Resected human specimens show hypertrophy of the muscularis mucosae, thinning of the muscularis propria, excessive submucosal fat deposition, loss of myenteric plexus neurons, and replacement of ganglia by Schwann cells. [150] Reversible abnormalities in colonic nerve plexi exist in chronic laxative abusers who have not yet developed typical radiographic changes. [151] Toxic effects of anthraquinones on the colonic myenteric plexus nerves are the likely cause of the cathartic colon syndrome, although it is possible that a subgroup of patients with chronic idiopathic constipation has a developmental anomaly of the myenteric plexus which leads to chronic laxative ingestion. [152] Treatment of cathartic colon centers on withdrawal of irritant laxatives. Bulking agents, a high-fiber diet, and bowel retraining are the most effective measures. In the early phases of bowel retraining, use of an osmotic laxative or Fleet enemas may be helpful. Patient cooperation is critical; lack of compliance is a common problem. [146] In refractory cases, surgical approaches have been used, the most effective being total or subtotal colectomy, [153] but resection should be considered only after failure of maximal medical therapy in light of the reversibility of some cases. [130]

Drugs Resulting in Ischemic Colonic Injury

Several substances compromise mucosal blood flow through vasospasm, thrombosis, or both, resulting in ischemic injury (see Chapter 81). Although ischemic colitis is not uncommon in older adult patients with mesenteric atherosclerotic disease, its presence in a younger patient should prompt a search for a predisposing cause, such as medications. [153] The symptom complex manifested by these patients is fairly uniform, consisting of the abrupt onset of severe abdominal pain, bloody or nonbloody diarrhea, tenesmus, nausea, vomiting, and fever. Rebound tenderness and guarding, with hypoactive or absent bowel sounds, may be noted, although less striking physical findings may be found. Leukocytosis is variably present, and plain or contrasted abdominal radiographs may reveal “thumb printing.” Endoscopy may show mucosal friability, edema, erythema, granularity, ulceration with or without pseudomembranes, or necrosis. [155], [156] and [157] As in atherosclerotic mesenteric vascular disease, the junction of the distributions of the superior and inferior mesenteric vessels (from the distal end of the transverse colon to the proximal descending colon) is a common site of injury in drug-induced ischemic colitis.

Oral Contraceptives Transient ischemic colitis in otherwise healthy young women taking oral contraceptives was first described in 1968. [155] Mesenteric thrombosis, both arterial and venous, has been extensively described in association with oral contraceptives; arterial thrombosis carries twice the mortality of venous thrombosis but is half as common. [156] Although the typical presentation is that of classic ischemic colitis, symptoms can be indistinguishable from those of Crohn's disease. [157] Estrogens can cause a hypercoagulable state, vasospasm in the mesenteric vessels, and endothelial proliferation with subendothelial fibrosis, all of which may play a role in ischemic colitis. [156] High-dose estrogen preparations, high-dose progesterone combinations, depot progesterone dosages, and sequential estrogen/progesterone therapy have all been implicated in mesenteric thrombosis. [156], [157] The duration of oral contraceptive use in these patients ranges from 10 days to 11 years. The dose of the estrogenic fraction correlates with thrombogenicity. [119], [155], [156]

Vasopressin Vasopressin, a vasoconstrictor used to treat bleeding esophageal varices, decreases colonic blood flow in a dose-dependent fashion. A case of reversible ischemic colitis associated with intravenous vasopressin infusion has been reported. [158]

Ergotamine The association between ergot preparations and ischemic colitis is presumably related to vasospasm. Stillman and associates [159] described a 50-year-old woman with no risk factors for mesenteric ischemia who developed acute bloody diarrhea and acute colitis in the splenic flexure area while taking ergotamine tartrate; her symptoms resolved after discontinuation of ergotamine. Rectal ulceration, with obliteration of small blood vessels, endothelial proliferation, and vascular wall thickening, can develop in patients using ergotamine suppositories.

Alosetron Alosetron, which had been approved for treatment of diarrhea-predominant irritable bowel syndrome, was withdrawn from the market because of reports of ischemic colitis, but it has been reintroduced under controlled usage for severely symptomatic patients. [160]

Cocaine Several reports of severe, ischemic colitis in patients using high doses of cocaine have been published. [161], [162] Cocaine-induced ischemic colitis should be strongly suspected in any young or middle-aged person with abdominal pain and bloody diarrhea, particularly if there are no potential thromboembolic sources and if there is no history of estrogen use. [161] Inflammation can involve the rectum, which is an unusual location for ischemic colitis. The putative mechanism of cocaine-related ischemic colitis is catecholamine-induced mesenteric vasospasm by this powerful sympathomimetic agent. [161]

Dextroamphetamine A case of reversible ischemic colitis attributed to intense mesenteric vasoconstriction has been described in a 47-year-old man taking dextroamphetamine as his only medication. [154] His acute presentation of abdominal pain and bloody diarrhea resolved after cessation of dextroamphetamine therapy. Mesenteric angiography was normal.

Methamphetamine Methamphetamine, a drug frequently sold illegally as “ice” or “crystal meth,” has been implicated in several cases of ischemic colitis. [163]

Neuroleptics Ischemic colitis has been linked to the use of neuroleptics, especially tricyclic antidepressants, in some case reports. [164], [165]
Digitalis Preparations Digitalis preparations have been associated with ischemia in the small or large intestine; isolated colonic ischemia has not been reported. It is likely that these reports represent a manifestation of the clinical setting of digitalis use (i.e., systemic hypoperfusion), although digitalis preparations have been shown to cause mesenteric vasoconstriction in laboratory animals. [166]

Miscellaneous Drug-Induced Colitides

Nonsteroidal Antiinflammatory Drugs Several inflammatory syndromes have been associated with the use of NSAIDs. Colitis in previously asymptomatic individuals has been associated with numerous NSAIDs, including mefenamic and flufenamic acid, diclofenac, indomethacin, enteric-coated aspirin, ibuprofen, phenylbutazone, naproxen, and piroxicam. [34], [167], [168] and [169] It has been estimated that 10% of newly diagnosed colitis cases may be related to NSAID use. [170] Typical patients are older (average age, 63 years) with no gender predilection and present with diarrhea and either occult or gross lower gastrointestinal bleeding. [168] Some have weight loss or fever. The majority are anemic; many have an elevated erythrocyte sedimentation rate and leukocytosis. Endoscopic findings were variable and range from mild proctitis to ulcerative pancolitis. Ulcerations or other inflammatory changes can occur at any point in the colon, and can be focal or diffuse. Treatment is primarily withdrawal of the offending NSAID, although treatment with steroids, sulfasalazine, or even surgery for complications such as bleeding and perforation may be required. Medical treatment with steroids and sulfasalazine has been used on several occasions. In a 1992 review of NSAID colitis by Gibson and colleagues, [168] all 12 patients who were rechallenged with NSAIDs had relapses. Relapse of quiescent IBD was described in 19 patients; these patients were significantly younger than those with de novo NSAID-induced colitis, the median latency period between NSAID exposure and colitis symptoms was less than 1 week and relapse occurred in all eight patients rechallenged with NSAIDs. [168] A similar experience was described by Gleeson and colleagues [171] who reported an average age of 53 years. Most cases were self-limited, improving rapidly upon withdrawal of the NSAID and with 4- to 8-week courses of 5-ASA products; only one of the 23 patients in this study required surgery (for toxic megacolon). An increased rate of spontaneous colonic perforation or hemorrhage is associated with NSAID use. [34], [168] NSAIDs have been associated with perforated colonic diverticula, proctitis related to NSAID suppository use, eosinophilic colitis, and diaphragm disease of the colon. [34], [172], [173] NSAIDs have also been implicated in the development of collagenous colitis. [34], [173] The pathogenesis of NSAID-induced colonic injury is uncertain but probably is mediated by the effects of cyclooxygenase inhibition leading to loss of the mucosal cytoprotection and immunosuppression afforded by inducible prostaglandins. Studies using selective gene deletion and pharmacological inhibitors in rodents implicate both cyclooxygenase 1 and 2 in the pathogenesis of intestinal inflammation. [174], [175] Loss of vasodilating prostaglandins and production of vasoconstricting leukotrienes and cytotoxic oxyradicals associated with lipoxygenase activation could impair mesenteric blood flow. Epithelial injury and enhancement of colonic mucosal permeability by NSAIDs, with resultant increased susceptibility to luminal bacterial toxins, may also play a role. [176] One report of apparent NSAID-induced colitis occurring in a patient taking misoprostol raised some doubt about the role of prostaglandins in the pathogenesis of NSAID colitis; uncoupling of mitochondrial oxidative phosphorylation was offered as an alternative hypothesis. [177]
Gold Gold salt–induced colitis in patients with rheumatoid arthritis is probably caused by local toxicity of the drug. Up to 95% of orally administered gold is excreted in the feces, and stainable gold is present in mucosal biopsy specimens. [178] Most patients are women; clinical manifestations may include bloody diarrhea, abdominal pain, tenesmus, fever, leukocytosis, and even fulminant colitis. [179] Onset of colitis can be delayed for several weeks after cessation of gold therapy. [180] Diagnosis is usually made by the endoscopic appearance of ulceration and friability, often with hemorrhage; lesions are most often found in the rectosigmoid, although colitis may be diffuse. [178] Biopsies may reveal nonspecific acute and chronic inflammation, occasionally with eosinophils; some have histological findings that might cause confusion with Crohn's disease. [178], [181] Treatment is primarily withdrawal of gold therapy and supportive care with an average recovery time of 2 weeks, although surgery, steroids, British anti-Lewisite (BAL), and sulfasalazine have been used with success. [178] One case of eosinophilic gold-induced colitis responded to oral cromolyn therapy. [182] The older literature reports a 40% mortality with this complication; however, a review of 14 cases reported between 1980 and 1986 reveals no deaths. [178]
Isotretinoin Isotretinoin, a synthetic analog of vitamin A used in treatment of severe cystic acne, has been linked to acute colitis and to the reactivation of quiescent IBD. Martin and colleagues [183] reported that cessation of therapy resulted in prompt colitis resolution, whereas rechallenge caused an almost identical recurrence.
Antibiotics Hemorrhagic colitis associated with ampicillin, amoxicillin, and erythromycin differs from typical *C. difficile* colitis in that patients present with bloody diarrhea, generally do not have pseudomembranes, have predominantly right-sided colitis, rapidly improve with discontinuation of antibiotics, and test negative for *C. difficile* toxin. [184], [185] The pathogenesis is unknown, although this may represent a variant of *C. difficile* disease or an overgrowth of an unrecognized pathogen.
Chemotherapeutic Agents Rapidly dividing intestinal epithelial cells are particularly susceptible to the toxic effects of cancer chemotherapeutic agents with almost complete blockade of DNA synthesis by cytotoxic doses of antimetabolites. [186] Multiple chemotherapeutic agents cause colonic damage, including cytosine arabinoside, methotrexate, cyclophosphamide, and 5-fluorouracil. Clinical manifestations range from mild segmental colitis to fulminant ulcerative colitis with toxic megacolon. [186], [187], [188] and [189] The pathogenesis is probably multifactorial and includes direct epithelial injury by chemotherapeutic agents, invasion of the mucosa by intestinal pathogens, and ischemic injury. [186], [187] and [188] Cytosine arabinoside induces a three-stage pattern of damage consisting of initial injury—replacement of normal mucosal cells with atypical undifferentiated cells, with conspicuous absence of mitotic figures; progressive injury—cellular necrosis and glandular dilation, with persistent lack of mitosis; and regeneration—resumption of normal mitotic activity, with mature goblet cells in the bases of crypts. [187] These changes can probably be extrapolated to most chemotherapeutic agents. [188]
Methyldopa Colitis associated with methyldopa therapy presents as bloody or nonbloody diarrhea with prompt resolution of symptoms after drug withdrawal. Three patients who were rechallenged with methyldopa demonstrated symptom recurrence. [190]
Flucytosine Flucytosine, an antifungal agent, been associated with the development of colonic inflammation resembling idiopathic ulcerative colitis. [191]
Sodium Phosphate Bowel Preparation Solution Focal colitis caused by oral sodium phosphate bowel preparation solution has been described. In 687 consecutive patients who underwent sodium phosphate bowel preparation, unexplained aphthous ulceration was present in 18 patients (2.6%), with resolution within 1 to 8 weeks when reexamined. [192]

COLONIC ULCERS

A number of conditions other than medication use are associated with colonic ulceration (Table 85-5). Common presenting symptoms include hematochezia, abdominal pain, and a mucopurulent rectal discharge. Diarrhea correlates with the surface area affected and is uncommon with isolated ulceration. Careful endoscopic and histological examinations can help distinguish these conditions using the criteria established in Table 85-5.

TABLE 85-5 Clinical Characteristics of Colonic Ulcers

Isolated Nonspecific Colonic Ulcer

In a review of 127 patients with colonic ulcers, the average age was 45 years, with a range of 8 to 84 years and a 55% female predominance. [193] Sixty-seven percent of patients had cecal ulcers, another 18% had ascending or transverse colonic lesions, and 15% had descending or sigmoid ulcers. Virtually all were solitary ulcers located on the antimesenteric side of the lumen, ranging from 0.5 to 6.5 cm in diameter. [193], [194] Cecal ulcerations are most often found near the ileocecal valve, and are round or oval in configuration, with sharply demarcated margins and relatively normal surrounding mucosa. [193], [195], [196] Histology is nonspecific, with acute and chronic inflammation. [193], [196]

Pathogenesis The cause of nonspecific colonic ulceration remains unknown; therefore the diagnosis is one of exclusion. Several hypotheses for the origin of nonspecific colonic ulceration include ischemia, cecal diverticulosis, acid, and miscellaneous causes. Microvascular thrombosis and vascular abnormalities, including thickening of vascular walls, thrombosis, thrombus organization, and recanalization within local vessels, in areas underlying and adjacent to nonspecific colon ulcers suggest a localized form of ischemic colitis, perhaps promoted by fecal stasis. [194], [195], [196] and [197] However, ischemic injury usually occurs in the watershed area of the descending colon and splenic flexure, not the cecum, and right-sided fecal impaction is relatively rare. [198] Finally, thrombosis may be secondary to the adjacent inflammation, making determination of cause and effect difficult. Based on the observation that 50% of cecal ulcerations had histological evidence of cecal diverticula, it has been reported that cecal diverticulitis could result in ulcer formation. [184] However, less than 15% of colonic ulcers occur in the sigmoid colon, the site of highest

incidence of diverticulosis, and cecal nonspecific ulcers are almost invariably located on the antimesenteric border of the lumen, in contrast to the mesenteric location of cecal diverticula. [194], [198] It has been postulated that because nonspecific ulcers frequently occur in the cecum just distal to the ileocecal valve (where colonic contents are usually neutral to slightly acidic in pH), an altered acid-base status of this region could lead to cecal ulceration. Correlations have been noted between the use of corticosteroids, NSAIDs, oxyphenbutazone, and oral contraceptives and the occurrence of colonic ulcers. [193], [195], [198] However, causation has not been established for any of these substances, and they cannot be implicated in a substantial majority of colonic ulcers. [199] Other potential causative explanations include digestive enzymes, foreign body trauma, neurological stress, lipomas, bacterial or viral infections, and unknown toxins. [194], [200] The cause of nonspecific colon ulceration at this point remains unclear and is almost certainly multifactorial.

Clinical Features Most of the historical and physical examination findings are nonspecific. In a 1982 review by Ona and colleagues, [193] the signs or symptoms most frequently cited were acute or chronic right lower quadrant abdominal pain (50% of cases) with symptoms similar to those of appendicitis; lower gastrointestinal bleeding (33% of cases) most commonly presenting as hematochezia; perforation, with acute surgical abdomen (19%); and abdominal mass (16%), which is most common in left-sided or transverse colonic ulcers. Other reported findings include obstruction, fever, and leukocytosis. Hemoccult-positive stool is occasionally seen in the absence of any other demonstrable source of gastrointestinal blood loss.

Diagnosis Colonoscopy is the diagnostic test of choice and has shifted management of this condition from the surgical to the medical realm. The findings on air-contrast barium enema are abnormal in 69% to 75% of cases but are nonspecific, consisting of luminal narrowing, filling defects, mucosal irregularities, localized colonic spasm, or mass effects. [193], [200] Sigmoidoscopy misses most colonic ulcers by virtue of their predilection for cecal location. [193] In the setting of brisk bleeding from a colonic ulcer, mesenteric angiography is sensitive (89%) but nonspecific. [193] A CT scan is useful primarily in cases with associated perforation or abscess.

Differential Diagnosis Because colonic ulcers are histologically nonspecific, diagnosis is based on exclusion of other potential entities. Solitary rectal ulcers occur distally and have a characteristic histological appearance (discussed later in the chapter). Ulcers associated with Crohn's disease are usually multiple, may be longitudinal, and are often associated with inflammation elsewhere in the gastrointestinal tract. [195] Infectious causes of colonic ulceration include tuberculosis, *Entamoeba histolytica* cytomegalovirus (especially in immunocompromised patients), and *Salmonella typhi* and are usually multiple in number. Diagnosis can often be made by biopsy. [176] Tuberculosis of the colon usually results in multiple transverse cecal ulcers with associated nodularity and deformity of the ileocecal valve and biopsies diagnostic of tuberculosis, either by culture or histology. [201] Ischemic ulcers occur in the splenic flexure and the rectosigmoid junction of older patients; frequently, these are multiple lesions with a serpiginous or linear configuration, irregular margins, and abnormal surrounding mucosa. [195] Biopsy is nonspecific. Stercoral ulcers usually occur in the sigmoid area in association with fecal impactions (discussed later in the chapter). Malignancy (including carcinoma and lymphoma) must be ruled out histologically, because gross appearance is not diagnostic. [195] Other miscellaneous causes of colonic ulceration which have been reported include systemic lupus erythematosus, Behçet disease, Wegener granulomatosis, essential mixed cryoglobulinemia, and Churg-Strauss syndrome. [193], [202], [203] and [204] These can usually be differentiated by the setting of their underlying disease.

Prognosis and Therapy The earliest reports of nonspecific colonic ulceration were of ulcers discovered during surgery for complications (perforation, abscess, or bleeding) or during postmortem examination. As recently as 1974, surgery was the recommended treatment for all nonspecific colon ulcers. However, in 1980, Blundell and Earnest [198] described four patients who had nonspecific ulcers discovered at colonoscopy. Three of these patients were managed conservatively, with satisfactory clinical outcomes. Currently, it is recommended that uncomplicated colonic ulcers be followed endoscopically, with multiple biopsies taken during each endoscopy to document healing and to rule out malignancy and infection. The optimal interval between colonoscopies is uncertain; 4 to 6 weeks seems a reasonable period based on healing rates. [193], [194], [198] Surgery including oversewing of the ulcer, local ulcer excision, and right hemicolectomy is recommended for ulcers complicated by perforation, substantial bleeding, or associated intra-abdominal abscess, or for those that fail to heal with observation. [193], [196]

Dieulafoy-type Colonic Ulceration

In 1898, Georges Dieulafoy described three cases of previously asymptomatic patients exsanguinating from minute gastric ulcerations less than 2 mm in diameter, with rupture of a relatively large submucosal artery into the gut lumen. Several reports have been published detailing bleeding from similar colonic lesions found in the rectum, cecum, anal verge, and elsewhere in the colon. [205], [206], [207], [208] and [209] The colonic Dieulafoy ulcer is a rare lesion; Dy and colleagues, [206] in the largest published series, reported an incidence of five patients with Dieulafoy colonic ulceration among 3059 patients presenting with gastrointestinal bleeding. Gender distribution is roughly equal among males and females, with ages ranging from 20 to 94 years. Histologically identical to Dieulafoy-type lesions elsewhere in the gastrointestinal tract, colonic lesions are typically solitary mucosal defects, extending no deeper than the upper submucosal layer, with erosion of an underlying submucosal large-caliber artery (Fig. 85-6). The artery is tortuous and curved toward the mucosa, with erosion at the apex of its curve. There is no associated arterial aneurysm, vasculitis, or other vascular anomaly with little or no inflammation in the ulcerated area. [205] The cause is unknown, although some have postulated that the pulsations of a large submucosal artery may cause mechanical damage to the overlying mucosa, allowing an inflammatory reaction to the luminal contents to further erode the exposed arterial wall. [205] Clinically, patients present with the acute onset of massive bleeding; they are otherwise asymptomatic. The mucosal lesions are notoriously difficult to visualize on endoscopy; selective mesenteric angiography has been useful in localization. Systemic vasopressin infusion has not been successful in managing bleeding from these lesions. The definitive therapy has traditionally been segmental surgical resection. [205] Endoscopic therapy of Dieulafoy lesions has been increasingly used, and now may be considered the intervention of choice. [206], [210] Endoscopic methods that have been successfully employed have included vascular clipping, band ligation, epinephrine injection, absolute ethanol injection, sclerotherapy followed by electrocoagulation, and injection followed by heater probe thermocoagulation. [210], [211] and [212]

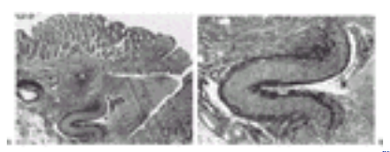

FIGURE 85-6. Dieulafoy ulcer of the colon. **A:** Low magnification shows a thick-walled, tortuous muscular artery just below the muscularis mucosa, with fresh ulceration overlying the artery at the site of bleeding. **B:** Higher magnification reveals details of the site of bleeding, at the apex of the artery's curve toward the mucosa. (From Barbier P, Luder P, Triller J, et al. Colonic hemorrhage from a solitary minute ulcer. Gastroenterology 1985;88:1065.)

Stercoral Ulcer (Huntley Syndrome)

Colonic ulceration caused by ischemic pressure necrosis from a stercoraceous mass may result in colonic perforation, with resultant peritonitis. [213] In Serpell and Nicholls' review [214] of stercoral perforation, the median age of patients was 60 years, with a range of 16 to 89 years. There was a slight female predominance. Risk factors included chronic constipation (61%) and conditions associated with constipation, such as confinement to a nursing home or other chronic care facility (23%), renal failure, or transplantation (13%); use of constipating medications (aluminum hydroxide-containing antacids, narcotics, phenothiazines); hypothyroidism; and colonic strictures. Foreign bodies have also been implicated. [213], [214] The actual incidence is unknown. In an early review of 175 unselected autopsies, 4.6% were found to have stercoral ulcerations; half of these had perforations. [215] However, later autopsy studies revealed a rate between 0.04% and 0.3%. [216], [217] A later review found only 64 reported cases of colonic perforation as a consequence of stercoral ulcer. [214]

Patients who have perforated ulcers usually present with complaints of abdominal pain and signs of peritoneal irritation (80%–100%). [214] An abdominal mass (23%) or a fecal mass on rectal examination (6%) may be palpable. Plain radiographic findings include pneumoperitoneum (53%), marked fecal loading (30%), and calcified fecaliths within the colon (21%). Contrast radiography is rarely helpful. [214] The correct preoperative diagnosis is rarely made, although survival is improved if the diagnosis is established. [218] Nonperforating stercoral ulcers are rarely diagnosed but must be considered in a constipated patient presenting with abdominal pain, rectal bleeding, and leukocytosis.

Perforating stercoral ulcers are usually located on the antimesenteric border of the sigmoid or rectosigmoid colon (77%), with 47% of these within the sigmoid alone. [214] Other reported sites include the cecum (9%), the descending colon (5%), and the splenic flexure (2%). Resected specimens reveal sharply demarcated, irregular ulcers that conform to the contours of the fecal masses present. Histologically, the colonic mucosa is necrotic and denuded, with acute and chronic inflammatory changes. [215]

The pathophysiology of stercoral ulceration is related directly to the presence of a hard mass of feces (scybalum), which may be present for months to years. [214] The

pressure of the scybalum on the colonic wall exceeds the capillary perfusion pressure, which causes ischemic necrosis, with resultant ulceration and eventual perforation. [214], [218] The sigmoid predominance is probably caused by progressive desiccation of the fecal mass in the distal colon, the narrower luminal diameter of the sigmoid, and the relatively poor colonic blood supply in this area. [214]

The differential diagnosis of stercoral ulceration is limited and includes idiopathic (spontaneous) colonic perforation and perforation from trauma, malignancy, infection, or other cause. Spontaneous colonic perforation, in particular, may be confused with stercoral perforation. It often occurs during a difficult bowel movement related to an acute tear in the mucosa with no inflammation (as opposed to the round or ovoid perforations seen in the bases of stercoral ulcerations).

Surgical resection or proximal diversion is required for definitive therapy of both perforated and nonperforated stercoral ulcers. Intravenous antibiotics are indicated as adjunctive therapy; the majority of deaths occur as the result of uncontrolled sepsis. [214] Resection of the perforation with end colostomy and Hartmann pouch or mucous fistula has been associated with a lower mortality (23%) than other procedures (53%) and has been recommended as the surgical procedure of choice. [218] Lavage of the peritoneal cavity is required to reduce fecal contamination and intraoperative colonic lavage to remove scybala proximal to the site of the perforation may prevent recurrence of ulceration. [219]

Solitary Rectal Ulcer Syndrome (SRUS)

Although first described by Cruveilheir in 1829, the classic 1969 review by Madigan and Morson [220] established the diagnostic criteria for what is now known as the SRUS. This syndrome, with more than 400 cases reported in the literature, primarily affects young adults; the average age is in the third and fourth decades, with a range from 10 to more than 80 years. There is a slight female predominance. [221]

Patients with SRUS typically present with symptoms related to bowel disturbance; 70% to 90% present with constipation, tenesmus, incomplete evacuation, straining at stool, or lower abdominal pain with rectal bleeding in 56% to 89%. [221] Passage of mucus per rectum, overt rectal prolapse, and fecal incontinence are less frequent. One large review found that 26% of patients with endoscopic discovery of a solitary rectal ulcer were asymptomatic. [222] Systemic symptoms are uncommon, and bleeding is rarely significant enough to warrant transfusion.

Gross endoscopic appearance of SRUS is variable; the lesion may appear as a single, well-demarcated ulcer up to 5 cm in size, as multiple ulcers, as a polypoid lesion, or as a flat region of erythematous mucosa. Typically, the lesion appears on the anterior rectal wall (68%–95% of cases) approximately 6 to 10 cm from the anal verge. [221], [222] Specific histological criteria are used to establish the diagnosis, as defined by Madigan and Morson. [220] The lamina propria is replaced by fibroblasts, smooth muscle, and collagen, with associated hypertrophy and disorganization of the muscularis mucosa termed *fibromuscular obliteration of the lamina propria* (Fig. 85-7). Displacement of the mucosal glands into the submucosa and erosion of the mucosal surface may also be seen; the occasional presence of submucosal cystic glands has led to speculation that SRUS and colitis cystica profunda are identical or closely related syndromes with a common cause. [222] Endoscopic ultrasonographic findings in colitis cystica profunda and SRUS are nonspecific; it has been suggested that endoscopic ultrasonography be used to rule out malignancy and to assess the extent and severity of disease. [223] Levine and colleagues [224] noted that diffuse collagen infiltration of the lamina propria is seen almost exclusively in SRUS and can be used to differentiate this syndrome from Crohn's disease, ulcerative colitis, and chronic ischemic colitis. Malignancy, amebiasis, lymphogranuloma venereum, secondary syphilis, and endometriosis [225] must also be considered in the differential diagnosis.

FIGURE 85-7. Solitary rectal ulcer syndrome is characterized by fibromuscular obliteration of the lamina propria with crypt distortion. (Hematoxylin and eosin stain; original magnification ×200. Courtesy of John Woosley, M.D., Chapel Hill, NC.)

The pathophysiology of SRUS is uncertain. Self-digitation (seen in up to 50% of patients with SRUS) has been suggested as a cause, as have a congenital anomaly of the anterior rectal wall, a localized form of IBD, and infectious agents, although convincing support of these hypotheses is lacking. Prolapse-induced rectal mucosal trauma or ischemia has been strongly implicated as a possible cause of SRUS. [223] The incidence of mucosal or full-thickness rectal prolapse ranges from 13% to 100% in published series of patients with SRUS. [221] A combination of rectal prolapse and a high fecal voiding pressure (caused by overactivity of the external anal sphincter or failure of puborectalis relaxation during defecation) has been theorized to cause local ischemic injury and trauma to the rectal mucosa, resulting in ulceration. [226], [227] However, other studies have failed to find electromyographic evidence of a hyperactive anal sphincter in a majority of patients. [221]

Treatment of SRUS depends on the gross morphology of the lesion and on the presence or absence of rectal prolapse. Patients with polypoid lesions usually are younger and are more likely to be asymptomatic, tend to have a better prognosis, and respond to conservative medical therapy. [221] Such therapy includes bowel retraining, the use of bulk laxatives, and reassurance. Antiinflammatory drugs (i.e., corticosteroids, salicylates, sucralfate enemas) have been used with varying degrees of success, but controlled trials have been performed. Surgery is advised for patients with rectal prolapse because of their poor response to medical therapy. A 65% overall response rate to surgical intervention was noted in Tjandra's review, [221] with best results in patients with polypoid lesions. A more recent review of 81 patients with SRUS treated surgically revealed a 55% to 60% long-term response to surgical intervention with a minimum follow-up interval of 12 months (median 90 months). [228] The procedure of choice in patients with rectal prolapse is abdominal rectopexy. [229] Anteroposterior rectopexy, local excision, colonic resection, and, rarely, diverting colostomies have been successfully employed in nonprolapsing patients with intractable symptoms refractory to medical therapy. [221], [229] Prolonged evacuation time is predictive of poor prognosis. [214] Although not typically associated with carcinoma, there have been cases of unexpected colorectal malignancy found in resected solitary rectal ulcers. [230]

TYPHLITIS

Typhlitis (from the Greek “typhlos,” meaning blind sac), an acute necrotizing colitis principally involving the cecum, was originally described in 1970 by Wagner and colleagues in terminally ill leukemic children with severe neutropenia. [231] Synonymous terms include neutropenic enterocolitis, necrotizing enterocolitis, and ileocecal syndrome because inflammation may involve the terminal ileum, ascending colon, and appen- dix. [232], [233] and [234] Typhlitis occurs primarily in severely immunosuppressed patients with leukemia, but has been described with combination immunosuppression for other malignancies or renal transplant and autologous bone marrow transplant, autologous blood stem cell transplantation, drug-induced granulocytopenia, aplastic anemia, cyclic neutropenia, and the acquired immunodeficiency syndrome (AIDS). [234], [235], [236] and [237] The rate of typhlitis in autopsy series of children with acute leukemia ranges from 10% to 24%. [232], [234] There is a suggestion of increasing frequency, attributed to more aggressive chemotherapeutic regimens for both hematologic and solid tumors. [238], [239] No race or gender predilection or specific regimen of chemotherapy is apparent.

The clinical spectrum of disease varies from mild, self-limited cecal inflammation to fulminant necrosis and perforation. Symptoms and signs usually develop at the

nadir of neutropenia 1 to 2 weeks after completion of induction chemotherapy and is less common during consolidation. Virtually all patients are neutropenic and febrile. Most patients have abdominal pain (localized to the right lower quadrant in approximately 40% to 60% of cases) and many have nausea, vomiting, abdominal distention, and diarrhea (20%–45% bloody), with associated stomatitis and necrotizing pharyngitis, indicative of diffuse mucositis. Peritoneal signs or shock suggest the possibility of perforation or sepsis. Positive blood cultures usually grow enteric bacteria, especially *Pseudomonas* or *Candida* species organisms.

Typhlitis is difficult to diagnose because of nonspecific symptoms, signs, and radiographic findings. [232] In the appropriate clinical setting, helpful radiographic patterns include abdominal plain films showing a fluid-filled, distended cecum with dilated small bowel loops, diminished or absent colonic gas, “thumb printing” of the ascending colon, evidence of a right lower quadrant soft tissue mass with small bowel displacement, or cecal pneumatosis. CT scan may reveal symmetrical cecal wall thickening (average about 10 mm) with pericecal fluid or a soft tissue mass if an abscess is present (Fig. 85-8). Ultrasound examination of the right lower quadrant may show the target or halo sign of a solid mass with echogenic center (collapsed mucosa and intestinal contents) and hypoechoic periphery (thickened bowel wall). [238] This finding is nonspecific and also has been seen with intestinal hemorrhage, ischemic colitis, intussusception, and lymphoma. Barium enema may be useful in diagnosing typhlitis but is hazardous due to a risk of perforating the necrotic bowel. [239] Instillation of air by endoscopy may be similarly hazardous; however, a gentle, flexible sigmoidoscopy may be useful to exclude IBD or pseudomembranous or ischemic colitis.

FIGURE 85-8. Computed tomographic scan reveals a massively dilated cecum with thickened walls, spiculation of pericolic fat, and inflammatory changes in the soft tissues of the right flank of a patient with typhlitis. (Courtesy of David Warshauer, M.D., Chapel Hill, NC.)

Typhlitis must be considered in any neutropenic patient with fever, abdominal pain, and diarrhea. The differential diagnosis includes pseudomembranous colitis secondary to *C. difficile* drug-induced or infectious colitis, appendicitis, diverticulitis, ischemic colitis, Crohn's disease, intussusception, intramural hemorrhage, or leukemic infiltrate.

Inflammation almost always involves the cecum but may additionally affect the terminal ileum or ascending colon, or the patient may have sporadic ulcers throughout the large and small intestine. The involved segments are dilated, edematous, and often hemorrhagic on external appearance. The cecal wall is thickened and hemorrhagic; necrotic material covers the ulcerated mucosa. Superficial ulcers can coalesce to form larger lesions. The serosal surface usually remains intact despite severe mucosal damage. Microscopically, there is marked submucosal edema with hemorrhagic necrosis of the mucosa but without a significant inflammatory reaction or leukemic infiltrate. Fungal organisms may be seen, and bacteria (usually gram-negative rods) may surround and infiltrate small blood vessels. [232], [233], [240]

The pathogenesis is unknown, but proposed causes include leukemic infiltration of the bowel, intramural hemorrhage and necrosis, local ischemia, toxic effects of chemotherapy, gastrointestinal stasis with bowel erosion, bacterial translocation, or a combination of these factors. The following sequence of events may occur: failure to maintain an intact epithelial barrier of the right colon (from the listed factors); bacterial invasion of bowel wall; intramural proliferation of bacteria secondary to decreased phagocytosis and killing (neutropenia); production of bacterial endotoxins with subsequent necrosis, hemorrhage, and perforation; and sepsis. In the spectrum of mucosal barrier injury, typhlitis is the most severe gastrointestinal manifestation. [241] It is unclear why the cecum is always affected. [232], [233]

Survival in this illness depends on prompt recognition of the condition, appropriate management, and rapid return of normal levels of neutrophils. Management is primarily medical, with selective surgical intervention. Medical therapy includes nasogastric suction for bowel rest, intravenous hydration, broad-spectrum antimicrobial therapy with *Pseudomonas* coverage, and avoidance of antimotility agents. If fever persists for more than 72 hours after antibiotics are begun, antifungal therapy with amphotericin B should be considered and a CT scan performed to identify an abscess. Granulocyte transfusions have been used with some success, but their benefit has not been proven. Surgery has been effective in patients failing medical therapy, and its use should depend on prognosis of underlying primary disease. Indications for surgery include evidence of free intraperitoneal perforation, persistent or life-threatening gastrointestinal hemorrhage, clinical deterioration suggesting uncontrolled sepsis, and abscess. The preferred procedure is a right hemicolectomy with ileostomy and mucous fistula formation. Total excision of the necrotic focus is imperative because incomplete removal uniformly results in death. [242], [243] Typhlitis has a high mortality rate (averaging 40%–50%) whether treated medically or surgically. Patients who develop typhlitis during induction and are medically treated are likely to relapse during subsequent chemotherapy (up to 67%). [244] Allowance of complete healing is advocated before resumption of chemotherapy to minimize risk of relapse.

COLITIS CYSTICA PROFUNDA

Colitis cystica profunda is a rare, benign disease most often involving the rectum. It is characterized by the presence of submucosal, mucus-filled cysts. This lesion was first reported by Stark in 1766 and was termed colitis cystica polyposa by Virchow in 1863. In 1957, the term colitis cystica profunda was used to differentiate this condition which is located below the muscularis mucosae from colitis cystica superficialis, in which multiple mucus-filled cysts are limited to the mucosa in association with pellagra and celiac sprue. [245], [246]

Colitis cystica profunda can be solitary or multiple in a localized, segmental, or diffuse distribution. In a review of 144 cases, 85% were localized lesions, typically involving the rectum; there was a slight female preponderance and a median age of 30 years. [247] Symptoms most often include blood or mucus discharge from the rectum with variable diarrhea; abdominal, rectal, or sacral pain; and tenesmus. Bulky or fibrotic lesions may rarely produce either partial or complete obstruction. [248] The localized form is often found on digital rectal examination, which reveals one or more smooth, firm masses not adherent to the underlying muscle layer, a thickened rectal wall, or stenosis.

Lesions are usually found within 12 cm of the anal verge and are commonly located on the anterior rectal wall. Endoscopic findings range from normal overlying mucosa to mucosal edema, erythema, friability, or even ulceration overlying a polypoid submucosal mass with or without umbilication. Obvious cysts may be present and when multiple, can form a mass up to 3 cm in size. Rectal stricture or prolapse may be seen. Barium enema may demonstrate no abnormalities or may show thickened valves of Houston, increased presacral space, various mucosal abnormalities, filling defects, circumferential stricture, or visible prolapse. [249] Transrectal ultrasound may be helpful by localizing cysts in rectal submucosa and confirming absence of lymph node involvement or invasion of the muscular layer. [223], [250] The differential diagnosis of these symptoms and findings is extensive and includes broad categories of inflammatory, infectious, and neoplastic diseases. [245] Definitive diagnosis of colitis cystica profunda is based on typical histological findings and absence of malignant features. Microscopically, the submucosal layer is enlarged by cysts which occasionally involve the muscularis propria and serosa (Fig. 85-9). Submucosal cysts are found in a variety of conditions [249] and must be differentiated from a well-differentiated mucinous adenocarcinoma. The cysts may be bordered by a well-differentiated colonic epithelial lining ranging from tall columnar to squamous cells, or they may have no lining at all. The lamina propria stroma may be replaced with collagen and misoriented smooth muscle cells. Adjacent mucosal edema, superficial ulceration, acute and chronic inflammation, pseudomembranes, and distorted crypt architecture may be present.

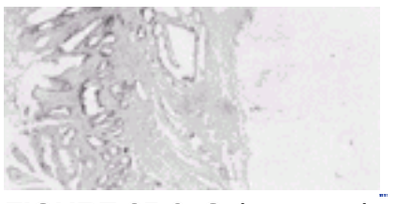

FIGURE 85-9. Submucosal mucin-filled cysts are characteristic of colitis cystica profunda.

The pathogenesis is not known; however, three mechanisms have been proposed. [244], [249] A congenital origin and herniation of epithelium owing to a weakened muscularis mucosa are two unsubstantiated theories. An acquired origin is supported by the absence of colitis cystica profunda in large pediatric autopsy series, an association with conditions causing trauma of the bowel wall, regression after diverting colostomy, and experimental studies implicating an inflammatory cause. Colitis cystica profunda may be one manifestation of a spectrum of disease states that includes SRUS and internal rectal prolapse. Rectal prolapse occurs in up to 54% of patients with colitis cystica profunda, and the anterior location and lamina propria fibrosis resemble SRUS. [220], [221], [249] Localized colitis cystica profunda is probably caused by ischemia, secondary to trauma induced by rectal prolapse. Defecography showing prolapse and abnormal pelvic electromyography are frequently seen, [247], [251] but these findings are not always present, suggesting that inflammation and mucosal trauma also contribute to the pathogenesis of this lesion.

The diagnosis of colitis cystica profunda must be considered to avoid inappropriate or radical surgery for suspected cancer. Because shallow mucosal biopsies are usually inadequate, definitive diagnosis may require a surgical excision. The usual course of this disease is a chronic, stable appearance of the rectal mucosa; however, cysts, ulcers, and symptoms may come and go. The lesions are not premalignant, however, adenocarcinoma may be located adjacent to colitis cystica profunda. [252] The severity and duration of symptoms should guide choice of treatment options. Most patients can tolerate symptoms with treatment consisting of reassurance, dietary fiber to soften bowel movements, and education to avoid straining during defecation and digital manipulation of the rectum. Only a small preliminary experience has reported the benefits of rectal prolapse repair. Local surgical procedures to excise cysts and ulcers, such as transanal excision, posterior proctectomy, electrocautery, or injection sclerosis, are usually adequate, although lesions may recur. [245], [248], [253], [254] Resectional surgery is usually unnecessary. Diverting colostomy, performed in the most disabled patients, alleviates the symptoms. Complications such as hemorrhage, obstruction, severe pain, or rectal stenosis need surgical intervention.

PNEUMATOSIS CYSTOIDES INTESTINALIS

This uncommon condition is characterized by multiple, thin-walled, noncommunicating, gas-filled cysts with no epithelial lining in the wall of the small or large intestine. Less frequently, other areas can be involved, including the stomach, duodenum, and extraluminal structures (e.g., mesentery, lymph nodes, omentum, gastrohepatic/falciform ligaments, peritoneum). [255] Usually pneumatosis cystoides intestinalis is discovered unexpectedly in an asymptomatic or minimally symptomatic patient and follows a benign course. Occasionally, it is associated with more fulminant illness such as bowel infarction, pseudomembranous enterocolitis, or necrotizing enterocolitis. After serious illness is excluded, pneumatosis intestinalis can be classified as either primary (idiopathic) or secondary, the latter being associated with a variety of conditions. Pneumatosis is most commonly associated with chronic obstructive pulmonary disease, intestinal obstruction, collagen vascular diseases (scleroderma; dermatomyositis, mixed connective tissue disease), systemic amyloidosis, and iatrogenic conditions (after surgery or endoscopy). Pneumatosis has occurred in patients with late-stage AIDS and characteristically involves the cecum and right colon. There is an association with cryptosporidial diarrhea, [256], [257] *C. difficile* colitis, [258] and Crohn's disease, especially with steroid use. [259] In Koss's review in 1952, [255] only 15% of cases were classified as idiopathic. He also reported an increased male prevalence of 3.5:1, but more recent reports suggest an equal male-to-female ratio. Pneumatosis intestinalis may be seen at any age, but in adults it usually occurs between 30 and 50 years of age. [260]

If symptoms are present, the most common complaints are diarrhea, vague abdominal discomfort, and abdominal distention with occasional hematochezia, mucus from the rectum, and weight loss. Typically, the condition is discovered incidentally during radiographic or endoscopic evaluation or at laparotomy. The abdomen may be tender, and occasionally an abdominal mass is palpable; however, fever and peritoneal signs are unusual. [261] Secondary cases of pneumatosis intestinalis typically involve the small bowel and ascending colon, whereas idiopathic cases tend to involve the left colon. The rectum is infrequently involved. [260], [262] The cysts range in size from a few millimeters to several centimeters and are typically found in clusters. A segmental distribution with skip areas is common, and from a few centimeters to a meter of bowel can be involved. An association with sigmoid colon redundancy has been suggested. [262] Colonic transit has been shown to be normal or even slow. Complications occur in about 3% of cases and include volvulus, pneumoperitoneum, intestinal obstruction, intussusception, tension pneumoperitoneum, hemorrhage, intestinal perforation, and recurrent asymptomatic pneumoperitoneum. [260]

Diagnosis is most commonly made on plain radiograph of the abdomen, on which linear, curvilinear, or cystic lucencies are seen in the bowel wall (Fig. 85-10). Additionally, pneumoperitoneum or retroperitoneal air may be found. Barium studies may help confirm location within the bowel wall. However, abdominal CT scan is more sensitive than conventional radiography in detecting intramural gas, which parallels the bowel wall. [262] CT scan can also detect portal or mesenteric venous gas, which, when associated with pneumatosis, is highly suggestive of bowel infarction. Endoscopically, pneumatosis appears as multiple, pale to bluish, rounded, soft polyploid masses protruding into the lumen. Because the cysts contain air under pressure, they deflate with a pop or hiss sound if punctured. [261] Submucosal pneumatosis of the colon can mimic polyposis, pseudopolyposis, or intramural hematomas on barium study; endoscopy can help differentiate causes. Enterogenous intestinal cysts are rare and occur in children and young adults. They are usually single, intramural, and most often involve the terminal ileum; their normal intestinal mucosal lining helps to differentiate them from pneumatosis. Lymphangiomas of the peritoneum differ in that lymph and not gas is present within cysts and no giant cells line these areas. Diffuse emphysema caused by infection with gas-producing organisms is distributed in all tissue spaces. In fat necrosis and sclerosing lipogranulomatosis, a fat stain is positive.

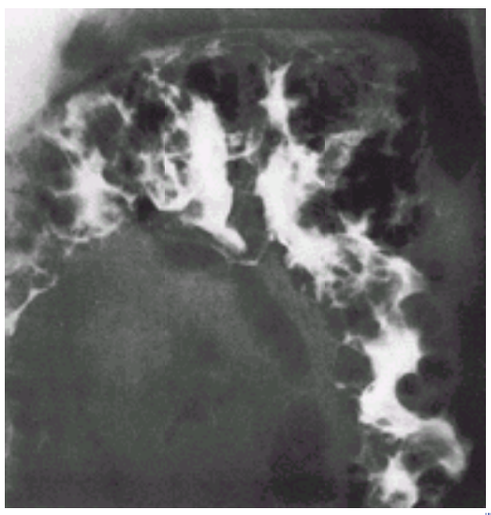

FIGURE 85-10. Pneumatosis cystoides intestinalis in an asymptomatic person. The intramural collections of gas simulate multiple colonic filling defects. Note that the filling defects in this condition appear to be more radiolucent than the soft-tissue masses in the intestinal polyposis syndromes.

The cysts in pneumatosis cystoides intestinalis have a submucosal or subserosal location and contain a high concentration of hydrogen (up to 50%). [263] The serosal cysts usually occur near the mesenteric border. [260] They may be partially lined by endothelial cells and are surrounded by foreign body multinucleated giant cells. Inflammation with neutrophils, eosinophils, plasma cells, lymphocytes, and epithelioid granulomas can be observed. Koss [255] postulated that fibrosis progresses until cysts disappear. The cause of pneumatosis is unknown, but several theories exist. The mechanical theory suggests that gas is forced into the bowel by one of several routes: pulmonary, trauma, mucosal breaks, anastomoses, obstruction, increased pressure, or increased peristalsis. The bacterial theory proposes that gas-producing bacteria invade the bowel wall. Finally, the biochemical theory postulates that excessive hydrogen produced by bacterial fermentation of carbohydrate in the intestinal lumen is absorbed and trapped within the intestinal wall by a process called counterperfusion supersaturation. [264] Pneumatosis patients seem to produce excess

hydrogen. Exposure to alkyl halides (chloral hydrate, trichloroethylene, chloroform) can enhance hydrogen production in patients with pneumatosis cystoides coli by inhibiting bacterial hydrogen consumption. Indeed, associations between pneumatosis coli and chloral hydrate use (rapidly metabolized to its active metabolite trichloroethanol) have been reported and an epidemic of pneumatosis in Japan has been linked to trichloroethylene which is used in the watch-making and camera industries. [265], [266]

In asymptomatic patients, treatment is indicated only for associated illnesses, because the cysts usually resolve spontaneously. Medical therapy may be tried for symptomatic lesions, but recurrences may ensue. [267] High-flow oxygen breathing using 55% to 75% oxygen to achieve PO_2 values between 200 and 350 mm Hg for 4 to 10 days may result in cyst resolution. [260], [261] To avoid pulmonary and central nervous system toxicity, hyperbaric oxygen at 2.5 atm for 2.5 hours on 2 or 3 consecutive days has also been successful. [268] Antibiotic treatment with metronidazole or ampicillin and elemental diets have been used to resolve cysts. [260], [269], [270] Surgical resection should be reserved for severe, refractory symptoms or to manage complications. Unfortunately, surgery is not always successful, and pneumatosis may become more extensive after resection. [271] Surgery is indicated in fulminant cases of pneumatosis in which delay may lead to extensive necrosis of bowel, sepsis, and death. History, physical examination, CT scan of the abdomen, and evaluation for the presence of metabolic acidosis (especially lactic acidosis) and marked hyperamylasemia may help differentiate the patient with intestinal infarction. Mortality is high in these cases, even with surgery. [260], [261], [271] Finally, pneumatosis occurs in organ transplant patients; if present without an underlying systemic illness, it is usually a self-limited and benign illness but is a poor prognostic sign in the setting of systemic complications. [272]

MALAKOPLAKIA

This rare chronic, granulomatous, inflammatory disorder was described in 1902 by Michaelis and Gutmann and named by von Hansemann in 1903 (from the Greek: malakos, “soft”; plakos, “plaque”). It most commonly affects the urinary tract, but it can involve many other organs, including the male or female genital tract, skin, lung, bone, brain, and gastrointestinal tract. [273] The most common site of gastrointestinal malakoplakia is the distal colon and rectum, although all regions of the gastrointestinal tract may be involved. [275] There is a bimodal distribution of age incidence, with a small cluster of children younger than 13 years of age and a later peak among middle-aged adults. The average age of the adults was 57 years (range, 18–88 years), with a slight male preponderance; [275] most were Caucasian. The patient may be asymptomatic or may have diarrhea, abdominal pain, rectal bleeding, or symptoms of intestinal obstruction. Physical findings may include abdominal tenderness, rectal or abdominal mass, or weight loss.

The lesions are yellowish, soft plaques or nodules 1 to 20 mm in size or larger, usually elevated and sometimes with a central depression. [274], [275] and [276] They can be single, multiple, or involve adjacent structures (i.e., lymph nodes, mesentery, or retroperitoneum). Malakoplakia can present as an intestinal mass, stricture, or fistula, thereby mimicking other inflammatory or neoplastic processes.

Diagnosis is usually made on histological examination of biopsy material. Diagnosis by fine-needle aspiration has been reported. [277] Histologically, there is a diffuse histiocytic infiltrate with a strongly periodic acid-Schiff (PAS)–positive eosinophilic granular cytoplasm (von Hansemann cells) containing the characteristic basophilic, laminated cytoplasmic calculospherules called Michaelis-Gutmann bodies.

Predisposing conditions include chronic infections by coliform bacteria (especially *Escherichia coli*) [278], [279] and granulomatous processes such as sarcoidosis and tuberculosis. [273] Pulmonary malakoplakia has been associated with *Rhodococcus equi* infection in immunocompromised patients, especially those with AIDS. [280], [281] In addition, malakoplakia has been identified in patients who are immunosuppressed by steroids, immunosuppressant agents (transplant patients), hypogammaglobulinemia, or AIDS. [282] McClure [273], [274] reported that about one third of patients with gastrointestinal malakoplakia had associated colorectal carcinoma, and up to one half had a coexistent malignancy. Of interest, carcinoma-associated colonic malakoplakia is usually adjacent to the tumor. [283]

Although the pathogenesis is unclear, some theories exist. Many authors believe that there is a defect in the phagocytic or digestive activity of the macrophages. [284], [285] One patient had low levels of intracellular cyclic GMP with poor release of a-glucuronidase during phagocytosis. More recently, two kidney transplant patients with malakoplakia improved significantly after immunosuppressive therapy was tapered or discontinued, lending support to an immune origin. [282]

Because this condition is rare, no systematic evaluation of treatment has been undertaken. The possibility of associated malignancy or infection mandates a thorough history and physical examination. Excisional biopsy or fulguration can be used to treat localized intestinal malakoplakia. If involvement is more diffuse or extensive, empiric trials of antituberculosis medications, antibiotics (e.g., trimethoprim-sulfamethoxazole, ciprofloxacin), or cholinergic agonists (bethanechol, especially in patients with hypogammaglobulinemia) and stopping immunosuppressive agents have been used with varying degrees of success. [275], [285], [286] and [287]

CHAPTER 86

William L. Hasler and Chung Owyang

IRRITABLE BOWEL SYNDROME

DEFINITION

Irritable bowel syndrome (IBS) is characterized by altered bowel habits and abdominal discomfort in the absence of organic disease. No clear diagnostic markers exist for IBS; thus, all definitions are based on the clinical presentation. The Rome II criteria for the diagnosis of IBS include at least 3 months of continuous or recurrent abdominal pain or discomfort that has two of the following features: relief by defecation, association with a change in the frequency, and a change in stool form (Table 86-1). [1]

At least 3 months of the following continuous recurrent symptoms:
Abdominal pain or discomfort that is relieved by defecation or is associated with change in frequency or consistency of stool
and
Disturbed defecation involving two or more of the following characteristics at least 25% of the time:
Altered stool frequency
Altered stool form (e.g., lumpy or hard, or loose or watery)
Altered stool passage (e.g., straining, urgency, or feeling of incomplete evacuation)
Passage of mucus
Bloating or feeling of abdominal distention

TABLE 86-1 Criteria for Diagnosing Irritable Bowel Syndrome

SOCIETAL IMPACT

IBS is the most prevalent digestive disease, accounting for 12% of visits to primary care physicians and 28% of referrals to gastroenterologists. [2] IBS is the seventh most common outpatient diagnosis with a rate of 10.6 visits per 1000 population per year. [3] Over 2 million prescriptions are written for IBS. [4] Although usually an outpatient disorder, IBS was the major discharge diagnosis in 96,000 inpatients as recently as 1976. [5] As awareness of the disorder has increased and hospital admission criteria have become stricter, admissions for IBS have markedly decreased. [6] Nonetheless, health care costs for the management of IBS are high. In a survey of health service utilization, the odds of a patient with IBS incurring charges were 1.6-fold greater than for a similar asymptomatic individual, which translated into overall median yearly charges of $742 in 1992 dollars for each patient with IBS compared to $429 for controls. [7]

IBS produces health consequences in addition to its economic costs. One survey [8] reported greater impairments in health-related quality of life in patients with IBS than the U.S. general population Decrements are most pronounced in energy/fatigue, role limitations caused by physical health problems, bodily pain, and general health perceptions. Another study noted that persons with the most intense IBS symptoms had the lowest quality of life measures. [9] IBS produces disability rates equal to or greater than severe organic gastrointestinal disease and is the second leading cause of absenteeism behind the common cold, with patients with IBS missing three times as many work days yearly as persons without IBS. [10], [11] and [12] The impact of IBS is emphasized by a British study reporting that 8% of patients with IBS retire early due to their symptoms. [13]

EPIDEMIOLOGY

IBS is a disorder of young people, with most new cases presenting before age 45. [3] However, some reports suggest that older adults are troubled by IBS symptoms up to 92% as often as middle-aged persons. [12], [14], [15], [16] and [17] Indeed, patients over 65 years of age make 500,000 physician visits per year for IBS. [4] Many of the diagnoses of “painful diverticular disease” given to older adult patients may represent IBS. [18] Functional gastrointestinal disorders also are prevalent in pediatric populations. IBS symptoms were reported by 14% of high school students and 6% of middle school students in one study and in 16% of students between 11 to 17 years of age in another. [19], [20] and [21] Women are diagnosed with IBS two to three times as often as men (Fig. 86-1). [3], [22], [23] Moreover, women make up 80% of the population with severe IBS. [24] Studies indicate that a history of abdominal pain or irregular bowel habits in first-degree relatives is significantly associated with IBS and dyspepsia. [25] Whether the familial associations represent similar exposures in a shared environment, heightened familial awareness of gastrointestinal symptoms, or genetic factors remains to be determined. Fewer Asians and Hispanics appear to develop the syndrome relative to other ethnic groups. [24], [26] The epidemiology of IBS outside the Western world is poorly characterized.

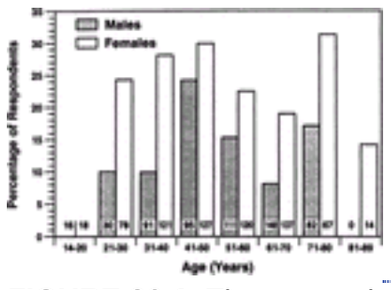

FIGURE 86-1. The age and gender distributions of individuals with symptoms of irritable bowel syndrome (IBS) are shown. The peak age range of symptom reports is in the forties, although both younger and older persons experience symptoms. Women report IBS-like symptoms significantly more than men across all ages. (From Longstreth GF, Wolde-Tsadik G. Irritable bowel–type symptoms in HMO examinees. Prevalence, demographics, and clinical correlates. Dig Dis Sci 1993;38:1581.)

The number of patients with IBS who seek medical care is considerably less than the number of individuals who experience symptoms. Using strict criteria, 9% to 22% of the population experience symptoms diagnostic for IBS, yet only a small fraction (9%–33%) seek medical attention, suggesting that other factors are important in the decision to obtain medical care. [14], [15], [27], [28]

CLINICAL FEATURES

Gastrointestinal Symptoms

IBS is a heterogeneous disorder with distinct symptom presentations. Different subsets of IBS can be defined based on the dominant symptom.

Abdominal Pain According to the new Rome II criteria, abdominal pain or discomfort is a prerequisite clinical feature of IBS. [29] The intensity and location of abdominal pain in IBS are highly variable, even within an individual patient. Abdominal pain in IBS is localized to the hypogastrium in 25%, the right side in 20%, the left side in 20%, and the epigastrium in 10% of patients. [30] The pain is generally crampy or achy, although sharp, dull, gaslike, or nondescript pains are also common. [31] It may be mild enough to be ignored or it may interfere with daily activities. Despite this, malnutrition due to inadequate caloric intake is exceedingly rare with IBS. Sleep deprivation also is unusual because abdominal pain is usually present only during waking hours. However, one study indicated that patients with severe IBS frequently wake repeatedly during the night and more than half of these patients reported that they were awakened by their abdominal pain. [32] Hence nocturnal pain is a poor discriminating factor between organic and functional bowel disease. Several factors exacerbate or reduce pain in IBS. Many patients report increased symptoms during periods of stress or emotional turmoil such as that associated with job or marital difficulties. Defecation may provide temporary relief from the pain of IBS, while meal ingestion may exacerbate the discomfort usually 60 to 90 minutes postprandially. This is especially true after consuming foods rich in carbohydrates and fat. [33] In addition female patients with IBS commonly report worsening symptoms during the premenstrual and menstrual phases. [34] Pain that is progressive, prevents sleep, leads to anorexia or inability to eat, or is associated with weight loss warrants exclusion of organic disease.

Alteration in Bowel Habits Patients with IBS present with constipation, diarrhea, or constipation alternating with diarrhea. With constipation, stools usually are hard and may be scybalous or pelletlike. Long periods of straining may be required for fecal evacuation both in constipation- and diarrhea-predominant patients. [35] Constipation can persist for weeks to months, interrupted by brief periods of diarrhea. Feelings of incomplete fecal evacuation may lead to multiple attempts at stool passage daily. In diarrhea-prone patients, stools characteristically are loose and frequent but of normal daily volume. Generally, diarrheal stools occur only during waking hours, often early in the day, and an urgent desire to defecate after a meal is reported by 36% of patients. [36] Mucus discharge has been reported in up to 50% of patients with IBS. [36] As with abdominal pain, fecal urgency and loose stools may develop during stress. Early descriptions of IBS observed patient populations who presented with painless diarrhea, representing 17% in one report. [31] However, disorders such as lactase deficiency were less readily appreciated and others such as microscopic and collagenous colitis were undefined; thus, it is conceivable many patients with functional diarrhea had one of these entities. In fact, painless diarrhea does not strictly fulfill the Rome II criteria to be classified as IBS. A recent survey revealed that women with IBS report mucus discharge, a sensation of incomplete fecal evacuation, pelletlike stools, and distention more commonly than men. [37] It is important to note that symptoms of IBS typically wax and wane over time. Patients may have some days with symptoms and some days without. In a 12-week trial study of 59 patients with IBS, Hahn and colleagues [38] found that the population reported pain or discomfort on 50% of days. On 33% of days bloating was reported, while altered stool formation and passage were found, respectively, on 25% and 18% of days. For more than half of the study period 50% of the patients had at least one symptom. The symptoms lasted on average for 5 days or less, although pain/discomfort and bloating tended to last the longest. Symptoms not associated with IBS that warrant exclusion of organic disease include nocturnal diarrhea, rectal bleeding, malabsorption, and weight loss.

Other Gastrointestinal Symptoms Upper gut symptoms are common in IBS, with 25% to 50% of patients reporting heartburn, early satiety, nausea, and vomiting; up to 87% note intermittent dyspepsia. [39] It appears that there is a great deal of overlap between dyspepsia and IBS. A community-based study in Spain [40] reported that the prevalence of IBS was higher among subjects with dyspepsia (31.7%) than among those who reported no symptoms of dyspepsia (7.9%). Conversely among the subjects with IBS, 55.6% reported symptoms of dyspepsia. Other studies [41] indicated that functional abdominal symptoms can change over time. Those with predominant dyspepsia or IBS can flux between the two. In contrast, those with predominant reflux symptoms seldom changed to dyspepsia or IBS. Thus it is conceivable that functional dyspepsia and IBS are two manifestations of a single, more extensive digestive system disorder. IBS symptoms are prevalent in patients experiencing noncardiac chest pain, but not in those experiencing cardiac chest pain, suggesting overlap with other functional gut disorders. [42] Patients with IBS may report increased gas production and abdominal distention, although most do not produce excess gas. [43] Another study indicated that the majority of patients with IBS have impaired transit and tolerance of intestinal gas loads. [44] This may be responsible for gas retention and the symptoms of gas and bloating in patients with IBS. Other patients with IBS may demonstrate a maximum rate of gas excretion greater than healthy subjects. [45] Although their total gas production was not increased, hydrogen production was higher. In these patients an exclusion diet reduced symptoms and produced a fall in maximum gas excretion. [45] In a recent study it was demonstrated that the perception of intestinal gas accumulation depends on the mechanism of retention. [46] Obstructed evacuation increased symptom perception whereas gas retention in a hypotonic gut was virtually unperceived. Computed tomography has shown increased lateral profiles in patients with IBS which was postulated to result from altered gastrointestinal motility or tone. [47] Another study has reported that those patients with significant bloating are most likely to have gained weight and more commonly had weak abdominal muscles. [48] This observation, however, was not confirmed by a subsequent study which showed no anterior abdominal muscle weakness in patients with IBS with gas and bloating. [49]

Extraintestinal Symptoms

Although gastrointestinal symptoms predominate, extraintestinal complaints are common in IBS. Patients with functional gut disorders visit primary care physicians three times as often for nongastrointestinal problems as do healthy persons and undergo more appendectomies and hysterectomies. [22], [50], [51] and [52] Chronic pelvic pain is much more commonly reported by patients with IBS than patients with inflammatory bowel disease. [53] Genitourinary dysfunction, including dysmenorrhea, dyspareunia, impotence, urinary frequency, nocturia, and a sensation of incomplete bladder emptying, is prevalent. [31] Impaired sexual function is reported by 83% of patients with IBS versus 30% of patients with inflammatory bowel disease and 16% of patients with peptic ulcer. [54] An association between IBS and primary fibromyalgia has been noted, with two thirds of patients with IBS reporting rheumatologic symptoms. Conversely, IBS symptoms are found in 42% of patients with fibromyalgia. [55] Patients with both IBS and fibromyalgia have worse scores on health-related quality of life indices than patients with either disorder alone. [56] The presence of fibromyalgia in patients with IBS seems to be associated with severity of bowel symptoms. [57] At the same time co-morbidity with fibromyalgia results in somatic hyperalgesia in patients with IBS. [58] Similarly, 63% of patients with chronic fatigue syndrome report symptoms of IBS. [59] Patients with functional bowel disorders have higher incidences of peptic ulcer disease, hypertension, low back pain, headaches, and rashes than the general population and more commonly report fatigue, loss of concentration, insomnia, palpitations, and unpleasant tastes in the mouth. [30], [60], [61]

PATHOPHYSIOLOGY

The pathogenesis of IBS is poorly understood, although roles for abnormal gut motor and sensory activity, central neural dysfunction, psychological disturbances, stress, and lumenal factors have been proposed. Unfortunately, there is no single pathophysiological abnormality that clearly separates IBS from organic gastrointestinal disease or from normalcy.

Gastrointestinal Motor Abnormalities

Abnormal Colonic Motor Activity The myoelectrical activity of the colon is comprised of slow waves, which regulate the frequencies of some phasic contractions, and spike potentials, which elevate the membrane potential above a contractile threshold. [62] Spike potentials may occur in the form of short-spike bursts (SSBs) of 5 to 15 seconds' duration which are temporally in phase with the slow-wave activity. Long-spike bursts (LSBs) of 15 to 60 seconds' duration are unrelated to the slow wave. [23], [63], [64] SSBs are responsible for generation of short-duration contractions, which are nonpropagative and segmenting in character leading to fecal mixing and resistance to stool passage. [62] LSBs produce long-duration contractions, some of which are nonpropagative and some of which may propel feces in either an oral or aboral direction. Finally, high-amplitude propagated contractions (HAPCs) are intensely propulsive, beginning in the right colon and occurring once or twice daily, producing mass movements of feces and defecation. [62] Studies of colonic myoelectrical and motor activity under unstimulated conditions have not shown consistent abnormalities in IBS. A predominant slow-wave frequency of 3 cycles per minute (cpm) with increased 3 cpm motor activity was observed in both diarrhea- and constipation-predominant patients with IBS in an older study that has not been confirmed by more recent studies. [65], [66] Furthermore, similar slow-wave abnormalities are demonstrable in psychoneurotic patients without bowel symptoms suggesting that the myoelectric disturbance is neither diagnostic for IBS nor pathogenic of symptoms. [67] Constipation-predominant patients were reported to exhibit increased numbers of SSBs while diarrhea-prone patients had reduced SSB activity. [63] Most investigators have observed no colonic motor abnormalities under basal conditions although others have reported increases in basal motility. [65], [66], [67], [68] and [69] Increased numbers of HAPCs have been noted in diarrhea-predominant patients with IBS compared to healthy volunteers. [70] Using scintigraphic assessment of colonic transit, selective acceleration in right colon transit has been shown in some patients with IBS with diarrhea. [71] It is unknown if these are pathogenic motor abnormalities in IBS or if all diarrhea-prone patients exhibit these findings. Similar studies have not been reported in constipation-predominant IBS, although patients with idiopathic constipation exhibit delayed right colon transit. [72] In contrast to the unstimulated colon, colonic motor abnormalities are more prominent under stimulated conditions in IBS. In normal volunteers, meal ingestion induces a rapid increase in spike potential and contractile activity that peak 20 to 30 minutes after eating, decrease to a basal level after 50 to 60 minutes, and may exhibit a second increase at 80 minutes. [63] Conversely, patients with IBS may exhibit increased rectosigmoid motor activity for up to 3 hours after eating. [64], [73] Although this response is most prominent in diarrhea-prone patients, constipated patients with IBS also show an exaggerated gastrocolonic response albeit to a lesser degree. [74] In contrast to healthy volunteers, sham feeding increases rectosigmoid motility in IBS suggestive of a cephalic phase of the gastrocolonic response in affected patients. [75], [76] and [77] Provocative stimuli induce exaggerated colonic motor responses in patients with IBS compared to healthy volunteers. Inflation of rectal balloons both in diarrhea- and constipation-predominant patients with IBS leads to marked distention-evoked contractile activity that may be prolonged. [64], [78] Patients with painful IBS exhibit greater increases in rectosigmoid motility after cholinergic stimulation than patients with painless diarrhea. [79] Intravenous cholecystokinin induces painful rectosigmoid contractions that reproduce the presenting symptoms in patients with IBS with postprandial pain. [80] An exaggerated motor response is demonstrable in patients with IBS after colonic perfusion of deoxycholic acid. [81] In contrast, one study reported rectal motor characteristics in response to isobaric distentions were not different between patients with constipation-predominant IBS, patients with slow transit constipation, and healthy controls. [82] On the other hand, sensations of urge were reduced in slow transit constipation and sensations of pain were increased in IBS. Until recently most of the colonic motility studies in IBS were performed in the rectosigmoid colon. Recording from the transverse, descending, and sigmoid colon, Chey and colleagues [83] reported that the motility index and peak amplitude of HAPCs in diarrhea-prone patients with IBS were greatly increased compared to healthy subjects. These were associated with rapid colonic transit and accompanied by abdominal pain. Similar findings were made by another group who reported increased numbers of HAPCs and reduced duration of increased colonic tone postprandially in a similar group of patients. [84]

Abnormal Small Bowel Motor Activity Small intestinal motor patterns under unstimulated conditions are organized and well characterized. During fasting, the migrating motor complex (MMC) cycles every 90 to 120 minutes to clear the proximal gut of undigested debris. Prolonged manometric studies suggest subtle abnormalities in fasting small intestinal motility in IBS. Decreases in MMC contractile amplitudes in constipation-predominant patients with IBS and reductions in MMC cycle length in diarrhea-predominant individuals have been characterized, although these abnormalities have not been universally described. [85], [86] These abnormalities have not been observed during sleep. [85], [86] and [87] Studies involving nonlinear analysis of 24-hour jejunal motility revealed that patients with IBS had increased irregularities for the intercontractile intervals during phase II of MMC. [88] Other physiological motor patterns include discrete clustered contractions (DCCs), which are bursts of phasic contractions occurring every minute in the duodenum or jejunum, and prolonged propagated contractions (PPCs), which are intense ileal complexes that evacuate the ileum and prevent coloileal reflux. In patients with IBS, DCCs and PPCs have been reported to make up a larger fraction of fasting recording time; however, this has not been confirmed by investigations (Fig. 86-2). [35], [89], [90], [91] and [92] It is unlikely that these complexes have pathogenic significance as their occurrences are similar in patients with constipation and with diarrhea.

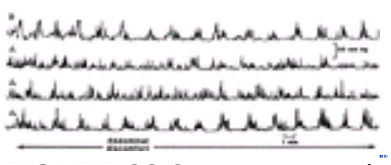

FIGURE 86-2. A manometric recording of small intestinal motility from a patient with irritable bowel syndrome shows 30 minutes of discrete clustered contractions in the duodenum and jejunum, which are associated with discomfort. (*D* duodenal pressure recording; $J_{1,2,3}$ jejunal pressure recordings). (From Kellow JE, Phillips SF. Altered small bowel motility in irritable bowel syndrome is correlated with symptoms. Gastroenterology 1987;92:1885.)

As in the colon, small intestinal motor abnormalities under stimulated conditions have been described in IBS. The fed-motor pattern is a period of intense irregular phasic contractions that occurs for 2 to 3 hours after eating. In both constipation- and diarrhea-predominant IBS, the duration of the fed pattern is shorter than in healthy volunteers. [35] Increases in the postprandial intestinal contraction frequency have been observed in diarrhea- and constipation-predominant IBS [92] although the contractile amplitudes were lower in constipation-predominant patients. [93] Some studies [94] further demonstrated that increased frequency of retrograde propagation of duodenal pressure waves occurred postprandially in both constipation-prone and diarrhea-prone patients with IBS. This abnormal propagation pattern of duodenal pressure waves was associated with symptoms in this group of patients. Intravenous cholecystokinin evokes exaggerated high-amplitude ileal contractions in diarrhea-predominant patients with IBS, while the anticholinesterase neostigmine induces frequent DCCs in both diarrhea- and constipation-prone patients. [95] Small intestinal transit of a meal is reportedly delayed in patients with IBS with constipation or distention plus abdominal pain whereas transit is characteristically accelerated in diarrhea-predominant patients. [18] Ileocecal function in IBS is variable with one study demonstrating delayed ileal emptying and decreased ileocecal clearance compared to healthy individuals and a second study reporting accelerated ileocecal transit both in constipation- and diarrhea-predominant patients. [96], [97]

Other Motor Abnormalities In addition to colonic and small intestinal motility disturbances, IBS is associated with motor abnormalities in other smooth muscle sites. Decreases in lower esophageal sphincter pressures and abnormalities of esophageal peristalsis have been found in IBS including increased spontaneous motor activity, repetitive contractions, and simultaneous waves in the esophageal body. [64], [98] In contrast, the upper esophageal sphincter, which is striated muscle, exhibits no manometric abnormalities in IBS. Gastric slow-wave dysrhythmias (tachygastria, bradygastria) have been reported in dyspeptic patients with IBS symptoms. [64] Fasting gallbladder volumes and residual volumes after contraction are greater in patients with IBS, whereas gallbladder emptying is impaired, although there is no increase in gallbladder disease with IBS. [99], [100] However, another study has reported that constipation-predominant patients exhibit enhanced gallbladder contraction, whereas patients with diarrhea exhibit impaired contraction compared to controls. [101] Sphincter of Oddi dysfunction has been described in association with IBS with demonstration of impairment of the sphincter relaxation in response to exogenous cholecystokinin. [102] Detrusor instability of the bladder has been demonstrated in 10 of 30 patients with IBS compared to 1 of 10 controls. [103] Similarly, patients with IBS exhibit hyperreactive airway function after administration of the smooth muscle stimulant methacholine. [104]

Visceral Sensory Abnormalities

A major focus of investigation is to define the visceral sensory abnormalities, which may be responsible for sensations of pain, gas, or bloating in IBS. Perception of abdominal symptoms is mediated by afferent neural pathways which are activated by visceral stimuli acting on chemoreceptors (which sense osmolarity, temperature, pH, etc.), mechanoreceptors (which are located in the gut wall and discharge in response to changes in tension), and receptors in the mesentery which may play a role in painful stimulation of the gut. [105] Information from these activated receptors is carried in spinal afferent nerves which synapse in the dorsal horn of the spinal cord. From there, the impulses are transmitted to the brain where conscious perception occurs. It is postulated that IBS results from sensitization of afferent pathways such that normal physiological gut stimuli not perceived by healthy individuals induce pain in the patient with IBS. The sensitizing event responsible for induction of symptoms in IBS is unknown.

Disturbed Sensation Under Basal Conditions The temporal association of symptoms with gut myoelectric and motor events provides evidence for disturbed visceral

sensation under unstimulated conditions. Myoelectric recordings show correlations between the appearance of intense, fused colonic SSBs and abdominal pain in constipation-predominant patients with IBS. [64] Irregular jejunal motor activity has been described coincident with the development of abdominal pain although other investigators have detected no abnormal motor patterns. [86], [106], [107] In one study, 61% of PPCs were associated with symptoms in patients with IBS compared to 17% in controls. [89] Similarly, DCCs were correlated with abdominal pain reports in 4 of 12 patients with IBS but in no healthy volunteers. [89] Another investigation has shown that nearly half of patients with IBS perceive different phases of the MMC as discomfort, a tugging sensation, or frank pain. [35] Thus, in contrast to healthy individuals, patients with IBS possess the ability to sense physiological motor events in the gastrointestinal tract. These findings may provide an explanation for older studies postulating a role for intestinal gas in the generation of abdominal symptoms in patients with functional bowel disorders. It was once believed that affected patients had abnormal amounts or distributions of intestinal gas. Early investigators described an entity called the splenic flexure syndrome, which consisted of severe left upper quadrant abdominal pain associated with apparent gas collections in the splenic flexure on abdominal radiographs. [108] Relief could be obtained by defecation, passage of flatus, or administration of an enema, and symptoms were reproducible by inflation of a balloon in the splenic flexure. Subsequent studies have shown that the absolute volume of gas in patients who complain of gas and bloating is normal. Using a washout technique, total volumes and transit times of intestinal gas were similar in asymptomatic individuals and in subjects complaining of excess gas. [43] However, patients with complaints of excess gas refluxed more gas from the intestine to the stomach and complained of distention and pain at low volumes of gas infusion that did not affect the controls. Thus, in addition to showing abnormal propulsion of intestinal gas, abnormal sensitivity to physiological amounts of intestinal gas is demonstrable in patients with functional symptoms.

Disturbed Sensation Under Stimulated Conditions As with studies of motor activity, patients with IBS frequently exhibit exaggerated sensory responses to visceral stimulation. Postprandial symptoms in IBS are associated with characteristic motor patterns. Postprandial pain has been temporally related to entry of the food bolus into the cecum in 74% of patients. [18] Some patients with concurrent nonulcer dyspepsia and IBS experience postprandial pain in association with increased rectosigmoid pressure. [109] Similarly, food has been shown to induce intestinal bursts that correlate temporally with pain. [110] A recent study showed that lipids lowered the thresholds for the first sensation of gas, discomfort, and pain in patients with IBS. [88] Furthermore, patients with IBS had an increased area of referred pain after lipids which was not observed in healthy subjects. Hence postprandial symptoms in patients with IBS may be explained in part by a nutrient-dependent exaggerated sensory component of the gastrocolonic response. Exaggerated symptoms can be induced by visceral distention in patients with IBS. Rectal balloon inflation produces nonpainful and painful sensations at lower volumes in patients with IBS than in healthy controls without altering rectal tension, suggestive of visceral afferent dysfunction in IBS (Fig. 86-3). [111] This effect persists even after exclusion of psychological factors such as neuroticism. However more recent studies [93], [94] suggested that psychological factors influenced pain thresholds in patients with IBS as stress altered sensory thresholds. When perception tests that minimize psychological influences were used, many patients with IBS showed normal sensory threshold. On the other hand, sexual abuse was not associated with lower pain threshold in patients with IBS. The visceral hyperalgesia of IBS appears to be selective for mechanoreceptor-activated stimuli as perception of intestinal mucosal electrical stimulation is normal in IBS. [112] In patients with IBS visceral hypersensitivity is not limited to the colon and rectum. Enhanced sensitivity to distension of the small bowel has been demonstrated. Jejunal sensitivity is increased after feeding in patients with IBS. [113] Furthermore nonperceived rectal stimulation appears to modify the intensity of jejunal perception to a greater extent in IBS than in healthy individuals. Similar studies showed gastric and esophageal hypersensitivity in patients with nonulcer dyspepsia and noncardiac chest pain, respectively. [111], [114] Furthermore, patients with IBS, nonulcer dyspepsia, or both all exhibited similar hypersensitivity to small intestinal distention, raising the possibility that these conditions have a similar pathophysiological basis. [115]

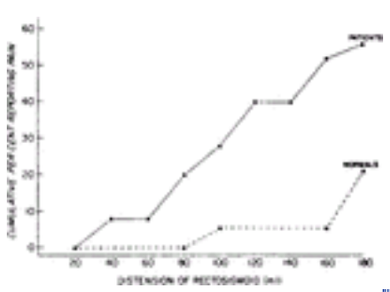

FIGURE 86-3. Perception of rectal balloon inflation is compared in healthy volunteers (*dashed line*) and patients with irritable bowel syndrome (IBS) (*solid line*). More patients with IBS reported pain with rectal distention. Furthermore, they experienced pain at much lower volumes than the healthy volunteers. (From Whitehead WE, Engel BT, Schuster MM. Irritable bowel syndrome: physiological and psychological differences between diarrhea-predominant and constipation-predominant patients. Dig Dis Sci 1980;25:404.)

Other studies of patients with IBS and nonulcer dyspepsia report enhanced sensitivity to esophageal distention, suggestive of a generalized visceral hyperalgesia in the functional bowel disorders. [116], [117] One group has categorized patients with IBS into three groups based on the response to rectal distention, including (a) those with a sensitive rectum, with a low sensory threshold to distention and normal to low intrarectal pressures, (b) those with a stiff rectum, with normal to low sensory thresholds and high pressures, and (c) those with an insensitive rectum, with a high sensory threshold and normal or high pressures. [118] The sensitive-rectum subtype was found in 57% of diarrhea-predominant patients versus 7% of patients with constipation. Seventy-five percent of diarrhea-predominant patients exhibited abnormal balloon distention responses versus 30% of constipated patients, suggesting that visceral hypersensitivity is not universal in IBS. This has been questioned in a study involving both rectal and sigmoid distention in patients with IBS. [119] In an investigation of patients with IBS with normal perception of rectal distention, all exhibited abnormal responses to sigmoid distention including alterations in colonic compliance and reflex relaxation. The duration of symptoms does not seem to be a factor in the degree of visceral hypersensitivity. No differences in threshold pressures for sensations of urgency and discomfort in patients with fewer than 2 years of symptoms have been observed compared to those with more than 5 years of complaints. [120] Finally, some investigators have postulated that IBS symptoms may result from interaction of visceral sensory dysfunction and abnormal gut motor patterns. In a study of women with IBS, those who exhibited enhanced perception of small intestinal distention had abnormal postprandial intestinal motor patterns. [121] In addition to visceral hyperalgesia, patients with IBS exhibit abnormal pain referral patterns with balloon inflation of the stomach, small intestine, or colon. [62], [122], [123] In contrast to healthy controls who perceive discomfort in only one quadrant with colonic distention, patients with IBS experience pain diffusely in the right upper and lower quadrants, right flank, hypochondrium, and epigastrium as well as in the back, shoulders, thighs, and chest (Fig. 86-4). [122] One group has proposed that, when alterations in viscerosomatic referral patterns are coupled with hypersensitive perception of rectal distention, visceral sensory abnormalities can be detected in nearly all patients with IBS and thus represent objective markers for the disorder. [124] These investigators further showed that repetitive sigmoid colonic distentions could induce development of rectal sensory abnormalities in 100% of patients with IBS, although the number of patients studied was small. [125]

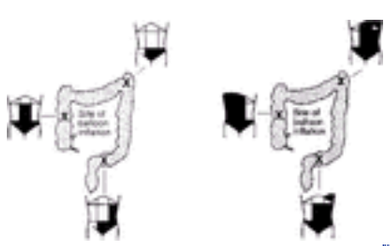

FIGURE 86-4. Pain referral patterns upon inflation of colonic balloons is compared in healthy volunteers (**left**) and patients with irritable bowel syndrome (IBS) (**right**). Colonic distention in healthy volunteers produced discomfort generally localized to a single abdominal quadrant while inflation in patients with IBS produced diffuse abdominal pain, providing evidence for altered viscerosomatic pain referral in IBS. (Adapted from Mayer EA, Gebhart GF. Basic and clinical aspects of visceral hyperalgesia. Gastroenterology 1994;107:271.)

In contrast to enhanced gut sensitivity, patients with IBS do not exhibit heightened sensitivity elsewhere in the body. Patients with IBS and Crohn's disease exhibit higher touch and pain thresholds with electrical stimulation of the skin than volunteers without these conditions. [126] Furthermore, patients with IBS, lactose intolerance, and healthy volunteers exhibit similar perception of ice water immersion of the hand. [127] Thus, the afferent pathway disturbances in IBS appear to be selective for visceral innervation with sparing of somatic pathways.

Central Nervous System Factors

The role of central nervous system factors in the pathogenesis of IBS is strongly suggested by the clinical association of emotional disorders and stress with symptom exacerbation and the therapeutic response to therapies that act on cerebral cortical sites.

Central Neural Dysfunction It is unknown whether IBS represents a primary gut disturbance with inappropriate input from the central nervous system or a central nervous system disorder with centrally directed changes in gut motor and sensory activity. [128] It is further undefined if the peripheral afferent nerve pathways that project from the gut to the brain exhibit abnormalities. New technologies are being developed to study this issue. Using cerebral evoked potential recordings, investigators reported that afferent pathways stimulated by esophageal distention are not abnormal in noncardiac chest pain and concluded that perceptual disturbances result from abnormalities in the central nervous system. [129] Conversely, evoked potential recordings in patients with nonulcer dyspepsia and patients with IBS show abnormal waveform latencies and amplitudes suggestive of visceral afferent dysfunction. [130], [131] Thus, the presence of peripheral afferent dysfunction in IBS is uncertain. Recent studies indicated that visceral hypersensitivity in IBS appears to be related to alterations in the nervous system rather than biochemical parameters such as the tension and strain of the gut wall. [132] Cerebral functioning in IBS is poorly understood; however, methodologies to assess neurological disease are being used to address this issue. Both mental stress and administration of the cholinesterase inhibitor neostigmine evoke increases in colonic motility and changes in electroencephalographic waveforms which are exaggerated in patients with IBS compared to healthy volunteers, suggesting that both the gut and brain are hypersensitive in IBS. [133] More recently, positron emission tomography has been employed to quantify regional cerebral blood flow in IBS. [134] In healthy individuals, rectal distention increased blood flow in the anterior cingulate cortex, a region that has been postulated to mediate the affective responses associated with pain. In contrast, patients with IBS exhibited no increased blood flow in this region but showed altered prefrontal cortical blood flow during sham rectal distention. This observation has been refuted by a functional magnetic resonance imaging (MRI) study, which reported that patients with IBS activated the anterior cingulate cortex to a greater extent than healthy controls in response to a painful rectal stimulus. [135] This suggests heightened pain sensitivity of the brain-gut axis in IBS, with a normal pattern of activation. The implications of these findings are unclear but they raise the possibility that central neural disturbances may play primary pathogenic roles in the induction of symptoms in IBS.

Abnormal Psychological Features Abnormal psychological features are recorded in up to 80% of patients with IBS, especially in referral centers; however, no single psychiatric diagnosis predominates. [3], [111], [136], [137] The lifetime incidences for major depression, somatization disorder, generalized anxiety disorder, panic disorder, and phobias are higher in patients with IBS than in healthy controls. [138], [139] An early investigation observed that 80% of patients with IBS had underlying depression or anxiety, whereas another study reported hysteria or depression in 72% of patients with IBS compared to 18% in normal volunteers. [31], [137], [140] Conversely when depressed patients are examined, 25% meet criteria for IBS compared to 2.5% of nondepressed controls. [141] Similarly IBS is found in 59% of dysthymic patients. [142] A significant overlap of panic disorder and IBS has been observed, with similar demographic and clinical characteristics. [143] In one study, 46% of patients with panic disorder met criteria for IBS versus 2.5% of controls. [144] Increases in neuroticism and decreases in extroversion are reported in IBS. [140] Additional abnormalities associated with IBS include hostility, hypochondriasis, and increased interpersonal sensitivity. [111] In an illness attitudes assessment, three abnormalities specific to IBS were bodily preoccupation, hypochondriacal beliefs, and disease phobia. [145] Psychological abnormalities predate or occur simultaneously with the onset of bowel symptoms in 67% to 85% of patients, suggesting that it is not the symptoms of IBS that induce psychiatric disease. [111], [146], [147] and [148] An association between prior sexual or physical abuse and development of IBS has been reported. [10], [149] Rates of severe lifetime sexual trauma, severe childhood sexual abuse, and any lifetime sexual victimization are significantly greater in patients with IBS than individuals with inflammatory bowel disease. [150] Forms of sexual abuse associated with IBS include verbal aggression, exhibitionism, sexual harassment, sexual touching, and rape. [151] Sexually traumatized patients experience significantly higher rates of lifetime development of depression, panic disorder, phobia, somatization, ethanol abuse, and sexual dysfunction. Furthermore, they exhibit higher rates of physician visits and more gastrointestinal and nongastrointestinal symptoms, and they undergo more surgeries. [149] Another study has reported histories of sexual abuse in 40% of patients with functional lower gastrointestinal disease both in tertiary referral centers and in private gastroenterology practices (Fig. 86-5). [152] Prior sexual abuse is more common in constipated patients and is not prevalent in patients with functional upper gut symptoms. In a complementary study, patients with prior abuse were more likely to report symptoms of IBS than those with no history of abuse. [153] From a pathophysiological standpoint, sexual abuse was not associated with lower pain threshold in patients with IBS. [154]

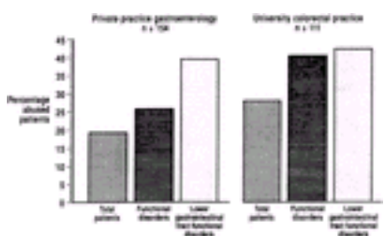

FIGURE 86-5. The prevalence of prior sexual abuse is shown for all patients seen in a private gastroenterology practice and a university practice as well as for patients with functional gut disorders in general and those localized to the lower gastrointestinal tract. Previous sexual abuse was reported significantly more often in those patients with functional lower gut disorders (such as irritable bowel syndrome) in both practice environments. (From Leroi AM, Berier C, Watier A, et al. Prevalence of sexual abuse among patients with functional disorders of the lower gastrointestinal tract. Int J Colorectal Dis 1995;10:200.)

Only a small fraction of individuals with symptoms of IBS present to a physician. Investigators have attempted to characterize differences between symptomatic individuals who seek medical attention and those who do not, known as nonreporters. Patients with IBS have been shown to exhibit more personality abnormalities and greater illness behavior than nonreporters. [50] Similarly, patients with IBS possess psychiatric disturbances greatly exceeding the general population; however, nonreporters are not different from asymptomatic individuals. [146] How a person responds to his or her symptoms determines whether he or she will present to a physician. Patients with IBS have histories of more frequent and serious childhood illnesses resulting in school absences and pediatrician visits and report that gifts were provided during childhood illness, suggesting that their expectations for illness behavior involve a reward. [60], [155]

Role of Stress on Visceral Function in Health and IBS The role of the central nervous system in modulating gastrointestinal function has intrigued researchers for decades. Early investigations of the effects of stress reinforce the importance of the brain-gut axis in the regulation of colonic activities. Painful somatic stimuli, such as ice water immersion of the hand or tightening of a circumferential band around the head, were shown to produce rectal spasm and mucosal engorgement. [156] Psychological stressors have been shown to have similar effects. One hoax involved telling a medical student during proctoscopy that a rectal cancer had been found, after which he was shown a piece of potato that he was told was a biopsy of the alleged malignancy. [157] As with the painful stimuli, the rectum exhibited intense contractions and mucosal reddening, which disappeared when the hoax was revealed. Similarly, in seven constipated subjects and eight with diarrhea-prone IBS, changes in rectosigmoid motility were inducible with stressful interviews. [158] Hostile or aggressive reactions provoked increased motor activity, whereas passive reactions or dejection led to motor quiescence. Other stressors such as anger, ball sorting, and stimulus differentiation testing increase colonic motility or spike potential activity in patients with IBS and controls. [68], [69], [159] The central nervous system also modifies visceral perception that suppresses or enhances afferent impulses from the gastrointestinal tract. [105] Hypnosis reduces perception of rectal distention in diarrhea-predominant patients with a lesser effect on constipated patients. [160] The lack of effect of hypnotherapy on rectal compliance or motor activity is indicative of active suppression of visceral afferent function by central nervous system activity. Stressful stimuli also induce physiological responses elsewhere in the gastrointestinal tract. Vertigo induced by cold caloric stimulation of the external ear delays gastric emptying and converts the fed-motor pattern to fasting complexes. [161] Barium radiography of the small intestine performed on subjects during stressful interviews showed segmentation, spasm, widening of the mucosal folds, and areas of distention. [162], [163] Psychological stress, as with intense participation in a video game or driving in rush hour traffic, decreased cycling of the intestinal MMC in healthy volunteers. [164] The relative effects of stress on small intestinal motility in patients with IBS compared to healthy individuals are controversial. Using radiotelemetry capsules in the small intestine, long periods of mental stress induced motor abnormalities in 19 of 22 patients with IBS compared to 1 of 10 controls. [107] In 7 patients, MMC cycling was eliminated and, in 18 patients, there were episodes of irregular motor activity lasting 1 to 6 hours. However, another study showed equivalent suppression of MMC activity in patients with IBS and controls as well as inhibition, rather than induction, of DCCs in both subject groups, suggesting that the intestine in patients with IBS may not be more susceptible to stress than asymptomatic controls. [165] Current stressful events may exacerbate symptoms in a large subset of patients with IBS, although they are not likely to be the cause of IBS. A strongly positive relationship has been reported between daily stress and daily symptoms in women with IBS. [166] Disturbances of sleep have been correlated with symptom development in IBS, especially in the morning. [167] In addition to current stressors, a history of severe emotional upheaval in the distant past often is elicited upon careful questioning. Loss of a parent, either through death or marital dissolution, has been reported to be an important stressor in one third of patients. [168], [169] and [170] A strong association between IBS and posttraumatic stress disorder has also been noted. [171] Furthermore, military veterans returning from the war in the Persian Gulf presented with gastrointestinal complaints and exhibited visceral hyperalgesic properties similar to those of patients with IBS, suggesting that a subset of persons with Gulf War syndrome may in fact have IBS. [172]

Other Studies on the Pathogenesis of IBS

Induction of IBS by Gastrointestinal Infection Some recent studies correlate development of IBS with a prior gastrointestinal infectious illness. In an investigation of 544 patients with confirmed bacterial gastroenteritis, one fourth reported persistently abnormal bowel habits 6 months later. [173] Seven percent developed IBS with a

3.4-fold increased risk in women compared to men. A similar study of 75 patients with acute gastroenteritis requiring hospital admission observed that 20 had persistent symptoms for more than 6 months compatible with the diagnosis of IBS. [174] Similarly, another group [175] reported that about a third of patients with IBS experienced an acute "gastroenteritis-like" illness at the onset of their chronic IBS symptomatology. The previously cited studies have shown that IBS following an enteric infection occurred more commonly in females, and affected younger rather than older patients and those who had a protracted acute diarrheal illness. Psychometric assessment at the time of acute infection found that those who developed IBS had higher scores for anxiety, depression, somatization, and neuroticism compared to those who recovered. Increases in ileal mast cell density are reported in IBS, raising the possibility that subtle inflammation is pathogenic. [176] The microbes involved in the initial infection were *Campylobacter Salmonella* and *Shigella*. [173], [174] and [175] Those patients with *Campylobacter* infection who were toxin-positive were more likely to develop postinfectious IBS. [177] Increased rectal mucosal enteroendocrine cells, T lymphocytes, and increased gut permeability were acute changes following *Campylobacter enteritis* which could persist for more than a year and may contribute to postinfectious IBS. [178] In a provocative study, Pimentel and associates [179] reported that of 202 patients with IBS 78% had small intestinal bacterial overgrowth. Forty-eight percent of the subjects who had eradication of bacterial overgrowth experienced symptomatic improvement. This interesting finding has far-reaching clinical implications but requires confirmation.

Role of Malabsorption or Intolerance to Specific Foods The role of carbohydrate malabsorption as a cause of bloating, pain, and diarrhea in IBS has been extensively evaluated. Lactase deficiency is a well-described syndrome where ingestion of milk products causes symptoms similar to those in IBS. Using hydrogen breath testing, 25.8% of one group of patients with presumed IBS exhibited lactase deficiency but 52% of these individuals did not relate their symptoms to lactose ingestion. [180] Another study of lactase-intolerant patients with IBS reported that symptoms were independent of lactase supplementation when given in placebo-controlled fashion, suggesting that lactase deficiency was not pathogenic of IBS in these patients. [181] Conversely, a recent hydrogen breath test analysis of patients with presumed IBS identified a subset of patients with lactase deficiency unsuspected by the clinical history who responded to dietary lactose exclusion. [182] This observation was confirmed in another study which reported that the majority of patients with IBS with lactose malabsorption (which was previously clinically unrecognized) placed on a lactose-restricted diet noticed markedly reduced symptoms both in the short term and the long term. [183] These studies suggest that lactose malabsorption should be excluded before diagnosing IBS. Malabsorption of other sugars has been proposed as a cause of symptoms in some patients with IBS. In one study, fructose and sorbitol, which are found in fruits as well as soft drinks and candy, produced prominent symptoms in most subjects; however, dietary exclusion of these sugars was not performed. [184] A more recent investigation reported increased symptoms in patients with functional gastrointestinal disease after lactose or fructose plus sorbitol compared to healthy controls. [185] In this study, 40% of patients experienced symptom reduction after restriction of the offending carbohydrate. A study in Israel indicated that combined carbohydrate malabsorption was common in IBS and may contribute to symptomatology in many of the patients investigated. [186] However, the weight of available evidence suggests that carbohydrate malabsorption is not the cause of symptoms in most patients with IBS in the United States, although intolerance to certain sugars probably plays a role in some individuals. Food hypersensitivity likely plays only a minor role in most patients, although some individuals with IBS may have a true allergic component to their symptoms. In a study of 14 patients with diarrhea-predominant IBS who noted symptoms after eating wheat, dairy products, coffee, tea, or citrus fruits, a blinded challenge with the offending food led to worsening of the symptoms in six patients; this was associated with elevations in rectal prostaglandin E_2. [187] However, subsequent studies [188], [189] have reported that only a small fraction of diarrhea-prone patients with IBS improve on an exclusion diet, an effect that may not be greater than with placebo. Even those individuals with positive skin test responses to particular foods do not show symptom resolution upon dietary exclusion of those foods. [190]

Disturbed Neurohumoral Activity Systemic disturbances in neural and hormonal activity have been explored as pathogenic factors in IBS. Efferent vagal dysfunction is suggested by demonstrations of reductions in vagally mediated increases in lower esophageal sphincter pressure after abdominal compression, impaired pulse variability with inspiration, and reduced ratios of insulin-induced peak gastric acid output to pentagastrin-stimulated maximal acid output in subsets of patients with IBS. [191] Decreases in digital temperatures and enhanced peripheral electromyographic activity have led investigators to postulate a diffuse autonomic neural disturbance in IBS. [192] A quantitative assessment of sympathetic adrenergic and cholinergic and cardiovagal cholinergic function revealed abnormalities in 9 of 33 patients with IBS. [193] Another investigation suggested that constipation-predominant patients with IBS exhibit abnormalities of cholinergic function, while diarrhea-prone individuals have evidence of adrenergic neural dysfunction. [194] Parasympathetic tone was significantly lower in the constipation-predominant patients with IBS compared with the diarrhea-predominant patients with IBS. [195] Prolongation of rapid eye movement (REM) sleep with episodes of sleep apnea has been reported in IBS, raising the possibility that the central nervous system exhibits abnormalities outside of the brain-gut axis. [196], [197] Blunting of a-adrenergic pathways in the central nervous system is suggested by the observation of impaired growth hormone release in patients with IBS, but not patients with ulcer or healthy controls, in response to a2-adrenoceptor stimulation. [198] Patients with IBS appear to have an exaggerated response to corticotropin-releasing hormone (CRH). [199] Not only did exogenous CRH induce a higher plasma corticotropin level in patients with IBS, it also produced abdominal symptoms accompanied by a greater motility index in the colon as well as duodenal dysmotility in this group of patients. Diarrhea-predominant patients with IBS showed a significant postprandial increase in cortisol which was not evident in healthy subjects or constipation-predominant patients with IBS. [200] Hormonal disturbances have been postulated to be pathogenically important in patients with IBS who experience symptoms during menses. [52], [201] Abnormal circulating pancreatic polypeptide, neurotensin, insulin, motilin, cholecystokinin, and gastrin levels are reported in some patients with IBS. [202], [203] and [204] In women with IBS, higher urinary norepinephrine, epinephrine, and cortisol levels have been observed. [205] The roles of these neurohumoral disturbances in the pathogenesis of IBS are unclear but are likely to be epiphenomenal. Serotonin (5-HT) is present in abundance in the gastrointestinal tract. It may play an important role in the regulation of gastrointestinal motility and visceral perception. One study indicated that 5-HT–containing enterochromaffin cells in the colon were increased in diarrhea-predominant patients with IBS compared to healthy subjects or patients with ulcerative colitis. [206] Furthermore, postprandial plasma 5-HT plasma levels were significantly higher in diarrhea-predominant patients with IBS compared to healthy controls. [207] This suggests a possible role for 5-HT in the postprandial symptoms of these patients and provides a rationale for the use of 5-HT antagonists in the treatment of this disorder.

Abnormal Stool Characteristics Abnormal characteristics of the fecal material have been postulated as symptom inducers in IBS. As bile acids induce colonic contractions, investigators have proposed that diarrhea-predominant patients with IBS have bile acid malabsorption. [63] Bile acid binders such as cholestyramine are used in IBS with anecdotal reports of success; however, this may be due to the general constipating effects of the resin. However, one study reported that about one third of patients with IBS had bile acid malabsorption and 70% of these patients responded to bile acid sequestrants whereas only 15% responded to conventional therapy. [208] Others have proposed that elevated levels of fecal short-chain fatty acids may cause diarrhea in IBS; however, symptoms do not correlate with fecal levels of these compounds. [209] An investigation revealed that diarrhea-prone patients have lower fecal concentrations of total short-chain fatty acids, acetate, and propionate, and higher levels of *N*-butyrate than controls. [210] Gut flora disturbances have been suggested as causes of symptoms in some patients, and trials to modify the dominant organisms have met with some success in reducing symptoms. [211], [212] The demonstration of increased hydrogen production in patients with functional gut disease after lactulose is supportive of qualitative and/or quantitative alterations in the fecal flora of some patients with IBS. [185] Regardless, to date there is little convincing evidence that stool characteristics are abnormal in IBS.

DIAGNOSTIC APPROACH TO THE PATIENT WITH PRESUMED IBS

History and Physical Examination

Confident diagnosis of IBS relies on recognition of characteristic symptom profiles as well as the detection of alarm findings (weight loss, bleeding, fever, or palpable masses) which are more suggestive of organic disease. The symptoms that define IBS also are prominent complaints of many other conditions including malignancies, inflammatory diseases, infections, and ischemic diseases of the gastrointestinal tract as well as some nongastrointestinal conditions. Several investigators have attempted to ascertain if specific symptom patterns can distinguish IBS from more severe illnesses. In a questionnaire survey, Manning and colleagues [213] defined four symptoms that were significantly more common in IBS than organic disease including relief of abdominal pain upon defecation, looser stools with onset of pain, more frequent stools with the onset of pain, and abdominal distention. Ninety-one percent of patients with IBS had two or more of these symptoms versus 30% of those with organic disease. Other symptoms which were common but which did not distinguish IBS from organic disease included passage of mucus, a sensation of incomplete evacuation, fecal urgency, harder or less frequent stools at pain onset, pain eased by passage of flatus, and defecation before breakfast, at night, or between meals. In a study by Kruis and associates, [214] an absence of organic disease was predicted by (a) the combination of pain, flatulence, and irregular defecation, (b) symptoms persisting for more than 2 years, (c) pain described as burning, cutting, very strong, or terrible, (d) a defecation pattern of alternating defecation and constipation, (e) pencil-like or pellet-like stools, and (f) the passage of mucus in the stools. These initial investigations have been followed by international assemblies that have devised the commonly employed Rome I, and more recently Rome II, criteria. [29]

Studies have quantified the reliability of symptom-based criteria in the diagnosis of IBS. An early evaluation observed that the Manning criteria could distinguish IBS from organic disease with a sensitivity of only 58% and a specificity of 74%. [215] In a second study, the Manning criteria were found to discriminate IBS from organic disease with a sensitivity and specificity of 90% and 87%, respectively, while the Kruis system exhibited a sensitivity of 81% and a specificity of 97%. When employed together, the two sets of criteria exhibited 80% sensitivity and 97% specificity for the diagnosis of IBS. [216] A retrospective analysis [217] determined that, in the absence of alarm symptoms or physical findings, the Rome I criteria had a sensitivity of 65%, a specificity of 100%, and a positive predictive value of 100% for the diagnosis of IBS. Furthermore, no patient required revision of the diagnosis in a 2-year follow-up. When evaluated prospectively, the positive predictive value of the Rome I criteria

was 98%. [217]

The physical examination of the patient with IBS usually is normal. Abdominal compression may elicit tenderness that is vague and poorly localized. Tender bowel loops are commonly palpable. [22] Masses, adenopathy, hepatosplenomegaly, ascites, blood in the stool, or autonomic or peripheral neuropathy are suggestive of organic disease and are not consistent with IBS.

Laboratory and Structural Findings

A minimal laboratory and structural evaluation has been advocated as a screen for organic disease in the patient with presumed IBS. Basic testing includes a complete blood count to assess for anemia, leukocytosis, or leukopenia, a sedimentation rate to screen for inflammation, thyroid chemistries to exclude hormonal causes of altered bowel function, and serum electrolytes and stool studies for ova and parasites or *Giardia* antigen in patients with diarrhea. For diarrhea-predominant individuals, hydrogen breath testing to exclude lactose intolerance should be considered. [218] Empiric dietary lactose restriction is an alternative when breath testing is not available. For pain-predominant patients, plain abdominal radiography during an episode of pain can exclude intermittent bowel obstruction. [218] Sigmoidoscopy is recommended for most young individuals (<50 years old) to rule out distal obstruction in patients with constipation and inflammatory diseases in those with diarrhea. In diarrhea-predominant patients, random biopsies are obtained to search for microscopic colitis. Sigmoidoscopy should reveal normal anatomy in IBS, although increased mucus secretion, mucosal engorgement, and pain with air insufflation are commonly noted. [22] In patients over the age of 50, colonoscopy or air-contrast barium enema radiography are indicated because of the prevalence of colonic neoplasm in this age group. A technical review for practice guideline development by the American Gastroenterological Association [218] delineated factors to be considered when determining the aggressiveness of the diagnostic evaluation. These include the duration of symptoms, the change in symptoms over time, the age and sex of the patient, the referral status of the patient, prior diagnostic studies, a family history of colorectal malignancy, and the degree of psychosocial dysfunction. Thus a younger individual with mild symptoms requires a minimal (or in select cases no) diagnostic evaluation while an older person or an individual with rapidly progressive symptoms should undergo a more thorough exclusion of organic disease.

The validity of this approach has been subject to scrutiny. In the absence of alarm findings, a normal complete blood count and sedimentation rate provide 83% sensitivity and 97% specificity for the diagnosis of IBS. [30] However, a study of 196 patients satisfying the Rome I criteria found no diagnostic yield from sedimentation rates, thyroid profiles, and stool examinations in the absence of specific historical or physical examination findings. [180] Furthermore, barium enema radiography or lower endoscopy revealed only one case with colon cancer, nine with polyps, and one with colitis out of a sample of 196 patients. [180] In data from two other multicenter trials, lactose intolerance was diagnosed in 23% of patients, colonic structural abnormalities were found in 2%, abnormal thyroid chemistries were observed in 6%, and positive fecal ova and parasites were detected in 2%. [219] Nevertheless, a thorough initial evaluation of the patient with presumed IBS precludes the need for further diagnostic testing years later. In 112 patients with IBS followed for a median of 29 years, organic disease developed in only 10 patients a median of 15 years after the original diagnosis of IBS. [220]

TREATMENT

The treatment of IBS ranges from patient education and dietary modifications to medications or even psychological intervention. Some patients, especially those with new onset symptoms, will express relief that they do not have a serious condition such as cancer. Whenever possible, the physician should resist the temptation to rely on drugs which might provide only limited efficacy and which could provoke unacceptable side effects. Nonetheless, medications are prescribed at 75% of outpatient visits for IBS. [3] High placebo response rates ranging from 30% to 70% have diminished the ability of controlled studies to detect therapeutic benefits of drug therapies of IBS. [221] Reviews have judged that few studies offer convincing evidence of drug efficacy, although some benefit for antispasmodics in reducing pain and for loperamide in controlling diarrhea has been observed. [222], [223] Critiques of published IBS drug trials raised methodological concerns about the peer-reviewed literature including studies too short in duration to detect efficacy, poorly designed crossover protocols in which washout periods between active drug and placebo were inadequate, inappropriate statistical methods, and large placebo effects which would mandate the enrollment of hundreds of patients to detect a statistically significant drug effect. [221] In the design of new studies, these critiques recommended careful description of the randomization method, use of international diagnostic criteria, use of placebo control and double-blinding, and defining clear outcome measures.

Dietary Measures and Fiber Supplements

Dietary modifications are commonly recommended in IBS, although little controlled investigation has been performed. It is reasonable to limit fat intake as lipids most potently activate exaggerated motor reflexes such as the gastrocolonic response. Patients with bloating and diarrhea should restrict their intake of poorly digestible sugars such as fructose and sorbitol. A subset of patients with excess gas may derive benefit from additional dietary modification. Certain foods promote intestinal gas production. Pork and bean meals increase colonic gas passage from 15 to 176 mL/h as a consequence of maldigestion of oligosaccharides such as stachyose and raffinose. [224] Fiber content in the diet also can contribute to gas generation. A high-fiber diet with beans produces 49.4 mL of gas/h vs. 10.9 mL/h on a liquid low-fiber diet. [225] However, most patients with IBS who complain of excess flatus in fact produce normal amounts of gas. Exclusion of foods associated with increased flatulence including beans, onions, celery, carrots, raisins, bananas, apricots, prunes, brussels sprouts, wheat germ, pretzels, and bagels has been reported to reduce flatus expulsions in uncontrolled reports of patients with excess gas (Table 86-2). [226]

Normoflatulogenic Foods
Meat, fowl, and fish
Vegetables (e.g., lettuce, cucumber, broccoli, pepper, avocado, cauliflower, tomato, asparagus, zucchini, okra, olives)
Fruits (e.g., cantaloupe, grapes, berries)
Carbohydrates (e.g., rice, corn chips, potato chips, popcorn, graham crackers)
Nuts
Miscellaneous (e.g., eggs, non-milk chocolate, flavored gelatin, fruit ice)
Moderately Flatulogenic Foods
Pastries
Potatoes
Eggplant
Citrus fruit
Apple bread
Extremely Flatulogenic Foods
Milk and milk products
Vegetables (e.g., onions, beans, celery, carrots, brussels sprouts)
Fruit (e.g., raisins, bananas, apricots, prune juice)
Miscellaneous (e.g., pretzels, bagels, wheat germ)

Adapted from VanNess MM, Cattau EL. Flatulence: pathophysiology and treatment. Am Fam Physician 1985;31:108.

TABLE 86-2 Foods and Flatus Production

Fiber supplements are widely recommended for treating IBS and exhibit several properties that theoretically should be beneficial in IBS including enhanced water retention and bulking of the stool, formation of gels to provide stool lubrication, and binding bile acids which could cause symptoms in some cases. [227] Of note, patients with IBS do not consume less dietary fiber than healthy individuals. [228] Studies in animal models have observed induction of propagative colonic motor activity with augmentation of dietary fiber content. [229] In a review of human investigations, bran increased fecal weight in 18 of 20 studies and accelerated fecal transit in 16. [230] Bran accelerated colonic transit in healthy volunteers with an initial colonic transit time of 3 or more days, whereas it retarded propulsion in those with a transit time of 1 day suggesting that dietary fiber promotes a more regular bowel pattern in normal individuals. [231] Psyllium reduces perception of rectal distention, indicating that fiber may have positive effects on visceral afferent function as well. [232]

Fiber supplements that have been studied in IBS in placebo-controlled fashion include bran, psyllium, process flea seed husk (ispaghula), and calcium polycarbophil. Because of high placebo response rates and enrollment of small numbers of patients, studies have failed to document a therapeutic benefit of fiber supplementation in the IBS population as a whole. [221] Most investigations report increases in stool weight, decreases in colonic transit times, and improvement in constipation. [233], [234], [235] and [236] Others have noted benefits in patients with alternating diarrhea and constipation, pain, and bloating, however most studies observe no responses in patients

with diarrhea- or pain-predominant IBS. [237] It is possible that different fiber preparations may have dissimilar effects on selected symptoms in IBS. One study observed symptom exacerbation in 55% of patients with IBS with bran, while only 10% experienced symptom improvement. [238] A crossover comparison of different fiber preparations found that psyllium produced greater improvements in stool pattern and abdominal pain than bran. [239] Furthermore, bran exacerbated complaints of abdominal distention while psyllium supplements reduced such complaints. A third study reported increases in flatulence with bran therapy. [240] Additionally, patients with IBS were noted to benefit from placement on a fiber-restricted diet but with use of commercial bulking agents as needed suggesting that low-fiber diets may be advisable in some patients. [241]

Medication Treatments

Osmotic Laxatives For patients with constipation-predominant IBS who do not respond to fiber, osmotic laxatives are often recommended to effect defecation. Available agents include hypertonic salt solutions such as milk of magnesia, poorly absorbable sugars such as lactulose and sorbitol, and isotonic electrolyte solutions containing polyethylene glycol. There is little controlled literature to support the use of osmotic laxatives specifically in IBS, although several studies do report benefits for polyethylene glycol solutions in accelerating colonic transit and increasing stool frequency in patients with idiopathic slow transit constipation. [242]
Antidiarrheal Agents Peripherally acting, opiate-based agents are the initial therapy of choice for diarrhea-predominant IBS. Physiological studies demonstrate increases in segmenting colonic contractions, delays in fecal transit, increases in anal pressures, and reductions in rectal perception with these drugs. Placebo-controlled investigations of loperamide report decreases in stool frequency and urgency, improved consistency, reduced borborygmi, and benefits in well being in patients with diarrhea or alternating diarrhea and constipation. [243] Other agents have been proposed for use in patients with IBS with diarrhea. An uncontrolled study of diarrhea-predominant patients with IBS noted a 70% response to bile acid–sequestering drugs. [208] Acid suppressing drugs in the H_2 receptor antagonist and proton pump inhibitor classes have been reported in an uncontrolled trial to reduce diarrhea in IBS. [244]
Antispasmodic Agents Antispasmodic agents are the most commonly prescribed agents for IBS and are the initial recommended therapy for pain-predominant IBS. [218] Included in this category are agents that block cholinergic nerve function, drugs that prevent calcium flux, direct gut smooth muscle relaxants, and agents that act via unknown pathways. From a physiological standpoint, anticholinergic drugs and calcium channel antagonists are potent inhibitors of the gastrocolonic response. [245], [246] A metaanalysis of 26 double-blind clinical trials of antispasmodic agents in IBS reported better global improvement (62%) and abdominal pain reductions (64%) compared to placebo (35% and 45%, respectively), although none of the medications analyzed (cimetropium, pinaverium, trimebutine, octylonium, and mebeverine) are approved in the United States. [247] A second metaanalysis of controlled trials of cimetropium, hyoscine, mebeverine, octylonium, pinaverium, and trimebutine quantified improvements in global well being in 56% versus 38% of patients on placebo and reductions in pain in 53% compared to 41% of patients on placebo. [248] Anticholinergic agents are the major class of antispasmodics prescribed in the United States. In small trials, dicyclomine, prifinium, and cimetropium have been reported to reduce symptoms including fecal urgency and pain in IBS compared to placebo. [249], [250] However, issues of blinding, study duration, and statistical analysis raise questions as to the validity of these conclusions. [221], [249] The gut selective anticholinergic M_3 muscarinic receptor antagonist zamifenacin has been demonstrated to blunt the colonic motor response to meal ingestion and shows promise as therapy for pain-predominant illness. [251] In animal models, M_3 receptor antagonists inhibit diarrheal responses to stress, serotonin, prostaglandins, and castor oil. [252] Calcium channel blockers have been proposed for use in IBS because of their smooth muscle relaxant properties and their inhibitory effects on the gastrocolonic response. A double- blind trial of diltiazem did not show global improvement, but did observe trends to reduced diarrhea and abdominal pain. [253] In a randomized, placebo-controlled trial, pinaverium reduced the duration of abdominal pain in IBS. [254] Octylonium produced significant improvements in the number of pain episodes, the severity of distention, and global assessments in a placebo-controlled trial in 325 patients. [255] Peppermint oil relaxes gastrointestinal smooth muscle via reduction of calcium influx. [256] In a recent large trial, 79% of subjects experienced pain reduction, 83% reported less abdominal distention, 83% had reduced stool frequency, and 79% passed less flatus, values that were all superior to placebo. [257] A metaanalysis of eight randomized, controlled trials reported a trend toward therapeutic benefit of peppermint oil in IBS, however this could not be definitively concluded due to methodological concerns. [258] Peppermint oil may also be of benefit in children with IBS, as the agent has been shown to reduce abdominal pain severity in 75% of cases. [259] Other antispasmodics unavailable in the U.S. that do not act via inhibition of cholinergic activity or calcium flux have been used for IBS. Mebeverine is a smooth muscle relaxant similar to papaverine which inhibits ileal and colonic motility in patients with IBS. [260] Two small studies have reported benefits for mebeverine over placebo while a third investigation observed no improvement. [260], [261] In a nonplacebo-controlled trial [262] both the short- and long-acting forms of mebeverine have been reported to be “effective” or “very effective” by more than 80% of patients with IBS. Trimebutine is an antispasmodic which stimulates small intestinal motility by acting on peripheral opiate receptors but inhibits colonic motility via a aloxone-insensitive pathway. [263] In the largest placebo-controlled trial involving 60 patients with IBS, [264] there were no differences in pain relief with trimebutine versus placebo.
Antidepressant Agents Antidepressant agents in the tricyclic class have demonstrated clear efficacy in selected IBS subsets, but the mechanisms of their beneficial effects are uncertain. In diarrhea-predominant patients with IBS, imipramine slows propagation of jejunal pressure waves and delays orocecal and whole gut transit indicative of a motor inhibitory effect. [265], [266] Some investigations have reported reduced perception of luminal distention suggestive of inhibition of visceral afferent transmission, although other studies have shown no effects on visceral perception. [267], [268] The effects of tricyclic antidepressants on central neural processing of painful visceral stimulation are unknown. A controlled trial of amitriptyline reported benefits in global well being, abdominal pain, and bowel pattern and identified young age and increased extroversion as predictors of drug response. [269] Studies of trimipramine have reported improvements in vomiting, depression, sleeplessness, and fecal mucus with variable reductions in pain compared to placebo. [270] Placebo-controlled trials of desipramine observed decreases in pain, stool frequency, and depression which were confined to diarrhea-predominant patients. [271] Nortriptyline given in combination with fluphenazine was reported to reduce pain and diarrhea compared to placebo. [272] The efficacy of antidepressant agents in other classes in treating IBS is less clear. In contrast to tricyclic agents, the selective serotonin reuptake inhibitor (SSRI) paroxetine accelerates orocecal transit raising the possibility that this drug class may be useful in constipation-predominant patients. [266] The SSRI citalopram blunts perception of rectal distention and reduces the magnitude of the gastrocolonic response in healthy volunteers. [273] A small placebo-controlled study of citalopram in patients with IBS reported reductions in pain. [274] An investigation of mianserin, with serotonin 5-HT $_2$ and 5-HT $_3$ receptor antagonist and a $_2$-adrenoceptor antagonist effects, reported reductions in pain, distress, and functional disability compared to placebo. [275] A metaanalysis of tricyclic and nontricyclic antidepressants reported an odds ratio for clinical improvement of 4.2 (confidence interval 2.3–7.9) (Fig. 86-6). [276] On average, 3.2 patients needed to be treated to produce symptom improvement in 1 patient. A second metaanalysis of all antidepressant trials in IBS reported an odds ratio for improvements in pain of 8.0 and for global improvement of 4.4. [277]

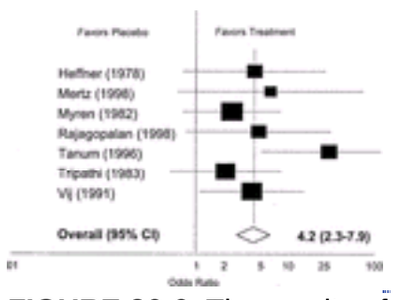

FIGURE 86-6. The results of metaanalysis of antidepressant medications on the overall improvement in gastrointestinal symptoms are shown. The *boxes* represent the odds ratios favoring active drug or placebo while the *horizontal lines* show the 95% confidence intervals. The box sizes are proportional to each study’s weight in the analysis. When the data are pooled, the odds ratio for a benefit of antidepressant treatment is 4.2 with a 95% confidence interval ranging from 2.3 to 7.9. (From Clouse RE, Prakash C, Anderson RJ, Lustman PJ. Antidepressants for functional gastrointestinal symptoms and syndromes: a meta-analysis. Gastroenterology 2001;120:3252[abst].)

Serotonin Receptor Antagonists Serotonin receptor antagonists have been evaluated as therapies for diarrhea-predominant IBS. Serotonin acting on 5-HT $_3$ receptors enhances the sensitivity of afferent neurons projecting from the gut. [278] In humans, the 5-HT $_3$ receptor antagonists ondansetron, granisetron, and alosetron reduce perception of painful visceral stimulation in IBS. [279], [280] 5-HT $_3$ receptor antagonists also induce rectal relaxation, increase rectal compliance, and delay colonic transit. [281], [282], [283] and [284] In small, placebo-controlled trials, ondansetron and granisetron provided relief of loose, frequent stools and flatulence. [279], [280] Large, 12-week placebo-controlled trials of alosetron reported reductions in discomfort and improvements in stool frequency, consistency, and urgency in nonconstipated patients with IBS. [285], [286], [287] and [288] A follow-up 48-week study confirmed the long-term efficacy of alosetron. [289] For unclear reasons, women with IBS derived greater benefit than men. An additional trial reported superior responses to alosetron than the antispasmodic agent mebeverine. [290] Subsequent investigations reported improvements in quality of life, improving physical, social, and mental parameters. [291] However in postrelease surveillance, 70 cases of severe constipation or

ischemic colitis were observed including 10 cases that required surgery and 3 deaths that could potentially be attributed to the drug. [292] As a consequence, the medication was voluntarily withdrawn by the manufacturer, but has since been reapproved for limited use. Preliminary studies in nonconstipated patients with IBS of a newer 5-HT $_3$ receptor antagonist cilansetron have shown improvements similar to alosetron in reduction in abdominal pain and diarrhea. [293] Follow-up investigations will determine if side effects might undermine the use of this agent. In addition to its effects on the 5-HT $_3$ receptor, serotonin modulates gut perception via action on 5-HT $_4$ receptors. In a controlled trial in 18 patients with diarrhea-predominant IBS, the 5-HT $_4$ receptor antagonist SB-207266-A slowed orocecal transit and tended to decrease rectal sensitivity. [294] These effects were associated with symptomatic improvement.

Other Medication Treatments Prokinetic medications, which stimulate gastrointestinal motility, have been proposed for constipation-predominant IBS. In placebo-controlled trials, the 5-HT $_4$ receptor agonist cisapride produced modestly increased stool frequency, improved stool consistency, reduced straining, and acceleration of whole gut transit. [295], [296] This drug was withdrawn from the general market in 2000 because of the risk of cardiac dysrhythmias and is currently available only to restricted patient populations. Recent pharmaceutical research has focused on novel 5-HT $_4$ receptor agonists which exhibit prokinetic activity by stimulating peristalsis (Fig. 86-7). In patients with IBS with constipation, tegaserod accelerated small intestinal and ascending colon transit. [297] In animal studies, tegaserod stimulates peristalsis, accelerates transit, and blunts afferent responses to distention. [298] Clinical trials have reported reductions in discomfort and improvements in constipation and bloating compared to placebo. [298], [299] A second investigational 5-HT $_4$ receptor agonist, prucalopride, was shown to accelerate gastric, small intestinal, and colonic transit and improve bowel function in patients with idiopathic slow transit constipation. [300] Studies are ongoing to assess the side-effect profiles of these agents. The peripheral dopamine receptor antagonist domperidone enhances gastric emptying and small intestinal transit but has little prokinetic activity in the colon and may blunt the postprandial gastrocolonic response. [301] One placebo-controlled trial reported improvements in flatulence, abdominal pain, and bowel dysfunction on domperidone while two other studies observed no benefits. [302]

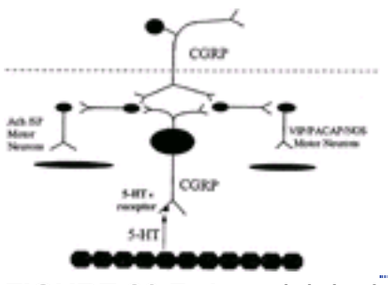

FIGURE 86-7. A model depicting the role of serotonin (5-HT) pathways in the mediation of peristalsis is shown. An extrinsic pathway activated by muscle stretch consists of calcitonin gene-related peptide (CGRP) neurons projecting to the spinal cord while an intrinsic pathway activated by mucosal stimulation consists of CGRP neurons within the enteric nervous system. Serotonin is released by mucosal enterochromaffin cells and acts on 5-HT $_4$ receptors in humans. The orad contractile arm of peristalsis is mediated by acetylcholine (*Ach*) and substance P (*SP*), whereas caudad relaxations are mediated by vasoactive intestinal polypeptide (*VIP*), pituitary adenylate cyclase activating peptide (*PACAP*), and nitric oxide synthase (*NOS*). (From Grider JR, Foxx-Orenstein AE, Jin JG. 5-Hydroxytryptamine $_4$ receptor agonists initiate the peristaltic reflex in human, rat, and guinea pig intestine. Gastroenterology. 1998;115:370.)

Because symptoms are often associated with menstrual cycling, investigators have searched for hormonal treatments for IBS. Continuous gonadotropin-releasing hormone (GnRH) administration reduces synthesis of the gonadotropins, follicle-stimulating hormone, and luteinizing hormone, with inhibition of cyclic gonadal hormone variations. Small trials of the GnRH analog leuprolide in patients with functional gastrointestinal symptoms reported improvements in nausea, abdominal pain, early satiety, bloating, and altered bowel habits for up to one year. [303], [304] A large multicenter trial of leuprolide reported improvements in abdominal pain, nausea, altered bowel habits, and quality of life in functional bowel disease patients. [305] The mechanisms of action of leuprolide are uncertain. In an immunosuppressed patient with intestinal pseudoobstruction, leuprolide evoked intense, propagative upper gut motor activity. [306] It is unlikely that this action is responsible for the clinical benefits of the drug in IBS as most patients with IBS do not exhibit pronounced dysmotility. As it induces amenorrhea and osteoporosis, leuprolide is unlikely to achieve widespread long-term use in IBS. Several agents have been promoted to reduce gas and bloating. Anticholinergics blunt the gastrocolonic response to a meal and reduce the increase in flatus caused by ingestion of beans. [226] Uncontrolled studies using silicone agents such as simethicone show reduction in excess bloating and flatus. [307] Activated charcoal has a large surface area to mass ratio (450–1800 m ^{2}/g) which allows it to be an excellent adsorbent of gas. [308] Small doses of activated charcoal decrease the number of flatus passages after ingestion of beans in healthy volunteers. The microbial a-galactosidase agent Beano reduces hydrogen production after black bean ingestion by healthy volunteers. In a controlled trial in healthy volunteers, pancreatic enzymes reduced bloating, gas, and fullness after eating high-fat, high-calorie meals compared to placebo. [309] No trials of Beano or pancreatic enzymes have been reported in IBS. In one study, the nonabsorbable antibiotic rifamaxin reduced hydrogen production, flatus emissions, and abdominal distention to greater degrees than activated charcoal in healthy volunteers and patients with functional bowel disease. [310] Mast cell degranulation inhibitors have been proposed as treatments for diarrhea-predominant patients by investigators who postulate a role for food allergy in IBS. One study evaluated 101 diarrhea-predominant patients with IBS with evidence of food hypersensitivity on the basis of exclusion diets. [311] Of those with positive skin prick tests for food allergy, 67% reported improved symptoms on sodium cromoglycate while only 41% with negative skin tests experienced relief. In a second uncontrolled report, sodium cromoglycate produced improvement in 67% of diarrhea-predominant patients with IBS when given for 1 month, especially in those with food allergy. [312] The response to sodium cromoglycate may be more impressive in pediatric populations with IBS symptoms where true food intolerance may be more prevalent. A multicenter trial reported that 97% of children (mean age 4 years) exhibited a clinical response to the drug over a one-month period. [313] These results, however, require confirmation in placebo-controlled fashion. Tranquilizers have been used for decades to treat IBS. Older studies reported benefits for phenaglycodol, meprobamate, heteronium plus amobarbital, propantheline plus phenobarbital, chlordiazepoxide, diazepam, medazepam, and alprazolam; however, many of these studies were small or poorly designed. [314], [315] and [316] Buspirone increases colonic compliance, however, its efficacy in reducing symptoms has not been convincingly demonstrated in IBS. [317] Coupled with their abuse potential and development of tolerance, the use of sedatives is not indicated in most patients with IBS.

Potential Future Therapies Investigations have been focusing on medications that blunt visceral hyperalgesia in IBS. Such “anti-afferent” agents might act though one or more mechanisms including (a) modification of release of pain-inducing mediators in the gut wall, (b) blockade or activation of peripheral afferent nerve receptors, (c) inhibition of afferent nerve transmission, or (d) modification of afferent activity in the central nervous system. [105] Some currently available drugs including calcium channel antagonists and opiate agents reduce visceral perception in association with reducing gut motor function or altering central nervous system processing of pain. [318] Kappa-opioid compounds inhibit somatic pain via action on peripheral sensory nerve endings. [319] In patients with IBS, the ?-opioid analog fedotozine increases the thresholds to colonic distention for first perception and pain without affecting compliance. [320] It also modifies neural reflexes in experimental gut inflammation, chemically induced peritonitis, and postoperative ileus. [321] In a double-blind, placebo-controlled, multicenter trial in 238 patients with IBS, fedotozine reduced pain and overall disease severity over a 6-week period. [322] Alpha $_2$-adrenoceptor agonists also have been proposed to reduce perception of visceral pain. In healthy volunteers, the a $_2$-adrenoceptor agonist clonidine increased colonic and rectal compliance and decreased tone, urgency, and pain during balloon distention. [323] This suggests possible use for this class of drugs in pain-predominant IBS. Conversely, the a $_2$-adrenoceptor antagonist yohimbine increased tone and perception of colorectal distention. Another a $_2$-agonist lidamidine reduced perception of rectal distention compared to placebo in 50 patients with IBS. [324] This drug has been reported to have benefit in treating patients with IBS. [325] Substance P has been postulated to participate in the mediation of visceral pain via activation of neurokinin receptors. In animal models, neurokinin-1 (NK $_1$) receptor antagonists have decreased stress-induced defecation as well as reduced the colonic response to the central nervous system stress mediator CRH. [326] Preliminary studies of the NK $_1$ receptor antagonist CJ-11,974 have reported benefits in reducing symptoms in patients with IBS with trends to reductions in visceral sensitivity. [327] Physiological studies suggest that other agents may have visceral analgesic effects. The somatostatin analog octreotide reduces perception of rectal distention via inhibition of visceral afferent pathways in healthy volunteers. [328] Patients with IBS with fecal urgency were shown to exhibit a similar response to octreotide. [329] Additionally, octreotide reduced the increased pressures that resulted from rectal distention in these patients. In a second study, octreotide blunted perception of rectal distention without altering luminal compliance in an IBS population with more constipation-predominant patients. [330] Subsequent work using cortical and spinal evoked potentials showed that octreotide specifically inhibits spinal afferent transmission from the rectum, documenting a peripheral site of action for the somatostatin analog. [331] Finally, intravenous oxytocin increases the thresholds for perception of colonic distention via opiate-independent pathways without affecting luminal compliance. [332] To date, no placebo-controlled trials of the clinical efficacy of these agents have been performed, thus their use in IBS is unproved.

Psychological Therapy

Psychological therapy has been most commonly employed for patients with IBS with psychosocial features that do not respond to standard therapies. A systematic

review of controlled psychological treatments in the literature from 1966 to 1994 uncovered only 14 studies that exhibited appropriate study design. [333] Eight studies reported that psychological treatment was superior to control treatment while six observed no benefits. Because of methodological inadequacies, it was believed that the efficacy of psychological therapy of IBS was not established and that further trials were needed. Nonetheless, many investigators have proposed a range of treatments for IBS including psychotherapy, cognitive therapy, biofeedback, and hypnosis.

Psychotherapy has shown promise in patients who do not respond to medications. In 101 patients with IBS, 3 months of dynamically oriented psychotherapy plus medications provided greater improvements in somatic symptoms than medical treatment alone. [334] A second psychotherapy study of medically refractory patients reported reductions in abdominal pain and diarrhea, but not constipation, as well as improvement in depression. [335] A long-term follow-up of patients undergoing psychotherapy showed maintenance of symptom control at one year, while individuals who declined psychotherapy had relapsed. Group psychotherapy, including techniques such as psychodrama, in which the patient involves other group members in his or her bowel symptoms, does not reduce abdominal pain or improve bowel habits although anxiety levels may decrease. [336]

Cognitive therapy produces improvements in bowel symptoms in some patients with IBS. When compared with daily symptom monitoring, cognitive therapy produced clinical improvement in 80% of patients versus 10% of the symptom-monitoring group. [337] Similarly, patients with IBS undergoing cognitive therapy experienced greater reductions in bowel symptoms than did patients assigned to a self-help support group or to a symptom-monitoring wait list. [338] The benefits of cognitive therapy have been reported to persist in long-term follow-up after completion of the treatment. [339] A recent trial compared therapeutic responses on standard medical therapy to standard medical therapy plus a multicomponent program consisting of IBS education, muscle relaxation, cognitive coping strategies, and assertiveness training. [340] The combination therapy group reported superior reductions in symptoms and improved quality of life, although perception of rectal distention was unaffected by either therapy. Another study suggested that listening to a therapeutic audiotape on IBS provided results nearly as good as those achieved with hypnotherapy. [341]

Biofeedback and stress reduction techniques have been employed by some clinicians. Muscle relaxation training and stress-reduction education reduced bowel symptoms in an uncontrolled study, especially in patients who exhibited improved depression and anxiety. [342] When followed up at 4 years, 50% reported sustained improvements in pain, diarrhea, nausea, and flatulence. Similarly in another study, the frequency and severity of painful IBS attacks were decreased compared to antispasmodic drugs. [343] Additionally, relaxation treatment was shown to reduce primary gastrointestinal symptoms to a greater degree than symptom monitoring. [344] However, other studies have shown no improvement in bowel symptoms. A 3-month relaxation-response meditation program produced significant improvements in flatulence, belching, bloating, and diarrhea. [345] In a novel study, patients were trained to reduce symptoms by listening to their bowel sound pattern through a stethoscope and attempting to modify their borborygmus. [346] This bowel sound biofeedback led to improved symptomatology in three of five patients enrolled, with long-term success in two of the five. In uncontrolled studies computerized biofeedback video games have been found to reduce stress and improve relaxation in significant fractions of patients with IBS. [347]

Hypnosis has been proposed for refractory cases of IBS. In a study of 30 patients with IBS, hypnosis provided better improvements in abdominal pain, distention, and well being but not bowel pattern after 3 months of treatment compared to psychotherapy. [348] When followed for 18 months after being instructed in autohypnosis, sustained remission was reported by most individuals although patients over the age of 50 or with underlying psychopathology were less likely to respond. Subsequently the authors reported a success rate of 85% in more than 200 patients with IBS treated with hypnosis. Another controlled trial of hypnosis also reported improvements in abdominal pain, constipation, and flatulence. [349] No correlation was observed between initial susceptibility to hypnosis and treatment gain. In addition to improving symptoms of pain, bloating, bowel habit, nausea, and flatulence, a hypnosis trial reported beneficial effects on quality of life measures including physical and psychic well being, mood, and work attitude. [350] Furthermore, patients treated with hypnosis missed less work and visited their physicians less frequently than control patients. An anorectal manometric study of 15 patients with IBS demonstrated reduced perception of rectal distention with hypnosis suggesting that hypnosis may inhibit afferent pathways mediating perception of visceral discomfort. [160]

Alternative Medicine

Because of the lack of universally effective, well-tolerated prescription therapies for IBS, many individuals turn to alternative medicine for symptom relief. Recent investigations have begun to explore the use of such measures in scientifically rigorous fashion. An open trial in a small number of diarrhea-predominant patients with IBS reported therapeutic benefits from arrowroot. [351] Similarly, artichoke leaf extract reduced symptom severity in an open study of patients with IBS. [352] In a placebo-controlled, double-blind trial in 24 patients with IBS with predominant bloating, *Lactobacillus* had no significant effect. [353] Conversely in a study in which freeze dried cultures of *Streptococcus faecalis* were administered in placebo-controlled fashion, 81% of patients with IBS noted an improved sense of well being versus 41% with placebo. [212] In another placebo-controlled study, administration of *Lactobacillus plantarum* produced superior reductions in flatulence in 60 patients with IBS. [354] In a large placebo-controlled, double-blind, multi-armed trial of a number of herbal remedies, abdominal pain, stool pattern disturbances, and quality of life were not better with *Fumaria officinalis Curcuma xanthorrhiza* Ayurvedic, or spagyric remedies. [355] In contrast, a randomized, controlled 16-week trial of traditional Chinese herbal medicine reported benefits in bowel symptoms as well as global well being as rated both by the patients and their gastroenterologists. [356] A small uncontrolled study demonstrated improvements in bloating and overall well being after acupuncture. [357] Although inconclusive, these studies suggest there is a role for further investigation into the usefulness of alternative approaches to treating IBS.

APPROACH TO DIFFERENT SUBSETS OF PATIENTS WITH IBS

The management of the patient with IBS is dependent on the predominant symptom. In the technical review for practice guideline development published by the American Gastroenterological Association, specific therapeutic trials of 3 to 6 weeks' duration were proposed for each symptom subtype prior to embarking on a more extensive diagnostic evaluation (Fig. 86-8). [218]

FIGURE 86-8. Recommendations of a technical review for practice guideline development for the initial management of irritable bowel syndrome are shown based on the dominant symptom subtype. (From Hahn B, Watson M, Yan S, et al. Irritable bowel syndrome symptom patterns; frequency, duration and severity. Dig Dis Sci 1998;43:2715.)

Constipation-Predominant Patient

The management of the constipation-predominant patient with IBS involves measures to increase stool water and bulk and reduce the effort of defecation. The most widely used and efficacious compounds for this purpose are bulking agents in concert with a high-fiber diet. Patients should be cautioned that fiber supplements may take several weeks to produce satisfactory results and should be introduced gradually to prevent excess gas. Additionally, any medications that slow colonic transit should be discontinued. Patients with an inadequate response should be given an osmotic agent such as milk of magnesia or an isotonic solution containing polyethylene glycol in addition to the fiber program.

In patients with refractory constipation, further diagnostic testing may be needed to rule out other functional or structural diseases. Using radiopaque markers or colonic scintigraphy, generalized delays in colonic transit indicate the presence of slow transit constipation (also known as colonic inertia) while localized delays suggest functional outlet obstruction in the distal colon. Defecography (cinefluoroscopy of the defecation process) can identify puborectalis muscle dysfunction, rectocele, or rectal prolapse as independent causes of constipation. In IBS, defecography studies have shown an inability to widen the rectoanal angle as well as impaired perineal descent during simulated defecation indicative of diffuse alterations in pelvic floor mobility. [358] Anorectal manometry, in addition to demonstrating sensory abnormalities, can screen for Hirschsprung's disease. These techniques are useful for detecting patients who might be better treated surgically or with a

biofeedback program of bowel retraining. Laboratory studies can screen for porphyria or lead toxicity.

Diarrhea-Predominant Patient

Controlling diarrhea in IBS centers on reducing defecation frequency and urgency and improving stool consistency. Opiate agents such as loperamide are most effective as initial therapy of diarrhea in IBS. Individuals with prominent meal-related symptoms may achieve benefit from antispasmodic agents in the anticholinergic and calcium channel antagonist classes. Tricyclic antidepressants and bile acid binding agents may also be useful in some diarrhea-prone patients. A careful dietary history should screen for foods containing lactose, sorbitol, or fructose. Other dietary manipulations usually are without benefit and are not encouraged in most patients. Use of sodium cromoglycate for food hypersensitivity is unsubstantiated in most diarrhea-prone patients.

Patients not responsive to these therapies may be considered for additional testing. Duodenal aspiration is rarely required to exclude giardiasis. Endomysial antibodies can screen for celiac sprue. Small intestinal biopsy and barium radiography may be performed to rule out Crohn's disease or celiac sprue. Stool volume and fat quantitation can assist in the diagnosis of secretory processes or malabsorption. Laxative screens are indicated for the evaluation of refractory or atypical symptoms.

Painful IBS

Controlling abdominal pain in IBS can be challenging. Narcotics should be avoided because of the risks of tolerance and dependence. Antispasmodic drugs are the preferred initial agents for pain-predominant IBS. Antidepressant medications may benefit an additional subset of patients with more severe symptoms. The GnRH analog leuprolide can be considered for rare patients with refractory symptoms, especially those prominently associated with menstrual cycling.

Further evaluation to investigate the cause of pain in medication-refractory cases should be directed at objective historical and examination findings. Upper endoscopy may detect acid-peptic injury in cases of severe dyspepsia or heartburn. Liver and pancreatic chemistries and imaging tests, such as abdominal ultrasonography or computed tomography, are obtained if hepatobiliary or pancreatic disease is suspected. Small intestinal barium radiography can detect atypical presentations of Crohn's disease, while gastric scintigraphy or gastrointestinal manometry may be obtained in the patient with associated nausea and vomiting. Exclusion of intestinal bacterial overgrowth may be obtained with hydrogen breath testing. Rare patients will need laboratory testing to exclude lead toxicity or porphyria.

PATIENT OUTCOME

Most long-term studies of IBS report that symptoms persist for more than 5 years in greater than 75% of patients despite appropriate therapy. Only 34 of 103 patients were symptom-free on long-term follow-up in an older study. [359] A second investigation followed 50 patients with IBS at 2-month intervals for 12 to 31 months. [360] In 44 patients, the qualitative nature of the symptoms did not change with long-term follow-up although symptom severity was variable. A follow-up of 4581 individuals with IBS reported that only 5% were symptom-free after 5 years. [361] This lack of significant improvement in patients with IBS may not hold true for all populations with IBS symptoms. In a study of elderly Danes, 50% to 79% of subjects suffering from IBS on initial inquiry no longer experienced symptoms on 5-year follow-up. [362]

Even though symptoms persist in many patients with IBS, their quality of life can be enhanced by appropriate physician intervention. In one study, 18 of 44 patients noted reduced symptom intensity after 12 to 31 months of continued medical follow-up. [360] Of 34 fully employed patients, 20 lost no work in the first year after diagnosis. Only 7 patients lost more than 2 weeks because of their symptoms, as a consequence of improved coping skills. A second investigation of 43 patients with IBS reported that abdominal pain and the overall sense of well being were reduced after 5 years of follow-up while other symptoms were unchanged. [363] Those who improved exhibited reduced anxiety compared to those who did not. Symptom resolution was observed in 20% of 97 patients with IBS who were studied for 5 to 7 years on a treatment program of antispasmodic drugs, bulking agents, and high-fiber diets and significant symptom reduction was reported in an additional 42% of individuals. [359] Patients who were male, had a short history of symptoms, had a history of recent acute onset of symptoms, exhibited predominant constipation, and noted a good initial response to treatment were most likely to achieve good long-term improvement. Other studies have found that reductions in anxiety and fear of cancer correlate with improvement over a 6-month period. [364] In the longest follow-up reported to date (median 29 years), fewer return visits to physicians were reported for patients who had undergone inquiry about psychosocial issues and precipitating factors and who had been given detailed discussions about their diagnosis and treatment (Fig. 86-9). [220] These studies suggest that counseling, reassurance, and education provided by the physician, judicious use of medications, and continued interest in a patient's well being may promote successful outcomes in many patients with IBS.

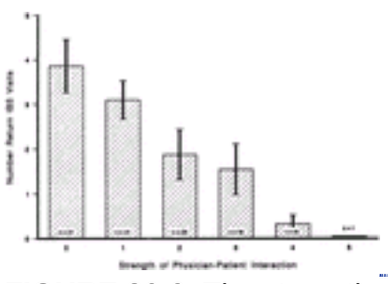

FIGURE 86-9. The strength of the physician-patient interaction is correlated with the number of return visits noted for patients with irritable bowel syndrome (IBS) in follow-up. In general, those patients who experienced a better interaction with their physicians required fewer return visits for care of IBS. Those physicians who documented that they took careful histories and provided reassurance and discussion about IBS did not need to see these patients as frequently in follow-up. CHAPTER 87

Tonia M. Young-Fadok and Michael G. Sarr

DIVERTICULAR DISEASE OF THE COLON

A diverticulum (plural: diverticul *a*) is a saclike protrusion of the colonic wall. The spectrum of diverticular disease encompasses diverticulosis, diverticulitis, and diverticular bleeding. *Diverticulosis* is merely the presence of diverticula. *Diverticulitis* refers to symptomatic inflammation of a diverticulum. “Complicated” diverticulitis refers to a diverticular abscess, fistula, small bowel or colonic obstruction, or free intraperitoneal perforation; “simple” diverticulitis is the absence of these complications.

This chapter initially discusses the common epidemiology, etiopathogenesis, pathophysiology, and natural history of diverticular diseases of the colon. A detailed discussion of the clinical presentation, diagnosis, and treatment follows, concentrating on the specific diverticular diseases and addressing special situations dictating a more individualized approach. Attempts have been made to concentrate on recent literature and technology whenever appropriate and to identify and discuss controversies.

EPIDEMIOLOGY

The epidemiology of diverticular disease of the colon has changed markedly during the twentieth century. Diverticular disease was rarely encountered at the beginning of the 20th century. Indeed, the first reported surgical resection for complicated diverticulitis was performed by W. J. Mayo and colleagues in 1907. [1] The apparent prevalence of diverticulosis has increased from 5% to 10% in 1918 [2] to 35% to 50% in an autopsy series from 1969; [3] there are no good recent, population-based studies. Prevalence of colonic diverticula is well known to increase with age from about 5% at 40 years of age, to 30% at age 60, and to 65% by age 85. [4], [5]

The predominance of males reported in the early series has changed more recently to either equal distribution or to a slight female preponderance. [4] The gender distribution appears also to vary with age. In one series, 60% of symptomatic patients were women, [6] but, in patients under 50 years, men predominated with a male-to-female ratio of 2.2:1. In several other reports, male preponderance has also been noted in patients less than 40 years of age. [7], [8]

Geographic variations also exist both in the prevalence and anatomic pattern of diverticulosis. Westernized countries have prevalence rates of 5% to 45%, depending on the method of diagnosis and age of the population. [3], [9] Diverticular disease in these countries is predominantly left-sided, with right-sided diverticulitis present in only about 2% of symptomatic patients. [10] This distribution differs markedly in Africa and Asia, [2], [11] where the prevalence of diverticulosis is less than 0.2%, and diverticulitis is usually right-sided. With Japan and Singapore adopting a Western lifestyle, these cultures have experienced an increase in the prevalence of diverticulosis. [12], [13] A review of 13,947 barium enema examinations performed over a 15-year period in Tokyo revealed a steady increase in the incidence of diverticulosis of the right colon. [14] Somewhat surprisingly it remains right-sided; [3] moreover, 70% of symptomatic patients are less than 40 years old. [13] In Hong Kong, diverticulosis involves the right colon in 76% of patients, [15] and right-sided diverticulitis accounts for 17% of patients with acute diverticulitis, [16] a much greater percentage than in Western cultures.

ETIOPATHOGENESIS

Painter and Burkitt [5], [17] first speculated that low dietary fiber was a major factor predisposing to development of diverticulosis. They recognized that where those who were native to Africa had a diet high in dietary fiber and produced a large volume of daily stool output, diverticulitis was distinctly unusual. This concept, however, remains controversial. [11], [18], [19] One study of a cohort of 47,000 men provided strong evidence for a primary role of lack of fiber in the etiopathogenesis of left-sided diverticulosis; [20] a diet low in fiber content increased the risk of symptomatic diverticular disease. Diverticular disease is also less common in vegetarians than nonvegetarians. [21] Of related interest, a low-fiber diet may be a common etiologic factor in the development of both diverticulosis and colon cancer. In one report of 7000 patients, an excess number of colon and rectal cancers was noted in the first 2 years after diagnosis of diverticular disease, [22] an incidence not explained solely by investigations performed for the evaluation of diverticular disease.

Other dietary factors have been examined. There is no substantially increased risk associated with smoking or with caffeine or alcohol intake. [23] The recognized association of acute diverticulitis with obesity in men under 40 years of age agrees with observations that a high intake of total fat or red meat plus a diet low in fiber particularly augments the risk of symptomatic diverticular disease. [20] Whether fat and red meat are independent risk factors or merely markers of a lower fiber diet remains speculative.

PATHOPHYSIOLOGY

Pathology

The typical colonic diverticulum is a false or pulsion diverticulum; that is, it does not contain all layers of the wall as in a true (congenital) diverticulum. Mucosa and submucosa herniate through the muscle layer of the colon, separated from the intraperitoneal space only by the serosa. Diverticula develop at the four constant points of the colonic circumference where the vasa recta penetrate the circular muscle layer. [24] These vessels enter the wall of the colon on each side of the mesenteric tenia and on the mesenteric border of the two antimesenteric teniae (Fig. 87-1). Of special note, diverticula do not develop in the rectum, presumably related both to the coalescence of teniae into a continuous longitudinal muscle layer and the absence of associated potentially weakened areas in the rectum.

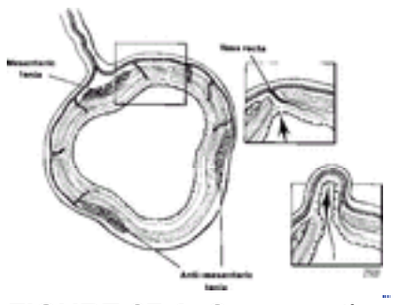

FIGURE 87-1. Cross-section of the sigmoid colon. The main illustration indicates the points of penetration of the vasa recta around the bowel circumference. **Inset:** The development of a diverticulum at one such point of weakness. (From Young-Fadok TM, Pemberton JH. Colonic diverticular disease: epidemiology and pathophysiology. In: Rose BD, ed. UpToDate in medicine [CD-ROM]. Wellesley, MA: UpToDate, 1997.)

Diverticula are distributed unevenly throughout the colon. In Western cultures, 95% of patients with diverticula have sigmoid diverticula. Diverticula are limited to the sigmoid colon in 65% of patients, whereas, in 24%, diverticula involve predominantly the sigmoid but with other segments of the colon involved to a lesser degree; in 7% of patients the distribution is equally divided throughout the colon, while in only 4% diverticula are limited to a segment proximal to the sigmoid. [25] Similarly, 95% of all operations for diverticular disease are directed at the sigmoid colon. [6]

Pathophysiology of Diverticular Disease

Diverticulosis The points at which diverticula develop, that is, where the vasa recta penetrate the colon wall, [26] are considered to be areas of potential weakness within the wall of the colon. Most patients with sigmoid diverticula exhibit grossly evident myochosis, that is, thickening of the circular muscle layer, shortening of the teniae, and lumenal narrowing. While there is no apparent hypertrophy or hyperplasia of the muscular layer of the colonic wall, there is increased deposition of elastin in the teniae. [27] Structural changes in collagen content of the wall of the sigmoid colon are similar to those resulting from aging but are greater in magnitude [28] and may decrease resistance of susceptible segments of the wall to abnormal increases in intralumenal pressure. Similar changes in patients with connective tissue disorders, such as the Ehlers-Danlos and Marfan syndromes, may explain the appearance of diverticula at an early age. Application of the principles of the law of LaPlace may explain, in part, the development of colonic diverticula. The law states that pressure (*P*) is proportional to wall tension (*T*) and inversely proportional to the radius (*R*) of the colon—that is, $P = k\ T/R$ (where k is a conversion factor). Normally intralumenal pressure is the same throughout the colon. However, segmentation of the colon (a motility process in which proximal and distal segmental muscular contractions separate the lumen into isolated chambers) is believed to be exaggerated in diverticulosis. Strong occlusive contractions at both ends of the chamber lead to marked segmental increases in intralumenal pressures (Fig. 87-2), [29] which may predispose to herniation of mucosal diverticula at the sites where the blood vessels penetrate the muscular layers of the colon. As the sigmoid colon is the segment of the colon with the smallest diameter, elevation of intralumenal pressure will result in even greater increases in wall tension compared to larger segments of the colon. Whether the thickened teniae of the sigmoid colon are a result of the environmental milieu such as a lower fiber diet and less bulky stools (and a resultant less wide colonic diameter), a response to increased intralumenal pressure, a primary genetic variation in muscle structure and function, or an acquired abnormality from some other as yet undefined cause remains unknown.

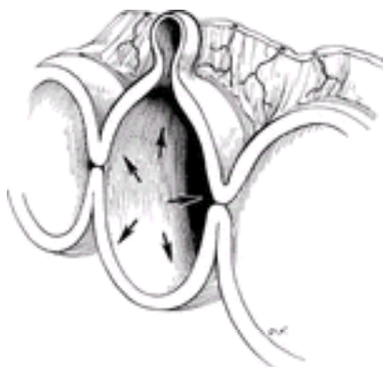

FIGURE 87-2. Painter and Burkitt's concept of segmentation causing formation of pulsion diverticula. (From Pemberton JH, Armstrong DN, Dietzen CD. Diverticulitis. In: Yamada T, ed. Textbook of gastroenterology, 2nd ed. Philadelphia: JB Lippincott, 1995:1870.)

Diverticulitis Inflammation of the wall of the diverticulum and the surrounding peridiverticular tissue has a range of clinical manifestations from subclinical inflammation to generalized peritonitis. The underlying cause of the inflammation must involve a micro- or macroscopic perforation of this thin-walled diverticulum. It was previously believed that obstruction of the ostia of the diverticula, for example, by fecaliths or lumenal material, led to increased intradiverticular pressure and subsequent perforation; this hypothesis is now thought to be rare. [11] Increased intralumenal pressure in the involved segment of the colon secondary to abnormal motor activity and/or local trauma of inspissated food particles may erode the wall of the diverticulum. Inflammation and focal necrosis result in perforation. Frequently, a small perforation becomes walled off and contained by pericolic fat and mesentery, with a localized abscess resulting, or with resolution without further consequence. In contrast, with a more extensive inflammatory reaction, surrounding hollow organs adhere to the inflamed segment of colon and intestinal obstruction or an internal fistula may develop. Poor containment, as may occur in antimesenteric diverticula, results in free intraperitoneal perforation and peritonitis. In summary, diverticula occur at weakened points in the intra-abdominal, teniae-bearing colon where intramural vessels penetrate the muscular layer. Development of diverticula appears to be multifactorial. Localized increases in intralumenal pressure may be caused by abnormal motor patterns that predispose to exaggerated segmentation and are likely exacerbated by a low-fiber diet. Morphologic changes in the muscle and collagen content of the bowel wall lead to decreased tensile strength of the wall; these changes are similar to, but more pronounced than those that occur with age. Local trauma to the wall of the diverticulum may produce inflammation, resulting in either localized perforation with peridiverticulitis or free intraperitoneal perforation with generalized peritonitis. Similarly, local trauma to the vasa recta within the diverticula can predispose to hemorrhage.

NATURAL HISTORY

Understanding the natural history of diverticular disease is critical in determining which patients will develop complications if left untreated (and who are therefore appropriate candidates for operative intervention) and those who are best served by a more conservative approach.

Diverticulosis

Of patients with significant diverticulosis, 70% remain asymptomatic and never develop complications related to their diverticulosis. With long-term follow-up, however, as many as 15% to 25% of patients with diverticulosis will develop acute diverticulitis, and 5% to 15% will exhibit diverticular bleeding (Fig. 87-3). As the majority of patients remain asymptomatic, the mere presence of multiple diverticula does not indicate the need for intervention other than possibly recommending a high-fiber diet in an attempt to decrease the incidence of complications.

FIGURE 87-3. The natural history of diverticulosis. (From Young-Fadok TM, Pemberton JH. Colonic diverticular disease: natural history, clinical features and diagnosis. In: Rose BD, ed. UpToDate in medicine [CD-ROM]. Wellesley, MA: UpToDate, 1997.)

Diverticulitis

Diverticulitis may present with manifestations ranging from mild abdominal discomfort to perforated diverticulitis with fecal peritonitis, sepsis, and even death. Diverticulitis can be divided into simple and complicated presentations (Fig. 87-4). Complicated diverticulitis describes localized or free intraperitoneal perforation, obstruction, abscess, or fistula, which arise in 25% of patients with their first episode of acute diverticulitis; nearly all of these patients will eventually require operative treatment. Simple diverticulitis accounts for 75% of episodes and refers to the absence of complications; the majority of these patients respond rapidly to medical therapy.

FIGURE 87-4. The natural history of diverticulitis. (From Young-Fadok TM, Pemberton JH. Colonic diverticular disease: natural history, clinical features and diagnosis. In: Rose BD, ed. UpToDate in medicine [CD-ROM]. Wellesley, MA: UpToDate, 1997.)

Simple Diverticulitis Most patients with simple diverticulitis are initially treated conservatively (see Fig. 87-4); 85% respond rapidly, but 15% will require operative intervention. [30] Long-term follow-up of patients after their first episode of acute diverticulitis suggests a readmission rate of 2% per patient year; [30] thus, elective colectomy is not necessary for all patients who respond to medical therapy. Indeed, after successful conservative therapy of the first attack of diverticulitis, 30% to 40% of patients remain asymptomatic, 30% to 40% have episodic abdominal cramps without frank diverticulitis, and about one third proceed to a second attack of acute diverticulitis. [4] Older data suggest that the prognosis is worse with a second attack because the rate of complicated diverticulitis approached 60% and the mortality rate doubled. [4], [31] Only 10% of these patients remained asymptomatic after nonoperative resolution of a second attack of acute diverticulitis. These older studies form the basis for the current recommendation that operation should be recommended after two confirmed attacks of diverticulitis, with one episode of sufficient severity to merit hospitalization. In 2001 Chautems and colleagues [32] reported on 110 patients treated conservatively for a first episode of diverticulitis. Of 83 in whom complete follow-up was achieved, 15 patients (18%) recurred once and only 6 (7%) recurred twice or more. Nine of these patients required inpatient therapy. Two patients underwent operation, and no emergency procedure was required. The authors concluded that recurrent diverticulitis may be treated in a similar fashion to a first episode and that medical therapy remains a valuable alternative to surgery. This study was useful in having a long median follow-up of 10.5 years, but the conclusions were hampered by a high death rate of 34% from unrelated causes during follow-up.

Complicated Diverticulitis Most patients with complicated diverticulitis require operative intervention (see Fig. 87-4). With the first attack of acute diverticulitis, 15% to 29% of patients [30], [33] require operative treatment, most of whom have complicated diverticulitis. The mortality rate is 1% to 5%. [30] Indications for emergency or early operative intervention are generalized peritonitis, nonresolving intestinal obstruction, abscess not amenable to radiologically guided percutaneous drainage, clinical deterioration, or failure to improve with appropriate conservative management (Table 87-1). Indications for elective operative intervention are recurrent or intractable symptoms, persistent mass, inability to exclude carcinoma, functional colonic obstruction, presence of a fistula, and previous percutaneous drainage of an abscess. Several unique situations are discussed below.

ABSOLUTE	RELATIVE
Complications of diverticulitis	
Peritonitis	**Symptomatic stricture**
Abscess (failed percutaneous drainage)	**Immunosuppression**
Fistula	**Right-sided diverticulitis**
Obstruction	**? Young patient**
Clinical deterioration/failure to improve	
Recurrent episodes	
Intractable symptoms	
Inability to exclude carcinoma	

TABLE 87-1 Indications for Operative Treatment of Acute Diverticulitis

Those who are treated operatively are generally believed cured, even though the standard extent of resection may leave diverticula in the remaining proximal colon. Diverticulosis progresses in the remaining colon in about 15% of patients, [34] and future operative treatment is required in as many as 2% to 11%. [34], [35] and [36] Up to 27% of patients after a sigmoid colectomy may describe abdominal pain postoperatively in the same location; these persistent symptoms, however, may be secondary to coexistent irritable bowel syndrome rather than to recurrent diverticulitis.

CLINICAL PRESENTATION AND MANAGEMENT OF DIVERTICULAR DISEASES

Diverticulosis

Diverticulosis in the majority of patients is asymptomatic. Some patients with uncomplicated diverticulosis have symptoms of cramping, bloating, flatulence, and irregular defecation; it is unclear if these symptoms are related directly to the underlying diverticulosis or to the coexistence of irritable bowel disease. Because older patients with this symptom complex are investigated with a contrast enema and the prevalence of diverticulosis in the elderly is so common, this ostensible association of symptoms and diverticulosis has often been made, but a true causal relationship is unproven.

Diverticulitis

Presenting Symptoms Constant, noncolicky, left lower quadrant pain is the most common complaint occurring in 70% of patients. The pain has often been present for several days prior to presentation, assisting differentiation from other causes of an acute abdomen; only 17% of patients have symptoms of less than 24 hours. [6] When carefully questioned, almost half the patients describe previous episodes of similar, though less intense, pain. Nausea and vomiting occur in 20% to 60%, diarrhea coexists in one fourth to one third of patients, [37] and recent obstipation has been present in half. Urinary symptoms, such as dysuria, urgency, and frequency, coexist in 10% to 15%.

Presenting Signs Physical examination reveals abdominal tenderness, usually in the left lower quadrant. A tender mass is palpable in 20%. [4] Right lower quadrant tenderness may result from a redundant, inflamed sigmoid colon lying to the right of the midline or, less frequently, from right colonic diverticulitis. Generalized peritoneal signs suggest free perforation and peritonitis. Abdominal distention occurs in two thirds of patients. Low-grade fever and mild leukocytosis are common but not always present; 14% of patients have no fever, and 45% have a normal white count. [38] Urinalysis may reveal a sterile pyuria apparently secondary to adjacent inflammation; mixed colonic flora, fecaluria, or pneumaturia strongly suggest a colovesical fistula. Similarly, fecal discharge from the vagina is pathognomonic of a colovaginal fistula.

Diagnosis The diagnosis of diverticulitis should be suspected and made primarily on the basis of the history and physical examination. In the acute stage, when complicated diverticulitis is suspected, imaging studies can confirm the diagnosis and exclude other sources of acute abdominal signs; in contrast, elective evaluation

after resolution of an acute episode of diverticulitis should evaluate and visualize the whole colon.

Diagnosis in the acute setting. Abdominal radiographs are useful and appropriate in excluding other causes of acute abdominal pain, rather than in making the diagnosis of diverticulitis. In addition, the presence of free air on the abdominal radiograph signifies an abdominal emergency and obligates further evaluation. The diagnosis of acute diverticulitis can frequently be made on the basis of the history and physical examination alone. Published guidelines have recommended that when the clinical picture is clear additional tests are not necessary to make a diagnosis. [39], [40] and [41] This may, however, occasionally, be a disservice to the patient. A clinical diagnosis alone may be incorrect in up to one third of patients. [42] In addition, should there be additional unconfirmed attacks, the patient may potentially be put at risk when surgical management is refused, whereas had there been evidence of an earlier attack, a surgical approach might have been prudent, and the decision to proceed with resection would have been possible. Thus in the patient who has symptoms of sufficient severity to merit hospitalization, our preference is to obtain radiographic confirmation with computed tomography (CT). [43] After an episode of uncomplicated acute diverticulitis, complete evaluation of the colon can be performed electively. The immediate use of CT is not controversial if the diagnosis is not secure or if complicated acute diverticulitis is suspected. CT has become the investigation of choice for diagnosis, recognition of complicated disease (abscess, fistula, obstruction), potential therapeutic intervention, and quantifying resolution of disease. Ambrosetti and colleagues [44] performed a prospective comparison of CT and water-soluble contrast enema in 420 patients over an 11-year period. Among 136 patients that subsequently underwent colonic resection, 132 had histologically proven diverticulitis. CT was more sensitive than contrast enema (98% v. 92%, respectively) and identified all patients who had an associated abscess, while contrast enema only provided indirect evidence of complicated diverticulitis in 29% of these patients. Helical CT with rectal contrast only has a sensitivity of 97% and specificity of 100%, similar to studies using oral contrast. [45] This technique may avoid the risks, discomfort, and costs of oral and intravenous (IV) contrast and allows for immediate scanning. The CT features of acute diverticulitis (Fig. 87-5) include increased soft tissue density in pericolic fat secondary to inflammation in 98% of patients, air-filled diverticula in 84%, bowel wall thickening in 70%, soft tissue masses representing a pericolic phlegmon and pericolic (usually intramesenteric) fluid collections representing abscesses in 35%. [46], [47] In 10% of patients, acute diverticulitis cannot be distinguished from carcinoma, as both may show focal thickening of the bowel wall; features more suggestive of acute diverticulitis are fluid at the base of the mesentery, edematous thickening of the mesentery, and mesenteric vascular engorgement. [48] CT can identify complicated diverticulitis—that is, peritonitis (diffuse inflammatory changes and scattered, loculated fluid collections), fistula formation (usually inferred from air or rectally administered contrast in bladder, vagina, or abdominal wall, rather than direct visualization of the fistulous tract), and obstruction. CT more clearly stages the extent of extralumenal inflammation, which is underestimated by contrast enema. [44], [47] Findings on CT can be classified as mild (localized colonic wall thickening and inflammation of pericolic fat [see Fig. 87-5]) or severe (abscess, extralumenal air- or water-soluble contrast [Fig. 87-6]); the latter findings have been employed as criteria for elective resection in patients responding initially to medical therapy with resolution of acute clinical symptoms. [49] In addition, CT functions as a therapeutic modality when combined with percutaneous drainage of localized abscesses in selected patients; this approach avoids the need for emergent operative intervention and permits an elective, single-stage resection in the future. [50] Contrast radiography or colonoscopy generally should be avoided in patients with suspected acute diverticulitis due to concerns that overzealous infusion of even water-soluble contrast or insufflation of air may lead to rupture of previously contained diverticulitis. However, a single-contrast enema using water-soluble contrast is safe in the acute phase if performed carefully. Pneumoperitoneum or evidence of generalized peritonitis should be absolute contraindications to the use of barium as the contrast agent. [51] Some physicians prefer a water-soluble contrast enema, even in the absence of these findings, in any patient suspected of having acute diverticulitis in the event there is an unsuspected leak (Fig. 87-7). Contrast enema has the advantage of evaluating the colonic lumen, is less expensive and more readily available than CT, and in some practices is the initial procedure of choice; in the patient in whom the diagnosis of uncomplicated acute diverticulitis is secure, however, contrast enema examination adds little therapeutically useful information.

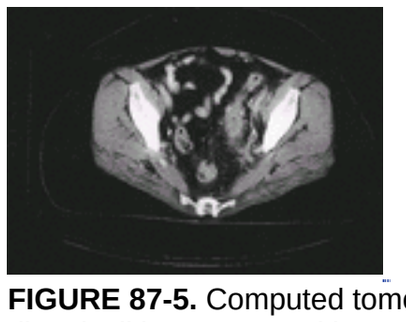

FIGURE 87-5. Computed tomography with oral and intravenous contrast in a 59-year-old woman with increasing abdominal pain for 3 weeks. Mild changes of diverticulitis are seen with narrowing of colonic lumen, bowel wall thickening in the midsigmoid, tissue stranding in pericolic pelvic fat, and diverticula. There is no pericolic fluid collection. (From Young-Fadok TM, Pemberton JH. Colonic diverticular disease: natural history, clinical features and diagnosis. In: Rose BD, ed. UpToDate in medicine [CD-ROM]. Wellesley, MA: UpToDate, 1997.)

FIGURE 87-6. Computed tomography with oral and intravenous contrast in a 60-year-old woman with a 2-week history of crampy lower abdominal pain, fever, and chills showing a low-density mass adjacent to the sigmoid in the left pelvis. The central, low-density region within the mass, the pockets of surrounding gas, and inflammatory changes in pericolic tissues are consistent with diverticular disease.

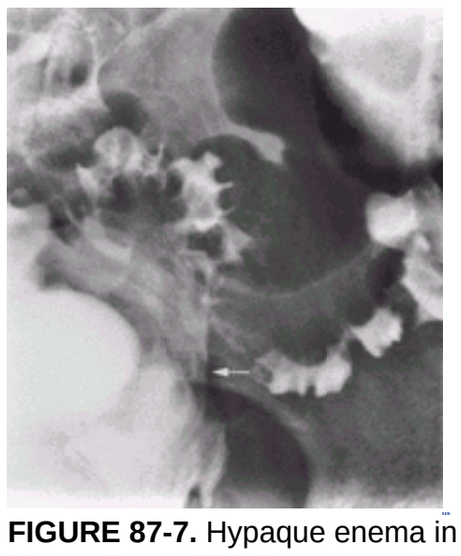

FIGURE 87-7. Hypaque enema in a 79-year-old woman shows nonanatomic distribution of contrast (*arrow*) around the rectum, demonstrating perforation. (From Young-Fadok TM, Pemberton JH. Colonic diverticular disease: natural history, clinical features and diagnosis. In: Rose BD, ed. UpToDate in medicine [CD-ROM]. Wellesley, MA: UpToDate, 1997.)

High-resolution, graded-compression ultrasonography may offer an innovative method to evaluate acute diverticulitis in experienced hands. Visualization of an abnormal colonic segment, as evidenced by mural thickening greater than 4 mm and involving a segment 5 cm or longer at the point of maximal tenderness, is found in 85% of patients and represents the most specific sonographic feature. [52] In cross-section, the thickened colon has the appearance of a target (Fig. 87-8). Inflamed diverticula, mural abscess, extralumenal gas bubbles, peridiverticular abscess, and inflammation may be visualized. Reported sensitivities of ultrasonography range from 85% to 98%, with specificities of 80% to 98%, [52], [53] but undoubtedly are highly operator-dependent. Although ultrasonography is less widely accepted and

validated in the evaluation of diverticulitis than CT, it may be a useful additional tool—for instance in following resolution of an abscess, or in allowing percutaneous, transrectal, or transvaginal drainage of an abscess.

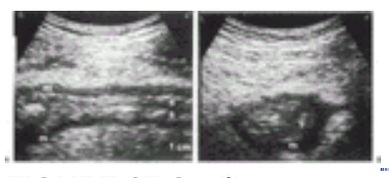

FIGURE 87-8. Ultrasonographic findings of sigmoid diverticulitis. Longitudinal and transverse sections showing thickening of the entire wall and the hypoechoic muscularis propria (*m*), with lumenal narrowing. *s* mucosa/submucosa. (From Schwerk WB, Schwarz S, Rothmund M. Sonography in acute colonic diverticulitis. Dis Colon Rectum 1992;35:1077.)

Diagnosis in the elective setting. After resolution of acute diverticulitis, evaluation requires imaging of the entire colon to determine the extent of disease and to rule out coexistent lesions, such as polyps or carcinoma. Pancolonic imaging may be achieved with colonoscopy, or flexible sigmoidoscopy plus barium enema. An investigational method currently being developed, virtual colonoscopy (also colography or colonography) (Fig. 87-9), may prove to be useful in the elective setting. This technique employs air insufflation of the colon and rapidly acquired CT images, which allow computer generation of a three-dimensional image of the colonic lumen. On occasion, diverticulitis may lead to stricture formation with the characteristic appearances of carcinoma; this finding requires further intervention as for suspected colon cancer.

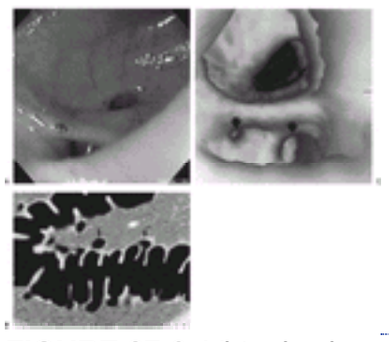

FIGURE 87-9. Virtual colonoscopy. **A:** View of diverticula as seen on routine colonoscopy. **B:** Two-dimensional image of diverticula (*arrows*) obtained by spiral computed tomography scan. **C:** Three-dimensional reconstruction (virtual colonoscopy) illustrating diverticula (*arrows*). (From Young-Fadok TM, Pemberton JH. Colonic diverticular disease: natural history, clinical features and diagnosis. In: Rose BD, ed. UpToDate in medicine [CD-ROM]. Wellesley, MA: UpToDate, 1997.)

Treatment

Decision to observe or operate. Treatment must be individualized for each patient; correct initial therapy depends on clinical acumen (see Table 87-1). The spectrum of disease can be divided into mild symptoms, moderate to severe symptoms, and diffuse peritonitis (Fig. 87-10). The first and last groups require little decision making regarding operative intervention; the second group is the more challenging.

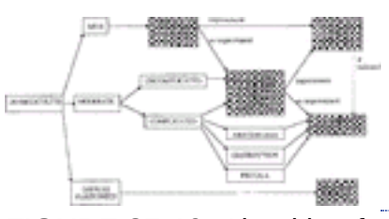

FIGURE 87-10. Algorithm for treatment of acute diverticulitis. (From Young-Fadok TM, Pemberton JH. Colonic diverticular disease: acute diverticulitis. In: Rose BD, ed. UpToDate in medicine [CD-ROM]. Wellesley, MA: UpToDate, 1997.)

Mild symptoms. Patients with mild diverticulitis are characterized by left lower quadrant pain, low-grade fever, and minimal physical findings without peritonitis. These patients are best treated as outpatients with a liquid diet and broad-spectrum oral antibiotics such as ciprofloxacin and/or metronidazole. Exceptions include the very elderly or immunosuppressed patients and other high-risk groups, such as diabetics. Patients can be followed for increasing fever, pain, or inability to tolerate oral intake. Hospitalization is only necessary if the patient fails to improve. Diet is reintroduced as symptoms resolve. Once the episode has resolved, the colon should be evaluated 2 to 4 weeks later.

Moderate to severe symptoms. This patient group can be distinguished by the presence of more severe, left-sided abdominal pain, fever, chills, obstipation, and left lower quadrant peritoneal irritation. Classic symptoms do not initially require advanced diagnostic imaging, and medical therapy is instituted on the basis of a clinical diagnosis. [54], [55] When the diagnosis or extent of disease is in doubt, CT or water-soluble contrast enema should then be considered. In stable, immunocompetent patients, initial treatment is conservative with bowel rest, intravenous fluids, and broad-spectrum parenteral antibiotics. Antibiotics need to be active against gram-negative rods and anaerobes; a single antibiotic, active against both aerobes and anaerobes, appears to be as effective as combination therapy (i.e., a second or third generation cephalosporin, or an aminoglycoside combined with an anaerobically active agent such as metronidazole or clindamycin). [41], [56], [57] The aim is to obtain a clinical response to avoid the need for early, nonelective operative intervention. Except for patients with generalized peritonitis, this approach is usually successful. CT may help to identify patients likely to respond to medical therapy. [50], [58] Three outcomes are possible: improvement, failure to improve, or deterioration. Clear improvement should occur within 24 to 48 hours, with a decrease in pain, fever, tenderness, and leukocytosis. [6], [11], [59] Oral intake can be resumed once abdominal tenderness has resolved. Workup is completed 2 to 6 weeks after the acute phase has settled, either with colonoscopy or flexible sigmoidoscopy combined with barium enema. Fiber supplementation of the diet helps to prevent recurrence in 70% of patients. [59] If there is no objective improvement, the diagnosis may be incorrect or complicated diverticulitis is present. CT should be obtained. Abscesses amenable to treatment should be drained percutaneously at the time of the CT. Operative intervention is necessary if there is no reversible condition, if abscesses cannot be drained, or if drainage does not result in improvement. If a patient's condition deteriorates and there is no treatable condition on CT, operative exploration should proceed without waiting.

Peritonitis. Diffuse peritonitis mandates initial resuscitation, broad-spectrum parenteral antibiotics, and operative intervention; diagnostic studies are rarely necessary. Perforated diverticulitis is a serious disease carrying a mortality rate of 6% for purulent peritonitis and 35% for fecal peritonitis. [60]

Which operation—surgical principles. The surgeon's aims are to remove the septic focus by resecting the involved segment of colon, to treat the associated obstruction or fistula, and, if possible, to restore bowel continuity, while minimizing morbidity and mortality.

Preoperative preparation. In nonemergency situations, mechanical bowel preparation with or without oral antibiotics is usually possible and helps to decrease the rate of wound infection. Patients should be warned of the possibility of a stoma and the abdomen marked for optimal stoma placement preoperatively, taking into consideration body habitus, belt line, and so forth. Preoperatively placed ureteral stents are usually unnecessary but may be helpful if there is intense pericolonic inflammation. Positioning the patient in a modified lithotomy position allows a circular stapler to be passed transanally if anastomosis is possible; this positioning also allows intraoperative proctoscopy to assess and empty the rectum if necessary.

Intraoperative assessment. Under emergency conditions, the abdomen is explored through a midline incision; a laparoscopic approach may be possible electively at least 6 weeks after the episode of diverticulitis has resolved. Assessment of peritoneal contamination, proximal obstruction, and fecal load determine the advisability of a primary anastomosis (Hinchey classification; Table 87-2). [61] For instance, class I and II disease may still allow a primary anastomosis, depending on whether the abscess is removed en bloc with the resected segment (as with an intramesenteric abscess), or whether the abscess has been well controlled by the peritoneum, can be safely drained without local contamination, and is distant from the anastomotic site.

STAGE	CHARACTERISTICS
I	Pericolic or mesenteric abscess
II	Walled-off pelvic abscess
III	Generalized purulent peritonitis
IV	Generalized fecal peritonitis

Adapted from ref. 61.

TABLE 87-2 Hinchey Classification of Diverticulitis

In elective or semi-elective situations, resection and primary anastomosis are usually possible, as the inflammatory condition is well localized or has resolved significantly. After resection, the ends of the bowel for anastomosis must be well vascularized, nonedematous, and tension-free. The distal margin of resection should be in the upper third of the rectum, since there are no diverticula distal to this point. The proximal resection should extend to where colon becomes soft and nonedematous. While it is not absolutely necessary to remove all diverticula-bearing colon proximal to the intended anastomosis, [36] attempts should be made to remove the majority of diverticula on the left side of the colon. Absolute contraindications to primary anastomosis are fecal or purulent peritonitis; relative contraindications include severe co-morbid conditions that might jeopardize blood flow, poor nutrition, and immunosuppression. [54] In emergency situations with peritoneal contamination, a two-stage procedure is appropriate (Fig. 87-11). The most common two-stage approach involves resection of the diseased colon, oversewing of the rectal stump, and an end colostomy–a Hartmann procedure. In patients with fecal or purulent peritonitis, this approach is the preferred method. Creation of a mucous fistula from the rectal stump is not possible after resection of the entire sigmoid. Many surgeons mark the rectal stump with a long, nonabsorbable suture and tack it to the anterior abdominal wall or sacral promontory for ease of location in the future. The colostomy can be closed 3 months later.

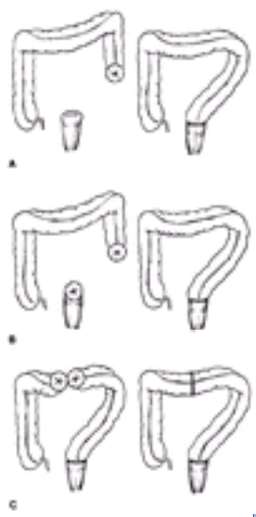

FIGURE 87-11. Two-stage approaches to resection of diverticular disease. Common among the approaches is that the offending segment of diverticular disease is resected at the first operation. **A:** Stage 1: The Hartmann procedure. Diseased sigmoid colon is removed, the fecal stream is diverted, and the rectum is oversewn. Stage 2: Intestinal continuity is reestablished by a descending colorectostomy. **B:** Stage 1: Diseased sigmoid is removed and both ends of bowel are brought to the surface, one as an end colostomy and the other as a mucous fistula. Stage 2: Intestinal continuity is reestablished as in (**A**). **C:** Stage 1: Diseased sigmoid colon is resected and a colorectostomy is constructed and protected by a diverting transverse colostomy or diverting loop ileostomy. Stage 2: Closure of the transverse colostomy is achieved. (From Pemberton JH, Armstrong DN, Dietzen CD. Diverticulitis. In: Yamada T, ed. Textbook of gastroenterology, 2nd ed. Philadelphia: JB Lippincott, 1995:1870.)

The Hartmann procedure removes the source of sepsis, but reversal of the colostomy requires a formal celiotomy and is often difficult because of adhesions and difficulty identifying the rectal stump. [6], [11] Up to one third of patients are left with a permanent stoma. [62] Relative contraindications to an unprotected anastomosis include presence of a chronic abscess cavity and mild systemic illness, in which case the patient may be better served by creation of a protected primary anastomosis. This increasingly popular two-stage approach entails resection, primary anastomosis, and proximal diverting stoma; the second stage then involves a simple stoma closure. This approach is employed when there are relative contraindications to primary anastomosis, but no purulent or fecal peritonitis, and the bowel is nonedematous. This option has advantages because the second-stage stoma closure may often be accomplished through the stoma site alone, especially if a diverting loop ileostomy (our preference) is used, thereby not mandating a full celiotomy. Another factor in the emergent setting is that bowel preparation is not possible, and a large fecal load precludes a primary anastomosis. Consideration may be given to intraoperative lavage in selected patients to permit primary resection and anastomosis. In addition to mobilization of the affected sigmoid, mobilization of the splenic and sometimes the hepatic flexure may help. [43] Bowel proximal to the sigmoid is occluded with tape, and immediately above this, the lumen is cannulated with large bore corrugated plastic tubing (anesthesia ventilator tubing). The end of the tube is passed off the field. The cecum, appendix base, or distal ileum is cannulated with a Foley catheter through which warm saline containing 50 mL of povidone iodine solution per liter is infused until the efflux is clear. Lavage was performed in 33 of 62 patients undergoing non-elective operation for diverticulitis: 18 with stage I Hinchey disease, 10 with stage II, and 5 with stage III. [63] Only one anastomotic complication occurred. The outdated classic three-stage procedure (Fig. 87-12) is no longer indicated [55] as it has a mortality rate of 26% versus 7% after a two-stage resection. [60] In rare and exceptional cases, if mesenteric inflammation precludes a safe dissection of the involved segment from the iliac vessels and ureters, or if the patient is unstable, it may be necessary simply to drain the area and create a proximal stoma. In rare circumstances (i.e., areas lacking a well-qualified abdominal surgeon), drainage and diversion are the optimal patient care. This allows for stabilization and early transfer to a large center for definitive therapy.

FIGURE 87-12. Three-stage resection of diverticular disease. **A:** Stage 1: Diverticular abscess is drained and the fecal stream diverted by a double-barreled colostomy. **B:** Stage 2: Sigmoid diverticular disease is resected and a colorectostomy constructed. **C:** Stage 3: The colostomy is closed to restore intestinal continuity. (From Pemberton JH, Armstrong DN, Dietzen CD. Diverticulitis. In: Yamada T, ed. Textbook of gastroenterology, 2nd ed. Philadelphia: JB Lippincott, 1995:1870.)

Laparoscopic versus open approaches. Laparoscopic techniques may be valuable in several facets of diverticular disease. [64] These include diagnosis, diversion, resection of the affected segment of colon, and restoration of colonic continuity (either as a staged procedure or primarily). Absolute contraindications to the laparoscopic approach are free perforation with fecal peritonitis or extensive purulent peritonitis because of the limitations on complete exploration and clearance of contaminated material. Both single institution [65], [66] and multicenter studies [67] have demonstrated benefits of the approach in terms of reduced ileus and hospital stay, with comparable complication rates to laparotomy. Randomized trials confirming superiority of the approach, however, have not been performed. The inflammation that may accompany diverticulitis is often challenging, even in open procedures. Resolution of the inflammatory component permits a successful laparoscopic approach in most cases. [64] The presence of a colovesical, colovaginal, or coloenteric fistula reduces the chances of completing the procedure laparoscopically, as does prior use of a drain, but neither are absolute contraindications to this approach. Even in open cases, the bladder side of a colovesical fistula frequently requires nothing more than pinching off the fibrous fistula track and leaving the bladder decompressed with transurethral catheter drainage, and the same principles apply to the laparoscopic approach. Ureteral stents may be helpful, and the firm tubular structure of the stent in the retroperitoneum can usually be detected with the laparoscopic instruments, making lighted stents unnecessary. As with open procedures, it is helpful to approach the mass in the sigmoid from both cephalad and caudad directions, having identified normal tissue planes away from the phlegmon. Significant experience is required to identify these planes. A low threshold for conversion to laparotomy should be maintained to avoid damage to vessels and ureter. The same extent of resection should be accomplished laparoscopically as for an open procedure, namely proximal resection of the sigmoid back to soft, pliable tissue, and distal resection to a point where the tenia have coalesced, usually to a point below the sacral promontory. This thus precludes an extracorporeal anastomosis and mandates an intracorporeal stapled anastomosis.

Complications

Obstruction. Diverticular obstruction of the colon is rarely a true or complete mechanical obstruction. However, obstipation due to functional obstruction is a common presenting complaint. Evaluation often shows a ratty stricture of the involved segment, with a picket fence appearance (Fig. 87-13). The primary concern is differentiation from carcinoma (Fig. 87-14); even with negative biopsies, resection is usually unavoidable for this suspicious appearance. Resection with primary anastomosis is often possible, with colostomy if the preoperative bowel preparation is inadequate. In rare situations, acute diverticulitis leads to complete mechanical large bowel obstruction; this requires an emergent exploration. The inflammatory reaction may also involve secondarily the small bowel, leading to a small bowel obstruction; if this fails to respond to nonoperative treatment, operative intervention may be necessary.

FIGURE 87-13. Contrast enema revealing picket fence appearance of the sigmoid colon, associated with symptoms of obstruction.

FIGURE 87-14. Barium enema demonstrating constricting lesion in sigmoid colon in a region of diverticulosis. There is also a 3-cm localized collection of barium (*arrow*) off the lateral colonic wall consistent with an abscess cavity. The most likely radiologic diagnosis is diverticulitis but carcinoma cannot be excluded.

Perforation. Free intraperitoneal rupture of diverticulitis is unusual but is associated with high mortality rates of 20% to 30% [60], [68] and appears to be more common in severely ill or immunocompromised patients. Treatment involves an emergent two-stage procedure with resection of the involved segment and proximal diversion.

Abscess. Abscesses occur in 15% of patients with acute diverticulitis presenting without peritonitis [49] and in 30% to 56% of patients requiring early operative intervention for diverticulitis. [6] Prior to the introduction of radiologically guided, percutaneous techniques of drainage, abscesses mandated operative intervention, often requiring a two-stage procedure. Percutaneous drainage now permits a future, elective, single-stage operative approach in 60% to 80% of patients; [69], [70] and [71] indeed, in selected patients with severe co-morbid conditions, which contraindicate operative therapy, catheter drainage alone may relieve symptoms and provide definitive treatment. [70] The catheter should remain in place until drainage is less than 10 mL in 24 hours; this approach may take up to 30 days. [70] Contrast radiographs through the drainage catheter (sinograms) can show persistent communication between the colon and the abscess cavity and may be one way to follow resolution of the abscess. The route of drainage is preferably through the anterior abdominal wall; abscesses deep in the pelvis or obscured by other organs may be accessed transgluteally or through the rectum or vagina, [72], [73] but these approaches are less optimal for patient comfort and catheter care. Operative intervention is indicated if improvement does not occur.

Fistula

Incidence. Fistulas account for up to 20% of all indications for operative intervention in complicated diverticular disease. [74] Because 90% of diverticular inflammation involves the sigmoid colon, fistulization most commonly arises from this segment. Colovesical fistulae (Fig. 87-15) comprise 65% of diverticular fistula, 25% are colovaginal fistulae, and less common are coloenteric and colouterine fistulae, [74] but fistulae can form with any hollow organ and have been described in many unexpected sites (Fig. 87-16).

FIGURE 87-15. Barium enema in a 54-year-old woman with pneumaturia and left lower quadrant pain. A fistulous tract (*closed arrow*) arises in the midsigmoid passing into an abscess cavity (*arrowhead*) and then into bladder, where contrast is also seen (*open arrow*). (From Young-Fadok TM, Pemberton JH. Colonic diverticular disease: hemorrhage. In: Rose BD, ed. UpToDate in medicine [CD-ROM]. Wellesley, MA: UpToDate, 1997.)

FIGURE 87-16. Barium enema in a 64-year-old man with 3 weeks of right hip pain. There is extravasation of barium from a perforated sigmoid diverticulum with collection of contrast material in an abscess cavity (*white arrow*) adjacent to the diverticulum. A fistulous communication extends from the abscess cavity to the right

lower quadrant and extends to the region of the right hip (*black arrow*). (From Young-Fadok TM, Pemberton JH. Colonic diverticular disease: acute diverticulitis. In: Rose BD, ed. UpToDate in medicine [CD-ROM]. Wellesley, MA: UpToDate, 1997.)

Colovesical fistulae are the most common form of diverticular fistula and, conversely, diverticulitis is the most common cause of colovesical fistula, accounting for 40% to 89% of cases. [75] Although acute diverticulitis has an overall slight female predominance, males comprise the majority (66%–78%) of patients with colovesical fistulae secondary to diverticulitis. [74], [76] The uterus appears to protect the bladder from the inflamed sigmoid; indeed, 50% to 68% of women with colovesical fistulae and 83% of patients with colovaginal fistulae have had a previous hysterectomy. [74], [75], [77]

Clinical features and diagnosis. Colovesical fistulae are illustrative of most forms of diverticular fistulae. Only about 50% of patients will give a history of diverticulitis; in the remainder, diverticulosis is diagnosed when the fistula manifests clinically. [76] Patients describe passage of feculent matter and/or gas during urination; this manifests as pneumaturia in 67% to 75% of patients, dysuria in 56% to 94%, or fecaluria in 50% to 76%. [74], [75] and [76] Crampy abdominal pain, diarrhea, hematuria, and passage of urine through the rectum occur in a much lower percentage of patients. [74], [76] Physical examination is characteristically unremarkable. Urinalysis is invariably abnormal with pyuria or fecal particulate matter; cultures reveal a polymicrobial growth. Such findings suggest a fistula but not the etiology, which may be diverticulitis, Crohn's colitis, or carcinoma. CT, barium enema, colonoscopy, cystoscopy, cystogram, and intravenous urography have all been used for the diagnosis of colovesical fistula. The reported diagnostic yield of each modality varies widely in different reports. The diagnostic yield from contrast enema and colonoscopy tends to be low (20%–26% and 0%–3%, respectively) [75], [76] but these studies are valuable in assessing the proximal colon. Although the actual fistula is rarely demonstrated, abnormalities suggestive of the diagnosis are present in up to 100% of barium enemas and 25% of colonoscopies. If the diagnosis remains questionable after these studies, or if further anatomic delineation is required, CT is the most accurate and sensitive test. Occasionally the fistula itself is opacified, but more commonly colonic thickening adjacent to an area of thickened bladder, associated diverticula, and the presence of rectally administered contrast material or more commonly gas in the bladder (prior to instrumentation of the urinary tract) are present and are highly sensitive and specific for colovesical fistulae. [78] Gas bubbles within organs other than the bowel are highly suggestive of fistulization. [46] Although CT may not actually delineate the fistula tract, associated findings predict the location of the involved segment of colon and provide important information regarding extralumenal inflammation and its relationship to the ureters. Cystoscopy, lauded by some authors, directly identifies only 20% of fistulae but strongly suggests the diagnosis by localizing inflammation and bullous edema of the bladder mucosa in the vast majority (96%) of patients. [75] Others consider such changes too nonspecific and find cystoscopy useful in only 37% to 46% of patients. [74], [76] Similarly, retrograde cystography and intravenous urography objectively demonstrate the fistula in less than 30% of patients and generally are of little clinical benefit.

Treatment. In general, diverticular fistulae do not close spontaneously, but also the presence of a fistula is rarely an indication in itself for urgent operative intervention; indeed, the very rare instance of an acute initial presentation of a fistula may be an indication to postpone operative correction until the acute inflammation inducing the fistula resolves. As most patients present electively and can tolerate a bowel preparation, a one-stage procedure with resection and primary anastomosis is usually feasible and is associated with decreased morbidity and hospital stay. [75] If extensive inflammation is present and operative intervention is required to treat nonresolving acute diverticulitis, a two-stage procedure may be necessary. The portion of the colon from which the fistula arises should be resected as previously described (see " Treatment"). Management of the fistula site at the bladder depends on the size of the fistula, the degree of local inflammation, and the anatomic site. In most patients, the fistula can be pinched off, and either no visible defect in the bladder wall or a very small defect will be evident. Merely leaving an indwelling transurethral bladder catheter for 7 to 10 days with or without closing the bladder defect with a few absorbable sutures over the site or leaving a closed suction drain in the region of the bladder defect is suitable management. With a larger defect, simple closure is almost always preferred to formal resection, which is almost never necessary, as the cause of the fistula originates in the colon, and the bladder itself is normal; any local induration usually settles rapidly once the inciting cause (the diseased segment of colon) has been removed. [54] These simple principles of minimal intervention apply to the distal aspect of most types of diverticular fistula, be they in small bowel, vagina, or uterus. Although operative management is usually recommended, there may be a rationale for conservative nonoperative management in highly selected patients, especially with severe co-morbid conditions, but no good follow-up studies are available to support this approach in most patients. In one series, six patients were managed nonoperatively for 3 to 14 years, treated only with prophylactic antibiotics; there were no complications and specifically no impairment of renal function and no urinary sepsis. [79] In the absence of urinary tract obstruction, observation appears safe in patients with significant contraindications to operative management; this nonoperative approach may, however, be unacceptable if the symptoms are bothersome.

Special Situations

Diverticulitis in the younger patient. Management of patients with their first episode of acute diverticulitis at less than 40 years of age is controversial. The current standard of therapy is to recommend resection after one episode, based on two premises: first, these patients suffer a more virulent disease; and, second, patients responding to medical therapy are much more likely to have recurrent diverticulitis and ultimately require surgical intervention. However, controversy exists as to the true virulence and natural history in this age group. Young patients comprise 12% to 29% of the larger series of patients with acute diverticulitis requiring operative treatment. [7], [8], [33], [54], [80] Common findings are a male predominance of from 2:1 to 4:1 [7], [8], [33], [54] and the coexistence of obesity in 84% to 96% of these patients. [8], [54] The concept that diverticulitis is more virulent in the young arises from follow-up studies of younger patients with their first episode of acute diverticulitis; 48% to 88% of this group will require operative treatment either acutely or in the future. [8], [54], [80] Others describe much lower rates of operative intervention (15%–41%) and a more successful nonoperative management approach. [7], [33] These inconsistencies may arise because the younger patient may undergo operation because of an incorrect diagnosis; [81] some series have quite high rates of incorrect diagnoses approaching 50%. [8], [54] This inordinately high rate is probably because the diagnosis of diverticulitis is not entertained in this young population, and the presence of localized peritonitis is interpreted as an abdominal catastrophe requiring emergent operative exploration. If CT or contrast studies are used more widely, the operative rate in young patients is actually only 15% versus as high as 33% in older patients; [33] however, the diagnosis of acute diverticulitis must first be entertained. The natural history of acute diverticulitis in this young population after initially successful medical management is also disputed. Some studies report readmission rates of 55% [82] and subsequent operative rates of 20% to 41%; [81], [82] and [83] others report no need for operation during a mean follow-up of more than 4 years. [84] When the total operative rates are examined with long-term follow-up, data are more consistent with an ultimate operative risk of about 50%. Some series have very high initial operative rates, [8], [54], [80] while others with a lower rate of acute operation (15%–25%) have higher rates at later times (29%–32%). [33], [83] Although there are no reliable convincing arguments that necessitate elective resection in this younger population after resolution of uncomplicated diverticulitis, in patients with no co-morbid conditions, early elective colectomy after one episode of acute diverticulitis seems the most reasonable recommendation. However, the issue may become one of individual patient evaluation of their risk and lifestyle concerns.

Immunocompromised patient. Pharmacological or functional immunosuppression is associated with an increased risk of perforated diverticulitis. This patient group includes those patients treated with chemotherapy, corticosteroids, and medications such as azathioprine, cyclosporine, and so forth, but the phenomenon is also apparent in diabetics and those with chronic renal failure. These patients may present with minimal symptoms and unimpressive abdominal findings even when they have advanced peritonitis; thus, the diagnosis is frequently delayed. While aggressive medical therapy is successful in 75% of normal patients with acute diverticulitis, operative intervention is necessary in most immunocompromised patients; [85] early operative intervention must be entertained in these patients, especially if they fail to show an objective response early in the course of aggressive medical treatment. Patients with connective tissue disorders, such as lupus, appear to have an increased risk of complicated diverticulitis over and above that related to immunosuppression from use of steroids. [86]

Right-sided diverticulitis. Right-sided diverticula comprise 5% of diverticulosis reported in Western countries [3] but up to 20% in Asian countries. [12], [13] Most of these cases are wide-mouthed, false diverticula. [15] Patients tend to be younger than those with left-sided disease. [12], [13] Because right-sided acute diverticulitis presents clinically as acute appendicitis, the correct preoperative diagnosis is made in only 4% to 16% of patients. If an objective diagnosis can be secured preoperatively, aggressive medical management should be undertaken. More commonly, the diagnosis is made or suspected only intraoperatively. If there is no peritoneal contamination, an obviously normal or absent appendix, and no worry of colonic malignancy, appropriate management involves parenteral antibiotics and an appendectomy if the appendix is present. [12], [13] If the diverticulitis is limited, consideration can be given to simple diverticulectomy [13] (and appendectomy). However, if there is diverticular perforation, extensive inflammation, or a colonic malignancy that cannot be confidently excluded, some form of right colectomy is justified. Primary anastomosis is usually possible, but one should not hesitate to construct an ileostomy and distal mucous fistula in the presence of severe peritonitis or in the compromised host. [12], [16]

Diverticular Bleeding

Incidence Diverticular bleeding is the most common cause of acute massive colonic blood loss, accounting for 30% to 50% of massive bleeding; [87], [88] although angiodysplasia makes up an additional 20% to 30%, [88] it is a more common cause of chronic or intermittent low-grade, lower gastrointestinal bleeding in patients over 65 years old. [89], [90]

Pathophysiology One explanation of the pathophysiology of diverticular bleeding is the hypothesis that as a diverticulum herniates, the vessel responsible for the weakness in the wall of the colon at that point becomes draped over the dome of the diverticulum, separated from the bowel lumen only by mucosa (see Fig. 87-1). With time, the artery is exposed to repeated local injury along its lumenal aspect secondary to inflammation and/or increased intralumenal pressure. Eccentric intimal thickening and thinning of the media occur in the vasa recta along the side adjacent to the lumen. [26] These localized changes in vessel wall structure may result in segmental weakness of the artery and rupture into the lumen. Right-sided diverticula tend to have wider ostia and domes than those in the left colon, possibly exposing vasa recta to injury over a greater length of the vessel wall and hence accounting for the higher incidence of hemorrhage recognized from right-sided colonic diverticula. [26] Others believe that the thinner wall of the right colon predisposes to diverticular bleeding. [31]

Natural History Bleeding will develop in 15% of patients with significant diverticulosis; in a third of these patients (5%) it is massive and can potentially lead to cardiovascular instability. [31] Many patients are older adults (mean age, 68–77 years) [87], [88] with co-morbid conditions that contribute to morbidity and mortality rates of 10% to 20%. [88], [91] Several studies have suggested that management with a specialized bleeding team may reduce mortality. [87] Bleeding stops spontaneously during 75% of episodes; a requirement for blood transfusion of less than 4 units in 24 hours is associated with spontaneous cessation of bleeding in 99% of patients. [92] The risk of rebleeding, however, is significant, ranging from 14% to 38%; [87], [92] with a second episode, the risk of further hemorrhage approaches 50%. [92] The right colon is the source of diverticular bleeding in 48% to 90% of these patients [26], [87], [93] despite the fact that 75% of all diverticula are left-sided, and when right-sided diverticula occur, they are usually associated with left-sided diverticula. [11]

Clinical Presentation The hallmark of diverticular bleeding is painless, bright red rectal bleeding. Most episodes are minor (<1 unit of blood), and up to 50% of patients [93] give a history of intermittent passage of maroon or bright red blood. Abdominal pain is usually absent; indeed, it is extremely rare for bleeding to coexist with acute diverticulitis. [26] Physical examination is usually unremarkable, without abdominal tenderness or mass. Less than 5% of patients with bleeding diverticulosis present with massive hemorrhage requiring transfusion: this bleeding is usually not of an acute exsanguinating form but rather is a persistent bleed.

Management Management of massive colonic bleeding has three components: resuscitation; diagnosis and localization of the site of bleeding; and subsequent management. A coordinated approach by gastroenterologists, radiologists, and surgeons, as members of a specialized bleeding team, has been shown to reduce mortality. [94] The American College of Gastroenterology has published practice guidelines addressing lower gastrointestinal bleeding. [95]

Resuscitation and initial assessment. After aggressive fluid resuscitation and cross-matching of blood, blood loss must be estimated, an assessment made of hemodynamic stability, and the source sought. The patient's age is not a great help in diagnosis nor is the physical examination. Rectal examination, anoscopy, and proctoscopy must be part of the initial assessment; massive hemorrhoidal bleeding, though rare, can be easily excluded. If initial assessment cannot determine whether bleeding is proximal, the appropriate diagnostic workup is initiated. If assessment does not indicate if bleeding is proximal or distal to the ligament of Treitz, an extended upper endoscopy should be performed, as massive hemorrhage from the upper gut is statistically more likely than from the lower gastrointestinal tract (82% vs. 18%); [87], [96] if negative, evaluation of the lower gastrointestinal tract should begin.

Diagnostic modalities. The aim of the diagnostic evaluation is twofold: to localize the site of bleeding should operative treatment become necessary; and to determine the cause of bleeding, because treatment of diverticular bleeding differs from that of other causes. Radionuclide "bleeding scan," mesenteric angiography, and colonoscopy have all been employed; the appropriate order in which they are used depends on the rate of bleeding and on available expertise. A combination of diagnostic modalities can successfully identify the source preoperatively in 90% of patients with massive bleeding. [97]

Colonoscopy. The role of colonoscopy in acute diverticular bleeding is evolving, but in some centers it has become the preferred initial approach. The first report of endoscopic management of a bleeding diverticulum, with irrigation of 1:1000 epinephrine, was in 1985. [98] Success has since been reported with the heater probe, [99] bicap probe, [100] injection therapies, [101], [102] and fibrin sealant. [103] Endoscopic "stigmata" with prognostic value have been reported. [104] Cumulative results of small studies suggest a 95% hemostasis rate. [105] Some proceed with emergent colonoscopy in unprepared bowel as blood is cathartic. [106] Others use enemas or rapid preparation with balanced electrolyte solutions given orally or through nasogastric tube. [107], [108] When performed successfully (i.e., satisfactory visualization of the mucosal surface), colonoscopy has a diagnostic accuracy of 72% to 86%. [106], [107] and [108] Advantages include precise localization and the potential for therapeutic intervention. Only a select few patients, however, are realistically amenable to colonoscopy, and include those with low volume, intermittent colonic bleeding.

Radionuclide imaging. Two types of radionuclide bleeding scans have been employed. The first uses a sulfur colloid labeled with technetium 99m (^{99m}Tc). Scans obtained shortly after intravenous injection can image the area of bleeding, even if the rate of bleeding is as low as 0.1 mL/min. This method is exceedingly sensitive. The short half-life of the marker within the intravascular space (the sulfur colloid is rapidly cleared by the spleen and liver) limits the usefulness of this imaging modality to patients who are actively bleeding during the short duration that the label remains in the vascular space. Because of this exceedingly short functional half-life of efficacy, this imaging modality has been replaced with the so-called tagged red cell scan, which uses ^{99m}Tc pertechnetate to label or "tag" autologous red blood cells removed from the patient prior to reinjection into the patient (Fig. 87-17). Abdominal images are obtained frequently during the first 30 minutes, and then every few hours for up to 24 hours. The major advantage of this label is that patients may be scanned several times over 24 hours thereby imaging the site of intermittent bleeding or localizing the appropriate quadrant of the abdomen.

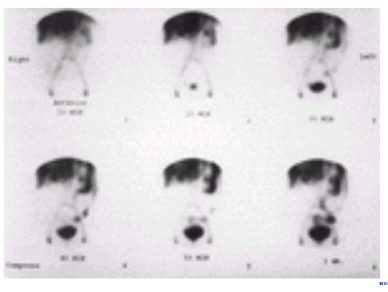

FIGURE 87-17. Technetium 99 (^{99m}Tc)–labeled red blood cell scan for evaluation of lower gastrointestinal bleeding in a 63-year-old woman with a 24-hour history of bright red blood from the rectum. Increased activity in the distal transverse colon near the splenic flexure progresses toward the descending colon and sigmoid colon by termination of the examination at 1 hour. Findings are consistent with a bleeding source in the distal transverse colon near the splenic flexure. (From Young-Fadok TM, Pemberton JH. Colonic diverticular disease: fistula. In: Rose BD, ed. UpToDate in medicine [CD-ROM]. Wellesley, MA: UpToDate, 1997.)

Radionuclide bleeding scans have advantages and disadvantages. Advantages are their noninvasiveness and sensitivity. One series demonstrated a sensitivity of 97%, specificity of 83%, and positive predictive value of 94%. [109] The disadvantages of radionuclide scans are that they localize bleeding to a general area of the abdomen without necessarily localizing the bleeding source to a specific organ, for example, colon versus small bowel, and thus accuracy rates range from 24% to 91%. [31] Poor organ localization occurs because the extravasated blood may move within the hollow organ in either a peristaltic or antiperistaltic direction, and, in addition, localization to an area of the abdomen cannot objectively define a site in the colon; for example, bleeding from a redundant sigmoid colon may appear as extravasation in the right lower quadrant suggesting bleeding either from the right colon or the distal small bowel. Hence, radionuclide imaging is often used prior to angiography to confirm bleeding rates sufficient to justify the use of the more invasive selective angiographic studies.

Angiography. In the absence of a likely source in the distal colon or rectum, the first mesenteric vessel examined is the superior mesenteric artery, because 50% to 80% of diverticular bleeding, and virtually all bleeding from angiodysplasia, occur in segments of the colon and bowel supplied by this artery. [110] If no source is found, the inferior mesenteric and celiac vessels are then studied. Successful localization of the anatomic site of bleeding varies from 14% to 72%, [88], [91], [111] and depends on the rate of bleeding (sensitivities are as low as 0.5 mL/min), timing (the patient must be actively bleeding at the time of the intravenous contrast administration), and the expertise of the angiographer. Angiographic localization is 100% specific, but sensitivity varies with the pattern of bleeding; with acute bleeding, sensitivity approaches 50% but decreases to 30% with a pattern of recurrent hemorrhage. [112] A positive angiogram is associated with an 86% likelihood of operative treatment. [112] The use of radionuclide imaging to screen for active bleeding may reduce the frequency of negative arteriograms, [96] but some groups maintain that the incidence of negative arteriograms is increased by the delay inherent in performing radionuclide scans. [88] Complications of urgent arteriography occur in about 9% of patients and include arterial thrombosis, mesenteric or peripheral embolization of atherosclerotic debris from the aorta (occurring during catheter manipulation), and renal failure. The advantages of angiography are that bowel preparation is not required, and the anatomic localization provided is organ-accurate, especially in the colon. Moreover, angiographic techniques may allow therapeutic intervention with selective infusion of vasoconstrictor agents or vascular embolization. Vasopressin can be infused directly into the artery supplying the segment of colon bleeding by a subselectively positioned intraarterial catheter (Fig. 87-18). Up to 91% of patients receiving intraarterial vasopressin will stop bleeding; however, as many as 50% will rebleed on cessation of vasopressin. [88] In these patients, however, vasopressin may permit resuscitation, stabilization, and bowel preparation with the goal of resection and primary reanastomosis. [88] Transcatheter embolization is a more definitive means of controlling hemorrhage, but it is associated with an incidence of colonic infarction in up to 20% of patients embolized. Attempts to reduce this risk have included use of temporary occluding agents or have employed a "superselective" catheterization technique. [113]

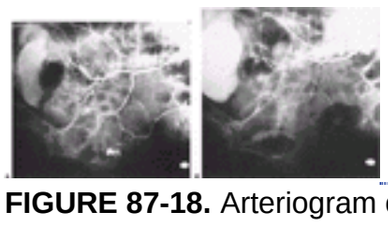

FIGURE 87-18. Arteriogram of the inferior mesenteric artery in a patient with diverticular bleeding. **A:** Extravasation of contrast medium into the lumen of the descending colon. **B:** Arteriogram of the same patient after infusion of vasopressin. Note the markedly reduced flow in the left colonic and sigmoidal branches. (From Pemberton JH, Armstrong DN, Dietzen CD. Diverticulitis. In: Yamada T, ed. Textbook of gastroenterology, 2nd ed. Philadelphia: JB Lippincott, 1995:1870.)

Management approach. During resuscitation, the management rationale is determined by categorizing patients into one of three groups: hemodynamically unstable with active bleeding; continuing bleeding but hemodynamically stable; and hemodynamically stable with apparent cessation of bleeding (Fig. 87-19).

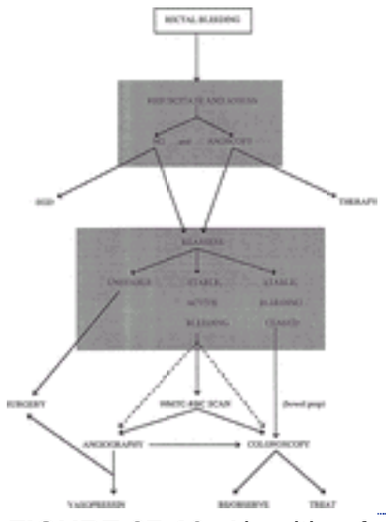

FIGURE 87-19. Algorithm for management of diverticular bleeding. (From Young-Fadok TM, Pemberton JH. Colonic diverticular disease: acute diverticulitis. In: Rose BD, ed. UpToDate in medicine [CD-ROM]. Wellesley, MA: UpToDate, 1997.)

Hemodynamic instability. Persistent instability despite aggressive resuscitation requires emergency operative intervention in 18% to 25% of patients with diverticular bleeding who require blood transfusion. [92], [114] Every attempt should have been made to exclude an upper gastrointestinal source of bleeding (e.g., nasogastric intubation or even emergency gastroscopy), because the operative approach is markedly different for the surgeon. At operation, a careful exploration is undertaken looking for an obvious source or a mass. Because diverticular bleeding is not associated with acute diverticulitis, the involved diverticulum is not immediately evident externally. Indeed, most patients are elderly and would be expected to have colonic diverticula. Without preoperative localization, the decision of what or where to resect becomes problematic. Multiple techniques have been described, including dividing the colon into sections by applying occlusive clamps across the bowel and determining which section fills with blood; this technique, which requires the presence of ongoing massive bleeding, is generally unsatisfactory. A much better approach involves intraoperative colonoscopy, [97] possibly after a rapid on-the-table intraoperative bowel preparation using an infusion catheter placed into the cecum, through which a warmed electrolyte solution is rapidly infused and a transanal catheter to control the efflux of infusate from below. This approach allows the possibility of a localized segmental colectomy involving only the site of bleeding. If, however, no obvious colonic site can be identified, and the bleeding is massive and life threatening, the surgeon may need to perform an abdominal colectomy involving the entire colon susceptible to diverticula and angiodysplasia. Thus, all possible attempts at specific localization preoperatively and intraoperatively are important to limit the extent of colectomy required. A source of bleeding is ultimately identified in 78% of patients undergoing emergent operation for lower gut bleeding. [97]

Hemodynamically stable with continued active bleeding. The most straightforward approach is to start with a tagged red blood cell scan. If positive, it can serve as a useful screen before mesenteric arteriography, which may permit infusion of vasopressin to stop the bleeding and allow bowel preparation for future operative treatment should the bleeding recur. Infusion begins at 0.2 units/min, with repeat angiography after 20 minutes; if bleeding persists the dose of vasopressin is increased to 0.4 to 0.6 units/min. [115] If the bleeding is controlled, the infusion should be continued in an intensive care setting for 24 to 36 hours and then tapered over 24 hours. [115] In the high-risk patient who has failed the initial vasopressin trial but has significant contraindications to operative intervention, embolization may be used followed by close observation for ischemic complications. If angiography is negative, the next step in the diagnostic algorithm (see Fig. 87-19) is colonoscopy, which may identify a source and/or localize the site of active bleeding. Diverticular bleeding is rarely observed at colonoscopy and is often a diagnosis of exclusion. If the radionuclide scan does not demonstrate bleeding, angiography is unlikely to be helpful. Colonoscopy is then performed after bowel preparation. Some institutions proceed directly to angiography, especially for massive bleeding, whereas others use a rapid bowel preparation prior to colonoscopy. Of note is that barium enema (versus water-soluble contrast) has no role in the management of acute colonic bleeding; it prevents angiography because of retained barium.

Hemodynamically stable, bleeding stopped. The patient who has stopped bleeding provides a diagnostic challenge, but also allows a semi-elective evaluation, which involves bowel preparation and colonoscopy in preference to contrast enema.

Operative Treatment The need for operative intervention varies with the degree of bleeding. With severe or massive rectal bleeding, 24% to 78% of patients will require operative intervention. [88], [92], [97], [107] Preoperative localization of the site of bleeding and the use of vasopressin as a temporizing measure have reduced operative morbidity from 37% after emergency resection to 9% after segmental colectomy. The operative mortality of 9% to 11% generally reflects co-morbid conditions. [88], [97], [114] When the source of bleeding has been localized, a segmental colectomy is performed, and the rate of rebleeding is 0% to 14%. [88], [92], [116] Blind segmental resection of the most involved diverticula-bearing segment carries a rebleeding rate as high as 42% [116] and an ultimate morbidity and mortality of 83% and 57%, respectively, and thus is contraindicated. [116] Even in patients with extensive diverticular disease, if the site of bleeding has been localized objectively, a segmental resection eradicating the bleeding site is adequate. [88] Abdominal colectomy is reserved for the patient who continues to bleed without a documented site of bleeding but is associated with a relatively high morbidity and mortality (37% and 11%–33%, respectively). [88], [92], [117] Although the rebleeding rate after abdominal colectomy approaches 0%, [116] abdominal colectomy is associated with relatively disabling diarrhea in the elderly (in about 15%) and socially unsatisfactory diarrhea in a larger percentage. Thus, this extent of operation should not be undertaken lightly.

CHAPTER 88

Gail Hecht

BACTERIAL INFECTIONS OF THE COLON

Some clinical features of infectious colitis differ from those associated with infection of the small bowel. In general, colonic infections manifest as small volumes of diarrhea, usually less than 1 L/day, whereas small bowel infections induce larger volumes. Lower abdominal pain and tenesmus typify bacterial colitis, whereas central, crampy, abdominal pain suggests small intestinal infection. The presence of gross blood or mucus in the stool is indicative of bacterial or amebic co- litis, findings rarely associated with viral or bacterial infections of the small bowel. Acute inflammatory changes (e.g., erythematous, friable, ulcerated mucosa) associated with co- litis can be visualized by sigmoidoscopy or colonoscopy, but such changes are difficult to see with infection of the small bowel.

Individuals with bacterial colitis who seek medical attention tend to have more severe symptoms, such as bloody diarrhea, fever, and abdominal pain. Pathogens most typically associated with such clinical manifestations include *Campylobacter, Shigella* and *Salmonella* species, *Escherichia coli* O157:H7, and *Entamoeba histolytica.* In the face of this symptom complex, ulcerative colitis and, in older patients, acute ischemic colitis, must also be considered. The nonspecific nature of symptoms associated with infectious colitis requires that stool cultures and examination for parasites be performed to identify a specific pathogen. Colonic biopsies may be necessary to exclude the diagnosis of ulcerative or ischemic colitis.

Considered in this chapter are the five major bacterial pathogens that infect the colon: *Shigella* and *Campylobacter* species, *Clostridium difficile* enteroinvasive and enterohemorrhagic *E coli* and the bacterial and viral pathogens that cause anorectal disease, *Chlamydia trachomatis, Neisseria gonorrhoeae, Treponema pallidum* and herpes simplex virus (HSV) and human papillomavirus (HPV). This group of infections most typically occurs in homosexual men. Additional information regarding infections of the gastrointestinal tract can be found in Chapter 74 and Chapter 75.

SHIGELLA

Classification

The genus *Shigella* originally isolated and described by Shiga in 1898 [1], consists of four species or groups (A through D) of gram-negative, aerobic rods: *S dysenteriae* (group A), *S flexneri* (group B), *S boydii* (group C) and *S sonnei* (group D). Each species, with the exception of *S sonnei*, is divided into several serotypes, defined by the cell wall O antigen. Only *S flexneri* is further divided into subtypes. The distribution of *Shigella* species worldwide correlates with the level of development and hygiene, the basis of which is not understood. *S dysenteriae* a particularly virulent strain associated with significant morbidity and mortality, occurs in less developed countries and has pandemic potential. *S flexneri* is also most commonly isolated in developing countries, especially those with tropical climates. *S sonnei* which causes mild cases of watery diarrhea, accounts for most of the cases of *Shigella* infection in industrialized nations, including the United States and countries of western Europe. *S boydii* is rarely isolated.

Epidemiological Aspects

Shigella whose only reservoir is humans, typically causes bacillary dysentery. Although having a single reservoir should offer an advantage for control of infection, *Shigella* remains one of the most common causes of bloody diarrhea. This dilemma is likely explicable by its exquisitely low infecting dose. Transmission is person to person through contaminated hands, fomites, food, and water. [2] Contributing to its survival is the emergence of antibiotic-resistant strains. About 165 million cases of *Shigella* species infection are reported annually worldwide, [3] 163 million of which occur in developing countries. In the United States, about 15,000 cases are reported annually, [4] although the actual incidence is likely twice this number. An estimated 1.3 million deaths occur each year from *Shigella* species infection. [3] Most episodes of shigellosis occur in children younger than 5 years of age (69%), accounting for 61% of the deaths.

In industrialized countries, shigellosis is primarily a problem in subpopulations exposed to substandard hygienic practices (e.g., day-care centers, custodial institutions, and nursing homes). An outbreak of *S sonnei* infection was reported, however, in association with playing in a neighborhood park recreational spray fountain. [5] *Shigella* is a cause of traveler's diarrhea in 4% of adults returning from foreign travel with diarrhea. [6] Ingestion of contaminated food or water is the most common mode of transmission in developing countries.

Shigella is highly contagious, requiring a very small innoculum to establish infection. Ingestion of as few as 180 organisms induced diarrhea in 22% of healthy volunteers, [2] but ingestion of 10 [7] *Salmonella* species organisms resulted in an infection rate of only 50%. [7] *Shigella* persists as a pathogen because fecal organisms in patients suffering acute shigellosis are abundant (about 10 [9] per gram of stool), and they survive harsh environmental conditions for long periods.

Of greatest concern epidemiologically is *S dysenteriae* type 1, because of the severity of the associated clinical symptoms and potential for serious complications and the propensity of this strain to cause pandemics. In the face of emerging antibiotic resistance, these traits present a major health concern, [8] as highlighted by epidemics of resistant dysentery in Asia and Africa.

Pathogenesis

The pathogenesis of *Shigella* is multifactorial and includes the production of enterotoxins (important but not essential) and the organism's ability to invade and destroy host tissues, resulting in large part in the extensive inflammatory response associated with this infection. *Shigella* lipopolysaccharide may play a role in initiating inflammation by activating the inflammatory-associated transcription factor nuclear factor-?B (NF-?B). [9] About 30 gene products are involved in *Shigella* invasion and its intercellular spread, [10], [11] encoded on large virulence plasmids present in all *Shigella* species. [12] Some of these encoded proteins comprise a type III secretion apparatus, a multiprotein complex that allows direct delivery of bacterial proteins into host cells. Recognition of host cell components by bacterial sensors may trigger the secretion of bacterial factors through this apparatus. A complex series of host cell signals then ensues, ultimately resulting in bacterial invasion and spread. [10], [11] The ability of *Shigella* to invade and colonize the intestinal epithelium is crucial to the establishment of disease and associated morbidity.

Shigella species also elaborate toxins that play a role in disease, including enterotoxins, cytotoxins, and neurotoxins. The classic *Shigella* toxin, Shiga toxin (Stx), is produced by *S dysenteriae* type 1, although other strains likely produce similar toxins. The 70-kd Stx consists of one catalytic A subunit and five B subunits involved in binding the toxin to host receptors, a structure common to many bacterial toxins. The Stx receptor, globotriaosylceramide (Gb_3), is internalized by receptor-mediated endocytosis after toxin binding. [13] A role for this receptor-ligand interaction in *Shigella*-associated disease is suggested by the correlation between the number of receptors per cell and fluid secretion after Stx administration. [14] Once internalized, the catalytic A subunit is released, leading to cytotoxicity through inhibition of protein synthesis. The absorptive capacity of the intestinal epithelium is impaired, thus contributing to diarrhea. Stx does not activate adenylate or guanylate cyclase, as do other bacterial enterotoxins, but it is biologically similar to the Shiga-like toxins secreted by enterohemorrhagic *E coli.* Like those toxins, it can affect renal endothelial cells, resulting in hemolytic uremic syndrome (HUS).

Other *Shigella* enterotoxins have been identified. *Shigella* enterotoxin 1 (ShET1), a 55-kd holotoxin also of the A and B subunit structure, is unique to the *S flexneri* 2a serotype. As for Stx, the gene encoding this protein is also located within the chromosome. The presence of such a toxin was predicted by studies in monkeys showing that small intestinal secretion accounted for the watery diarrhea seen early in shigellosis. [15] ShET2, a 64-kd holotoxin expressed by 80% of diverse *Shigella* serotypes, also contributes to the watery diarrhea associated with infection. Unlike Stx and ShET1, the gene for ShET2 is carried on the large virulence plasmid that confers invasion. [16] Another *Shigella*-secreted protein, designated SigA, with both cytopathic and enterotoxic activity, has been reported. [17] SigA, a 103-kd product encoded within the chromosomal *she* pathogenicity island of *Shigella* has serine protease activity likely accounting for its toxic effects.

Invasion is more important than toxin production in shigellosis. [18] Infection of macaques with isogenic mutant strains of *S dysenteriae* that lacked either the invasion plasmid or the Stx gene showed that the invasive but nontoxigenic strain induced disease undistinguishable from wild-type *Shigella* except that the diarrhea in response to Stx-expressing strains was bloodier. A correlation between the level of Stx production and bleeding has been suggested in humans. [19]

The cardinal feature of *Shigella* is its ability to invade the host intestinal epithelium. This is initially achieved by invasion of M cells, specialized epithelial cells strategically positioned over lymphoid follicles. After entering M cells, the internalized organisms traverse these cells and emerge into the gut-associated lymphoid tissue of the terminal ileum and colon, where they are engulfed by macrophages. In contrast to the usual scenario whereby engulfed organisms are destroyed, *Shigella* organisms induce macrophage apoptosis, [20] releasing interleukin-1ß (IL-1ß), [21] thus recruiting neutrophils to and across the intestinal epithelial layer. Intercellular tight junctions are breached, and lumenally situated *Shigella* directly access the subepithelial space and basolateral pole of the host intestinal epithelial cell, the only membrane domain through which these microbes can invade. [22], [23] *Shigella* organisms disseminate intercellularly throughout the intestinal tissue and destroy the epithelium. This marked inflammatory cell infiltrate and tissue destruction characterize shigellosis.

Clinical Features

Most individuals infected with *Shigella* species have a benign, self-limited course lasting 5 to 7 days in adults and 2 to 3 days in children. Some adults, however, experience a subacute presentation characterized by 2 to 3 weeks of waxing and waning diarrhea. Such a presentation may mimic new-onset ulcerative colitis, especially because the endoscopic appearance of the mucosa is similar. In such cases, it is prudent to perform stool cultures; if *Shigella* is isolated, treatment with appropriate antibiotics should rapidly resolve the symptoms. A long-term carrier state for *Shigella* has been described, defined as fecal shedding after the resolution of symptoms from acute dysentery caused by *S sonnei* or *S flexneri* but this state appears to be rare. [24], [25]

Shigella dysentery is characterized by acute diarrhea containing blood and mucus and accompanied by fever and abdominal pain. The presentation may occur in two phases: the initial one characterized by the abrupt onset of frequent (every 20 to 30 minutes), watery diarrhea, followed by the second, or dysenteric, phase 12 to 72 hours later. In this phase, the passage of small amounts of blood-tinged mucus or blood clots occurs. About half of patients infected with *Shigella* experience bloody diarrhea, but the bleeding may be occult. Onset of fever occurs 1 to 3 days after infection, followed by abdominal cramps and diarrhea within 24 hours. In most patients, the diarrhea resolves after 7 days, although symptoms can persist for up to 30 days. A much more severe clinical course may be seen in children that includes fever, abdominal pain, malaise, vomiting, watery or bloody diarrhea, and tenesmus. [26] Patients experiencing more severe symptoms usually are malnourished or debilitated and without ready access to medical treatment.

The physical examination often reveals only lower abdominal tenderness, and bowel sounds are normal or increased. More alarming physical findings, such as rebound tenderness and ileus, are not typical of *Shigella* infection and should suggest an alternate diagnosis. Dehydration may occur in young children, especially with prolonged (48 hours) diarrhea and vomiting. Leukocytosis is unusual but is more likely to be seen in patients, both adults and children, with severe rectal histology. [27]

Confirmation of *Shigella* infection requires isolation and identification by stool culture. Stool cultures were positive as early as 3 days after oral challenge in volunteer studies and, if untreated, remained positive for an average of 27 days. [28], [29] Interestingly, not all patients with positive stool cultures suffered symptoms. Conversely, some volunteers with classic symptoms of *Shigella* dysentery had negative cultures; thus, a negative stool culture does not exclude the diagnosis. To optimize the isolation of *Shigella*, liquid stool specimens should be collected in a sterile container and inoculated promptly on media selective for *Shigella* and *Salmonella.* The presence of fecal leukocytes and erythrocytes greatly enhances the percentage of stool specimens that are positive for bacterial pathogens. Only 20% of stool cultures from adults with acute diarrhea were positive if performed nonselectively; however, the yield increased to 75% or greater if the specimen contained leukocytes. [30] A report of bloody diarrhea should also prompt a search for *E coli* O157:H7 and an examination of fresh stool to exclude *E histolytica* especially in patients with a history of foreign travel.

Complications

Shigella bacteremia is an uncommon but severe complication of *Shigella* dysentery, occurring most frequently in malnourished children, immunocompromised patients, and patients older than 65 years of age. *S flexneri* caused bacteremia in a middle-aged, immunocompetent women, [31] leading to the speculation that *Shigella* bacteremia may be underestimated because of failure to obtain blood cultures or prior administration of antibiotics. The mortality rate associated with *Shigella* bacteremia is high, about 20%, resulting from renal failure, hemolytic anemia, thrombocytopenia, gastrointestinal bleeding, and shock. [32]

Reiter syndrome, a triad of arthritis, urethritis, and conjunctivitis, most often complicates bacillary dysentery in men aged 20 to 40 years expressing the human leukocyte antigen (HLA)-B27 phenotype. About 1% to 2% of infected individuals develop Reiter syndrome, [25], [33], [34] 80% of whom are HLA-B27 positive. [34] Of the HLA-B27–positive individuals who suffer bacillary dysentery, about 20% develop Reiter syndrome.

The clinical presentation of Reiter syndrome can be quite variable, with mild forms being common [35] and genitourinary symptoms absent or minimal. Patients often present with asymmetric lower extremity arthritis or periarthritis 2 to 4 weeks after shigellosis or other bacterial dysentery. By this time, the intestinal symptoms have usually resolved, and antibiotic treatment is not indicated. The arthritic symptoms tend to be chronic and relapsing, even in the absence of dysentery. Reiter syndrome is therefore treated symptomatically with nonsteroidal antiinflammatory drugs.

HUS, most often associated with infection by enterohemorrhagic *E coli* that produces Shiga-like toxins (Stx1 and Stx2), is also a recognized complication of *S dysenteriae* infection. Shiga toxin and Stx1 of *E coli* are nearly identical structurally. HUS (microangiopathic hemolytic anemia, thrombocytopenia, and renal failure) is a direct result of Stx production. Stx gains access to the circulation and binds to tissues that express the Gb_3 receptor. In humans, renal tissue and endothelial cells

of the microvasculature express the highest concentration of Gb $_3$, accounting for the targeting of these tissues. Pathologically, the kidneys reveal microangiopathic damage and cortical necrosis secondary to thrombosed interlobular arteries. Since the 1960s, the mortality rate associated with HUS has dropped significantly, from 50% to less than 10%. [36] Still, about 30% of HUS survivors are left with permanent disabilities, including chronic renal insufficiency, hypertension, and neurological deficits. [37] Although other Stx-producing organisms cause HUS, infection with *S dysenteriae* type 1 is the most common cause in parts of Africa and Asia. [38], [39]

Treatment

Antibiotic treatment for shigellosis shortens the clinical course of illness and reduces the duration of fecal excretion of the organism. In otherwise healthy individuals, the diarrheal illness is often self-limited, lasting only 5 to 7 days, and therefore does not require antibiotic treatment. Antimicrobial therapy is recommended, particularly for elderly patients, malnourished children, patients with co-morbidities, those infected with the human immunodeficiency virus, health care workers, food handlers, and healthy children who attend day-care centers. In all cases, treatment of dehydration with either oral rehydration solution or intravenous fluids for mild to severe diarrhea is important. Antidiarrheal medications, on the other hand, have been shown to prolong symptoms and delay clearance of the organism and thus are not recommended. [40]

The antimicrobial treatment recommendations for shigellosis are rapidly changing as a result of the emergence of multidrug-resistant strains. Ampicillin had been an acceptable treatment option for shigellosis, but by 1990, [41] 32% of *Shigella* strains were resistant. Surveillance data from the United States in 1985 to 1986 found that only 7% of *Shigella* isolates were resistant to trimethoprim-sulfamethoxazole (TMP-SMX). [41] Therefore, TMP-SMX has been broadly endorsed for the treatment of shigellosis in the United States. [42], [43] and [44] Reexamination of TMP-SMX resistance in *Shigella* isolates in the United States showed that of 369 isolates collected between July 1995 and June 1998, [45] 59% were resistant to TMP-SMX, 63% were ampicillin resistant, 1% were cefixime resistant, and 0.3% were resistant to nalidixic acid. Multidrug resistance was identified in 13% of the isolates, but none of the isolates was resistant to ciprofloxacin. The increase in resistant *Shigella* isolates likely stems from imported cases or the induction of resistance after the introduction of new antibiotics. Based on these findings, the recommen-ded treatment options for shigellosis should be reconsidered (Table 88-1).

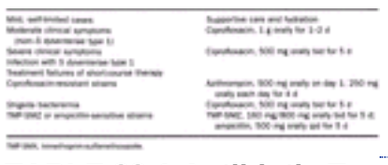

TABLE 88-1 Antibiotic Treatment Regimens for Adults with *Shigella* Infection

Many cases of shigellosis are self-limited and are easily managed with supportive care and hydration. Antimicrobial therapy should be reserved for the most severe cases and those warranting elimination of carriage as a public health priority. Ideally, selection of antibiotic therapy should be dictated by culture and antibiotic susceptibility data, but such testing requires at least 2 days. Therefore, antimicrobial choices are usually made empirically. TMP-SMX and ampicillin can no longer be regarded as appropriate empirical therapy for shigellosis, even in developed countries (see Table 88-1). For adults, quinolones provide effective therapy, [32] and ciprofloxacin, 500 mg orally twice each day for 5 days, led to the resolution or significant symptomatic improvement in 95% of patients with severe disease. [46] For mild infections, shorter courses of therapy may be adequate. Two consecutive 1-g oral doses are effective for strains other than *S dysenteriae* 1. [47] For *S dysenteriae* type 1 infections, however, treatment failures did occur with one- and two-dose regimens but not with the standard course of 500 mg twice per day for 5 days. [47] Azithromycin is an effective alternative to ciprofloxacin for resistant strains. The study from Bangladesh [46] demonstrated that azithromycin, 500 mg orally on day 1 followed by 250 mg per day for 4 days, was as effective (94%) as ciprofloxacin, 500 mg twice a day for 5 days (100%). Although concentrations of both of these drugs was 200 times greater in the stool than the minimum inhibitory concentration (MIC) for *Shigella* only ciprofloxacin reached a sufficient MIC in serum. Thus, ciprofloxacin is recommended in *Shigella* bacteremia. If sensitivity to TMP-SMX or ampicillin is demonstrated, the recommended doses are 160 mg/800 mg orally twice per day for 5 days and 500 mg orally 4 times per day for 5 days, respectively.

In children, the use of quinolones has been limited to compassionate use because of reports of arthropathic effects in the weight-bearing joints of immature animals. [48], [49] Data accumulated from hundreds of children who have received quinolones, however, failed to disclose arthropathies. [50], [51] and [52] A direct comparison of oral ciprofloxacin and intramuscular ceftriaxone as empiric therapy for acute diarrhea in children [53] showed ciprofloxacin to be safe and effective when administered as 10 mg/kg every 12 hours for 3 days. Nalidixic acid is also effective against shigellosis and is approved for use in children older than 3 months of age in the United States, but resistance develops rapidly. [54], [55]

CAMPYLOBACTER

Campylobacter species were not recognized as important human pathogens until the late 1970s. [56] *Campylobacter jejuni* and *Campylobacter coli* have now emerged as the most common bacterial enteropathogens in developed countries, [57] including the United States. [58] The Centers for Disease Control and Prevention (CDC) estimated that *C jejuni* was responsible for nearly 2 million illnesses in the United States in 1999, composing 14.2% of all food-borne infections, making *C jejuni* the leading cause of bacterial diarrhea in the United States, [58], [59] exceeding *Salmonella* species. The actual number of cases is estimated to be 30 to 40 times the reported number. [58]

Of the 18 species and subspecies of *Campylobacter, C jejuni, C coli, C lari, C upsaliensis, C hyointestinalis, C concisus, C mucosalis* and *C fetus* are confirmed pathogens of the human gastrointestinal tract. Of these, *C jejuni, C coli* and *C fetus* are most commonly associated with human disease, although newer diagnostic techniques have identified *C hyointestinalis, C concisus* and *C upsaliensis* at an increasing rate. [59], [60] In clinical laboratories, *Campylobacter* organisms are not routinely identified at the species level.

Campylobacter organisms are long (0.5 to 5.0 µM), gram-negative rods that are curved, S shaped, or spiraled. Isolation of this organism from stool is enhanced by immediate transfer into special transport medium and inoculation onto plating medium. If necessary, samples can be held at 4°C in transport medium for up to 24 hours.

Epidemiology

Foods of animal origin are the most common source of pathogenic *Campylobacter* species infection because the organisms colonize the gastrointestinal tracts of many animals, including chicken, lamb, pig, ox liver, [61] and cows. [62] Meats from retail outlets in the United Kingdom that were screened for the presence of *Campylobacter* revealed that various species were isolated from 73% of samples examined. [61] The highest contamination rate (14% to 98%) was found in chicken. [63], [64] Infection may also be acquired from contaminated water, unpasteurized milk, or direct contact with infected humans or pets. [57] Most cases of *Campylobacter* infection are sporadic and unrelated to outbreaks, making identification of the source difficult. The ingestion of undercooked poultry was responsible for 10% to 50% of *Campylobacter* species infections in case-controlled studies. Freezing diminishes the organism's viability. *Campylobacter* is also a cause of traveler's diarrhea. Seasonal variation of infection occurs in the United States and other temperate countries, with few infections occurring between January and April, a marked increase in May and June, and peak incidence in July and August, followed by a sustained plateau. [57]

Pathogenesis

The pathogenic mechanisms for the symptoms associated with *Campylobacter* infection remain undefined. Four major virulence properties of *C jejuni* and *C coli* have been recognized: motility, adherence, invasion, and toxin production. [65] Motility moves the organism near host cells so that it can attach and invade. Although the role of flagella in invasion is not defined, they are equired for this property. [65] Adherence of *Campylobacter* to host intestinal epithelial cells permits colonization, enhancing the concentration of secreted factors encountered by these cells. Adherence is presumed to be a prerequisite for invasion. The rate of invasion by

Campylobacter species varies considerably [66] but may be as low as 1% of the initial inoculum, [67] and intracellular killing of organisms occurs. [68] Thus, toxin production may be the most important pathogenic factor.

Campylobacter species produce several different toxins, including cytotoxins and possibly an enterotoxin. Controversy surrounds the production of a cholera toxin–like enterotoxin by *Campylobacter* species and its potential role in pathogenesis. [65] Although functional studies suggest that *C jejuni* and *C coli* may express a cholera toxin–like enterotoxin, no genes with cholera toxin similarity were identified on sequencing of the *C jejuni* genome. [69] *Campylobacter* species can produce several distinct cytotoxins, [65] and the best defined is the multisubunit cytolethal distending toxin (CDT). This toxin, clearly an important virulence factor, causes cell cycle arrest leading to a characteristic elongation and swelling of susceptible cells. Although intoxicated cells remain viable for prolonged periods of time (up to 72 hours), they eventually die. One of the subunits, CdtB, possesses DNase activity and induces DNA damage, ultimately leading to cell death. [70], [71] The role of CDT in *Campylobacter* pathogenesis is unclear. Other organisms, including pathogenic *E coli, Shigella* species, and certain *Helicobacter* species also express CDT, but the contribution of CDT to intestinal fluid secretion associated with infection by these strains is variable. *E coli* CDT failed to stimulate intestinal secretion in rabbit ileal loops, [72] but CDT from *S dysenteriae* induced intestinal fluid secretion and tissue damage in the suckling mouse. [73]

Clinical Aspects

The infective dose of *C jejuni* is as little as 500 organisms, [74], [75] suggesting that this pathogen, like *Shigella* species and *E coli* O157:H7, possesses mechanisms of protection against gastric acid. However, suppression of gastric acid by inhibiting the proton pump doubles the risk for *Campylobacter* species infection. [76] The typical course of infection is depicted in Figure 88-1. The incubation period is 18 hours to 8 days (average, 3.2 days). [77] Onset of symptoms may be abrupt, with abdominal cramps followed by diarrhea or a prodrome of fever, headache, malaise, and myalgia. Febrile-associated rigors occur in up to 22% of cases. When this influenza-like prodrome persists for 2 to 3 days in the absence of gastrointestinal symptoms, it predicts a more severe form of the infection. *Campylobacter*-associated diarrhea (up to 10 stools per day) is watery initially and progresses to bloody diarrhea after 1 to 2 days in about 15% of patients. [77] This may indicate extension of infection, with the endoscopic appearance in the colon ranging from mild hyperemia to severe mucosal destruction with friable, edematous, and even ulcerated epithelia. Histologically, acute inflammation predominated by neutrophils and crypt abscesses is seen. The absence of distorted crypts and a normal mucous cell population may aid in differentiation from inflammatory bowel disease (IBD) (Table 88-2). With chronic infection, however, the distinction becomes less clear. Further blurring of the boundary between *Campylobacter* species infection and IBD is the potential for relapse of the *Campylobacter* infection, reported in 15% to 25% of patients, and the possibility that IBD patients may be infected with *C jejuni*.

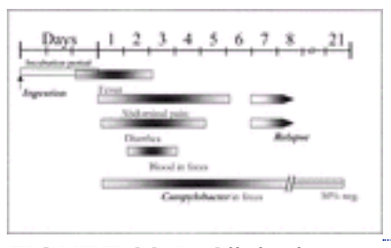

FIGURE 88-1. Clinical course of *Campylobacter* species infection. (Redrawn by V. K. Viswanathan; from Greenwood D, Slack R, Peutherer J, eds. Medical microbiology. 15th ed. 1997, Edinburgh: Churchill Livingstone, 1997.)

TABLE 88-2 Comparison of Histological Features that Help to Differentiate *Campylobacter* and Other Infectious Causes of Proctocolitis from Acute Infammatory Bowel Disease

The abdominal pain associated with *Campylobacter* infection may be sufficiently severe and localized to mimic appendicitis. This is usually caused by terminal ileitis and mesenteric adenitis, but true appendicitis may be present, and *Campylobacter* has been isolated from inflamed appendices. [78] Other symptoms include nausea and vomiting (15% of patients) and significant weight loss of up to 5 kg. Although most patients begin to improve after 3 to 4 days, they may excrete organisms for an extended period (mean, 37.6 days; maximum, 69 days). [79]

Antibodies against *Campylobacter* antigens can be detected in the serum at about day 5, with peak levels appearing within 2 to 4 weeks. [74] Short-term immunity to homologous strains is provided, but the duration and breadth of protection are undefined. The incidence and severity of *Campylobacter* infection decrease in at-risk groups over time, suggesting some level of long-term protection. Anti- *Campylobacter* antibodies have been reported in intestinal secretions. [79]

Complications

Intestinal and extraintestinal complications of *Campylobacter* infection have been reported. Intestinal complications include hemorrhage, [80] ulceration of ileostomy stomas, [81], [82] and toxic megacolon. Extraintestinal complications include erythema nodosum, [83] urticaria, [84] bacteremia, [85] cholecystitis, [86] pancreatitis, [87] abortion, [88] HUS, [89] and nephritis. [90] More commonly occurring complications, however, are reactive arthritis, Reiter syndrome (for which HLA-B27 tissue antigen gives a strong predisposition), and Guillain-Barré syndrome (GBS).

GBS is defined by flaccid paralysis, areflexia, and albuminocytological dissociation in the spinal fluid. It is caused by autoimmune-induced inflammation of peripheral nerves that disrupts their function. GBS is the leading cause of acute paralysis, although its incidence is only 1 to 2 per 100,000. [91] One third of GBS patients have either positive stool cultures or antibodies to *C jejuni* antigens. [92] Serum antibodies to *C jejuni* lipopolysaccharide share antigenic determinants with peripheral and central nervous system gangliosides. Because antiglycoconjugate antibodies are present in GBS patients, molecular mimicry of neural oligosaccharides by microbial pathogens may underlie GBS pathogenesis.

Diagnosis and Treatment

Definitive diagnosis of *Campylobacter* infection can only be made bacteriologically. Because diagnosis is delayed using this approach, rapid detection methods are being developed, including enzyme immunoassays of stool specimens, [93], [94] DNA probes, and polymerase chain reaction (PCR).

Besides oral rehydration, no specific therapy is required for most patients because symptoms are usually resolving by the time a confirmed diagnosis is made. Patients with severe dysentery, relapsing symptoms, systemic infection, or immunosuppression and those who are institutionalized, however, may benefit from antibiotic treatment. *C jejuni* and *C coli* are widely resistant to penicillins, cephalosporins, trimethoprim, sulfamethoxazole, rifampin, and vancomycin. [95] Erythromycin is usually the drug of choice for *Campylobacter* infection when antibiotic therapy is indicated. Resistance rates of *C jejuni* to erythromycin range from 0% to 11% but trend higher (0% to 68%) for *C coli.* In Thailand and Sweden, however, resistance to erythromycin is on the rise. [96], [97] The recommended dose of erythromycin is 500 mg twice daily or 250 mg four times per day for 5 days. Erythromycin stearate, which is acid resistant, stable, and incompletely absorbed, may offer a treatment advantage, but clinical evidence of superiority is lacking. Erythromycin ethyl succinate, 40 mg/kg/day in divided doses for 5 days, is the recommended treatment for children. When resistance or other reasons preclude the use of erythromycin, tetracyclines and chloramphenicol are reasonable alternatives, although the prevalence of tetracycline resistance is about 60%. Resistance rates of *Campylobacter* to fluoroquinolones are in the range of 41% to 88% in Europe and Asia. [98], [99] Although

quinolone resistance in the United States has increased more slowly, it is also on the rise, increasing in Minnesota from 1.3% in 1992 to 10.2% in 1998. [100] Similar rates of resistance have been reported in Canada. [101] This trend likely reflects acquisition of resistant strains from extensive antibiotic use, overseas travel, or poultry treated with fluoroquinolones. Azithromycin, 500 mg daily for 3 days, is an effective alternative in areas where fluoroquinolone resistance is high. [102] For systemic infection, an aminoglycoside, such as gentamicin or imipenem, may be warranted; simultaneous administration of oral erythromycin may aid in eradicating the intestinal infection.

CLOSTRIDIUM DIFFICILE

Although *Clostridium difficile* initially called *Bacillus difficile* because of its difficulty in culturing, was discovered in 1935, [103] it was not until 40 years later that Bartlett and colleagues identified that the cytotoxins of this organism were the cause of antibiotic-associated pseudomembranous colitis. [104] *C difficile* is a gram-positive, anaerobic rod that is fastidious in its vegetative state but sporulates in conditions that fail to support its growth. The ability of *C difficile* to sporulate allows it to persist for long periods in harsh environments, including dry surfaces and soil. This capacity for survival contributes to making *C difficile* the number-one cause of health care–associated diarrhea. [105] In addition, hospitals and long-term health care facilities are often reservoirs of this pathogen because establishment of infection is usually dependent on disruption of the indigenous intestinal microflora by antibiotic therapy. Although this organism is isolated from the stool of less than 3% of healthy individuals, it is found in about 20% of those hospitalized for longer than 1 week. [105], [106] *C difficile* can be cultured from the stool of up to 80% of healthy neonates and infants but fails to produce symptoms, possibly owing to lack of expression of receptors for the toxins (A and B) responsible for tissue damage.

Epidemiology

C difficile is the most common cause of nosocomial diarrhea, with an incidence ranging from 20 to 60 cases per 100,000 patient days. [107], [106] The incidence of hospitalization and death due to diarrhea caused by this organism may be increasing. [108] In contrast, the incidence of community-acquired *C difficile*–associated diarrhea is only 7.7 cases per 100,000 person-years of observation. [109] Although *C difficile*–associated diarrhea is rare in outpatients, this may in part reflect inadequate diagnostic efforts in patients receiving antimicrobials. An educational program that encouraged testing for *C difficile* in outpatients with diarrhea increased the rate of detection from 2.6% to 10.7%. [110]

There are three major risk factors associated with *C difficile* diarrhea. The first is exposure to antimicrobials. Antibiotics disrupt the normal colonic flora, allowing colonization after the patient is exposed to the organism or its spores. Clindamycin is highly associated with *C difficile* disease, and its removal from hospital formularies has controlled outbreaks. [111] Other antibiotics, especially ampicillin and cephalosporins, often predispose to *C difficile* infection, whereas others, such as parenteral aminoglycosides, vancomycin, and metronidazole, are less frequently implicated. For unclear reasons, third-generation cephalosporins are more highly associated with *C difficile* infection than are other broad-spectrum agents. [112]

The second risk factor is hospitalization. There is a direct correlation between length of hospital stay and percentage of patients infected. Among patients hospitalized for longer than 4 weeks, 50% acquired *C difficile.* [113] *C difficile* has been isolated from numerous sites within hospital rooms, including telephones, call buttons, bed rails, toilets, and bathroom floors, and from stethoscopes and the hands of health care workers. [106], [114] Patient-to-patient spread also occurs, particularly if a room is shared with an infected patient. [114]

Although antibiotic administration and hospitalization are essentially required for *C difficile* infection, most patients exposed to these two risk factors do not manifest symptoms. A third, but ill-defined, factor is needed. This may be host immunity because patients with *C difficile* diarrhea, versus colonization, generate lower levels of antibodies against *C difficile* and its toxins. [115] Other possible factors include host susceptibility and strain virulence.

Outbreaks of *C difficile*–associated diarrhea within hospitals are often due to a single strain or related group of strains. Three large outbreaks in geographically diverse areas were attributed to a single strain. [116] Some strains may have disseminated across different countries and continents, as determined by the collaborative international typing study. [117]

Pathogenesis

The pathogenesis of *C difficile* colitis is largely the result of the production and secretion of two potent toxins, A and B. [118], [119] These toxins are high-molecular-weight proteins, 308 and 270 kd, respectively, that enter the intestinal epithelial cells through specific, but as yet unidentified, receptors expressed on the apical surface. Once inside the host cell, these distinct yet highly homologous (49% amino acid identity) toxins exert similar biochemical effects, by inactivating Rho proteins (a family of small guanosine triphosphate–binding proteins) that regulate actin polymerization. Rho inactivation is accomplished by toxin-induced glucosylation of a specific threonine residue of the Rho proteins, such as Rho $_{ABC}$, Rac, and Cdc 42. [120], [121] This modification leads to the depolymerization of actin filaments, cytoskeletal collapse, and the characteristic-cell rounding that is the basis of the diagnostic tissue culture assay for *C difficile* toxin. The physiological effects on the intestinal epithelial cell are an increase in tight junction permeability [122], [123] and fluid secretion. [124], [125] In addition to the direct effects of toxins A and B on intestinal epithelial cells, a profound inflammatory response is elicited, contributing further to disruption of the tight junction barrier and increased lumenal fluid. Although most investigations have focused on toxin A, a study using human tissues demonstrated colonic damage in response to both. [125]

The marked inflammation associated with *C difficile* infection is a multifactorial response. One early event is activation of the inflammation-associated transcription factor NF-?B, which increases expression of many proinflammatory cytokines, including IL-8, [126] tumor necrosis factor-a, prostaglandin E $_2$, and leukotriene B $_4$. [127] Inhibitors of cytokine synthesis attenuate toxin A effects. [127] Toxin A can also cause monocytes to release IL-1ß and IL-6 [128] and neutrophils to be recruited to the intestine. [129] Inhibition of neutrophil infiltration of the intestine by specific antibodies [129], [130] or induction of neutropenia significantly reduced fluid secretion. [131] Inhibition or depletion of mast cells attenuated neutrophil activation and fluid secretion. [132], [133] These effects may follow an initial disruption of the intestinal epithelial barrier, allowing direct interactions between toxin A and the inflammatory cells residing within the lamina propia.

Enteric nerves and neuropeptides are involved in *C difficile*–associated disease. Substance P expression by nerve cells in spinal dorsal root ganglia is immediately up-regulated after exposure of the intestine to toxin A. Substance P binds to neurokinin-1 receptors that are expressed by macrophages, releasing tumor necrosis factor-a, a potent cytokine. [134] Neurokinin-1–deficient mice show a diminished response to intestinal toxin A. [135] Neurotensin (NT) is also involved in *C difficile* colitis. [136] Both NT and substance P receptors, whose expression is NF-?B dependent, are markedly up-regulated within 15 to 30 minutes of toxin A exposure. An NT receptor antagonist reduced the intestinal effects of toxin A, including mucosal mast cell activation. [136]

Immunity

Hospitalized patients receiving antibiotics but not colonized with *C difficile* showed no immune protection against *C difficile* colonization. [115] After colonization, high serum immunoglobulin G (IgG) levels against toxin A strongly correlated with asymptomatic carriage of *C difficile* whereas those with low serum levels of toxin A IgG antibody had a much greater risk for *C difficile* diarrhea. There was an eight-fold increase in the risk for *C difficile* diarrhea in patients with severe disease, defined using a modified Horn's index. [137] These data support the development of passive or active immunization strategies to control nosocomial *C difficile* diarrhea.

Clinical Features

The clinical manifestations of *C difficile* infection are broad, encompassing a carrier state devoid of symptoms, colitis without or with pseudomembranes, and fulminant colitis with megacolon or perforation. Antibiotics commonly cause diarrhea independent of *C difficile* infection. The mechanisms underlying the broad range of symptoms associated with *C difficile* are unclear but are likely attributable to host rather than bacterial factors and include toxin receptor density, status of the resident intestinal flora, and concentration of antibodies against bacterial or toxin antigens. Symptoms resulting from *C difficile* infection typically begin 4 to 9 days after initiation of antibiotic therapy, but diarrhea can develop even after antibiotic treatment has been halted in up to 30% of patients. This delay complicates the diagnosis of *C difficile*–associated diarrhea unless the clinician is aware of this scenario.

Antibiotic-associated, Non– *Clostridium difficile* Diarrhea The occurrence of mild diarrhea during antibiotic therapy is not uncommon, and only a minority (about

20%) [138] of these cases is due to *C difficile* infection. In general, antibiotics interfere with the digestion of carbohydrates by eliminating colonic bacteria that metabolize this energy source. Decreased carbohydrate metabolism can then lead to osmotic diarrhea, diminished production of short-chain fatty acids, and disruption of water and electrolyte absorption. [139] In these cases, evidence of *C difficile* infection is absent, and the colonic mucosa appears normal or mildly hyperemic. Discontinuation of antibiotics resolves the symptoms.

Asymptomatic Carriage of *Clostridium difficile* Although hospitalization is a risk factor for infection with *C difficile* most of these patients are free of symptoms, [106], [114] that is, are asymptomatic carriers. This subset of *C difficile*–infected individuals serves as a reservoir of this organism and thus contaminates the hospital environment. Asymptomatic carriers should not, however, be treated with antibiotics because this may prolong the carrier state.

Non-pseudomembranous *Clostridium difficile* Colitis About half of patients with diarrhea who are confirmed as positive for the *C difficile* organism or toxin have clinical symptoms similar to but less severe than those associated with pseudomembranous colitis. Typical manifestations include abdominal pain, cramps, watery diarrhea, malaise, nausea, and possibly dehydration and fever. Laboratory tests commonly reveal a neutrophilic leukocytosis. In fact, the sudden onset of leukocytosis in hospitalized patients with a history of, or currently receiving, antibiotics should immediately trigger testing for *C difficile* infection. [140] Sigmoidoscopy may show only friable and erythematous mucosa but no pseudomembranes.

Pseudomembranous Colitis Pseudomembranous colitis is the prototypic entity associated with *C difficile* infection. Symptoms, including diarrhea and abdominal pain, usually begin within 1 week of antibiotic administration but may not appear until even 6 weeks after antibiotics have been discontinued. [141], [142] Fever, chills, nausea, vomiting, dehydration, and tenesmus may accompany the diarrhea and lower abdominal cramping. Physical findings are nonspecific and include diffuse abdominal tenderness and distention. Occult blood may be present in the stool, but hematochezia is rare. Fecal leukocytes are detected in about half of patients, but peripheral leukocytosis is common and may serve as a surrogate marker of this infection. [140] Three patterns of leukocytosis have been reported: a sudden increase in the white blood cell (WBC) count correlating with symptoms of *C difficile* co- litis; leukocytosis preceding *C difficile*–associated symptoms; or exacerbation of preexisting leukocytosis plus nonspecific symptoms of *C difficile* disease. [140] In the last two scenarios, the diagnosis of *C difficile* colitis is generally delayed. Consideration of *C difficile* infection as a cause of unexplained leukocytosis is therefore recommended. Although not usually necessary, the diagnosis of pseudomembranous colitis can be confirmed rapidly by sigmoidoscopy. Characteristic yellow-white, raised plaques about 2 to 10 mm in diameter are seen (Fig. 88-2). These small plaques may coalesce and cover the entire mucosa. Microscopic analysis of biopsy samples from pseudomembranes shows the typical ummit or "volcano" lesion in which inflammatory cells, fibrin, and mucus exude from microulcerations in the surface epithelium (see Fig. 88-2). Although sigmoidoscopy usually reveals such findings in up to 30% of patients, pseudomembranes can be restricted to the more proximal colon. [143] Colonoscopy is not recommended, however, unless other diagnostic measures have failed.

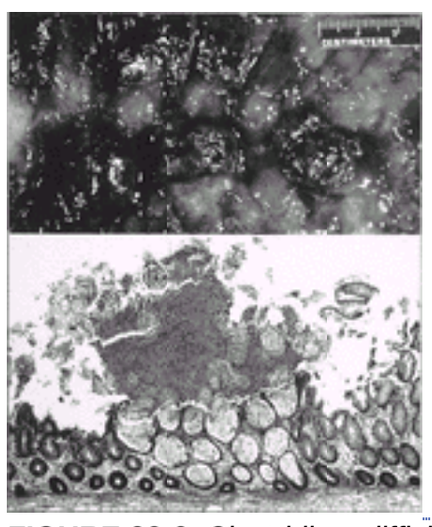

FIGURE 88-2. *Clostridium difficile* pseudomembranous colitis. The gross photo (*upper panel*) shows the severe, nearly confluent light-colored pseudomembranes that are typical of severe *C. difficile* pseudomembranous colitis. The pseudomembranes are composed of purulent debris and contrast sharply against the edematous surrounding dark-colored mucosa. The photomicrograph (*lower panel*) shows a classic type II volcano-like eruption with a mushroom-shaped cloud of adherent of inflammatory exudate. (Courtesy of Dr. Jerrold R. Turner, M.D., Ph.D., The University of Chicago, Chicago, IL).

Fulminant Colitis In fulminant *C difficile* colitis, transmural inflammation can lead to the most serious complications associated with this infection. These include ileus, perforation, megacolon, and even death [144] and occur in about 3% of patients. Fulminant colitis may present acutely or develop over the course of a milder infection. The symptoms are typically more severe with signs of toxemia, constant and localized abdominal pain with guarding, and decreased bowel sounds. Fever, tachycardia, and ascites may also be present. Severe leukocytosis (up to 40,000 WBCs/µL) can occur. Hypoalbuminemia may result from severe protein-losing enteropathy. [138] Diarrhea may actually decrease in the absence of clinical improvement, as a result of acute colonic dilation and paralytic ileus. The diagnosis of toxic megacolon is defined as dilation of the colon to more than 7 cm and severe toxemia, manifested as fever, chills, leukocytosis, and dehydration. A kidney-ureter-bladder radiogram can reveal a dilated colon (Fig. 88-3), and thickening of the colonic wall can be seen by computed tomography. Dilation of the small bowel with air-fluid levels may accompany the large bowel findings, thus mimicking intestinal obstruction or ischemia. [138] In the presence of perforation, abdominal guarding, rebound tenderness, rigidity, and diminished bowel sounds are typically seen. The presentation of acute abdomen in a patient with a history of current or recent antibiotic therapy mandates the urgent exclusion of *C difficile* colitis to prevent unnecessary surgical intervention. [145] In such cases, a limited and cautious endoscopy with minimal air introduction should be considered. The finding of pseudomembranes will establish the diagnosis of *C difficile* colitis. If, however, more severe signs, such as extreme leukocytosis (more than 30,000 to 80,000 WBCs/µL), hypotension, or metabolic acidosis are present, laparotomy and colectomy may be indicated as treatment for impending or existing colonic perforation. [145], [146]

Diagnosis

Unlike the diagnostic strategy for other enteric pathogens, stool culture for *C difficile* is not used because both toxigenic and nontoxigenic strains are detected by culture and high rates of isolation require strict anaerobic precautions. Isolates must then be tested for toxin production, delaying the diagnosis even further. Instead, the gold standard for diagnosing *C difficile* infection is a tissue culture assay for the presence of toxins A and B in the stool. [147], [148] Diarrheal stool is filtered and applied to cultured human fibroblasts that are examined 24 to 48 hours later for cytotoxic effects (cell rounding or detachment). Incubating the stool sample with a neutralizing antitoxin antibody and assessing for protection against cytotoxic changes confers specificity. Test results are reported as positive or negative because titers have no correlation with disease activity. [148] Although this test is highly sensitive (94% to 100%) and specific (99%), [142] it is expensive and is often not performed on site; thus, the incubation period is prolonged. Because both toxins A and B possess cytotoxic activity, this assay detects both. On a molar basis, however, toxin B

is much more potent than toxin A; thus, the stool cytotoxic effect is primarily due to toxin B.

Several enzyme-linked immunosorbent assays are now available for detecting *C difficile* toxins.[149] Although these tests are less sensitive than the cell culture assay, they are equally specific (99%), provide same-day results, and are currently used by most hospital laboratories. Sigmoidoscopy and colonoscopy are not required to diagnose *C difficile* colitis. If a rapid diagnosis is required, such as in an acutely ill patient, or if the diagnosis is in doubt, these tests can be performed, and the presence of pseudomembranes (see Fig. 88-2) essentially establishes the diagnosis of *C difficile* colitis.

Treatment

C difficile–associated colitis is a consequence of antimicrobial therapy; therefore, the first step in treatment is discontinuation of such drugs. This is sufficient to resolve symptoms in 15% to 23% of patients,[150] but those who do not respond require specific antibiotic treatment. Metronidazole and vancomycin are the mainstays of therapy for *C difficile* colitis. Metronidazole is the initial drug of choice because of its lower cost, excellent clinical efficacy, and rising concern regarding glycopeptide resistance in other organisms such as enterococci. The recommended dosage is 250 mg four times per day or 500 mg three times per day for 10 days. The efficacy of this therapy is greater than 95%.[151] Symptomatic improvement is typically seen within 2 to 3 days and resolution by 7 to 10 days.[152] Although metronidazole is absorbed, it accesses the colonic lumen by diffusing from the blood across the inflamed intestinal mucosa where permeability is enhanced. Excretion into bile also contributes to the intestinal concentration.[153] Metronidazole causes a metallic taste, induces alcohol intolerance, and may cause nausea.

Oral vancomycin, 125 mg four times daily for 10 days, was the initial drug of choice for treating *C difficile* colitis and has equal or better efficacy than metronidazole.[154] It is not well absorbed, accounting for high fecal levels and rare side effects. Expense and the emergence of resistant organisms have led to vancomycin being recommended for patients who have failed metronidazole treatment or are intolerant of this drug.[155] For severe or fulminant pseudomembranous colitis, however, initial treatment with vancomycin is recommended. The rationale is the superb delivery of vancomycin to the colon and a slightly, but potentially important, better efficacy in the treatment of pseudomembranous colitis.[152] In the case of ileus or toxic megacolon, however, intravenous metronidazole, 500 mg every 6 hours, should be given either alone or possibly in combination with vancomycin administered by nasogastric tube or rectally. Intravenous vancomycin has no role in the treatment of *C difficile* colitis.

Relapsing *Clostridium difficile* Colitis A minority (5% to 30%) of patients develop recurrent symptoms 1 to 2 weeks after the discontinuation of antibiotics for *C difficile* treatment[151] due either to relapse from the original infecting organism or reinfection by a different strain, especially if the patient remains in the hospital environment. A screen of 93 hospitalized patients with recurrent *C difficile* diarrhea revealed that nearly half (48%) of these cases were due to reinfection with a different strain.[156] Because recurrence of *C difficile*–associated diarrhea is not a result of antimicrobial resistance,[150] the first approach should be to administer another 10- to 14-day course of the antibiotic used initially. If only mild diarrhea is experienced, consideration should be given to symptomatic treatment without antibiotics. For multiple relapses, various treatment options exist (Table 88-3). The first is a 4-week course of either metronidazole or vancomycin or a tapering schedule of vancomycin over a several-week period (see Table 88-3). This regimen was curative in all patients tested, with no relapses seen during a 2- to 12-month follow-up.[157] An anion-binding resin, such as cholestyramine, 4 g given twice daily, which theoretically binds the toxins of *C difficile* may be added to this regimen. Patients must not take cholestyramine and vancomycin simultaneously, but should separate the doses by 3 hours, because the resin can bind and neutralize the antibiotic. The combination of vancomycin, 125 mg four times daily, plus rifampin, 600 mg twice daily, for 1 week has also proved effective for relapses.[158]

First relapse
- Symptomatic treatment only if diarrhea is mild
- 10- to 14-day course of metronidazole or vancomycin if symptoms are more severe or persistent

Second relapse:
- Vancomycin taper
  - 125 mg/6 h for 7 d
  - 125 mg/12 h for 7 d
  - 125 mg/d for 7 d
  - 125 mg every other day for 6 d (i.e., 3 doses)
  - 125 mg every 3 d for 9 d (i.e., 3 doses)

Other reported treatments for multiple relapses:
- Vancomycin in tapering dose as above plus cholestyramine 4 g bid
- Oral *Saccharomyces boulardii* in combination with metronidazole or vancomycin
- Vancomycin, 125 mg qid, and rifampicin, 600 mg bid for 7 d
- Intravenous immunoglobulin.

TABLE 88-3 Suggested Approach to Recurrent *Clostridium diffcile* Diarrhea and Colitis

More novel strategies for the treatment of *C difficile* infection are being developed.[159] *Saccharomyces boulardii* a nonpathogenic yeast, has been used to prevent antibiotic-associated diarrhea.[160] *S boulardii* also decreased significantly the number of relapses in patients treated with high-dose vancomycin (2 g/day), but not 500 mg/day or metronidazole (1 g/day) for 10 days.[161] Other strategies to reestablish normal flora include the administration of *Lactobacillus* species and rectal infusions of feces preceded, or not, by bowel irrigation.[162] Intravenous immunoglobulin and passive oral immunotherapies, such as bovine colostrum from cows immunized with *C difficile*, have produced increased serum antitoxin levels or resolution of symptoms.[163], [164] and [165]

Prevention and Control

Guidelines for the prevention and control of *C difficile* infection have been published by the American College of Gas- troenterology[155] and the Society for Healthcare Epidemiology of America[151] (Table 88-4). Because the most likely method of transfer of *C difficile* to patients is by means of the hands of health care workers, good hand-washing technique is the most important step in decreasing infection. Wearing gloves when handling *C difficile*–infected patients or working in their environment may further reduce transmission. The use of chlorine-containing disinfectants (1:100 dilutions or unbuffered hypochlorite or phosphate-buffered hypochlorite [1600 ppm]) decreases significantly environmental contamination.

TABLE 88-4 Practice Guidelines for the Prevention and Control of *Clostridium difficile* Infection

PATHOGENIC *ESCHERICHIA COLI* THAT CAUSES COLITIS

Of the five major classes of pathogenic *E coli* enterotoxigenic, enteropathogenic, enteroaggregative, enteroinvasive, and enterohemorrhagic,[166] only the last two groups primarily affect the colon. The symptoms associated with infection by these pathogens are similar to those seen in shigellosis. Enteroinvasive *E coli* (EIEC) carries the same large virulence plasmid that confers the invasive phenotype to *Shigella* strains.[167] Enterohemorrhagic *E coli* (EHEC) expresses Shiga-like toxins that are structurally similar to Shiga toxin and whose role in the development of HUS has been clearly established.

Enteroinvasive Escherichia coli

The first report of an invasive strain of *E coli* causing disease was associated with a food-borne outbreak.[168] EIEC is now recognized as a rare cause of traveler's diarrhea, usually transmitted through contaminated food.[169] The primary virulence factor of EIEC is its ability to invade. The genes required for this event are encoded on a large 140-megadaltons (MDa) virulence plasmid, identical to that possessed by *Shigella.*[167] Hence, the stages of EIEC entry into cells are essentially the same as for *Shigella:* attachment to cells, invasion of cells, intracellular multiplication, intercellular spread, and killing of host cells. Because invasion is the major virulence

factor of *Shigella* and EIEC, the associated clinical features closely resemble each other, that is, typical signs and symptoms of dysentery.

Laboratory identification of EIEC, however, is much more difficult than for *Shigella* because biochemical reactions used to distinguish many enteric pathogens, such as inability to ferment lactose and classic serotypes, are either variable or lacking. Although molecular approaches such as DNA probes and PCR can identify EIEC, [169] these methods are not widely used or available in the clinical setting. This limitation is of little consequence clinically because EIEC generally causes a milder illness than *Shigella* and treatment is guided by clinical symptoms.

As for most enteric infections, the first step in management is fluid and electrolyte replacement. Although antibiotics are usually not needed for EIEC infection, no clinical trials comparing antibiotic regimens have been performed. If clinically indicated, antimicrobial recommendations for the treatment of shigellosis can be applied to EIEC infection. It is not known whether antibiotic resistance data for *Shigella* species can be extrapolated to EIEC. In the absence of clinical trials, a reasonable empirical approach is treatment with either TMP-SMX 160 mg/800 mg twice per day, ampicillin, 500 mg four times per day, or cipro-floxacin, 500 mg twice per day for 5 days.

Enterohemorrhagic Escherichia coli

Infection with enterohemorrhagic *E coli* (EHEC) O157:H7 is a major health concern in the United States. EHEC strains, most notably O157:H7, cause severe morbidity and mortality in humans. Since its identification in 1982, more than 100 outbreaks have been reported. [170]

Epidemiology Before 1982, only one O157:H7 strain had been isolated by the CDC from a patient with bloody diarrhea. [171] Soon after, two major outbreaks were reported in those who had consumed hamburgers obtained from a single fast-food restaurant. [171] In 1999, the CDC estimated that *E coli* O157:H7 caused 73,000 illnesses and 60 deaths in the United States alone. Non-O157:H7, Stx-expressing *E coli* added another 37,000 estimated cases. [172] EHEC most commonly infects those of extreme age, although the median age is 14 years. [173] The highest incidence of infection occurs in children younger than 5 years of age. Elderly patients, particularly those who are bedridden, are more susceptible to infection and have a greater likelihood of developing HUS with subsequent mortality. [174] Cattle are the primary reservoir of EHEC O157:H7. [175] Over half the reported outbreaks are due to ingestion of beef products. [175] The prevalence of EHEC O157 in the feces (28%) and on carcasses (45%) of cattle is high. [175] Cattle are tolerant of intestinal colonization by *E coli* O157:H7 and do not develop systemic vascular damage [176] because of the lack of expression of the Gb_3 receptor for Stx in both the gastrointestinal tract and blood vessels within the gastrointestinal tract and kidney. [176] Other sources of EHEC infection include apple cider, vegetables, salads, cantaloupe, raw milk, mayonnaise, and water. [173] Cases of person-to-person transmission have been reported in day-care centers and health care facilities. [177], [178] A seasonal increase in the incidence of EHEC infection occurs in North America in the summer and early fall. Despite the increasing incidence of EHEC-associated illnesses, many hospital and microbiology laboratories do not routinely screen diarrheal or bloody stools for *E coli* O157:H7. When sought, this organism is identified in 15% to 39% of such stool specimens. [173]

Pathogenesis EHEC strains derive their virulence from a number of different factors, including infectivity at a dose of less than 100 organisms, [179] a consequence of resistance to the low pH of the stomach. Other virulence factors include expression of adhesins for initial attachment to host cells and gene products within the chromosomal pathogenicity island termed the *locus of enterocyte effacement* (LEE). LEE-encoded virulence proteins include intimin, an outer membrane protein that serves as a ligand for the LEE-encoded receptor that is translocated and inserted into the host cell membrane (*t*ranslocated *i*ntimin *r*eceptor, Tir), and other proteins that are secreted into host cells. [180] *E coli* O157:H7 also expresses a plasmid-encoded hemolysin and two Shiga-like toxins, Stx1 and Stx2, encoded on phages. These toxins, structurally similar to each other and to *S dysenteriae* toxin, are composed of an enzymatically active A subunit and five B subunits, and induce cytotoxicity by inhibiting host cell translation. Binding of these toxins to host Gb_3 receptors and internalization of the enzymatically active A subunit causes HUS. The susceptibility of cells to Stx directly correlates with the number of Gb_3 receptors expressed. [181] In humans, the highest concentration of receptors is found in renal tissue and on endothelial cells of the intestinal, renal, and central nervous system vasculature. [182] Toxin-induced damage to the endothelium causes fibrin thrombi deposition, intimal hyperplasia, and perivascular inflammation. The resulting thrombus formation and vasculitis lead to intestinal ischemia, vasculitis and hemorrhage, and hence hemorrhagic colitis. *E coli* O157:H7–induced colitis can microscopically resemble ischemic colitis; therefore, infection with this pathogen should be considered in patients presenting with colonic ischemia. [183] Histology of kidneys from HUS patients shows similar ischemic injury. Shiga and Shiga-like toxins are very potent; therefore, the concentration required to induce HUS is exceedingly small. [181]

Clinical Features The spectrum of symptoms associated with EHEC infection ranges from asymptomatic colonization to severe hemorrhagic colitis. The incubation period ranges from 3 to 9 days, with symptoms persisting for an average of 9 days in children and 6.5 days in adults. A minority (10%) of those infected with EHEC have nonbloody diarrhea or lesser clinical manifest-ations. [184] Patients with hemorrhagic colitis suffer severe abdominal cramps and diarrhea that becomes bloody after 2 to 5 days of illness. Blood loss may be minimal or up to 4 cups/day. [185] Vomiting occurs in up to 75% of patients. Ileus accompanies hemorrhagic colitis in 24% of patients. [186] Fever is absent in most cases, but a correlation between the degree of fever and elevation in the WBC count (more than 20,000 WBCs/µL) with the development of HUS and central nervous system injury has been reported. [187], [188] The physical examination is typically unremarkable, although right lower quadrant tenderness and abdominal distention may be present in children. Although colonoscopy is not necessarily indicated, mucosal edema, erosions, and hemorrhage, more severe in the proximal colon, may be seen. [185] Barium enema may show thumbprinting, indicative of mucosal edema. In addition to HUS, other complications associated with EHEC infection include intestinal hematoma causing intestinal obstruction, rhabdomyolysis, and pancreatic necrosis with resultant diabetes mellitus. [184] Rectal prolapse has been reported in 8% of children with HUS. [189]

Diagnosis The diagnosis of EHEC infection is important because its identification may not only improve patient care but also prevent person-to-person transmission and assist in identifying the source of the outbreak. Laboratory tests show most commonly an elevation in the WBC count (7,600 to 20,000 WBCs/µL) and a normal erythrocyte sedimentation rate. [171] Stool leukocytes are typically absent. EHEC O157:H7 is most often identified from diarrheal stool as clear colonies on sorbitol-enriched MacConkey agar (SMA) because this strain does not ferment sorbitol. Because up to 15% of diarrheal stools contain non-O157:H7 organisms that fail to ferment sorbitol, final identification of the O157 serotype requires agglutination tests with O157 antiserum. Presence of the H7 flagellar antigen is similarly identified using H7 antiserum. EHEC strains other than O157:H7 have been implicated in human disease including HUS, but many of these strains ferment sorbitol, thus complicating identification. The recovery of EHEC is greatest when stools are cultured early in the course of disease. [190] Recovery rates approach 100% if cultures are performed within the first 2 days of illness and remain high (91%) for up to 6 days. After 7 days of diarrhea, EHEC is recovered in only one third of stool samples. Often, EHEC cannot be cultured from stool after the onset of HUS because frequently the organism has been cleared from the intestinal tract by this time. Delay in the processing of samples and antibiotic therapy diminishes recovery rates. Although other methods of detection are being tested, including DNA probes and PCR for Stx, the gold standard for O157:H7 identification continues to be SMA culturing followed by O157 and H7 serotyping. This approach detects 75% to 88% of Stx-producing *E coli* that are of clinical concern. [191]

Treatment The most important treatment for those infected with EHEC is fluid and electrolyte replacement. Patients should also be closely monitored for blood loss and for associated complications, most importantly HUS. Antimicrobial therapy has no role in the treatment of this infection. It does not diminish the duration of symptoms or prevent complications, including HUS. A prospective study of children younger than 10 years of age with *E coli* O157:H7 infection found antibiotic therapy to be a risk factor for the development of HUS. [188] Exposure of EHEC to antibiotics increases the release of Stx, [192], [193] resulting in increased concentrations of Stx in the bloodstream and enhancing the likelihood of HUS. Although children who have not received antibiotic therapy may also develop HUS, it is recommended that children with acute diarrhea not be treated with antibiotics until infection with *E coli* O157:H7 has been ruled out. Although identical studies have not been conducted in adults, similar logic should be followed. As for infection with most enteric pathogens, neither antimotility agents nor opioid narcotics should be used in severe cases. These drugs depress colonic motility and increase the likelihood of distention that can further compromise the integrity of the colonic mucosa. Efforts to develop new nonantibiotic strategies for treating *E coli* O157:H7 infection are promising. One such approach has been to design a material that displays the Stx receptor, Gb_3, in the hope of adsorbing the harmful toxin and preventing its interaction with host cell receptors. One reagent, called Synsorb-Pk, is diatomaceous earth to which synthetic Gb_3 receptors have been attached. Oral administration of this compound to mice infected with Shiga toxin–producing *E coli* was not protective but did delay death by 1 day. [194] Another approach used a nonpathogenic *E coli* strain transformed to express an Stx receptor mimic on its surface. Mice infected with Stx-producing *E coli* were completely protected against an otherwise fatal dose of this pathogen. [195] The discrepant results for Synsorb-Pk and the Gb_3 mimic–transformed *E coli* may reside in their differential binding capacities because the transformed organisms have the potential to bind 10,000 times more toxin then Synsorb-Pk. [195] Gb_3 mimic–expressing *E coli* lacks the lipopolysaccharide O antigen and therefore does not colonize the gut.

Hemolytic Uremic Syndrome The association of infection by Stx-producing EHEC strains and HUS was first recognized and reported in 1983. [196] HUS develops in 10% to 15% of patients infected with *E coli* O157:H7, that is, 1.5 per 100,000 persons in the United States. [197] HUS is defined as microangiopathic hemolytic anemia, acute renal failure, and thrombocytopenia. Typically, this triad develops acutely after about 1 week of diarrhea. Because the Stx receptor Gb_3 is expressed by central nervous system vasculature, complications, including seizures (17% to 24%), cerebral edema, and coma (7% to 40%) are common. [198] More than half of HUS patients experience diminished sensorium. Renal sequelae range from mild proteinuria to severe nephropathy. HUS is the leading reason for kidney transplantation in children in the United States. [197] Most (75% to 100%) HUS patients have evidence of EHEC infection, but only 5% to 10% of those infected with EHEC progress to HUS. [179]

The median age of those who develop HUS is 2.7 years, with the peak ages ranging from 6 months to 5 years. [199] An initial high WBC count, performance of stool cultures early in the course of illness, and administration of antibiotics are associated with the development of HUS in children with *E coli* O157:H7 infection. [188] The administration of antimotility agents is an additional risk factor for HUS. [200] Histology of kidneys from HUS patients reveals severe endothelial cell injury, including separation of cells from the basement membrane and thrombotic microangiopathy. Cortical necrosis may also be seen. Injury to these cells stimulates the release of endothelin, a potent vasoactive peptide, which is likely responsible for the associated hypertension. [201] The mainstay of therapy for HUS is supportive measures. [173] Heightened awareness of this syndrome and its association with EHEC infection, coupled with improved fluid and electrolyte balance and dialysis, has decreased the associated mortality from 50% in the 1960s to about 5%.

Prevention The best treatment for infections with Stx-producing *E coli* is prevention. Because infection is usually a result of ingestion of contaminated food products, especially beef, elimination of EHEC from the food supply is the first step. [175] Beef should be adequately cooked so that pathogens are eliminated. An internal temperature of 160°F is effective. Good hand-washing habits and hygiene reduce secondary transmission. The size of outbreaks can be curtailed by prompt identification of the contaminating source.

SEXUALLY TRANSMITTED INFECTIONS OF ANUS AND RECTUM

The populations at greatest risk for acquiring anorectal infections are homosexual men and heterosexual women who engage in anorectal intercourse. The most commonly occurring infections in women are *C trachomatis, N gonorrhoeae* and *T pallidum.* In addition, infections with *E histolytica* HSV, and HPV are endemic in homosexual men. Infection with multiple pathogens occurs in 22% of this population who are symptomatic [202] and is associated with high-risk behaviors.

Bacterial Infections

Chlamydia trachomatis *C trachomatis*, a gram-negative, obligate, intracellular bacterium, is the leading bacterial etiology of sexually transmitted diseases in the United States. *C trachomatis* is represented by three biovars, two of which cause human disease: trachoma and lymphogranuloma venereum (LGV). The replication of trachoma is restricted to columnar epithelial cells, whereas LGV can also proliferate in macrophages, explaining the difference in symptoms. The clinical features associated with infection by *C trachomatis* range from asymptomatic proctitis, due to non-LGV biovars, to severe granulomatous proctitis, usually caused by LGV biovars. Sigmoidoscopic examination of individuals infected with non-LGV biovars may reveal normal mucosa or erythema, friability, and erosions. Histological examination of these tissues shows neutrophilic infiltration of the lamina propia. [203] In contrast, LGV biovars induce severe proctitis or proctocolitis manifested as pruritus, purulent rectal discharge, hematochezia, and diarrhea or constipation. Physical examination may reveal lymphadenopathy and lower abdominal tenderness. The sigmoidoscopic findings are more marked, revealing friable or bloody mucosa with multiple ulcerations. [203] The infiltrate is varied, showing eosinophils, mononuclear cells, and plasma cells in addition to neutrophils. Crypt abscesses and granulomas with giant cells may also be present and can lead to the mistaken diagnosis of Crohn's disease. Anorectal LGV may also cause strictures, fistula formation, and perirectal abscesses if left untreated, further confusing the diagnosis with Crohn's disease. *Chlamydia* species infection is diagnosed by culturing samples obtained by rectal swab in McCoy cells. Infected cells are identified by immunofluorescent staining, using a monoclonal antibody against *Chlamydia*-specific antigens, achieving a sensitivity and specificity of 90% and 100%, respectively. [204] The treatment of choice for chlamydial infection is tetracycline, 500 mg four times daily, or doxycycline, 100 mg twice daily, for 21 days. Less severe infections with non-LGV biovars may be treated with doxycycline, 100 mg twice daily for 7 to 10 days or a single 1-g oral dose of azithromycin. Surgical resection may be required to alleviate strictures.

Neisseria gonorrhoeae *N gonorrhoeae* is a gram-negative diplococcus that typically infects the epithelial lining of the endocervix and urethra but may infect other sites as well, including the rectum. A robust inflammatory response including submucosal abscesses occurs after attachment, internalization, and subepithelial delivery of the organism. Up to half of homosexual men assessed in sexually transmitted disease clinics are infected with this organism, with 40% manifesting only rectal involvement. Of infected women, only 20% had rectal infection alone. [205] Most gonorrheal anorectal infections are asymptomatic but when present include purulent, creamy, and sometimes bloody discharge accompanied by pruritus ani, tenesmus, and even constipation. Symptoms typically appear 5 to 7 days after exposure. Rare complications include stricture formation, abscesses, and fistulae. The sigmoidoscopic findings are nonspecific, including friable, erythematous mucosa with superficial erosions most prominent at the anorectal junction. Culture of material obtained by rectal swab plated on selective Thayer-Martin media is the recommended diagnostic test. Gram stain of this same material is also suggested but is only positive in about half of those infected. The treatment of choice for anorectal gonorrhea is ceftriaxone, 250 mg given intramuscularly, which cures more 98% of such infections. [206] Because of a high co-infection rate with *Chlamydia* species, it is recommended that all *N gonorrhoeae*–infected individuals also receive doxycycline, 100 mg twice a day for 7 days. [206] Alternative regimens include a single oral dose administration of 500 mg ciprofloxacin or 800 mg norfloxacin or a single intramuscular injection of spectinomycin (2 g), cefotaxime (1 g), or ceftizoxime (500 mg). [207] A follow-up culture is recommended for those receiving an alternate treatment regimen.

Treponema pallidum *T pallidum* is a spirochete capable of infecting damaged skin or mucosa. Anorectal syphilis is primarily diagnosed in homosexual men. Primary anorectal syphilis presents as a chancre of the squamous epithelial lining of the anal canal or in the rectum. These lesions, which develop 2 to 6 weeks after exposure, appear as 1- to 2-cm indurated lesions with a raised border. "Mirror" or "kissing" lesions may be present. [208] Anorectal chancres are often asymptomatic unless superinfected. The anorectal presentation of secondary anorectal syphilis is condyloma lata. This stage develops usually 6 weeks to 6 months from the time of the initial infection. Condyloma lata are smooth, wartlike lesions near or in the rectum. Colitis associated with secondary syphilis may also occur in the distal 15 to 20 cm of the colon. This lesion spontaneously resolves after 3 to 4 weeks. Intestinal lesions are rarely associated with tertiary syphilis, but rectal gummas have been reported. Anorectal syphilitic lesions show a chronic inflammatory infiltrate of lymphocytes, histiocytes, and plasma cells. [209] Dark-field microscopic examination reveals the presence of spirochetal organisms, but nonpathogenic spirochetes may also be present in the rectum. [210] Anorectal syphilis should be treated with a single intramuscular injection of 2.4 million units of benzathine penicillin. If intolerant of penicillin, doxycycline, 100 mg twice daily, or tetracycline, 500 mg four times daily, can be given orally for 2 or 4 weeks for early and latent syphilis, respectively. Proof of eradication should be sought 3 and 6 months after treatment.

Viral Infections

Herpes Simplex Virus HSV type 2 accounts for 90% of the cases of anorectal herpetic infections. The virus, for which humans are the sole reservoir, is transmitted by direct contact with an infected individual who is actively shedding viral particles. Symptoms of the primary infection begin 4 to 12 days after contact and spontaneously resolve after 3 weeks but recur. Symptoms associated with subsequent bouts range from none to severe and painful ulcerative proctitis. Other symptoms include tenesmus, pruritus ani, constipation, inguinal adenopathy, sacral and posterior thigh paresthesias, and urinary difficulty. The symptomatic triad of constipation, urinary retention, and anorectal pain is strongly suggestive of anorectal HSV infection. Anoscopic examination typically reveals vesicles, pustules, or shallow ulcers depending on the stage of the lesions. Biopsies of these lesions reveal acute and chronic inflammatory change, superficial ulcerations, and microabscesses. [211] Perirectal lesions are relatively uncommon, occurring in 19% to 27% of women and men, respectively. [212] Viral cultures should be performed to confirm the diagnosis. PCR can also be used to detect HSV DNA in clinical samples. [213] Depending on the severity of the symptoms, one may choose to treat mildly symptomatic individuals with only stool softeners, sitz baths, and analgesics or to employ antiviral therapy with acyclovir, 400 to 800 mg/day for 10 days, for painful infections. This approach has been shown to diminish both viral shedding and the duration of symptoms. [206]

Human Papillomavirus HPV enters basal germinal epithelial cells and replicates in the nucleus, resulting in increased cell proliferation. This response accounts for the skin and mucosal lesions that appear as irregular, verrucous lesions, called *anal warts* or *condyloma acuminata.* These lesions must be distinguished from the condyloma lata in syphilis that are more moist and smooth. Histological examination of condyloma acuminata shows an irregular, thickened epithelium containing areas of koilocytotic cells with peri- nuclear cavitation and nuclear atypia. Some HPV strains cause neoplastic lesions, including cervical and anal cancer. [214] The virus is transmitted through anal intercourse or auto- inoculation to the perianal area and anus. The latency period ranges from 1 to 6 months. If condyloma acuminata are present in the perianal area, anoscopic examination must be performed to determine whether lesions also exist inside the anal canal. Individuals with anal warts may be asymptomatic or complain of rectal discharge, bleeding, or pruritus ani. Diagnosis is by clinical observation, and anorectal syphilis and squamous cell carcinoma should always be excluded. This is accomplished by histological examination that distinguishes benign and malignant lesions and dark-field microscopy to exclude syphilis. Although curative treatment is still lacking, lesions can be controlled with either cryotherapy, which is 63% to 91% effective, [215], [216] or a 20% solution of podophyllin in tincture of benzoin, which removes 77% of lesions. [217] This solution is applied for up to 12 hours and may be repeated one or two times weekly until all lesions are gone. Its caustic nature precludes intranal use. Other therapeutic options include electrocautery, electrodessication, CO_2 laser, and surgery. Recurrence rates vary depending on the treatment modality used: 29% after surgery and 65% after podophyllin treatment. [218]

Sexual Transmission of Intestinal Pathogens In addition to the pathogens discussed previously, intestinal parasites, including *Entamoeba histolytic* and *Giardia lamblia* and other bacterial pathogens, such as *Shigella* and *Campylobacter* species, can be transmitted sexually. The signs and symptoms associated with infection by these pathogens in homosexual men are the same as those experienced by individuals who acquire these organisms by ingestion.

CHAPTER 89

Graeme P. Young and Finlay A. Macrae

NEOPLASTIC AND NONNEOPLASTIC POLYPS OF THE COLON AND RECTUM

A *polyp* is any protrusion above the mucosal surface. Polyps may take various sizes and shapes, including sessile or pedunculated. They can also be described according to texture of the mucosal surface, position, color, ulceration, bleeding, and histological type. Polypoid lesions of the large bowel are normally classified into three main subgroups (Table 89-1): epithelial polyps, subclassified into neoplastic polyps (consisting of adenomas or carcinomas) and nonneoplastic polyps; and submucosal lesions (which produce a polypoid appearance).

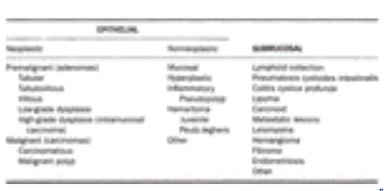

TABLE 89-1 Classification of Colorectal Polyps

Colorectal polyps are important for several clinically relevant reasons. First, they are easily detected and removed with modern flexible endoscopes (see Chapter 140). Largely because of this, our understanding of their role as precursors of colorectal carcinoma has increased (see Chapter 91). Ready access to polyps has led to the elucidation of the genetic basis of the major inherited polyposis syndromes. Furthermore, mutations in the adenomatous polyposis coli (APC) gene responsible for the major inherited syndrome, familial adenomatous polyposis (FAP), also occur in sporadic colorectal neoplasms—but in this case being acquired and developing only from a single clone of cells somewhere in the colon. Finally, interventional trials aimed at removal of adenomas or reduction of recurrence have demonstrated

polypectomy to be valuable for controlling colorectal cancer (see Chapter 34 and Chapter 91).

Neoplastic polyps are of greatest clinical significance because of their implication in the process of colorectal tumorigenesis. The natural history of the adenomatous polyp is variable, but it appears that when progression to carcinoma occurs, it generally takes 3 to 7 years. Based on the relationship of adenoma size to histological features as assessed at polyp resection, it also appears that as adenomas grow, they tend to become more villous and to progress from mild to severe dysplasia, before invasion through the muscularis mucosae (a key feature of cancer). The progression of adenomas in patients with hereditary nonpolyposis colorectal cancer (HNPCC) appears to be faster. With respect to future risk for cancer after polypectomy, the patient with an advanced adenoma (larger than 1 cm, with a substantial degree of villous histological change, or with severe dysplasia) or with multiple adenomas has a significant future risk for colorectal cancer that is not confined to the site of that adenoma.

Colorectal polyps do not usually cause symptoms and are frequently found during diagnostic, screening or surveillance procedures. When clinically suspected, the definitive diagnostic procedure is complete colonoscopy. Endoscopic polypectomy can adequately treat most adenomatous polyps, including some with focal malignancy. Malignant polyps with poor prognostic features may require surgical resection, however.

Nonneoplastic epithelial polyps have little or no malignant potential (see Chapter 90 and Chapter 91), except in the setting of inherited polyposis syndromes, in which they may be associated with cancers of the gastrointestinal tract and other organs. The malignant potential of submucosal lesions depends on their pathological nature.

Management of the patient with a colorectal polyp requires an understanding of the pathology, epidemiology, etiology, clinical manifestations, and course as well as the appropriate diagnostic studies and therapeutic options. [1], [2] and [3]

EPIDEMIOLOGY

Prevalence

Information on the prevalence of polyps comes from autopsy studies and from small-scale colonoscopic surveys. Autopsy studies generally show a higher prevalence rate of polyps and adenomas than endoscopic studies. In the United States, autopsy studies suggest an overall polyp prevalence of up to 50%, [4], [5], [6] and [7] but colonoscopic surveys suggest no more than 40%. [8], [9], [10], [11], [12], [13], [14] and [15] In autopsy studies, fixation of the colon and careful use of a magnifying glass allow detection of small polyps that are more readily missed during colonoscopy. Furthermore, subjects in autopsy studies are older. On the other hand, colonoscopic surveys may include patients with positive occult blood, which would bias them to a higher prevalence. [13]

More than 80% to 90% of polyps detected at colonoscopy are adenomas or hyperplastic polyps, and up to 75% are adenomas. [8], [9], [10], [11], [12] and [13] In the case of diminutive polyps (less than 5 mm), about half are hyperplastic. [16], [17]

Autopsy studies show that the prevalence of adenomas varies widely among countries and parallels the frequency of colorectal cancer in that country (Table 89-2), confirming the close association of adenomas with colorectal carcinomas. [4], [5], [6] and [7], [18], [19], [20], [21], [22], [23], [24], [25], [26], [27], [28], [29], [30], [31] and [32] Most studies show prevalence rates that are 30% higher in men than in women.

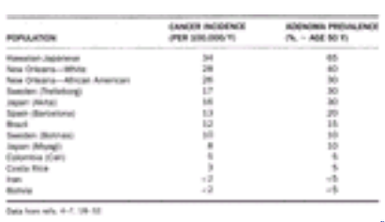

TABLE 89-2 Prevalence of Colorectal Neoplasia in Men

Age is the major determinant of adenoma prevalence. [4], [7], [25] Size at detection also increases with age. [24] Colorectal adenomas are uncommon in patients younger than 30 years of age (see Chapter 90). The prevalence of polyps other than adenoma or hyperplastic is unknown.

Anatomic Distribution

Colonoscopic studies and some autopsy studies show that colorectal adenomas are more common in the distal colon and rectum, similar to the distribution of colorectal cancer (Table 89-3). Distribution, however, relates to size. Small adenomas are more uniformly distributed throughout the entire colon, whereas large adenomas (greater than 1 cm) show a distal predominance. [7], [8] and [9], [33], [34], [35] and [36]

TABLE 89-3 Anatomic Distribution of Colorectal Adenomas

Hereditary Factors and Adenomas

Hereditary factors obviously play the key role in FAP and HNPCC; adenoma biology is characteristically disturbed in each and now well characterized at the molecular level (see Chapter 90 and Chapter 91). However, hereditary factors also play a role in the more common, sporadic adenoma, contributing to as much as 30% of the pathogenesis. [37], [38] and [39]

Analysis of family pedigrees in the state of Utah has identified an autosomal-dominant pattern of inheritance of adenomas. About 200 members of a large pedigree with familial clustering of colon cancer, without evidence of the known inherited syndromes of colorectal cancer, were systematically examined by flexible sigmoidoscopy. Twenty-one percent of family members, but only 9% of spouses, were found to have one or more adenomas. In comparison, hyperplastic polyps were found in 24% of family members and 29% of spouses. [37], [38] and [39]

Subsequent analyses of additional pedigrees continue to demonstrate a twofold to threefold increase in adenomas in family members compared with spouse controls. [40], [41], [42] and [43] Pedigree analysis using likelihood methods was used to estimate which of the possible mechanisms could account for familial clustering of adenomas. It was found that an autosomal-dominant inheritance of susceptibility to adenoma (and colorectal carcinoma) best explained the pattern of adenoma and carcinoma occurrence in the pedigrees. [37] In addition, the gene frequency was estimated to be 19% in that population. A case-control study addressing risk for cancer when a first-degree relative has had one or more adenomas showed risk to be increased, although these studies are few and difficult to interpret because adenomas usually go undiagnosed and are common. [44]

Considered together, these results suggest that familial or hereditary factors play at least a 20% role in the causation of adenomas. [37], [38], [39], [40], [41], [42], [43], [44] and [45] If it is the adenoma rather than cancer that signals the inherited risk, and if surveillance programs are based on family history of colorectal adenoma or cancer rather

than cancer alone, then the complexity, cost, and magnitude of these programs will increase dramatically. More information is needed on the risk to other family members when an adenoma is detected.

Association of Adenomas with Other Diseases

Associations between colonic polyps and other diseases are summarized in Table 89-4.[46,47,48,49,50,51,52,53,54,55,56,57,58,59,60,61,62,63,64,65,66,67,68,69,70,71,72,73,74,75,76,77,78,79,80,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96,97] and [98] None of the conditions with a strong association is common. In a prospective study of acromegalic patients, nearly 50% had adenomas, especially when older.[59]

DISEASE	POLYP TYPE	STRENGTH OF ASSOCIATION
Ureterosigmoidostomy	Adenoma/carcinoma[46–51] Juvenile[52,53] Inflammatory[48]	Strong
Acromegaly	Adenoma/carcinoma[54–59]	Strong
Streptococcus bovis infections	Adenoma/carcinoma[60–64]	Strong
Breast cancer	Adenoma[65–68]	Weak
Atherosclerosis	Adenoma[69–76]	Weak
Cirrhosis	Adenoma[77–80]	Weak
Skin tags	Adenoma[81–88]	Very weak
Cholecystectomy	Adenoma[89–96]	Very weak
Diverticula (colon)	Adenoma[97]	Very weak
Lymphoid follicles	Adenoma[98]	Very weak

TABLE 89-4 Disease Associations with Colorectal Polyps and Their Strengths

Nonneoplastic Polyps

The epidemiology of nonneoplastic polyps is not well studied except for the hyperplastic polyp, the second most common colon polyp.[16,99] Hyperplastic polyps usually are smaller than 5 mm in diameter and usually are found in the rectosigmoid area. Some studies have found an association between distal hyperplastic polyps and more proximal adenomas and colon cancer,[100,101,102,103,104,105] and [106] but others have not.[10,107,108,109,110] and [111] The predominant evidence from the larger and better controlled studies would suggest that hyperplastic polyps are not premalignant and do not identify a risk for colorectal neoplasia. In the U.S. National Polyp Study, individuals with distal hyperplastic polyps were no more likely than those without to have more proximal colorectal neoplastic polyps.[107] Unless other risk factors are present, asymptomatic patients found to have diminutive distal hyperplastic polyps at sigmoidoscopy do not need complete colonoscopy.

A possible exception to the rule about the benign and inconsequential nature of hyperplastic polyps is those individuals with multiple hyperplastic polyposis.[112] Despite the epidemiologic information indicating the lack of association between adenomas and hyperplastic polyps, molecular studies indicate that some hyperplastic polyps show genetic change that overlaps with those that accumulate in the adenoma-carcinoma sequence.[112]

Risk for malignant disease should be considered when hyperplastic polyps are numerous (more than 20, i.e., there is polyposis), large (more than 1 cm) or severely dysplastic, and proximally located (especially if more than five are proximal to sigmoid colon) and especially when there are serrated adenomas (adenomatous and hyperplastic change intermingled in a single polyp). Family history of high-risk hyperplastic polyposis or colorectal cancer also points to an increased risk.[113]

Hyperplastic polyps also take on significance in the context of their relationship to serrated adenomas. Serrated adenomas have the same sawtooth architecture as hyperplastic polyps, but cytologically, they have the features of neoplastic nuclei (dysplasia; see later discussion). A third pathway to colorectal cancer involving transition of a small proportion of hyperplastic polyps to serrated adenomas and passing through to cancer with low levels of microsatellite instability (MSI) has been proposed. Methylation is an important mechanism of inactivation of genes in this pathway, which also has the unusual coexistence of both chromosomal instability and MSI (see later). In this context, the finding of serrated adenomas with multiple hyperplastic polyps also signals a need for careful surveillance.[114]

ETIOLOGY AND PATHOGENESIS

The etiology of colonic polyps is identified by their histological type. For instance, inflammatory polyps result from the inflammatory and regenerative response to injury. Because of their clinical significance and prevalence, the remainder of this section focuses largely on neoplastic polyps.

Adenomas are benign neoplasms; all show dysplasia (by definition). Dysplasia is characterized by cells with enlarged, hyperchromatic, elongated, and less polar nuclei arranged in a picket-fence pattern (i.e., stratified), with variably decreased cytoplasmic volume, stroma, apoptosis, and cellular mucin and increased numbers of mitotic cells. These changes result in a more basophilic appearance to the adenomatous epithelium in hematoxylin- and eosin-stained sections.[115,116] Dysplasia ranges from mild to severe (Fig. 89-1). The term *severe dysplasia* has been used synonymously with, and is preferred over, the terms *carcinoma in situ* and *intramucosal carcinoma* when the severely dysplastic cells are confined within the basement membrane.[117,118] Severe dysplasia is characterized by marked cytologic change with severely disordered crypt architecture. Adenomas may be classified by predominant histology; tubular adenomas are the most common, constituting 80% to 85%.[119,120] Tubulovillous adenomas constitute about 10%, with villous adenomas making up the remaining 5%.[120]

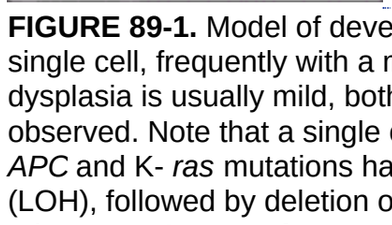

FIGURE 89-1. Model of development of a malignant colorectal carcinoma by a series of phenotypic changes and related genetic alterations. **Normal epithelium:** A single cell, frequently with a mutation in the APC gene (on chromosome 5), will give rise to the small adenoma in the next stage. **Small adenoma:** At this stage, when dysplasia is usually mild, both alleles of APC are affected by deletion or truncation (chromosome 5q). Changes in the level of methylation of DNA also may be observed. Note that a single cell in the clone has acquired an additional mutation in its K- *ras* gene (chromosome 12P). **Intermediate adenoma:** The cell with the *APC* and K- *ras* mutations has given rise to a new clone, forming an intermediate adenoma. An additional mutation in one of the cells, such as loss of heterozygosity (LOH), followed by deletion of a tumor suppressor gene (such as *DCC* [deleted in colorectal cancer] on chromosome 18q), gives this cell an additional survival advantage. **Large adenoma:** The cell with mutations and deletions in the *APC* and K- *ras* genes and LOH on chromosome 18q has clonally expanded into a large adenomatous polyp that has not invaded underlying mucosal layers. One cell of this clone acquires an additional mutation in the *p53* gene (chromosome 17p). **Carcinoma:** The cell that has accumulated mutations in the *APC* K- *ras* and *p53* genes and developed LOH on chromosome 18q has grown into a clone of malignant cells that penetrates through the lamina propria and invades underlying tissues. Note how cells are capable of lysing capillary walls and entering the vessels to be transported to distant sites where they form metastatic tumors. (Additional changes to proteolytic enzymes such as urokinase or telomerase may be required for metastatic behavior.) *M* mucosa; *LP* lamina propria; *MM* muscularis mucosae; *SM* submucosa; *MP* muscularis propria.

Cell Kinetics in Normal Epithelium and Polyps

The healthy colonic epithelium is characterized by constant cell proliferation and differentiation, resulting in total renewal of the surface epithelial cells about every 3 to 6 days. The proliferative compartment is situated in the basal third of the crypt. Daughter cells migrate up the crypt and out onto the surface. As the cells migrate, proliferation ceases, and maturation begins–goblet cells become common.[121,122,123] and [124] The process of cell proliferation and differentiation is highly regulated,

resulting in a homeostatic balance among cell production, maturation, and death. [121]

In adenomas, the normal homeostatic process is disordered. Cell proliferation extends up the crypt. Differentiation is delayed (with fewer goblet cells), and senescence is reduced. [115], [123], [125] The entire colonic mucosa of patients with adenomas may show increased epithelial cell proliferation. [124]

Proliferation and differentiation are not grossly disordered in hyperplastic or inflammatory polyps; cell proliferation is increased but remains confined to the basal third of the crypt. With increased cell production, there are increased epithelial cell elements and some infolding, leading to the characteristic polypoid appearance. However, cell maturation proceeds normally, and goblet cells are plentiful. [116]

Physical Formation of a Polyp

This enhanced proliferation and retarded cell maturation results in an increased number of cells. These undergo downward infolding of the crypts that interpose and branch between the normal crypt elements. [115], [122], [126], [127] Mesenchymal proliferation is also thought to play a role in the formation of adenomas, especially when villous change occurs. [122], [126], [128]

Environmental Factors

Epidemiologic studies suggest that environmental factors play an important role because worldwide variation in incidence is not fully explained by genetic variations. [129] Diet is probably the most important environmental factor. Smoking is also a risk factor for adenomas, and recent evidence also shows an association between tobacco use and colorectal cancer: 15 of 16 studies conducted after 1970 in men and, in the 1990s, women, showed this association. [130], [131], [132] and [133] The dietary factors that predispose to adenoma formation are similar to those that have been associated with colon cancer (see Chapter 91), although the evidence is less complete for adenomas. Although many diet-related factors have been proposed as potential causative agents, the strongest evidence points to fat, bile acids, and fecal bacteria. [134], [135], [136], [137] and [138] Fiber and dietary carcinogens also seem important, although recent studies have been less supportive of a preventive role for dietary fiber. [139], [140] and [141]

Dietary Fat The prevalence of colorectal adenomas, as with cancers, has been correlated with high dietary fat intake (animal fat intake greater than 40% of total caloric intake) [142] (Table 89-5). Conversely, dietary fat intake of less than 15% of total caloric intake has been correlated with a low frequency of colorectal adenomas and cancers. [78], [143], [144], [145], [146], [147], [148] and [149]

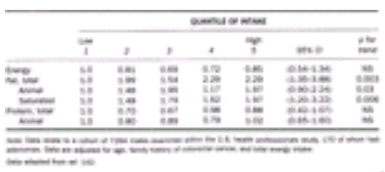

TABLE 89-5 Relative Risk for Colorectal Adenoma in Relation to Dietary Intake

Increased dietary fat has been shown in experimental animals to lead to increased hepatic synthesis of cholesterol and bile acids as well as their increased presence in colonic contents. Bacterial flora in the colon might convert these sterols into cholesterol metabolites and oxidized bile acids, which have tumor-promoting activity. [135] Higher fecal concentrations of bile acids and oxidized bile acids have been found in populations at higher risk for colorectal adenomas and cancers, compared with those at lower risk. Subjects living in areas with high prevalence of colorectal adenomas have higher concentrations of fecal bile acids. Similarly, subjects in these geographic areas have been found to have higher numbers of fecal anaerobic bacteria. There is also an association among high numbers of fecal anaerobic bacteria, increased amounts of metabolized cholesterol and oxidized bile acids in the feces, and the high prevalence of colorectal neoplasms in different populations. [134] and [135]

A likely exception to the relationship between dietary fat and colorectal cancer risk concerns fish oil. Fish and fish oil intake correlate inversely with colorectal cancer incidence. [145], [150] Fish oil consumption has been shown to reduce rectal epithelial proliferation. [145], [151] No studies seem to have related fish intake to adenoma prevalence. Obesity and lack of physical exercise are consistent relationships with colorectal neoplastic risk [152] and may induce adenoma or cancer growth by trophic effects of insulin induced in a state of obesity-related insulin resistance. [153]

Dietary Fiber Dietary fiber is a heterogeneous mix of plant-derived components, specifically nonstarch polysaccharides as well as undigested starch polysaccharides and noncarbohydrates that are resistant to digestion in the upper digestive tract; this complicates interpretation of epidemiologic data. Nevertheless, subjects consuming diets high in fiber that lead to large, bulky stools tend to have a lower frequency of colorectal adenomas and cancers. [78], [138], [142], [144], [147] Case-control studies of dietary fiber and colorectal neoplasia have shown more consistent protection from vegetable than cereal fiber sources, although with a notable recent exception. [137], [138], [147], [148] and [149], [151], [154], [155] However, recent animal studies focus on the relative solubility of different cereal fibers [156] and support the hypothesis that poorly soluble fibers, such as wheat bran, continue to be fermented throughout the colon, releasing metabolic products of fermentation along its length, including the distal colon, which is the region of highest risk for colorectal cancer in humans. [138] Among these products are the short-chain fatty acids: acetate, propionate, and butyrate. Apart from altering the pH to a more favorable acidic state, short-chain fatty acids are an important fuel for the colonocyte. Attention has focused particularly on butyrate, which is capable of inducing a more differentiated phenotype, reducing cell proliferation, inhibiting tumorigenesis, and regulating gene expression by inhibition of histone deacetylase. [156], [157] In carefully controlled animal experiments, tumorigenesis is inhibited, with one third of the protective effect accounted for by the measured stool parameters of fecal pH and butyrate production. [158] Butyrate also induces apoptosis in vitro in colon cancer cell lines by activating the caspase cascade [159] and blocks the cell cycle. The role of fiber in prevention of colorectal adenomas has been tested in several randomized controlled trials and is described later. Resistant starch, by definition, also escapes digestion in the small bowel and may benefit colonic physiology in similar fashion to the nonstarch polysaccharides. [160], [161] Resistant starch is being tested at present in a randomized controlled trial of high-risk individuals in HNPCC families (the CAPP-2 study).

Dietary Carcinogens Studies have demonstrated increased fecal mutagenic activity in the stools of patients at risk for development of colon adenomas and cancers. [135], [162], [163] Whether the increased fecal mutagenic activity is related to dietary fat intake, fecal bile acids, or bacteria is still unclear. One interesting line of investigation relates to metabolic activation of dietary procarcinogens such as heterocyclic amines formed in high-temperature cooking; acetylator status has been shown to correlate with risk for colorectal cancers and adenomas. [163], [164] Recent attention has also focused on fecal *N*-nitroso compounds, which are formed in the colon after meat ingestion and which may cause DNA adducts and be mutagenic. [165] Dietary carcinogens may be detoxified by hepatic enzymes (NAT 1 and 2), which are themselves polymorphic and have variable activity, thereby providing another explanation of familial risk. [166] Glutathione *S*-transferase *M1* and *T1* genes are also involved in the metabolism of polycyclic aromatic hydrocarbons, carcinogens found in tobacco smoke and the diet. [167]

Micronutrients Studies using antioxidants, such as vitamins A, C, and E and beta carotene, have attempted to decrease the production of mutagens in the stool as a way of decreasing colon adenomas and cancers. Randomized controlled trials of these antioxidants in subjects with previous adenomas have universally failed to show a reduction in the risk for metachronous adenomas or cancer. [168], [169], [170] and [171] However, beta carotene does reduce cell proliferation in the colon. [172], [173] This dichotomy highlights the multistage nature of colorectal carcinogenesis, with the opportunity for preventive agents to intercept the process at different stages. Because the actions of dietary agents may be stage specific, the final marker of benefit should be cancer, if this can be demonstrated. There is also evidence that calcium, perhaps by binding fecal fat, bile acids, and cholesterol, may confer a protective effect. [174] Calcium carbonate (3 g, i.e., 1200 mg of elemental calcium) reduced adenoma occurrence in a randomized controlled trial and is one of only a few interventions to do this. [175] Calcium (such as in calcium-fortified low-fat dairy products) also reduces cell proliferation in randomized controlled trials and inhibits tumorigenesis in animals. [176] Selenium also shows promise and is under active investigation. [177] and [178]

Molecular Genetics of Adenomas

Multiple alterations in DNA have been noted in adenomas. Aneuploidy, tetraploidy, allelic deletions, and hypomethylation have been observed in sporadic adenomas (chromosomal instability pathway) and in FAP. [179], [180] and [181] There is also altered patterns of expression of, or mutations in, oncogenes, such as *fos myc* and *ras* and deletions of the *APC* gene [182], [183] and [184] (see Fig. 89-1). Increasing data from studies of very small (2 mm) adenomas highlights the importance of *APC* mutation as the initiating (gate-keeping) event. [185], [186] In the alternate MSI pathway characteristic of HNPCC, replication errors occur during mitosis and mutations occur in other genes, including *TGFßRII MSH6* and insulin-like growth factor receptor type II. Inactivation of promoter regions by methylation (the CpG island methylator phenotype) of tumor suppressor and other genes (*p16, THBSI* E cadherin, and *HPP1*) or mismatch repair genes (*hMLH1* and *MGMT*) is another important molecular mechanism

that may be evident in adenomas. [114], [187]

A third pathway is initiated by silencing of the *HPP1* gene (due to methylation), loss of expression (also by methylation) of the DNA repair gene O^6-methylguanine DNA methyltransferase (causing loss of its expression), and progress through the serrated adenoma pathway to low-level MSI cancers. [187], [188]

These low-level MSI cancers have a higher frequency of K-*ras* mutations than microsatellite stable (MSS) cancers. [189] *hMLH-1* expression may also be lost in serrated adenomas and even in nondysplastic crypts within such polyps, although this usually leads to high-level MSI cancers. *HPP1* may also be the initiating event for this high-level MSI pathway. [187]

Molecular Changes in Hyperplastic Polyps

A range of genetic abnormalities has been described in sporadic hyperplastic polyps, including oncogenes and tumor suppressor genes, especially K-*ras* and *TGFßR11* and also loss of chromosome 1p. *APC* mutations, however, are very rare. These changes suggest a need to reevaluate the premalignant importance of hyperplastic polyps. Correlation of the clinical outcomes and molecular pathology of hyperplastic polyps may teach us further lessons about the pathogenicity of certain accumulated mutations.

ADENOMA-CARCINOMA SEQUENCE

It is generally accepted that most colorectal carcinomas arise from colorectal adenomas; probably all arise one way or another from dysplastic epithelia. The frequency, inevitability, and time course of this neoplastic progression is not clearly defined, and prospective observational studies of adenomas left in patients are unethical. The evidence for the adenoma-carcinoma sequence is thus derived from epidemiologic (see earlier and Table 89-2), morphologic, biologic, anecdotal clinical [190] and therapeutic data. Studies in FAP patients also support this sequence.

Morphologic Evidence

If the sequence is correct, adenomas and carcinomas should be closely associated. Thirty to 50% of those with adenomas have at least one other (synchronous) adenoma. [26], [27], [28] and [29], [190] Furthermore, having once had an adenoma, the likelihood of a future (metachronous) adenoma is increased. [28], [29], [30] and [31] In those with two or more synchronous cancers, 50% to 85% have a synchronous adenoma. Adenomas found in those with colorectal carcinoma are more advanced. [26], [30], [31] and [32]

If the adenoma-carcinoma sequence is correct, one would expect to find small adenocarcinomas arising within adenomas but few or no small adenocarcinomas arising de novo. Systematic morphologic studies of resected specimens show that when minute adenocarcinomas occur, they are frequently found within adenomas; de novo minute carcinoma is rare. [190], [191], [192] and [193]

The relative frequency of de novo versus adenoma pathway of cancer development is, however, now under debate. Japanese investigators claim that a sizable minority of cancers do develop without recognizable adenomatous co-pathology. [194] Japanese investigators studying Western patients have identified similar phenomena, indicating a need to review this question further in Western societies with high colorectal cancer incidence. [195], [196] and [197]

A plethora of reports of "flat adenomas" in Western populations are now appearing, implying a change in nomenclature rather than epidemiology or pathogenesis. [195], [196] and [197] Nevertheless, careful reports using magnifying colonoscopy and dye spray clearly show small flat cancers (with malignant invasion), especially where the central area is depressed. [198] As the resolution of colonoscopes improves and the Japanese skills at endoscopy are spread around the world, more may be found and the debate resolved. It should be noted, however, that the de novo process does not exclude dysplasia as the precursor—it simply establishes that some precancer lesions do not take on the polypoid shape.

If the adenoma-carcinoma sequence is correct, then carcinomas arising within adenomas should gradually increase in size and ultimately replace all the adenomatous elements with carcinoma. Indeed, the frequency of finding adenomatous tissue in a carcinoma varies inversely with the size and extent of invasion of the carcinoma. Associated adenomatous tissue is found in more than 50% of carcinomas with some mucosal invasion, in less than 20% of carcinomas with invasion of the muscularis propria, and in less than 10% of carcinomas with serosal invasion. Furthermore, the proportion of adenomas showing severe dysplasia, which is cytologically tantamount to cancer, is proportional to the size of the adenoma. These observations are founded on extensive experience with large series of adenomatous polyps from many centers, but they were initiated by the studies of Morson. [190]

Evidence from Progressive Genetic Changes

Molecular analysis of colorectal neoplasia at all putative stages of development reveals an apparent progressive accumulation of genetic abnormalities [185], [186], [199] (see Fig. 89-1). The most prevalent molecular genetic finding in the earliest neoplastic pathology identifiable (sporadic tumors developing through the chromosomal instability pathway)—aberrant crypt foci or microadenomas—is that of mutations in the *ras* oncogene. By the time these microadenomas have progressed to a size of 1 cm, about half have K-*ras* gene mutations, primarily in the codon 12 position. [182], [183], [184], [185], [186], [187], [188], [189], [190], [191], [192], [193], [194], [195], [196], [197], [198], [199] and [200] There is no further accumulation through to colorectal cancers. Mutations in the tumor suppressor *APC* gene on chromosome 5, which leads to a variety of neoplastic pressures in the cell, appear to be another early molecular event associated with small adenoma development (somatic mutations or deletions), but they are not present in aberrant crypt foci (except in FAP patients). [199], [200] and [201]

Larger adenomas frequently show an allelic loss of certain chromosomes, especially 5, 17, and 18. About one third of larger adenomas and carcinomas have allelic loss of chromosome 5, and half have allelic loss of chromosome 18. [186] Loss of function of the tumor suppressor gene *p53* on chromosome 17 occurs late in the adenoma stage and seems pivotal to the cancer phenotype. [202], [203] See Chapter 24 and Chapter 91 for a more detailed discussion.

Evidence from Familial Disorders

Familial Adenomatous Polyposis The increasing risk for occurrence of colorectal carcinoma with increasing numbers of adenomas is well established in the polyposis syndromes. Typical FAP is characterized by the development of more than 100 adenomas; the risk for colorectal carcinomas is virtually 100% if the colon is not removed. In addition, adenomas precede the appearance of carcinoma by about 5 to 7 years. Mutations in the *APC* gene occur constitutionally in FAP, whereas the same gene has mutations in the tumor cells (only) in sporadic colorectal cancers. [204], [205], [206] and [207]

Hereditary Nonpolyposis Colorectal Cancer In the HNPCC (Lynch) syndromes, carcinomas may arise through small precursor adenomas and flat adenomas. [45], [208], [209] This progression may occur quite rapidly, owing to an accumulation of oncogene mutations or suppressor gene deletions. Thus, the morphologic sequence of dysplasia to cancer is retained in the HNPCC pathway, but the molecular pathway is different. There are also subtle differences in pathology: more mucinous tumors at a more proximal location and a more prominent lymphoid reaction with tumor-infiltrating lymphocytes. MSI due to DNA mismatch repair is the hallmark feature of this sequence; frequency of MSI in adenomas is not yet clear. In HNPCC, the MSI pathway does not usually involve K-*ras DCC* or *p53.* [209] Molecular alterations in adenomas of patients with HNPCC involve a different pathway, including *TGFßRII* and *MSH6* itself. [188] Up to 15% of cancers show MSI, although only about 1% to 5% are due to a germ-line mutation of one of the mismatch repair enzyme loci *(MLH2, MSH1, MSH6, PMS2).*

Evidence from Clinical Observations

The average age at which adenomas develop (50 years) appears to precede the age of development of colon carcinomas (57 years). [26] Although it is considered unethical to follow an untreated adenoma for the possibility of progression, available evidence suggests that progression may occur. Adenomas have occasionally been left untreated because of patient noncompliance or technical difficulties; invasive carcinomas have been found to develop at the site of these adenomas. [190], [210], [211] Follow-up studies of patients who have had polyps smaller than 1 cm in diameter, demonstrated on barium enema in the precolonoscopic era when such lesions

were not surgically removed, have shown that cancers subsequently developed at this site (15%) or elsewhere in the colon (25%). [210]

The frequency of finding carcinoma within an adenoma also increases proportionally with increasing size, more severe dysplasia, and greater villous component of the adenoma. [190], [211], [212] Increasing numbers of adenomas is associated with increasing risk for future carcinoma. [190]

Evidence from Therapy

In a large, uncontrolled study, patients underwent periodic sigmoidoscopies, and all polyps that were found were removed. Most polyps removed were found to be adenomatous. The frequency of carcinomas occurring in a subsequent 7- to 14-year period was found to be about one third of the expected rate in an untreated population. [213] This has been confirmed in a retrospective study [214] and in the prospective National Polyp Study. [215] In the Murakami Study, [214] risk for subsequent cancer was highest in the patients who had biopsy alone and lowest when polypectomy was performed. In the National Polyp Study, patients underwent colonoscopy and polypectomy on enrollment with repeat colonoscopy at 1 year (in half) and at 3 and 6 years. No symptomatic cancers and five asymptomatic malignant polyps were found after almost 6000 patient-years of follow-up over more than 4 years. [215] This represents a 58% to 85% reduction in mortality rate from colorectal cancer, depending on whether the reference population is of average risk or includes adenomatous patients. In a study in patients with FAP who had colectomies and ileorectal anastomoses, it was found that periodic removal of adenomas from the rectal stump prevented the subsequent development of rectal carcinoma. [26]

Exceptions in the Evidence

There are exceptions to this adenomatous polyp–carcinoma sequence. There are rare reports of very small carcinomas developing de novo in apparently nonadenomatous epithelia. [216], [217] It is still possible, however, that the carcinoma may have arisen in a focus of the adenomatous epithelium that had not assumed a polypoid appearance (an event that has been observed in FAP), and that the carcinoma obliterated the dysplastic epithelium. The frequency with which this nonpolypoid progression occurs is important because effectiveness of strategies to prevent colorectal cancer through detection and removal of adenomatous polyps will be limited to the proportion that evolve through this pathway. [208], [218]

Although there is no precursor polyp, colorectal carcinoma in the setting of longstanding ulcerative colitis is believed to develop from a dysplastic focus. The progression from inflammation-injury-regeneration to dysplasia and then to carcinoma is believed to be analogous to the adenoma and dysplasia–carcinoma sequence. In addition, the dysplastic lesion in longstanding ulcerative colitis often assumes a raised plaquelike appearance. [219]

Overall, it would appear from these lines of evidence that most carcinomas arise from adenomas or an analogous dysplastic change in the colonic epithelium, even though different molecular biologic pathways may be responsible.

PRIMARY PREVENTION

A 20-fold change in risk for colorectal cancer has been observed in individuals at the extremes of the dietary spectrum. [78] If populations can be convinced to recognize unhealthy eating habits and change them, substantial control of colorectal cancer incidence could follow. The feasibility of this has already been explored in one of the first controlled trials of dietary intervention, the Australian Polyp Prevention Project. [169] In that study, adenoma recurrence after polypectomy was used as the surrogate for effect of diet on cancer. Except in the dominantly inherited colorectal cancer syndromes, the extreme of diet-related risk is greater than the degree of familial risk; hence, attention to dietary issues could have substantial impact. Unfortunately, the prospect for primary prevention by dietary means has suffered setbacks with the publication of the negative findings in the Arizona wheat bran trial and the National Cancer Institute study of low-fat plus fresh fruit and vegetables diet. [140], [141] The option of chemoprevention, especially by nonsteroidal antiinflammatory drugs, may have benefit. [220], [221], [222], [223], [224], [225], [226], [227], [228] and [229]

Dietary Intervention Studies

A study in New York of patients with FAP showed that wheat bran reduced adenoma formation in compliers, although not when analyzed on an intention-to-treat basis. [168] The Toronto Polyp Study [230] was a randomized controlled trial of low fat and high-fiber wheat biscuits versus normal fat and placebo biscuits in a population of adenoma patients. This study showed no beneficial effect of the intervention. The results, however, were not analyzed with respect to the size of adenomas developing during intervention, and the intervention biscuits necessarily involved some processing, which may have detracted from the fermentability of the fiber source.

The Australian Polyp Prevention Project [169] was a factorial randomized controlled trial in 424 subjects with recently removed adenomas, testing a low-fat diet (less than 25% energy as fat, red meat retained), a 25-g fine-particle unprocessed wheat bran supplement, and a 20-mg capsule of beta carotene. This trial proceeded over 4 years. None of the subjects randomized to the combination of low fat and wheat bran developed adenomas more than 9 mm in size, a result that was significant ($p < 0.03$) at both 2 and 4 years (Table 89-6). Trends for less dysplasia with wheat bran and fewer large adenomas with low fat were also seen. Although the proportion of patients with large adenomas was not the primary outcome parameter used to establish the sample size in the Australian Polyp Prevention Project, adenoma size was always considered an important outcome variable. Furthermore, pathological, [119] epidemiologic, anatomic, [33], [34] and [35] and molecular biologic [179] considerations all point to the importance of large adenomas in the pathogenesis of colorectal cancer. The Australian Polyp Prevention Project demonstrated the feasibility of compliance with dietary change in a high-risk group of patients (those with a history of adenomas). [169]

TABLE 89-6 Recurrence of Adenomas of Larger than 9 mm at 2 and 4 Years of Follow-up in the Australian Polyp Prevention Project

A larger randomized controlled trial of 13.5 g of processed wheat bran fiber versus placebo bran, not associated with fat reduction, showed no effect on adenoma recurrence of any size. [141] The National Cancer Institute Polyp Study also yielded a null result with a low-fat diet (less than 20% calories as fat) in combination with 3.5 servings per 1000 calories per day when compared with a no-change diet. [140] Neither of those latter studies combined a low-fat diet with wheat bran supplementation as in the Australian Polyp Prevention Project, but they have been influential in reducing enthusiasm for the preventative effects of dietary fiber.

SIGNS AND SYMPTOMS OF POLYPS

Colorectal polyps are usually asymptomatic. [231], [232] and [233] Most often, the polyps are discovered as an incidental finding during examination for intestinal or nonspecific abdominal complaints or other disorders or during screening endoscopy. Even in the case of FAP, in which adenomas number in the hundreds to thousands, symptoms occur late or result from development of colorectal carcinomas.

In a report of more than 800 hospitalized patients with colorectal polyps, 32% were found to be asymptomatic. [232] When symptoms occur, they tend to be in patients who have colorectal polyps of 1 cm in size or larger. The most common symptoms are rectal bleeding, both overt and occult, change in bowel habit, abdominal pain, and rectal prolapse. Of course, the association of these with a polyp may be coincidental. Furthermore, symptoms have little correlation with histological status, pathological condition, or location. [234]

Histological studies have shown that compared with carcinomas, adenomas tend to have minimal ulceration and an intact lumenal surface. Rectal bleeding tends to be intermittent and small in amount, only rarely resulting in anemia, with the exception of FAP. [235] Studies have demonstrated that only patients with polyps of 1.5 cm

in size or larger have consistently higher amounts of (usually occult) fecal blood loss than healthy control subjects. [236]

Many screening studies using fecal occult blood tests (FOBTs) demonstrate that 20% to 40% of asymptomatic patients with positive FOBT results have colonic or rectal adenomas, and 5% to 10% have cancer. Conversely, 15% to 40% of patients with adenomas have positive FOBT results, depending principally on the size of the adenoma. Newer fecal occult blood technology (immunochemical tests) and fecal DNA testing might increase both the sensitivity and specificity of fecal tests. [237], [238]

Less than 20% of patients presenting with frank rectal bleeding are found to have colorectal adenomas as the only obvious pathology. Rectal bleeding, especially of recent onset and in patients older than 40 years of age or those with other risk factors such as family history, should not be ascribed to coexisting hemorrhoids without a thorough evaluation of the anus, colon, and rectum. [239], [240]

A syndrome of profuse, watery diarrhea, resulting in massive fluid and electrolyte depletion, has been described for large villous adenomas, especially those located in the distal colon and rectum. [233], [241] Colorectal polyps, especially juvenile polyps, may occasionally undergo autoamputation, resulting in rectal bleeding. The presence of recognizable polyp tissue in the feces is extremely rare. [242], [243] Colocolic intussusception due to large polyps has been found in children. [244] Diffuse, nonspecific abdominal pain has been at times attributed to intussusception, particularly of larger polyps. Rectal prolapse of larger polyps also has been reported. [244]

Physical examination rarely reveals signs of colorectal polyps. A digital examination by an experienced person is important as part of all anorectal and colonic evaluations, especially because flat villous lesions close to the dentate line are easily missed at endoscopy, and the digital examination frequently reveals the diagnosis most easily.

MORPHOLOGIC AND CLINICAL FEATURES OF NEOPLASTIC POLYPS

The initial diagnosis is usually made by direct endoscopic visualization of the polyp, which should then undergo biopsy or be removed by polypectomy to determine its histological type. At the time of endoscopic examination, certain morphologic features may help classify the polyp, although these features can be misleading. [245], [246]

Because the chance of malignancy in an adenoma is proportional to its size, its villous component, and the degree of dysplasia, these parameters should be described by the pathologist. [247], [248], [249], [250] and [251] This alerts the clinician to the need to look especially carefully for malignancy in multiple sections in, for example, the large villous adenoma with severe dysplasia. It also partly determines the risk for future advanced adenomas in that individual, thereby guiding decisions on surveillance.

Tubular Adenomas

Tubular adenomas (Fig. 89-2 and Fig. 89-3; Color Fig. 89-2 and Color Fig. 89-3) usually are darker red than the surrounding mucosa, have a smooth surface, and tend to be smaller than villous adenomas. Histology shows the presence of infolding tubules. These adenomas may display the entire spectrum of dysplasia, ranging from mild to severe [26], [115], [120], [190] (Fig. 89-4 and Fig. 89-5; also see Color Fig. 89-4 and Color Fig. 89-5 and Fig. 89-9 and Fig. 89-10).

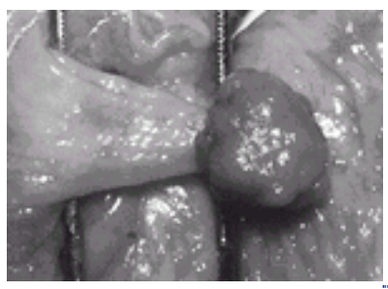

FIGURE 89-2. (See Color Fig. 89-2.) Macroscopic appearance of a pedunculated tubular adenoma. The forceps mark the base and the neck of the stalk.

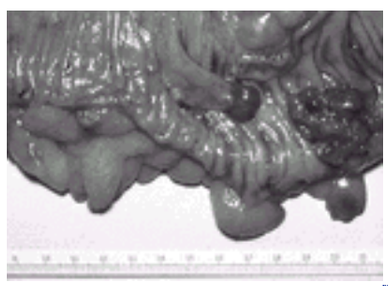

FIGURE 89-3. (See Color Fig. 89-3.) A synchronous, pedunculated, tubular adenoma adjacent to a sessile, tubulovillous adenoma. Synchronous adenomas not infrequently are found adjacent to each other. In this instance, a 1-cm, pedunculated, tubular adenoma is found about 5 cm from a 3-cm, sessile, tubulovillous adenoma. Note the smooth surface of the tubular adenoma and the smooth, lobulated surface of the tubulovillous, primarily tubular adenoma.

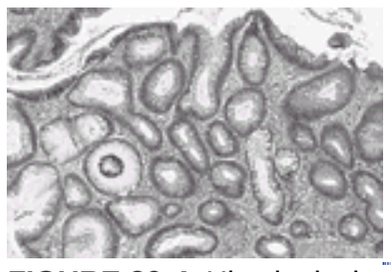

FIGURE 89-4. Histological appearance of a tubular adenoma with low-grade dysplasia. Architectural organization includes orderly, closely packed epithelial tubules. Cells have a normal nuclear-to-cytoplasmic ratio, nuclei have a predominantly basal orientation, and goblet cells are present.

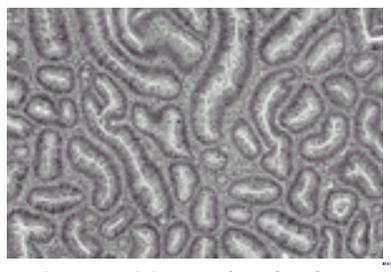

FIGURE 89-5. Histologic appearance of a tubular adenoma with low-grade dysplasia but slightly more architectural distortion than in Figure 89-4. There is also more cellular crowding, variation in nuclei, and occasional loss of basal polarity with an increased nuclear-to-cytoplasmic ratio. No goblet cells are seen. In the three-tier system of grading dysplasia, this could be classed as moderate in grade.

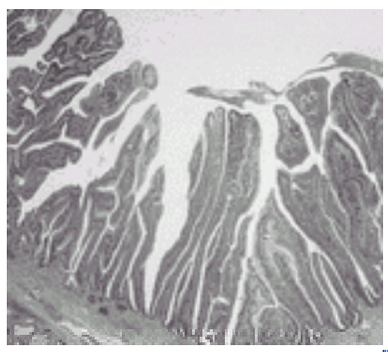

FIGURE 89-9. Histological section of a villous adenoma with typical frondlike appearance. Note the more marked architectural disturbance than seen with tubular adenomas. The nuclear-to-cytoplasmic ratio is increased, and nuclei are not always basally situated.

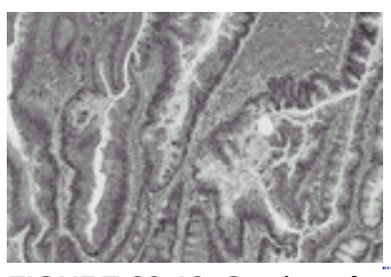

FIGURE 89-10. Section of a tubulovillous adenoma showing high-grade dysplasia. Note the substantial architectural disturbance and pallisading of nuclei.

Villous Adenomas

Villous adenomas constitute about 5% of all adenomas and tend to occur more often in patients older than 60 years of age [191], [192], [247], [248], [249] and [250] (Fig. 89-6, Fig. 89-7, Fig. 89-8, Fig. 89-9; Color Fig. 89-6, Color Fig. 89-7, and Color Fig. 89-9). When seen during endoscopy, they usually are larger and typically sessile compared with tubular adenomas. The surface has a shaggy, cauliflower-like or frondlike appearance, may be soft and velvety, and is often friable. A finely granular surface pattern and a reddish color with white spots may be seen, and spraying of dye may show a characteristic pattern. [248] Villous adenomas tend to be distal in location, large, and bulky. [248], [250]

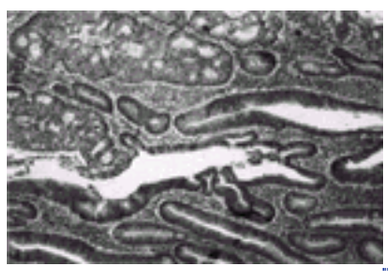

FIGURE 89-6. Histological appearance of a tubulovillous adenoma with severe dysplasia and contiguous carcinoma. Note the hyperchromatic elongated nuclei with loss of basal polarity and the increased nuclear-to-cytoplasmic ratio. There is a sharp and drastic transition between these adenomatous features and carcinoma.

FIGURE 89-7. (See Color Fig. 89-7.) This cecal villous adenoma is virtually circumferential, with submucosal carcinomatous invasion. The lesion is sessile in nature and has a cauliflower appearance with a shaggy, frondlike, friable surface that contrasts with the smoother, lobulated surface seen in Figure 89-2.

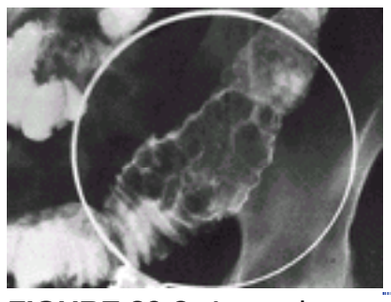

FIGURE 89-8. A very large, multilobulated, polypoid mass is demonstrated in the colon by radiography. Note the shaggy-appearing mucosal surface. The mass was

subsequently found to be a large, sessile, villous adenoma that was virtually circumferential, similar to the lesion in Figure 89-7.

Tubulovillous Adenomas

Tubulovillous adenomas contain at least a 25% villous component and at least a 25% tubular component, without either architectural type predominating. Their clinical behavior tends to be intermediate between that of tubular and villous adenomas [119] (Fig. 89-6 and Fig. 89-10; Color Fig. 89-6 and Color Fig. 89-10).

Flat Adenomas

Nonpolypoid adenomas, or flat adenomas (localized dysplasia without macroscopic protrusion), have been described, particularly in some cancer-prone families. These tend to be minimally raised if at all, small (usually less than 1 cm) discoid plaques, and they are often erythematous. Because they are not polypoid, they are often missed during colonoscopy. [45], [193], [194], [195], [196] and [197], [216], [217] and [218], [252], [253] and [254] Judicious use of air insufflation during colonoscopy is needed to detect these lesions because overinflation makes them very difficult to detect at colonoscopy.

A familial syndrome with flat adenomas has been described by Lynch and colleagues. [218], [255] Most of these "hereditary flat adenoma syndromes" are atypical (or "attenuated") FAP, with mutations in the 5'-proximal end of the gene producing a very short, truncated protein. Flat adenomas might be an early phase of adenomas in HNPCC, but this is less certain.

Despite their small size, more than one third of these flat adenomas have foci of high-grade dysplasia, especially if centrally depressed. [198], [255], [256] and [257] In addition, flat adenomas are often multiple and associated with small adenocarcinomas. [252], [253], [254], [255], [256], [257] and [258]

Serrated Adenomas and Mixed Hyperplastic-Adenomatous Polyps

Serrated adenomas have the architectural features of hyperplastic polyps but include intermingled glands with the cytologic features either of adenomas (dysplasia) or of hyperplastic glands [259], [260], [261] and [262] (Fig. 89-11; Color Fig. 89-11). They account for less than 1% of colorectal polyps. [260] Serrated adenomas are associated with a high frequency of high-grade dysplasia (up to 40%). Mixed hyperplastic-adenomatous polyps show the two types of histology in distinctly separate regions; they should also be treated with caution.

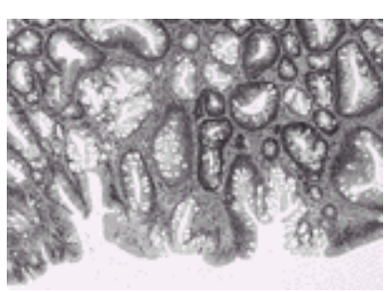

FIGURE 89-11. Histological section of a serrated adenoma showing intermingling of dysplastic and hyperplastic cytology, the latter being responsible for the serrated appearance at a lower power of magnification. Goblet cell density is highly variable. Typically, the hyperplastic cytology is more prominent toward the surface. Note the substantial architectural disturbance and the great variation in nuclear-to-cytoplasmic ratio between the different types.

MORPHOLOGIC AND CLINICAL FEATURES OF NONNEOPLASTIC POLYPS

The nonneoplastic polyps consist of distinct and unrelated groups: simple mucosal, hyperplastic, inflammatory (including pseudopolyps), hamartomatous (including juvenile polyps), and other submucosal polypoid lesions. Dysplasia does not occur by definition.

Simple Mucosal Polyps

Simple mucosal polyps are small, pearl-like excrescences with coloration and appearance similar to adjacent normal mucosa. They are usually smaller than 5 mm, consist of normal colonic mucosa, and have no known clinical significance. [119]

Hyperplastic Polyps

Hyperplastic polyps are usually small (less than 5 mm) and sessile, are found predominantly in the distal colon, and are pale in color. The frequency of hyperplastic polyps appears to increase with age. [19] They are characterized by elongated glands with papillary infolding and increased mucus (Fig. 89-12 and Fig. 89-13; Color Fig. 89-12 and Color Fig. 89-13), which often gives a serrated appearance to the surface of the polyp. [116], [126], [263], [264] The cribriform crypt pattern of adenomas is not usually seen. Such changes may be more easily discerned by using chromoendoscopy.

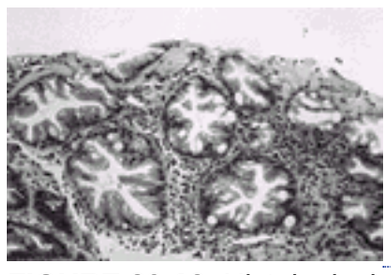

FIGURE 89-12. Histological appearance of a hyperplastic polyp, characterized by the typical elongated glands with papillary infolding, which produces a serrated surface appearance. The epithelial cells are well differentiated, with abundant cytoplasm, a normal nuclear-to-cytoplasmic ratio, and abundant goblet cells. The nuclei are not hyperchromatic, retain their basal polarity, and show no dysplasia. The starfish appearance of the hyperplastic crypts seen in cross section is characteristic.

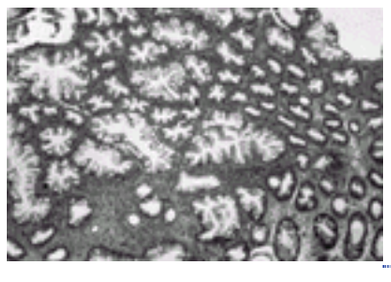

FIGURE 89-13. Histological appearance of adenomatous epithelium in a predominantly hyperplastic polyp. This polyp should be managed as if it were an adenoma.

Hyperplastic polyps have been associated with the presence of adenomas and even carcinomas in the same colon, [212], [265], [266] although larger studies report this association as serendipitous. Therefore, they are not considered a risk factor for colorectal cancer, unless in the context of hyperplastic polyposis or mixed polyps (see earlier). Despite their lack of malignant potential, hyperplastic polyps are often removed because it is not possible to be certain at endoscopy that they are not adenomas. [245], [246]

Inflammatory Polyps

Inflammatory polyps are usually found in the setting of severe inflammatory diseases of the colonic mucosa: ulcerative colitis, [267], [268] and [269] Crohn's disease, [270], [271] amebiasis, [272] strongyloidiasis, [273] tuberculosis, [274] solitary rectal ulcer syndrome, [275] ischemic colitis, [276] severe diverticular disease, [277] or schistosomiasis. When a polyp consists of residual islands of intact colonic epithelium in an area denuded of mucosa, the term *pseudopolyp* is often applied. Inflammatory polyps can also consist of exuberant masses of granulation tissue. Inflammatory polyps may be large and solitary, with marked inflammation and ulceration, and can thus appear to be malignant at endoscopy. [267], [269], [270] In schistosomiasis, the inflammatory polyp may contain schistosome eggs or adult worms. Dysplasia in schistosomiasis-associated polyps may be premalignant. [278]

Inflammatory polyps may produce symptoms of pain and obstruction [278] and may become pedunculated [278], [279] or filiform. [274], [280] Occasionally, they may occur in settings of minimal inflammation, such as ulcerative colitis in remission, [267], [281] or in a familial setting. [282] Inflammatory polyps must be carefully distinguished from dysplastic and neoplastic mass lesions [268] (Fig. 89-14).

FIGURE 89-14. Multiple inflammatory polyps are present throughout the colon in a patient with ulcerative colitis. Colonoscopy and biopsy are necessary for proper identification of the lesions.

The inflammatory "cap" polyp, found in the rectal area, is thought to be a result of mucosal prolapse. It is covered by a cap of inflammatory, hemorrhagic, or granulation tissue. Associated symptoms include mucous diarrhea, tenesmus, and rectal bleeding. Symptoms resolve after polypectomy. [283], [284] and [285] An unusual inflammatory polyp arising in the anorectal mucosa, and often presenting with rectal bleeding, is the inflammatory cloacogenic polyp. [275], [286]

Another inflammatory polyp has been termed the *inflammatory myoglandular polyp* because of the presence of inflammatory and granulation tissue in the lamina propria with abundant smooth muscle proliferation and hyperplastic glands with occasional cystic dilation. When symptoms are present, they consist of overt or occult rectal bleeding. [287]

Carcinoma can occur in inflammatory polyps; unusual inflammatory polyps in complex formations should be sampled. [268]

Hamartomatous Polyps

Juvenile Polyps Juvenile polyps, also known as *retention polyps* because they contain mucin cysts, are so termed because three fourths of them are found in children younger than 10 years of age. [288], [289] They tend to be single, pedunculated, cherry-red, and round and possess a smooth surface. They are often friable and ulcerated, bleed frequently, and tend to prolapse because of their pedunculated nature. [242], [289], [290], [291], [292] and [293] They are also liable to volvulus with resultant ulceration, hemorrhage, autoinfarction, and autoamputation. Histologically, juvenile polyps are hamartomas with distended, mucus-filled glands, often with cystic dilation and edematous lamina propria containing abundant vasculature. Juvenile polyps are rare in the first year of life and are thus presumed to be acquired and not congenital. They occur rarely in the second decade of life but become common again in adulthood. The true prevalence is difficult to determine. In one study, a frequency of about 2% was found in asymptomatic children. [294] In series of children seen for rectal bleeding, 30% have juvenile polyps, with up to half of these being multiple. [291], [292], [295] Of all polyps found in children younger than 15 years of age, up to 97% can be juvenile polyps. [242] Isolated pure juvenile polyps usually are not dysplastic and have no intrinsic malignant potential. Juvenile polyps also may occur in a familial setting, [296], [297] with a pattern of autosomal-dominant inheritance of polyposis (see Chapter 90). In familial juvenile polyposis, adenomatous and carcinomatous changes are frequent throughout the gastrointestinal tract and in family members. [296], [297], [298], [299], [300], [301], [302], [303], [304] and [305] Jass has provided guidelines for the diagnosis of juvenile polyposis as follows: [306]

- More than five juvenile polyps of the large bowel
- Juvenile polyps throughout the gastrointestinal tract
- Any number of juvenile polyps with a family history of juvenile polyposis.

Because solitary juvenile polyps occasionally have associated adenomatous changes, all juvenile polyps should be excised in toto. After removal, juvenile polyps recur only infrequently, with a rate of about 3% in 3 years. [294] If extensive adenomatous changes or severe dysplasia is seen, the patient may be considered for surveillance. [302], [303], [304], [305] and [306] Two candidate genes responsible for familial juvenile polyposis have been reported: the *PTEN* gene [307] and the *SMAD4*/ *DPC4* gene [308] on chromosomes 10 and 21, respectively. Recently, another locus, the bone morphogenetic receptor 1A gene *(BMPR1A)* has also been described in juvenile polyposis. [309]

Peutz-Jeghers Polyps Multiple hamartomatous polyps are found throughout the gastrointestinal tract in Peutz-Jeghers syndrome [310] and usually show prominent branching of smooth muscle. This is a rare autosomal-dominant syndrome of gastrointestinal hamartomatous polyposis associated with melanin spots of the lips, buccal mucosa, and extremities [311] (see Chapter 90). Peutz-Jeghers polyps are not considered premalignant, although the syndrome has occasionally been associated with an increase in carcinomas, mostly extracolonic. [312], [313], [314] and [315] The genetic locus for Peutz-Jeghers syndrome is the serine-threonine protein kinase gene on chromosome 19p. [316] Unusual hamartomas with abundant adipose tissue have been described. [317], [318]

Submucosal Polyps

Submucosal polyps represent elevations of the mucosal surface by submucosal lesions. They are diverse in origin.

Lymphoid Hyperplasia When a focus of diffuse lamina propria lymphocytes becomes hyperplastic, diffuse nodular lymphoid hyperplasia may result. [319], [320], [321] and

[322] Typically, the colonic (or more usually, small intestinal) mucosa is covered with polypoid nodules, generally 5 mm in size or smaller. [320], [321], [323], [324] Symptoms are unusual, and clinically significant nodular lymphoid hyperplasia is usually a condition of the small bowel in children, without any clinical significance. [320], [323], [325] In a series of 1000 consecutive autopsies, incidental nodular lymphoid hyperplasia was found in 3%. [326] Discrete lymphoid polyps, which appear pale yellow or white, may also occur but these do not produce symptoms. [327], [328] Diffuse nodular lymphoid dysplasia occurring in the large bowel needs to be distinguished from familial adenomatous polyposis; biopsy with histopathological diagnosis is important. [329], [330] The latter requires surgery; the former is usually coincidental and requires no intervention. Distinction between malignant lymphoma and multiple polyps can be difficult [331], [332], [333] and [334]; lymphoma has developed in a few patients with apparent nodular lymphoid hyperplasia. [321], [335], [336] It is unclear whether the malignant lymphoma represents a progression from the lymphoid hyperplasia or a de novo development of lymphoma.

Pneumatosis Cystoides Intestinalis Pneumatosis cystoides intestinalis refers to multiple air-filled cysts found within the submucosa of colon or small intestine. The air-filled cysts are easily recognizable by radiographic examination as well as endoscopy (Fig. 89-15). At endoscopy, they are seen as multiple polypoid lesions in the colonic mucosa, which on closer examination appear to be translucent polyps that may look like air blebs just underneath the mucosa. On biopsy, there is often a release of the submucosal air and deflation of the polypoid lesion. [337], [338]

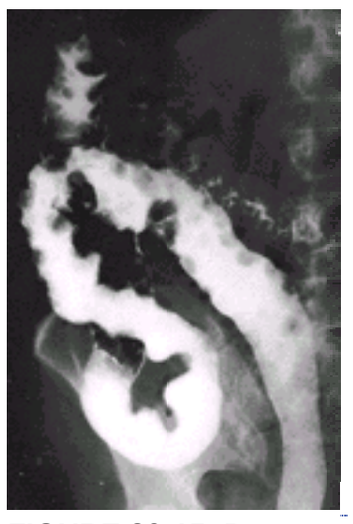

FIGURE 89-15. Pneumatosis cystoides intestinalis seen on barium-enhanced radiography. The intramural gas-filled cysts could have been identifiable on a plain abdominal radiograph.

Pneumatosis intestinalis is generally asymptomatic [337], [338] but can also be associated with pneumoperitoneum. [339], [340] Occasional cases associated with scleroderma or chronic obstructive pulmonary disease have been seen. [338] In these cases, the air-filled cysts may resolve after treatment with oxygen. [340] Pneumatosis intestinalis may also complicate ischemia, necrosis, or necrotizing enterocolitis, when it is often fatal. [336]

Colitis Cystica Profunda Colitis cystica profunda is usually a manifestation of rectal prolapse. The radiographic appearance of colitis cystica profunda is virtually indistinguishable from that of solitary or multiple colonic polyps. The endoscopic appearance can be alarming, mimicking a polypoid cancer. The polyps are sessile and consist of dilated, epithelium-lined mucous cysts within the muscularis mucosae. They are found most often in the rectum in association with inflammatory colitis, or after surgery. [341], [342], [343], [344] and [345] When seen within an adenoma, colitis cystica profunda has been referred to as *pseudoinvasion, epithelial displacement* or *misplaced epithelium*. [346], [347]

Lipomas Lipomas within the gastrointestinal tract are found most commonly within the colon, usually in the right colon on or near the ileocecal valve. These lesions tend to be solitary but may be multiple in 20% or more of cases. Radiographically, they often show up as slightly radiolucent submucosal lesions. At colonoscopy, they appear yellow with a normal mucosa overlying the polyp continuous with surrounding nonpolypoid mucosa. They are easily identifiable on probing with the biopsy forceps. Polyps with these characteristics need neither biopsy nor polypectomy. [348], [349]

Other Submucosal Lesions A number of other rare submucosal lesions also may present radiographically or endoscopically as polypoid lesions. Biopsies of the surface would reveal normal colonic epithelium. Deeper biopsies, or biopsy after submucosal saline injection to elevate the mass, may be required to reach the submucosal mass. Endorectal ultrasonography is particularly useful in diagnosing the origin of a submucosal tumor and whether invasion is present. Malignant submucosal lesions include carcinoids [350], [351]; metastatic carcinomas, most commonly malignant melanoma [352] and lymphoma [332], [333]; gastric cancer [353]; Kaposi sarcoma [349]; and plasma cell leukemia. [354] Benign lesions include lymphangiomas, fibromas, neurofibromas, [355] leiomyomas, myoblastomas, hemangiomas (including the blue rubber bleb syndrome), and endometriosis. [356] Other colorectal lesions may occasionally masquerade as polyps. Such lesions include hemorrhoids, condylomata, [357] enlarged anal papillae, fibrous anal polyps, inverted diverticula, [358] enteroenteric and ureteroenteric anastomoses, [359] and the residual stalk of a pedunculated polyp after polypectomy. [360] Inverted diverticula are important to recognize and not misdiagnose because “polypectomy” can result in perforation. They are rather flat and a little distensible, often with a slight central umbilication.

SCREENING FOR ADENOMAS

Detection of asymptomatic colorectal adenomatous polyps is achieved in the settings of colorectal cancer screening and postcancer and postadenoma surveillance, and as an incidental finding during colonoscopy for other reasons of early detection of colorectal cancer. [96], [361], [362], [363], [364], [365], [366], [367], [368] and [369] These issues are discussed in detail in Chapter 34 and Chapter 91.

Fecal Occult Blood Testing

FOBT is relatively ineffective at detecting polyps, especially small ones. On the other hand, polyps detected as a result of this type of screening are usually large, [236] and large polyps are known to bleed.

Sigmoidoscopy

Ten percent of colorectal neoplasms are located in the rectum, and an additional 35% to 45% occur in the sigmoid colon (see Table 89-3). The standard rigid sigmoidoscope has a potential depth of insertion of 25 cm, although on average, a 17- to 20-cm depth of insertion is achieved. A 60-cm flexible sigmoidoscope could achieve an average length of insertion of 48 to 55 cm and thus should detect between 50% to 70% of all colorectal neoplasms. [370], [371] and [372] In general, flexible sigmoidoscopy provides a two to three times higher yield of adenomas than rigid sigmoidoscopy. Flexible sigmoidoscopy, however, is more expensive, requires more skill, and takes longer to perform than rigid sigmoidoscopy. Nevertheless, it is preferred over rigid sigmoidoscopy because of its higher yield and greater patient comfort and acceptance. [373], [374]

Only one controlled trial of screening sigmoidoscopy has been reported; this demonstrated a mortality benefit for sigmoidoscopy when combined with other cancer-protective interventions, but the contribution from sigmoidoscopy is difficult to determine. [375] Two case-control studies have shown that patients who develop fatal distal colorectal cancer are 60% to 70% less likely to have had a rigid or flexible sigmoidoscopy in the previous 10 years compared with controls without cancer. [376], [377] Those studies are also somewhat difficult to interpret because it was not clear that the procedure led to more polypectomies, necessary for a direct impact on colorectal cancer. A large randomized controlled trial of flexible sigmoidoscopic screening for colorectal cancer has commenced in the United Kingdom, but results are not yet available. [378]

Flexible sigmoidoscopy alone will not detect all colorectal cancers. Even allowing for the fact that some proximal cancers will have distal adenomas signaling their presence, almost 80% of proximal cancers and significant adenomas will not be suspected at flexible sigmoidoscopy. [379] In later studies by Lieberman and associates, [369] nearly two thirds of asymptomatic patients with advanced proximal neoplasia had no adenomas in the rectum and sigmoid colon, and over half of the same patients had no adenomas distal to the splenic flexure. In a parallel study reported by Imperiale and colleagues, [370] 46% of patients with advanced proximal neoplasia had no distal polyps; however, there was a gradient of risk for proximal advanced neoplasia in patients with distal hyperplastic polyps (relative risk [RR], 2.6), distal adenomas (RR, 4.0) and distal advanced neoplasia (RR, 6.7) as well as with older age (RR, 1.3 per 5 years) and male sex (RR, 3.3).

Radiography

Use of barium enema for the screening of asymptomatic, average-risk people in large populations has not been reported. On the other hand, a place for virtual colonoscopy (spiral or multislice computed tomography scanning after bowel preparation) is emerging in screening. Accuracy is still less than with colonoscopy, but the procedure is safe, and costs are comparable with colonoscopy. [380], [381] and [382]

Colonoscopy

Although colonoscopy is highly sensitive and specific (when combined with histopathology) for colorectal neoplasia, its expense, discomfort, and potential complications can be prohibitive. In the absence of proof from randomized clinical trials, it is recommended by few national authorities as a screening tool for average-risk, asymptomatic people, although such trials are now in pilot phase. [383] In a study of 3121 veterans (mean age, 62.9 years) neoplastic lesions were found in 37.5%, with advanced lesions (more than 9-mm adenomas, villous lesions, high-grade dysplasia, or invasive cancers) in 10.5%. There were 30 cancers. Distal adenomas were a significant although nonspecific marker of proximal advanced disease. [371] Colonoscopy is considered an appropriate screening tool for selected high-risk groups: individuals who have, on the same side of the family, multiple first-degree relatives or a first- and second-degree relative with colorectal cancer, a single first-degree relative diagnosed before reaching 55 years of age, [41], [44], [231], [384], [385], [386] and [387] family members at risk for HNPCC, patients with longstanding ulcerative colitis, and those with a previous history of adenoma or cancer.

Several studies show only a modest increase (twofold) in lifetime risk for colorectal cancer in first-degree relatives of single-case families in which the index case is older than 55 years of age at diagnosis. [40], [388] Colonoscopic surveillance studies addressing family risk have rarely stratified their results with respect to the age of the index case. One has shown only a nonsignificant trend to higher yields when the index case was younger than 60 years of age. [231] Another showed a significant increase in adenoma incidence compared with controls, only when the index case was younger than 65 years of age. [389] Other than in HNPCC and FAP, relatively low yields of advanced neoplastic lesions in those undergoing colonoscopic surveillance and younger than 50 years of age regardless of the risk category have been consistently observed, because age is the dominant determinant of risk (yield). [231], [386], [387], [390], [391] Many authorities advise commencing screening at 50 years, or 10 years younger than the earliest age of onset in the family, whichever is earliest. A case-control study of endoscopy or barium enema experience before diagnosis of cancer, however, indicated a 50% reduction of risk with use of sigmoidoscopy, colonoscopy, or barium enema, a protection that extended for 6 years. [392]

DIAGNOSIS OF ADENOMAS

Digital rectal examination, FOBT, and sigmoidoscopy were discussed earlier and are also discussed in Chapter 34 and Chapter 91. In the symptomatic patient, their use is limited.

Radiography

Single-contrast barium enema has been shown to have about 75% sensitivity and specificity for detection of polypoid lesions [393], [394]; it is better with double-contrast (air-contrast) barium enema. [395], [396] Even so, most studies have found that double-contrast barium enemas miss a proportion of polypoid lesions subsequently detected at colonoscopy. [395], [397], [398] and [399]

Colonoscopy

When a patient is clinically suspected of having a colorectal neoplasm, colonoscopy is the procedure of choice (see earlier and Chapter 140). Colonoscopy allows detection, diagnosis, and removal of adenomas in most instances. Colonoscopy itself is safe, even in young children. [398], [400], [401], [402] and [403] Most complications are due to polypectomy (see “Polypectomy as Therapy”).

Colonoscopy is highly accurate for polyp detection but not infallible. [404], [405] and [406] Miss rates for adenomas of any size have been estimated at 17% from studies of paired colonoscopies performed within 120 days. [407] Three of 46 adenomas larger than 9 mm were missed in this study. This may be a biased estimate because the reason for performing the second colonoscopy may have been the suspicion of inadequate colonoscopy the first time. In a back-to-back tandem colonoscopy study, there was a 24% miss rate overall, with 6% of the adenomas larger than 1 cm being missed. [14], [408] In a study at St. Mark’s Hospital in London, colonoscopy and double-contrast barium enema were performed in tandem; 92% of polyps larger than 7 mm were detected at colonoscopy, compared with 74% by double-contrast barium enema. [409]

Small rectal tubular adenomas are not considered to represent a risk factor for future colorectal cancer [410] (Table 89-7) and are weak but significant predictors of proximal advanced lesions [367], [368], [411]; thus, one could question whether full colonoscopy is needed when these are detected. The question is somewhat academic because polyp removal requires an adequate bowel preparation to ensure safety (eliminating risk for explosion from electrocautery), and thus the patient is already prepared for total colonoscopy. The evidence that the future risk is low comes from sigmoidoscopic series in which the polyps were initially completely removed. [410] Complete removal is critically important. Indeed, most of the cancers found in an earlier series from the same institution occurred in incompletely removed adenomas, albeit mostly villous in histology.

	RELATIVE RISK*	95% CI
Single tubular adenoma <1 cm	0.5	0.4–1.3
Single TVA, VA, or TA >1 cm	3.4	2.3–4.8
Multiple adenomas	7.7	3.7–14.2

*Risk assessed from 1618 patients at St. Mark's Hospital, diagnosed in the pre-colonoscopy era.

TVA, tubulovillous adenoma; VA, villous adenoma; TA, tubular adenoma.

Data adapted from ref. 410.

TABLE 89-7 Risk for Colorectal Cancer After Polypectomy from Rectum or Sigmoid Colon

Colonoscopy or Radiography?

In general, colonoscopy is 10% to 12% more accurate than air-contrast barium enema and gives fewer false-positive results. [398], [399], [406], [412], [413] In addition, it allows for polypectomy and biopsy of all suspect lesions. Diverticular disease, redundant loops of colon, and poor coating or residual feces compromise the interpretation of barium enema examinations, particularly in patients older than 50 years of age, who are the ones most likely to have a neoplasm. [409]

When directly compared in a double-blind study, colonoscopy detected 95% of large adenomas, whereas barium enema detected only two thirds. [409] Comparing the diagnostic experience in more than 2000 patients with colorectal cancer, barium enema was 85.2% and consecutive colonoscopy 95% accurate. [413] Patient discomfort with barium enema is about the same as with colonoscopy.

The accuracy of both procedures, however, depends on the expertise of the examiner, and quality assurance programs should be maintained for both. Also, there are patients in whom colonoscopy cannot be completed to the cecum for anatomic or clinical reasons. In these patients, the air-contrast barium enema or virtual colonoscopy is required to detect proximal lesions (Fig. 89-16). Radiography should, therefore, be considered complementary to colonoscopy.

FIGURE 89-16. A pedunculated polyp demonstrated by double-contrast radiography. Note the lobulated appearance of the polyp surface. The mass was subsequently found at polypectomy to be a tubulovillous adenoma.

Concerning virtual colonoscopy, the ideal technique is still being developed; bowel preparation and technological refinements need further exploration before conclusions can be reached about how it compares with colonoscopy. Virtual colonoscopy has not been compared head to head with barium enema.

Biopsy and Histopathological Examination

Biopsy or polypectomy of a polypoid lesion is necessary because histopathological analysis is the definitive diagnostic test. Pathology review with the pathologist [414] is necessary to optimize biopsy and polypectomy procedures as well as handling of specimens. Separate specimen containers should be used when specimens are obtained from different sites; otherwise, lesions may be interchanged, and it may be difficult or impossible to determine which of several anatomically distinct lesions is the one showing adenomatous changes or malignancy on histological examination. Marking the site of a polyp with sterile India ink may help subsequent localization, especially if surgery is needed for malignancy within a polyp. Alternatively, a metal clip can be attached to the mucosa at the site.

NATURAL HISTORY /H3>

Nonneoplastic Polyps and Submucosal Lesions

The natural history depends on the type of lesion. Most nonneoplastic polyps are removed by endoscopic polypectomy for definitive diagnosis. Metastatic lesions, such as malignant melanomas and lymphomas, are aggressive tumors. Other lesions, such as lipomas and fibromas, usually pose no clinical concern.

Adenoma Growth and Malignant Conversion

Because of their potential premalignant nature, understanding the natural history of adenomatous polyps is of major clinical importance. Unfortunately, the natural history, growth rate, and likelihood of progression to malignancy of adenomas are still not completely understood.

Not all adenomas are destined to grow. A study using serial sigmoidoscopy to follow asymptomatic tattooed rectal polyps smaller than 1 cm (not all of which would have been adenomas) found that over the course of 3 to 5 years, only 4% of the polyps increased in size, 70% remained unchanged, 8% were smaller, and 18% disappeared spontaneously. [415], [416] Studies using serial barium enemas also suggest that most polyps (undefined type) grow very slowly, if at all. [417], [418]

A retrospective study examined the risk for colorectal carcinoma at the site of an adenoma 1 cm or larger left in situ. Altogether, 226 patients were followed for an average of more than 5 years with an average of five barium enemas per patient. During the course of follow-up, 37% of the polyps increased in size, colorectal carcinomas developed at the site of the index polyp in 10% of the patients, and colorectal carcinoma developed at sites at a distance from the index polyp in another 5%. The cumulative risk for carcinoma at the site of a polyp 1 cm or larger was estimated to be 3% at 5 years, 8% at 10 years, and 24% at 20 years. [210]

A prospective follow-up of the natural history of 215 unresected polyps less than 5 mm in diameter has been reported. At polypectomy 2 years later, about 50% were found to be hyperplastic polyps, 25% were mucosal polyps, and only 25% were adenomatous polyps. The course was variable. Usually, mucosal polyps regressed, and the adenomas and hyperplastic polyps enlarged, with a doubling in size in the 2-year period; however, no polyp was significantly larger than 5 mm, and no high-grade dysplasia or cancer was found. [419]

Using the available data on the growth rate of adenomas and carcinomas and including information on average age of diagnosis of adenomas by size and level of dysplasia and cancer, [190], [415] a mathematical model has suggested that for those that grow, it takes 2 to 3 years for a small adenoma (less than 0.5 cm) to grow to 1 cm in size and another 2 to 5 years for the 1-cm adenoma to progress to carcinoma. [419], [420] Invasion and metastasis probably takes another 2 years, and on average, death occurs 2 years after this. These results, when taken together, suggest that most adenomatous polyps enlarge only slowly if at all and that those most likely to progress to malignancy are those that have reached 1 cm in size.

If one compares adenoma prevalence data in autopsy studies (see earlier, 40% to 50% prevalence) with lifetime cumulative incidence of colorectal cancer (of about 4% to 5% in most Western countries), after allowing for multiplicity of adenomas, it can be deduced that only about 1 of 20 adenomas is destined for malignancy.

Adenoma Recurrence after Removal

In the National Polyp Study conducted in the United States, the rate of occurrence of new adenomas in patients followed by periodic colonoscopy and polypectomies was about 27.5% (a significant proportion were probably missed synchronous polyps) at 1 year and 32% at 3 years. These results suggest a new adenoma rate of about 5% per year on average in those who have had an adenoma, not allowing for missed adenomas. Those with more than two adenomas or severe dysplasia were more likely to have advanced neoplasia at follow-up, as were men older than 60 years of age with a family history of colorectal neoplasms. [399], [421] In this study, neither size nor histology was predictive of advanced lesions. All studies on risk for metachronous adenomas identify multiplicity as a risk factor for metachronous adenomas, whereas many show size as an independent predictor as well. [422], [423], [424] and [425]

Malignant Polyps

Severe dysplasia or “intramucosal carcinoma” within a polyp is not considered to be cancer because it does not breach the muscularis mucosae. Lymphatics in the colon do not extend beyond the muscularis mucosae into the lamina propria, and hence the possibility of spread is negligible. There have not been any confirmed reports of lymphatic invasion resulting from severe dysplasia or intramucosal carcinoma. [212], [426], [427] and [428]

Evaluation of invasiveness comes from pathological examination of a completely removed polyp and serial sectioning of it; otherwise, malignancy may be missed. [212] If the neoplastic lesion invades through the muscularis mucosae (with exposure to the lymphatics), the adenoma is then termed a *carcinomatous* or *malignant polyp*. [428] These may metastasize.

Misplaced epithelium (pseudoinvasion) may be difficult to distinguish from invasive carcinoma. In general, the displaced epithelial cells are surrounded by lamina propria and not by desmoplastic reaction and are similar to the overlying adenomatous epithelium. [346], [429] Hemosiderin deposition in the polyp indicates torsion.

THERAPY

Chemoprevention of Adenomas

Therapy may be directed at prevention of adenoma recurrence in the case of sporadic adenomas or FAP, or at regression of existing adenomas in FAP when removal or resection is to be avoided, such as small duodenal polyps and polyps in retained rectum after colectomy.

Dietary factors have been discussed under “Primary Prevention”—in reality, the interventional evidence comes from prevention of new adenoma formation, and it is assumed that the effect would be the same in those who have never had an adenoma.

At this stage, the most promising agents for chemoprevention are the nonsteroidal antiinflammatory drugs.

Nonsteroidal Antiinflammatory Drugs

Most evidence now indicates that use of nonsteroidal antiinflammatory drugs, specifically aspirin, is associated with reduced mortality from colorectal cancer. [220], [221], [222], [223], [224], [225], [226], [227], [228] and [229], [430] This effect extends to adenomas as seen in the Nottingham screening study [224] and, as a nonsignificant trend, in the Australian Polyp Prevention Project. Sulindac has been shown to be effective in reversing rectal adenoma growth in patients with FAP after ileorectal anastomosis. [225], [226] and [227] The European CAPP-1 and CAPP-2 trials are evaluating aspirin in randomized controlled trials in FAP and HNPCC, respectively. Celecoxib is effective in FAP. [431]

Evidence to date does not support chemoprevention with aspirin or sulindac in patients with sporadic (common) adenomas. [228], [229], [432] Use of celecoxib for sporadic adenomas, if proved of value, may achieve prevention without side effects that would be associated with aspirin or other cyclooxygenase-1–inhibiting agents.

polypectomy as Therapy

Endoscopy and snare polypectomy provide a simple and cost-effective means of managing colorectal polyps. [8], [433], [434] and [435] Cold snare polypectomy or garroting of small polyps is effective. [436] In practice, all polyps should be considered for removal because it is not possible to determine the histological type by visual appearance. The number of polyps that can be safely removed by polypectomy depends on their location and size.

Rectal polyps that are smaller than 5 mm, also referred to as *diminutive polyps* usually are benign and rarely produce bleeding. They may be left in place if they are multiple and appear flat and hyperplastic. At least three of them should be removed for confirmatory histological examination. [437], [438] They should all be subsequently removed if any is found to be an adenoma. Although hot biopsy [439], [440], [441] and [442] and bipolar electrocoagulation [440] have been advocated for eradication of diminutive polyps, these techniques can leave behind residual polyp (adenomatous) tissue [441], [442] and are more dangerous in the thin-walled cecum.

Polyps larger than 1 cm are usually adenomatous and should be removed in toto if pedunculated. If sessile, they may need to be removed piecemeal. [443], [444] Histological evaluation of the presence or degree of invasion of any carcinomatous foci could then be difficult or impossible, especially because the chance of malignancy increases with increasing size. [190] If there is any concern that residual polyp tissue may be left, the polypectomy site should be tattooed with sterilized India ink to facilitate follow-up evaluation. [445] This should also be done if there is a high index of suspicion that a polyp may be malignant. If polyps are inflammatory, hyperplastic, or otherwise nonadenomatous by histological examination, complete removal is unnecessary, but a sampling of several polyps from each cluster is required.

Multiple polyps require particular care. In patients with newly diagnosed FAP, colectomy, not polypectomy, is indicated. For multiple adenomatous polyps not due to FAP, when there is the possibility of removing them endoscopically, the colon should be cleared of polyps a section at a time to reduce the chance of complications. Note that the thinner wall of the cecal area and right colon requires care when removing polyps through cautery. [444], [446], [447]

Polypectomy is safe in adults [400], [401] and children [402] when performed by experienced physicians. Complications are generally related to polypectomy and the major complication rate is less than 2%. The requirement for hospitalization or surgical intervention (due usually to hemorrhage or perforation) is less than 0.3%, and death is rare. [400], [401] Polypectomy should be deferred in patients on anticoagulation and in those with severe bleeding diatheses, unstable cardiac arrhythmias, recent myocardial infarction, acute colitis, pregnancy (second or third trimester), recent colonic surgery, or abdominal abscess or perforation. [447] Some consider that aspirin should be ceased 1 week before colonoscopy in case polypectomy is required, but others do not; although the issue is unresolved, the risk would appear to be very low.

Removal of sessile polyps can be assisted by submucosal injection of saline (2 to 10 ml) to lift the polyp from the muscular wall and minimize the risk for perforation. Kits to facilitate this are commercially available.

The procedural aspects of colonoscopy and polypectomy, including patient preparation, premedication, antibiotic prophylaxis, polypectomy, and polyp retrieval techniques, are discussed in Chapter 140.

Laser Ablation and Argon Plasma Coagulation

Ablation with the neodymium:yttrium-aluminum garnet (Nd:YAG) laser or argon plasma coagulation are alternative methods for the rapid removal of large numbers of small polyps from segments of the colon. [46], [448], [449], [450], [451] and [452] In experienced hands, it is efficacious, rapid, and relatively safe; complications occur in about 5% of cases. [452] Perforation is rare, but extra care is needed in the thin-walled cecal area. [451] Such ablation should be restricted to the removal of multiple polyps after the histological diagnosis has been confirmed by previous biopsies or polypectomies. Laser ablation is also useful in the rectal stump of patients with FAP and in patients with cancer or large adenomas who are not surgical candidates, in whom it often results in rapid symptomatic relief. [452] Argon plasma coagulation has appeal because it is a nonlaser technique and does not require the rigorous training associated with the use of clinical lasers. It can also be applied tangentially, which is helpful in the colon and rectum. The depth of ablation is naturally limited to 3 to 5 mm, adding a potential increment of safety over lasers. The disadvantages, of course, are that laser and argon plasma ablation are destructive and do not yield specimens for pathologic evaluation. It is also possible that a focus of invasive malignancy in the polyp may be missed.

Surgical Resection

In cases in which a polyp is large and sessile or otherwise cannot be removed by endoscopic polypectomy, surgical resection may be necessary. Surgical resection is also indicated for some adenomas with invasive carcinoma (malignant polyps; see later). [453], [454] and [455] Large rectal adenomas may be extirpated by transanal excision using an operating sigmoidoscope and rigid snare under anesthesia or with an operating microscope in association with a sigmoidoscope. Other large polypoid lesions and malignant polyps need to be removed by laparotomy or laparoscopy. [456] Once laparotomy is indicated, many surgeons advocate the use of a formal segmental colectomy, including lymph node dissection. The extra resection adds little anesthesia time or perioperative mortality and morbidity. [455]

Severe Dysplasia and Intramucosal Carcinoma

Severe dysplasia and intramucosal carcinoma are nonmalignant adenomas and can be cured by adequate polypectomy.

The progression of severe dysplasia to invasive malignancy demands careful management and complete removal. Evaluation of a removed polyp by fragmental biopsy or piecemeal polypectomy is difficult. [118], [190], [453], [457] The presence of cancerous cells on a biopsy or cytology specimen may not reveal the malignant nature of a polyp without the architectural information provided by polypectomy.

Malignant Polyps

Definition and Prognosis The term *malignant polyp* refers to that situation in which severely dysplastic cells have penetrated the muscularis mucosae. [457] Care must

be taken to distinguish this from misplaced epithelium (pseudoinvasion; see earlier). [347], [429] The management of malignant polyps remains controversial. [435] There is general agreement that poor prognostic features include incomplete polypectomy, poorly differentiated carcinoma, and malignant cells within 2 mm of the polypectomy margin. [458], [459] and [460] The presence of venous or lymphatic invasion is an independent poor prognostic factor in some series. [121], [461], [462] Lymphatic invasion is, however, subject to observer variability. [463] Malignant polyps with venous (or lymphatic) invasion are almost always associated with higher-grade cancers, and when they occur in isolation from the other prognostic variables, they need to be taken into account with respect to the overall context of the patient's co-morbidity. [464] Controversial prognostic factors are the replacement of the bulk of the adenoma by carcinoma, sessile nature, and large polyp size. Sessile malignant polyps are generally considered to have a worse prognosis, and most usually have other poor-risk markers. [465] Of those with pedunculated polyps, most have invasion limited to the head, neck, or stalk.

Results of Removal Of 62 evaluable patients with malignant polyps who had endoscopic polypectomy, 4 (7%) had recurrence. [462] In other studies, patients who underwent endoscopic polypectomy for pedunculated malignant polyps did better. [466] In a retrospective review of 43 patients with pedunculated malignant polyps who were followed for almost 5 years, 19 patients initially underwent colonic resection, but none from either treatment group had a recurrence. [467] Most data indicate that successfully removed polypoid carcinomas do not spread and therefore do not require segmental resection unless poor prognostic features are present. [468] These guidelines, however, are derived from incomplete studies, and it is difficult to be rigid in their application. For the individual patient, it is necessary to weigh the estimated risks of surgery against the risks of leaving residual malignancy in situ after endoscopic polypectomy of a malignant polyp. The presence of poor prognostic features is generally accepted as a reason for colectomy (see Table 89-7), [118], [212], [410], [458], [459] and [460] but age of the patient and any coexistent morbidity should always be considered. The decision depends on an estimate of the risk that residual but localized cancer is present compared with the risk for perioperative mortality and morbidity in the individual patient. [469] Operative mortality rates range from 2% to 10%, increasing with the age of the patient. [455], [470] Because most patients with malignant polyps are in their seventh and eighth decades of life, the risk of colectomy is significant. Based on current evidence, [118], [190], [200], [457], [458], [459], [460], [461], [462], [463], [464], [465], [466], [467], [468], [469], [470] and [471] the following recommendations for management of malignant polyps can be made (Fig. 89-17):

1. A pedunculated malignant polyp with invasion of the head, neck, or stalk is adequately treated by polypectomy alone if the polypectomy was not piecemeal, the cancer was not poorly differentiated, and the resection margin was free of cancer for 2 mm.
2. Malignant polyps with involvement within 2 mm of the margin of resection or with nonassessable margins, polyps with invasion of the submucosa of the bowel wall (especially if there is less than 2 mm margin of clearance), and polyps containing poorly differentiated invasive carcinoma should be treated by colectomy unless the surgical risk is prohibitive. For sessile malignant polyps, invasion of the submucosa is highly likely, and surgery should usually be undertaken. Blood vessel and lymphatic involvement may influence a decision to perform colectomy but not strongly.
3. Malignant polyps treated by polypectomy alone should be followed by repeat colonoscopy within 3 to 12 months to assess for recurrence at the polypectomy site.

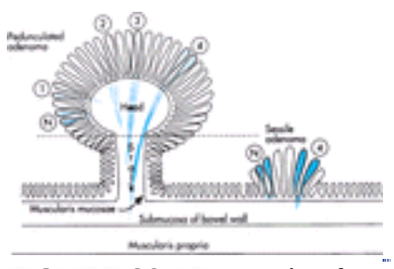

FIGURE 89-17. Levels of carcinomatous extension in malignant polyps—pedunculated versus sessile adenomas. When carcinomatous cells are contained within the mucosa, without breaching the muscularis mucosae and so extending into the "head" of the stalk, the lesions are known as noninvasive carcinomas, otherwise referred to as severe focal atypia or intramucosal carcinoma (*N*). Once cancer has invaded through the muscularis mucosae, the polyp is then termed a malignant polyp. Because lymphatics are present in the submucosa, metastatic spread is then possible. Increasing levels of invasion of the carcinoma, to the head (*1*), neck (*2*), stalk (*3*), and base of the stalk or submucosa (*4*), may carry worsening prognostic implications. A malignant sessile adenoma has, by definition, invaded the submucosa of the bowel wall (*4*). Noninvasive carcinomas (*N*) require no additional therapy after polypectomy. Usually, malignant polyps with invasions only of the head, neck, and stalk (*1, 2, 3*) and with clear resection margins (at least 2 mm) and no poor prognostic features (see Table 89-7) are adequately treated by polypectomy alone. In malignant polyps with invasion of the submucosa of the bowel wall (*4*) or with poor prognostic features, colectomy should be seriously considered for potential cure.

In all cases, patients must be informed of the rationale behind the physician's therapeutic decision and should participate in that decision. Patients should be aware that evidence-based guidelines are not available for the treatment of malignant polyps. [435]

FOLLOW-UP FOR METACHRONOUS ADENOMAS AND CANCERS

Current recommendations for following patients with adenomatous polyps vary, [435] and several prospective studies are addressing this issue. The current St. Mark's Neoplastic Follow-up Study is reexamining patients after previous polypectomies for adenomatous polyps at three different time intervals (1, 3, and 5 years) and randomized after stratification for risk. [472]

Predicting Recurrence of Adenomas

In the initial St. Mark's Neoplastic Follow-up Study, age, multiplicity of previous adenomas, and size of largest adenoma were independent risk factors for further development of clinically significant (metachronous) adenomas or cancer. [423]

These prognostic risk factors for adenoma recurrence have been confirmed in colonoscopic follow-up studies such as the U.S. National Polyp Study. In addition to multiplicity (more than two), the U.S. study also identified family history in association with older age (more than 60 years) at diagnosis of adenomas as a risk factor for future advanced neoplasms. This study critically found that an interval of 3 years after initial, complete polypectomy for adenomas was as effective as follow-up colonoscopy after 1 year. [215]

Rectal epithelial proliferation has been shown in some studies to predict future adenomas. [473]

Longer intervals might be equally effective, especially in those patients with small tubular adenomas in the rectosigmoid region. Although definitive data are not available, follow-up intervals extending to 10 years are being recommended for low-risk adenomas. [410], [421], [425], [435] The yield in such patients appears to be less rewarding than that in subjects without prior adenoma who are older than 60 years of age. [376], [377], [421]

The role of FOBT in adenoma surveillance remains unclear. FOBT is better than no follow-up at all and could be used in intervening years to maintain annual contact with patients and aid detection of rapidly developing interval cancers or large adenomas.

Predicting Future Occurrence of Cancer

Factors predicting future cancer are similar. In 1618 patients followed for a mean period of 14 years after initial sigmoidoscopy and polypectomy for rectal adenoma, the risk for subsequent rectal cancer depended on size, histological type, and multiplicity, with a size greater than 1 cm and villous architecture being the strongest risk factors (see Table 89-7). Conversely, patients with small tubular rectal adenomas without severe dysplasia had no increased risk for colon cancer. [410]

Patients who have undergone surgical resection of a primary colorectal cancer are not only at risk for recurrence of their first cancer but also at a threefold to fourfold increased risk for metachronous adenomas or cancer. [29], [30], [474] Patients with cancers, either sporadic or in HNPCC, with MIS are at particularly high risk. Therefore, follow-up should seek not only evidence of metastatic disease and recurrent disease at the surgical anastomosis but also development of a second primary cancer or an adenoma. If the entire length of the colon was not completely visualized before surgery (owing to tumor obstruction or poor preparation), a complete colonoscopy to look for synchronous lesions is indicated after 3 to 6 months. After the colon has been documented to be free from neoplasms, initial follow-up may be at 3 years,

as in the follow-up after polypectomy for adenomatous polyps. [475] Examining the anastomosis for local recurrence in the first 2 years after left-sided cancer is also advisable.

Surveillance Recommendations

When an adenoma is found, surveillance colonoscopy after 3 years suffices provided that the colonoscopist has reasonable confidence that polypectomy is complete and that the entire colon has been cleared of polyps. [399], [421], [425] If not, repeat within 3 to 6 months is indicated. If the repeat surveillance colonoscopy is clear of adenomas after 3 years, some consider that the interval may be lengthened to 5 years, although there is no good evidence to support this. For patients at higher risk for colorectal cancers, such as those at risk because of hereditary nonpolyposis colorectal cancer, more frequent examinations may be in order. On the other hand, patients with only small tubular adenomas in the rectum are not at increased risk for colorectal cancer and can be dismissed from follow-up or offered repeat examination at 5 years. [410]

The appropriate surveillance recommendations for patients with acromegaly are uncertain. If surveillance is to be undertaken, it should commence within a few years of diagnosis and be repeated at about 3-year intervals. [59]

IMPACT OF POLYPECTOMY ON CANCER INCIDENCE AND MORTALITY

The expectation is that introduction of polypectomy in the community should reduce the incidence and mortality from colorectal cancer. This has been, to date, difficult to document in national statistics. Trends in colorectal cancer incidence vary around the world, with a general trend upward in countries that follow or are adopting a Western lifestyle. [129] Yet despite the availability of screening and colonoscopic surveillance, the trend continues upward in some countries. One such country is Australia; the age-adjusted upward trend is 2% per annum in men and 1% per annum in women since the 1970s. [476] The continuing increase may be due to environmental factors that drive up the incidence despite polypectomy or may be due to an increase in early diagnosis of cancers ahead of an anticipated later decrease in cancer diagnoses. Fortunately, mortality has remained stable (age adjusted).

In the United States, however, improvements in national mortality statistics and apparently incidence are evident. [477] This improvement is multifactorial, including earlier diagnosis; better surgery, anesthesia, and postoperative care; and the impact of adjuvant therapy.

Four large-scale adenoma follow-up studies have examined the impact of colonoscopic surveillance on subsequent cancer development [215], [478], [479] and [480] (Table 89-8). The London, Danish, and Australian studies each showed that the incidence of cancer during follow-up was not significantly different from the incidence in age- and sex-matched population controls, implying a reduction from a higher risk if surveillance was not undertaken. Unfortunately, without control groups, the real significance is unclear. The U.S. National Polyp Study demonstrated a statistically significant reduction in risk in participants within the study compared with either population controls or an independent (but historical) population of adenoma patients who did not have colonoscopic follow-up (see earlier). This is the best study demonstrating effectiveness.

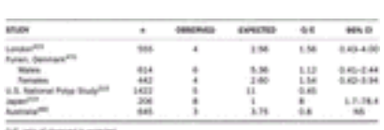

TABLE 89-8 Relative Risk for Colorectal Cancer in Subjects Undergoing Surveillance for Adenomas, Compared with Age- and Sex-Matched Control Groups

Acknowledgments

We wish to acknowledge assistance from Dr. Tony Thomas with provision of Figure 89-4 , Figure 89-5 , Figure 89-9 , Figure 89-10 , and Figure 89-11 , and the original contribution made to this chapter by Dr. Gordon Luk, the author of the first edition. Some of the structure and materials, including some figures, from the original chapter have been retained.

CHAPTER 90

Randall W. Burt and Russell F. Jacoby

POLYPOSIS SYNDROMES

The polyposis syndromes are a group of conditions in which multiple gastrointestinal (GI) polyps occur in the lumen of the gut (Table 90-1). Most of these syndromes are inherited, and most exhibit an increased risk for colon cancer. Many benign and malignant extraintestinal manifestations are also observed. The polyposis syndromes have traditionally been categorized according to polyp histology. Recent elucidation of the responsible genes has allowed refinement of the categorization as well as a more precise understanding of the phenotypes and cancer risks. The clinical importance of the syndromes relates to their inheritance as well as to their benign and malignant manifestations. Cancer prevention is often possible with proper management of patients and their families. The syndromes are also of great importance to biologic investigation. Recent elucidation of their genetic and molecular etiologies has contributed immensely to the understanding of cancer pathogenesis and cell biology.

Familial adenomatous polyposis
Gardner syndrome
Two thirds of Turcot syndrome families
Attenuated adenomatous polyposis coli
Syndromes with hamartomatous polyps
Peutz-Jeghers syndrome
Juvenile polyposis
Cowden syndrome
Bannayan-Riley-Ruvalcaba syndrome
Hereditary mixed polyposis syndrome
Gorlin syndrome
Polyposis syndromes with neural polyp histology
Neurofibromatosis type I
Multiple endocrine neoplasia type IIB
Isolated intestinal neurofibromatosis of the colon
Polyposis syndromes of uncertain etiology
Cronkhite-Canada syndrome
Hyperplastic polyposis syndrome
Polyposis syndromes with inflammatory polyps
Inflammatory bowel disease
Devon polyposis
Cap polyposis
Polyposis conditions arising from lymphoid tissue
Nodular lymphoid hyperplasia
Multiple lymphomatous polyposis
Immunoproliferative small intestinal disease
Miscellaneous noninherited polyposis syndromes
Leiomyomatosis
Lipomatous polyposis
Multiple lymphangiomas
Pneumatosis cystoides intestinalis

TABLE 90-1 Polyposis Syndromes

FAMILIAL ADENOMATOUS POLYPOSIS

Familial adenomatous polyposis (FAP) is the first described, the most common, and the best characterized of the polyposis syndromes. The first reports of FAP appeared in the medical literature in 1861 and 1873. [1], [2] The hereditary nature of this disease was recognized by 1882, and cases of associated malignancy were published in 1887 and 1890. The autosomal-dominant inheritance pattern of the disease was clearly established by 1934. [3]

FAP is now known to be an inherited condition characterized by hundreds to thousands of colonic adenomatous polyps that most often begin to emerge in the second and third decades of life. Colon cancer is inevitable if the colon is not removed. The condition includes Gardner syndrome, about two thirds of Turcot syndrome families, and attenuated adenomatous polyposis coli (AAPC), also called attenuated FAP. FAP and its variants arise from mutations of the adenomatous polyposis coli (APC) gene. Inheritance is autosomal dominant with nearly complete penetrance. Synonymous terms for FAP include *adenomatous polyposis coli* and *familial polyposis coli*.

Epidemiology

Estimates of the prevalence of FAP vary from 1 in 6850 to 1 in 31,250 people (2.29 to 3.2 cases per 100,000 population). [1], [4], [5] The frequency is fairly constant throughout the world, with men and women being affected equally. Up to one third of newly diagnosed cases, those not belonging to previously identified families, appear to represent new mutations. [1] About 0.5% of all colon cancer cases historically have arisen in the setting of FAP, [4] although the figure may now be as low as 0.07%, possibly owing to screening in identified FAP families. [5]

Genetics

***APC* Gene** FAP arises from germ-line mutations of the *APC* gene on the long arm of chromosome 5 (5q21–q22). The *APC* locus was identified in 1987. [6], [7] Four years later, the gene itself was identified and characterized. [8], [9], [10] and [11] The gene has been shown to be alternatively spliced in multiple coding and noncoding regions. The main transcript has 15 exons with 8532 base pairs (bp) that code for 2844 amino acids and result in a 311.8-kd protein. Exon 15 is large and constitutes more than three fourths of the coding region of the gene. The APC protein localizes to the nucleus and to the membrane and cytoskeleton in human epithelial cells. [12] It also homodimerizes [13] and binds to other proteins, including glycogen synthase kinase (GSK)-3ß, ß-catenin, ?-catenin, tubulin, EB1, and hDLG. [14] Mutational inactivation of the *APC* gene is not only responsible for FAP but also appears to be an early, if not the first, step in the pathogenesis of more than 80% of all colonic adenomas and colon cancers [14] (see Chapter 91). In FAP, one allele is inherited in a mutated form, and the mutation is present in every cell of the colon (and body). Adenoma formation is initiated when the second allele is damaged or lost by a somatic event. In sporadic adenomas, both alleles must be damaged or lost by somatic events for adenoma formation to begin. Thus, patients with FAP form large numbers of adenomas at a young age, whereas only one or several sporadic adenomas occur in a patient with sporadic polyps and at a much later age. Genes that require both alleles to be lost for disease to occur are called *tumor suppressor genes* of which *APC* is a prime example. The progression of adenoma to carcinoma after *APC* inactivation is similar in FAP and the sporadic setting, with accumulation of mutations in additional relevant genes, including K- *ras* and *p53* a gene or genes on chromosome 18 and possibly others [14], [15] (see Chapter 91).

***APC* Gene Function** An important function of the APC protein is control of cell growth through the Wingless and Wnt signaling pathway. [16] Activation of the pathway favors cell growth and suppression of apoptosis. In the nonstimulated state of this pathway, GSK-3ß forms a complex with APC, ß-catenin, and axin and phosphorylates these proteins. The phosphorylation of ß-catenin targets it for ubiquitin-mediated proteasomal degradation. A stimulus to the Wnt pathway causes uncoupling of ß-catenin from the complex, loss of phosphorylation of ß-catenin, and a resultant increase in cytoplasmic concentrations of this protein. ß-Catenin then translocates to the nucleus, where it interacts with the transcription factor, T-cell factor and lymphoid-enhancing factor (TCF-Lef). This transcriptional activation causes an up-regulation of a number of genes, including the oncogenes c- *Myc* and cyclin D1, and also matrilysin, c- *jun*, *fra-1*, urokinase-type plasminogen activator receptor, and the peroxisome proliferator-activated receptor-d (PPAR-d). These genes and possibly others presumably mediate the cell growth and antiapoptotic effects of the Wnt signaling pathway. Mutation of the *APC* gene results in a defective complex of GSK-3ß, APC, and axin. The complex is unable to bind or phosphorylate ß-catenin. This in turn gives rise to a persistent increase in cytoplasmic ß-catenin concentration and therefore a constitutive or constant activation of the entire Wnt signaling pathway. The APC protein also binds to microtubules and can promote microtubule assembly in vitro. [17], [18] It has been postulated that this association is part of the normal migration mechanism of the colonocyte up the colonic crypt. [19], [20] Mutated *APC* would then cause disruption of normal cellular positioning in the crypt, consistent with present models of carcinogenesis. A recent finding of great interest is that the APC protein has been shown to accumulate at the kinetochore during mitosis, contribute to kinetochore-microtubule attachment, and play a role in chromosome segregation in mouse embryonic stem cells. [21], [22] The APC protein itself may thus play a role in the chromosomal instability, seen as chromosomal loss of heterozygosity, that is often observed when APC function is lost.

***APC* Mutations in Familial Adenomatous Polyposis** More than 90% of APC germ-line mutations that cause FAP give rise to a truncated protein product. The causative mutations are insertions, deletions, and nonsense mutations that lead to either frame shifts and downstream premature stop codons or de novo premature stop codons. [23], [24] More than 825 germ-line mutations have been found to date in families with FAP. [25] More than 80% of these mutations are different and distinct for each family. The most common germ-line *APC* mutation observed in multiple unrelated families is a 5-bp deletion that results in a frameshift mutation at codon 1309. Although mutations have been found scattered throughout the gene, they are predominantly located in the 5' or proximal end of the gene. The number of colonic adenomas in FAP correlates to some extent with the location of the APC germ-line mutation (Fig. 90-1). AAPC is associated with mutations in the 5' part of the gene (5' to codon 158), [26], [27] and [28] in exon 9, [29], [30] and [31] and in the distal 3' end of the gene (3' to codon 1596). [30], [32], [33], [34], [35], [36] and [37] Profuse or dense polyposis has been reported with mutations in codons 1250 to 1464, with less dense polyposis proximal and distal to this location. [38], [39] As stated previously, the most frequent FAP mutation is at codon 1309. One study found that patients with mutations at that codon presented with symptoms at an average age of 20 years, whereas patient with mutations between codons 168 and 1580, excluding 1309, presented with symptoms an average of 10 years later. [40] Patients with mutations proximal to codon 168 and distal to codon 1580 presented at an average age of 52 years.

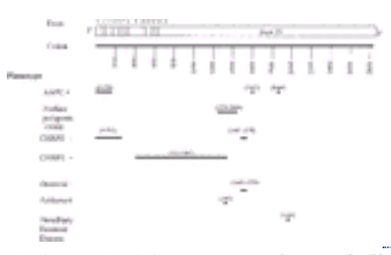

FIGURE 90-1. Location of disease causing mutations in the *APC* gene correlated with phenotypic manifestations. Courtesy of Cindy Solomon, M.S.

Correlations have also been found between the locations of the mutations in the *APC* gene and extracolonic manifestations of FAP (see Fig. 90-1). Congenital hypertrophy of the retinal pigment epithelium (CHRPE) is observed with mutations between codons 463 and 1387, [41] although mutations between codons 1444 and 1578 lack CHRPE expression. [42], [43] Thyroid cancer associates with *APC* mutations in the 5' end of exon 15. [44] A higher incidence of desmoid tumors is found with mutations between codons 1444 and 1578. [42], [43] A study of 269 patients with information on the presence or absence of desmoids and identified *APC* mutations found a wide but uneven distribution of mutations in patients with desmoids. [40] Desmoids occurred in 20% of patients with mutations proximal to codon 1444 but in 49% of patients with mutations distal to this codon. Sixty-one per cent of patients with mutations between codons 1445 and 1580 exhibited desmoid tumors, whereas only 18% had desmoids when the mutation was distal to that region. A number of studies have indicated that desmoid tumors occur more frequently with mutations in the 3' end of the *APC* gene and specifically distal to codon 1444. [43], [45], [46] and [47] Another study found that individuals with mutations between codons 1395 and 1493 had significantly higher rates of desmoids, osteomas, and epidermoid cysts compared with those with mutations between codons 177 and 452 and significantly more desmoids and osteomas compared with those with mutations between codons 457 and 1309. [48] None of the 79 patients with mutations between codons 177 and 452 developed osteomas, hepatoblastomas, periampullary region tumors, or brain cancers, whereas hepatoblastomas and brain cancers were seen only in patients with mutations between codons 457 and 1309. The correlation of germ-line mutation location with polyp density or extracolonic manifestation is not consistent, however, and identical mutations can be associated with differing phenotypes. [49], [50] Modifying genes and additional mutations of the *APC* gene are two hypotheses that might explain these observations. Finally, a polymorphism of the *APC* gene unique to people of Ashkenazi Jewish descent has also been identified. [51] This polymorphism, I1307K, is present in 6% of Ashkenazi people but in 12% with colon cancer and 29% with colon cancer and a family history of colon cancer. It confers an approximate 1.5- to 2-fold increased risk for colon cancer compared with the general population and is believed to cause disease by increasing the mutability of the *APC* allele on which it resides. [51], [52], [53] and [54]

Laboratory Genetic Testing Methods The laboratory methods used for genetic testing in FAP include protein truncation testing (PTT), gene sequencing, and linkage testing. [55] PTT exploits the observation that most *APC* mutations in FAP cause premature termination of the APC protein. The method examines for truncation of the APC protein in vitro and thus also ensures that a mutation is disease causing. [56] It must be understood, therefore, that PTT infers, but does not specifically identify, the disease causing mutation. PTT is successful in identifying evidence for a disease causing mutation in 80% to 90% of families with clinically defined FAP. Once a disease-causing mutation is inferred by PTT in an index case (a family member known to have FAP), other family members can be tested for the presence or absence of this mutation with near 100% accuracy. The cost is $750 to $1000 to examine for an unknown mutation and about $500 per person in relatives once a mutation is known to be present. DNA sequencing is more accurate than PTT, with the specific disease causing mutation being identified in more than 90% of families with known FAP. Once the mutation has been identified in an index case in the family, other family members can be tested for the presence or absence of that specific mutation by one of a number of highly accurate polymerase chain reaction–based methods. The accuracy for mutation finding in relatives at this stage is near 100%. A drawback with sequencing is that it is sometimes difficult to know whether a certain mutation is disease causing or a harmless polymorphism. Cost for sequencing is $800 if the mutation is not known and about $200 once the mutation is known. Additional laboratory genetic methods are often used in initial mutation finding, including denaturing gradient gel electrophoresis and single-strand conformation polymorphism testing. These methods can often narrow the area in which a mutation is found. They are thus frequently used in combination with PTT and sequencing to limit the area of DNA for specific mutation finding. Linkage testing employs DNA markers to track the segregation of a purported mutation through a family. The sensitivity of linkage in identifying genetically affected individuals approaches 99% because of the highly informative markers now available. Linkage is limited, however, in that two or three known affected people involving two generations must be available for sampling to apply the method successfully. Linkage is thus usually applied only when PTT or sequencing fail. The cost is about $245 to $260 per person tested.

Clinical Process of Genetic Testing Genetic testing is usually done on DNA obtained from the white blood cells of peripheral blood. A number of genetic testing laboratories now perform genetic testing for FAP and other inherited conditions. These laboratories can be identified at a website (http://www.genetests.org/). Genetic counseling is an essential prelude to genetic testing. [57] A number of important medical and psychosocial issues surround asymptomatic genetic testing. Children's rights are of particular concern when testing in children is being considered. All of these issues must be thoroughly understood by the physician and patient when genetic testing is anticipated. Informed consent for testing is then required before testing is done. [58] The physician must either be familiar with the issues or use trained genetic counselors. Details of genetic counseling are given in Chapter 54. There are three settings in which to consider genetic testing for FAP [59]: (1) testing

a person with some features of FAP, but where the clinical diagnosis is not certain; (2) testing a person with clinically defined FAP, but the mutation is not known in the family; and (3) testing relatives in an FAP family once the mutation is known. The first setting is usually defined as a person with at least 20 cumulative adenomas but no known family history of FAP. Finding a mutation confirms the diagnosis of FAP and allows relatives to be tested with high accuracy. Failure to identify a mutation does not rule out FAP, however, because initial mutation finding is 90% successful at best. Genetic testing in the second situation is similar, but the patient has more than 100 adenomas. Failure to find a mutation means that all close relatives must still be screened as if they have the condition because it was already clinically defined in one case. In the third setting, relatives of a person with a known APC disease mutation are tested for the presence or absence of that mutation. A positive test indicates the diagnosis of FAP, whereas a negative test (absence of mutation) essentially rules it out. Such individuals then need only average risk screening for colon cancer.

Clinical Manifestations

Colonic Polyposis The clinical diagnosis of FAP is made with the presence of at least 100 colonic adenomatous polyps or fewer polyps and an immediate relative with FAP [1] (Fig. 90-2 and Fig. 90-3; Color Fig. 90-2). The average number of adenomatous polyps in a person with fully expressed FAP is 1000, with some people exhibiting more than 5000 polyps. Fewer adenomas are seen early in the development of the disease and in AAPC (see later), with further subdivisions of expected polyp number now known to correlate with APC mutation location. [39]

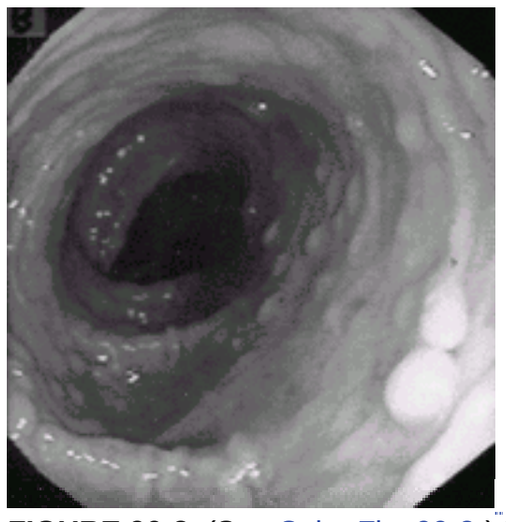

FIGURE 90-2. (See Color Fig. 90-2.) Early colonic polyposis in familial adenomatous polyposis.

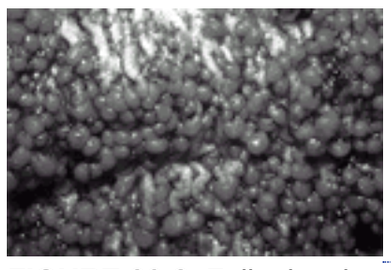

FIGURE 90-3. Fully developed colonic polyposis in familial adenomatous polyposis. Courtesy of Karen Kim, M.D.

Polyps most often begin to appear in the second or third decade of life. The mean age of polyp occurrence assessed by prospective rigid sigmoidoscopy is 15.9 years (range, 8 to 34 years), [60] although occurrence of polyps at younger and older ages has been reported. The average age of FAP diagnosis in patients presenting with symptoms is 35.8 years (range, 4 to 72 years). [1] The age of symptom presentation correlates with gene mutation location, which, in turn, correlates with colonic polyp density. [39], [40] Adenomatous polyps are usually distributed evenly throughout the colon, with a slight distal colonic excess. The size of the polyps depends on the stage at which the patient is examined. Even in fully developed cases, however, 90% of adenomas are less than 0.5 cm in diameter, and less than 1% of polyps are larger than 1 cm. Polyps may either carpet the colon with myriad small lesions or occur as more distinct and somewhat larger lesions. These patterns appear to have a genetic origin (see earlier), although striking heterogeneity of polyp number and growth rate also has been observed. [49], [61], [62] Histopathology demonstrates tubular adenomas, indistinguishable from common or sporadic adenomas. Villous and tubulovillous histologies are also seen, but much less frequently and usually in larger polyps. A histologic feature of FAP not observed in the general population is dysplastic or adenomatous epithelial cells in single crypts or even portions of single crypts. These are called *microadenomas* and are often seen in biopsy specimens of normal-appearing flat mucosa. [1] Budding of dysplastic epithelium from normal crypts is also observed. Aberrant crypt foci also have been reported to occur with increased frequency in FAP. [63] These lesions are similar to microadenomas but are identified with methylene blue staining of the colonic mucosal surface.

Colon Cancer Adenocarcinoma is the inevitable consequence of FAP unless the colon is removed. In the St. Mark's series, the average age at cancer diagnosis was 39 years. By 45 years of age, 87% had developed cancer, and by 50 years, 93%. Multiple colonic malignancies were present in about 48% of those with cancer (41% synchronous, 7% metachronous). Eighty-four percent of malignancies were at or distal to the splenic flexure, a fraction almost identical to that found in their series of random colorectal malignancies at that time. Average life expectancy after diagnosis of cancer was 2.6 years. Colon cancer has been reported as early as 9 years of age, although the occurrence of malignancy before adolescence is very unusual. [64] Polyp number correlates with cancer risk. A recent study found a 2.3-fold increase in cancer risk at diagnosis for those with more than 1000 colonic polyps compared with those with fewer than 1000 polyps. [65] Each 10-year older age group also exhibited a 2.4-fold increase in cancer risk. There remains a 25% incidence of colon cancer in newly diagnosed FAP patients, most likely due to the high rate of new mutations. [66]

Upper Gastrointestinal Polyps and Cancer

Stomach. Gastric polyps occur in 23% to 100% of FAP patients [67], [68], [69] and [70] (Fig. 90-4). In the gastric fundus and body, the polyps are most often nonneoplastic fundic gland polyps, considered hamartomas. These polyps are histologically seen to consist of simple hyperplasia of the fundic glands with microcysts. Endoscopically, the polyps are multiple sessile lesions, 1 to 5 mm in diameter, that are the same color as surrounding mucosa. Considerable variation in size and number is observed. The polyps are sometimes so numerous that they coalesce, forming areas of irregular, matted surface mucosa. Fundic gland polyps rarely cause symptoms. They have been observed to occur as early as 8 years of age. Size and number may gradually increase, remain static, or even decrease. [71] Fundic gland polyps may rarely progress to cancer. [72], [73] and [74] Similar polyps, although fewer in number, also are sometimes observed in the general population and possibly with chronic use of proton pump inhibitors. [75], [76]

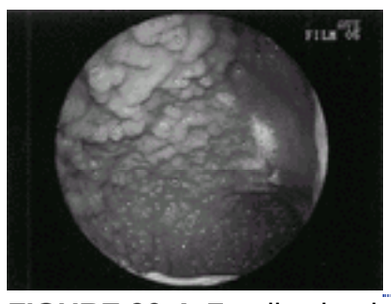

FIGURE 90-4. Fundic gland polyposis in familial adenomatous polyposis.

Adenomatous polyps occur in the stomach of about 10% of patients with FAP. They are most often confined to the antrum but are occasionally found in the body and fundus. [68], [77] The lifetime risk for gastric cancer in FAP is about 0.6%, believed in large part to arise from adenomatous polyps.

Duodenum and small bowel. Endoscopically visible duodenal adenomas are found in 50% to greater than 90% of FAP patients, and microadenomas are frequently observed. [70] The polyps are most commonly 1 to 5 mm in diameter and multiple. Most patients have numerous small adenomas scattered throughout the duodenum, particularly in the second and third areas, whereas in others, the polyps are restricted to the periampullary area. Adenomas may progress, often slowly, and there is evidence of an adenoma-carcinoma sequence similar both histologically and genetically to that observed in the colon. [70] Adenomas may sometimes grow large, exhibit villous histology and increasing degrees of dysplasia, and may cause symptoms. A scoring system has been developed to evaluate the severity of duodenal polyposis and is now widely applied as the *Spigelman staging system* [78] (Table 90-2).

POLYPS	1 POINT	2 POINTS	3 POINTS
Number	<4	5–20	>20
Size	0–4 mm	5–10 mm	>10
Histology	Tubular	Tubulovillous	Villous
Dysplasia	Mild	Moderate	Severe

Stage I, 4 or fewer points; stage II, 5–6 points; stage III, 7–8 points; stage IV, 9–12 points.
Adapted from ref. 78.

TABLE 90-2 Duodenal Adenomatosis Staging System

The lifetime risk for duodenal cancer, which most often occurs in the periampullary area, is 3% to 5%. [1], [70] The age of duodenal cancer diagnosis ranges from 17 to 81 years, with a mean between 45 and 52 years. Duodenal cancer is one of the leading causes of death in FAP patients who have had prophylactic colectomy. No consistent association between mutation location and the presence or severity of duodenal polyposis has been made, [70] although mutations downstream from codon 1051 have recently shown association with severe periampullary lesions. [79] One study also found that the occurrence and severity of lesions at the papilla segregated in certain FAP families. [80] The frequent clustering of adenomas and cancer in the periampullary area suggest that bile or pancreatic secretions may play a role in carcinogenesis, and a number of mechanisms have been suggested. [70], [77] Adenomas may occur throughout the small bowel but are concentrated for the most part in the proximal jejunum (50% of cases) and distal ileum (20% of cases). [81], [82] Malignancy is unusual, but small bowel cancer has been reported. Adenomatous polyps are also known to occur, possibly with increased frequency postoperatively, in the distal ileum after subtotal colectomy, colectomy with ileostomy, and colectomy with ileoanal pull-through. Distal ileal cancer also has been reported in these settings, but it is very unusual. Prominent lymphoid polyps may occur frequently in the terminal ileum of younger patients with FAP and should be differentiated from adenomas by biopsy.

Gallbladder, bile ducts, and pancreas. Both adenomatous change and cancer have been reported in the gallbladder, bile ducts, and pancreas. [67], [81], [83], [84] Lesions in these locations appear to be unusual, but their exact frequency is unknown. Biliary and pancreatic duct obstruction have arisen from both benign and malignant lesions.

Benign Extraintestinal Growths

Osteomas and dental abnormalities. Multiple osteomas were the first extracolonic lesion to be associated with colonic polyposis. [1], [85], [86] These lesions are benign bone growths found most commonly on the skull and mandible but may occur on any bone of the body. The size ranges from imperceptible to several centimeters in diameter, and they number from one to dozens. Osteomas may occur in children who are at risk for FAP before the onset of colonic polyposis, [87] but they can continue to occur throughout life. [88] Osteomas have no malignant potential and are not a clinical problem except for occasional cosmetic concern. Subtle radiopaque jaw lesions are often evident by panoramic dental radiographs in patients with FAP and no other apparent extraintestinal lesions of Gardner syndrome. [89], [90] Various dental abnormalities also have been described in FAP, including unerupted teeth, supernumerary teeth, dentigerous cysts, and odontomas. [86], [87], [91] These all may precede the development of colonic polyposis, and the prevalence is estimated at 17%, compared with 1% to 2% in the general population.

Cutaneous lesions. Epidermoid cysts, sebaceous cysts, fibromas, and lipomas have all been described as a part of FAP. [87], [92], [93], [94], [95] and [96] Epidermoid cysts occur most commonly on the legs, face, scalp, and arms, in that order, but they may appear anywhere on the body surface. [94] They range in size from millimeters to several centimeters. Although common in the general population, in FAP, they often occur before puberty, may precede the onset of polyposis, and occur at an average age of 13 years. Fibromas, ranging in size from millimeters to centimeters, are found most commonly on the cutaneous surface of the scalp, shoulders, arms, and back. The cutaneous lesions may cause cosmetic problems, and cysts occasionally become infected.

Desmoid tumors. Desmoid tumors (also called *desmoid fibromatosis*) are benign fibrous growths that occur rarely in the general population (5 to 6 per 10 [6] per year [97]) but frequently in FAP, affecting between 3.6% and 20% of patients. [98], [99] and [100] About 2% of all desmoids arise in patients with FAP, although the relative risk for the tumor in patients with FAP compared with the general population is 825. [101] The peak incidence of desmoids in FAP is between 28 and 31 years, although they may occur at any age. Independent predictors for desmoids include an *APC* mutation 3' of codon 1444 (see earlier section " Genetics"), family history of desmoids, female gender, and the presence of osteomas. [45] Desmoid tumors are one of the most common causes of mortality in FAP patients who have had prophylactic colectomy, with a 10% to 50% mortality rate from the tumor in those with desmoids and a 10-year survival rate of 63%. Desmoids may arise in musculoaponeurotic structures throughout the body, although they are most common in the abdomen. [100] They do not metastasize but may infiltrate adjacent structures, extend along facial planes, attach to and erode bones, and may engulf and compress blood vessels, nerves, ureters, and other hollow organs of the abdomen. Severe and even fatal clinical problems are sometimes caused by these tumors, especially if mesenteric vessels or other abdominal organs are obstructed. In the abdomen of FAP patients, mesenteric plaquelike lesions occur that may progress to mesenteric fibromatosis and finally desmoid tumors, often stimulated by surgery. [102] About half of abdominal desmoids are intra-abdominal, whereas the other half occur in the tissues of the abdominal wall. [98] Desmoid tumors usually enlarge very gradually and sometimes stop growing altogether. Only about one third of abdominal desmoids cause pain, although the most common symptom is abdominal pain. Intra-abdominal desmoids sometimes become massive, occupying much of the abdominal cavity and encasing many segments of viscera. These tumors may be the first manifestation of FAP in some patients and families. Furthermore, some families with APC mutations exhibit desmoids as their only disease manifestation. [47], [103] A distinctive histopathology has been demonstrated in desmoid tumors of young FAP patients, whose first manifestation of the condition was often this lesion. [104] Desmoids in FAP are monoclonal growths of hyperproliferative fibroblastic cells. [105] Excess cell growth appears to occur on the basis of *APC* gene inactivation and accumulation of ß-catenin in the cells. [106] The relationship of desmoids in FAP to sporadic cases is uncertain in view of the distinctive early histopathology [104] and the observation that *APC* gene mutations are uncommon in sporadic desmoids. [107]

Congenital hypertrophy of the retinal pigment epithelium. Multiple and bilateral patches of CHRPE, also called *pigmented ocular fundus lesions*, have been described as a common manifestation of FAP. [108] The lesions are discrete, darkly pigmented, round, oval, or kidney shaped and range in size from 0.1 to 1.0 disc diameters. The presence of bilateral or multiple (more than four) lesions is highly specific (94% to 100%) but only moderately sensitive (58% to 84%) for FAP. The lesion appears to be congenital, has been detected in a 3-month-old at-risk infant, and may be the earliest clinically detectable lesion of FAP. Careful slit-lamp examination is often required for detection. The presence of CHRPE correlates closely with mutations in specific areas of the *APC* gene (see earlier section " Genetics"). [41], [42] and [43], [109], [110] and [111]

Adrenal adenomas. Adrenal adenomas have been reported in FAP. [112], [113] Two studies found their occurrence to be significantly higher than in the general population, 7% and 13%, respectively, versus 3%. [114], [115] Several cases of functioning adrenal adenomas and adrenal carcinomas have also been noted in these same series, but any association is uncertain. Most adrenal masses in FAP are found incidentally on computed tomography (CT) done for other reasons. It has been recommended that adrenal lesions be managed similarly to those in the general population, which is generally hormonal investigation if relevant symptoms are present and needle biopsy if a simple adenoma is not indicated by CT or the lesion is 5 cm or larger. [114], [115]

Nasal angiofibroma. Nasal angiofibromas have been correlated with FAP in a number of patients. [116]

Extracolonic Malignancies A number of malignancies outside the colon are known to exhibit an increased lifetime risk in patients with FAP compared with the general population. These include duodenal and periampullary (3% to 5%), thyroid (2%), pancreatic (2%), gastric (0.6%), central nervous system (CNS; less than 1%), hepatoblastoma (1.6%), and possibly small bowel distal to the duodenum and adrenal. The most important are duodenal and periampullary because of their frequency. These and gastric cancer were discussed earlier under "Upper Gastrointestinal Polyps and Cancer." Thyroid cancers affect about 2% of individuals with FAP, have been reported in 112 FAP patients, [117] and exhibit a relative risk compared with the general population of 7.6 (95% confidence interval [CI], 2.5 to 17.7). [118] The mean age of diagnosis is 28 years, ranging from 12 to 62 years. A female preponderance is apparent, and the histology is predominantly papillary, commonly with a cribriform pattern. Familial aggregation has been observed, and mutation analysis of 24 patients revealed that most mutations identified were 5' to codon 1220. The relative risk for pancreatic adenocarcinoma in the John's Hopkins FAP registry compared with the general population was 4.46 (95% CI, 1.2 to 11.4). [118] The same study found no cases of biliary or adrenal cancer and no increased risk for lung or breast cancer. Hepatoblastoma affects 0.75% to 1.6% of children with FAP, exhibits a male predominance, and associates somewhat with mutations in the 5' end of the *APC* gene. This malignancy most often occurs in the first 5 years of life, with some risk up to 15 years of age. The risk for hepatoblastoma in children with FAP is 800-fold greater than in the general population. [119], [120]

Syndromes Related to Familial Adenomatous Polyposis

Gardner Syndrome In the early 1950s, Gardner and colleagues described a large kindred that exhibited typical FAP, but also very prominent extracolonic growths, especially osteomas, epidermoid cysts, and fibromas. [86] All of the other extracolonic lesions noted previously were eventually added to the phenotype of Gardner

syndrome. Discovery of the *APC* gene led to the knowledge that FAP and Gardner syndrome arise from mutations of that gene. Further, the expression of extracolonic manifestations correlates to some extent with location of the mutation in the gene, [121] although gene modifiers may still play a role. [122] The term *Gardner syndrome* is thus mainly of historical interest but will likely continue to be used for families with frequent and obvious extraintestinal manifestations of the condition.

Turcot Syndrome Turcot syndrome is characterized by colonic polyposis and CNS tumors. [123] About two thirds of Turcot syndrome cases arise from mutations of the *APC* gene and exhibit medulloblastoma-type CNS tumors as well as some anaplastic astrocytomas and ependymomas. [124], [125] Such cases are thus a variant of FAP and usually exhibit typical colonic polyposis. The other third of cases come from mutations of the mismatch repair genes and are thus a variant of hereditary nonpolyposis colorectal cancer (HNPCC). The CNS malignancies in HNPCC-related Turcot syndrome are glioblastoma multiforme tumors, and affected patients also exhibit fewer adenomatous polyps, typical of HNPCC. [125] The risk for cerebellar medulloblastoma in FAP is calculated to be 92 times that of the general population. [124] The occurrence of CNS malignancies is not a completely random event in FAP, however, because 40% of families with brain tumors include more than one affected person. *APC* mutation location correlations have not been made with CNS tumors.

Attenuated Adenomatous Polyposis Coli AAPC, also called attenuated FAP, arises from *APC* mutations at either the extreme proximal (5') parts of the *APC* gene, [26], [27] and [28] at the extreme distal (3') portion of the gene, [30], [32], [33], [34], [35], [36] and [37] or in certain parts of exon 9. [29], [30] and [31] Patients with AAPC have many fewer adenomas than those with typical FAP, often averaging about 30 and exhibiting a proximal colonic preponderance. Equally notable, however, is that the polyp number is extremely variable in many kindreds, with some members of the same kindred having a small number of adenomas whereas others have numbers approaching that of typical FAP. [26], [30], [31], [37] The lifetime colon cancer risk has been estimated to be about 80%, with the age at diagnosis about 50 years [37] and an average age at symptomatic presentation of 52 years. [40] The emergence of adenomas is also delayed about 10 years in my experience. The expression of upper GI polyps, however, both gastric and duodenal, does not appear to be attenuated in number, age at emergence, or cancer risk. [30], [36], [72], [74] AAPC may be difficult to diagnose without genetic testing because some patients exhibit very few adenomas, often proximal colonic, even at advanced ages.

Differential Diagnosis

All of the polyposis syndromes reviewed in this chapter are included in the differential diagnosis of a patient found to have GI polyposis. HNPCC must occasionally also be distinguished, particularly from AAPC. Histology is paramount to specific diagnosis because most of the syndromes have histologically characteristic polyps. The colonoscopic appearance of myriad 1- to 5-mm polyps is characteristic of FAP, although lymphoid hyperplasia and hyperplastic polyposis (HP) may mimic this appearance, emphasizing the importance of histology. Additional parameters to be considered in differentiating the various polyposis conditions include polyp distribution throughout the GI tract; polyp number and size; the presence of extraintestinal growths, lesions, or malignancy; and the family history of any of these features. Finally, genetic testing is a powerful tool that can now be used to make a definitive syndrome diagnosis in most cases, further allowing genetic testing in family members when the relevant mutation is found. Each of the polyposis syndromes in this chapter is characterized in terms of these parameters. The features that differentiate the polyposis syndromes are summarized in Table 90-3 and Table 90-4.

TABLE 90-3 Distinguishing Features of Familial Adenomatous Polyposis and the Hamartomatous Polyposis Syndromes

TABLE 90-4 Additional Conditions that Exhibit Gastrointestinal Polyposis

Clinical Course and Complications

Most individuals with FAP remain asymptomatic until colon cancer occurs. Adenomatous polyp development is slow and insidious. There are usually only a few, minute polyps when adenomas are first detected. Polyp number and size increase gradually over ensuing years. Symptoms from the disease are seldom experienced if a timely colectomy is performed. Left untreated, nonspecific symptoms eventually develop from the polyposis or the inevitable colon cancer. The most common symptoms include rectal bleeding (79%), diarrhea (70%), and abdominal pain (40%). [1] The average age at onset of symptoms is 32.8 years. Sixty-six percent of individuals who present with symptoms have already developed cancer. Age of symptom development can now be predicted somewhat by *APC* mutation location (see earlier), although these observations have little clinical applicability. Presymptomatic screening and appropriate prophylaxis are the favored approach in FAP.

Upper GI polyps are usually asymptomatic until cancer occurs, with the exception of polyps at the duodenal papilla or in the bile or pancreatic ducts, which may cause obstructive jaundice or pancreatitis. Symptoms from polyps and cancer are nonspecific and include abdominal pain, weight loss, GI blood loss, palpable mass, and lumenal obstruction.

The average life expectancy of patients with untreated FAP has been estimated to be 42 years but approaches that of the general population up to 18 years after colectomy. [126] The major causes of death after colectomy are duodenal cancer (particularly periampullary), desmoid tumors, and rectal cancer if a subtotal colectomy was done. [127], [128] and [129] Other cancers are occasionally observed, such as pancreatic, biliary, adrenal, and small bowel. The major causes of death in postcolectomy patients from one study were desmoid tumors in 11 of 36 patients (31%); periampullary cancer in 8 (22%); rectal cancer in 3 (8%); adrenal cancer in 1 (3%); and carcinomatosis in 1 (3%). [127] The remainder died of causes not directly related to FAP. Those with desmoid tumors died an average of 6.6 years after colectomy, whereas those with periampullary cancer died an average of 23.1 years after surgery. The average age at death for the entire group was 41.6 years. This must not be equated with overall life expectancy because only patients who had died were studied. The cumulative probability of an FAP patient developing extracolonic cancer of any type after colectomy in the St. Mark's Registry was found to be 11% by 50 years of age and 52% by 75 years, although most of the malignancies, like in other series, were in the periampullary region. [130] This overall risk was significantly higher than the compared risk in the general population of about 4% and 22% at ages 50 and 75 years, respectively.

Management

Diagnosis The diagnosis of FAP is made by finding characteristic clinical manifestations, specifically more than 100 colonic adenomas at any age; finding adenomas in a younger first-degree relative of a person with known FAP; and finding a disease-causing mutation in the *APC* gene in a person suspected of having FAP. A constellation of other findings, such as typical upper GI polyps and osteoma, can lead to a high suspicion of FAP. Thus, diagnosis virtually always involves colonoscopic examination with biopsy of the colon and frequently genetic testing. The indications and clinical process of genetic testing were outlined in the earlier section "Genetics."

Screening and Surveillance The primary goal of FAP management is to prevent cancer. In view of the extreme cancer risk in the colon and emerging knowledge of other cancer risks, empiric screening guidelines have been suggested on the basis of these risks and the likely ages of cancer development (Table 90-5).

TABLE 90-5 Cancer Risks and Screening Recommendations in Familial Adenomatous Polyposis

Colon screening. Colon screening with subsequent surgery has been definitively shown to decrease mortality from large bowel malignancy. A study from the Swedish National Polyposis Registry that included 431 FAP patients from 145 families found a mortality rate of 44% in self-presenting FAP patients compared with 1.9% in relatives who were called up for screening. [131] The Finnish polyposis registry found survival in postcolectomy FAP patients who had undergone screening because of a relative with known FAP to be equivalent to that in the general population and statistically much lower than that in FAP patients presenting with symptoms up to 18 years after colectomy. [126] Colon screening should be performed in those with a genetic diagnosis of FAP or in first-degree relatives of those with FAP if genetic testing is uninformative or has not been done. Generally accepted colon screening guidelines for typical FAP are annual sigmoidoscopy beginning at 10 to 12 years of age. [55], [132], [133] Screening intervals can be increased each decade and can change to average-risk screening at 50 years of age if polyposis is not present. [55] Those initially screened at an older age should probably have colonoscopy for the first examination. If surgery is delayed longer than a year after polyps emerge, annual colonoscopy should be considered for surveillance. For AAPC, colonoscopy should always be used for screening in view of polyp distribution but can reasonably be delayed until the late teens to mid-20s.

Upper gastrointestinal screening. Upper GI screening has not been demonstrated to improve prognosis but is nonetheless recommended in view of the cancer risk and expectation that mortality can be improved. The most commonly given recommendation is to begin screening at the age of 20 to 25 years, although some recommend an initial examination at the time of diagnosis and earlier screening if other family members have exhibited advanced duodenal disease at an earlier age. [70] Standard upper endoscopy should be supplemented with a side-viewing instrument to visualize the duodenal papilla properly. Endoscopic ultrasound or endoscopic retrograde cholangiopancreatography may also be indicated, depending on endoscopic findings or symptoms. A 1- to 3-year interval for reexamination is given as follows: (1) every 3 years for Spigelman stages I and II disease; (2) every 2 years for stage III disease; and (3) every 6 to 12 months for stage IV disease [70] (see Table 90-2). Another approach is every-3-year endoscopy if adenomas are not found and annually if they are. It would certainly seem reasonable to examine the stomach during endoscopy and to biopsy any polyps of concern because of size, color, or gross appearance. One study found that most patients with advanced duodenal and periampullary findings exhibited *APC* mutations downstream from codon 1051, [79] although more work is needed before this observation can be applied in the clinical setting.

Screening for other malignancies and desmoids. Screening for the other associated cancers and for desmoids is entirely empiric. The thyroid should be examined annually, starting at age 10 to 12 years, in view of risk and ease of examination. Some argue that other sites should be evaluated only for symptoms or if these cancers have occurred in relatives. Screening is not done for desmoids, but evaluation is done only for palpable masses or symptoms. At my institution, in addition to that described earlier, patients are presented with the option of abdominal CT with oral contrast every 3 years to examine the pancreas, small bowel, and adrenal glands, starting at age 20 to 25 years. Careful questioning is done for CNS symptoms and periodic head magnetic resonance imaging is recommended if any family member has had CNS malignancy. Pediatric gastroenterologists do a careful liver palpation annually during the first decade. [132] Specific biliary evaluation is done only for symptoms or issues raised on surveillance endoscopy. The small bowel is specifically examined periodically by x-ray or push enteroscopy if upper endoscopy demonstrates severe duodenal polyposis.

Ileal and rectal screening after colectomy. Adenomas may develop in the ileal pouch after colectomy with ileoanal pull-through surgery, or they may develop from rectal epithelium left at the time of such surgery. [82], [134] Whether there is risk for cancer in ileal pouch adenomas is uncertain, although cases have been reported. [135] Screening of the pouch should be done within 2 years after surgery and then every 6 months to 3 years, depending on the presence and number of adenomas. When subtotal colectomy with ileorectal anastomosis is performed, rectal adenomas often regress, [136] possibly because of changes in bile acid concentrations. [137] They almost always recur, however, and are associated with a substantial cancer risk. The most recent evaluation of cancer risk in the rectum after subtotal colectomy indicates a 40-year risk of 0.32. [138] Chronologic age was the only independent risk factor, but cancer was more common when *APC* mutations occurred in areas that give rise to dense polyposis. Sigmoidoscopy with ablation of recurrent adenomas is believed to minimize and delay cancer occurrence and is suggested every 3 to 6 months, depending on the rate of adenoma recurrence. [82] Ablation techniques include electrocautery, laser, heater probe, and argon beam coagulation.

Treatment

Colon and rectum. An appropriately timed colectomy remains the keystone of cancer prevention in FAP. It should be considered once adenomas emerge. Most centers prefer to wait until after high school if colonic adenomatosis remains minimal, although delay has been associated with some cancer occurrence, particularly in FAP patients older than 20 years of age. [139] Surgical options include: (1) subtotal colectomy with ileorectal anastomosis, and (2) total colectomy with mucosal proctectomy, ileal pouch construction, and ileoanal pull-through. Colectomy with ileostomy is rarely needed. Subtotal colectomy is a single-stage procedure with slightly less morbidity than the pull-through surgery, but in view of rectal cancer risk, it remains an option only for patients and families with few rectal adenomas, particularly when AAPC is the diagnosis. [66], [138] Mutation location may help in determining choice of procedures, but adenoma expression is quite variable, even with identical mutations, making clinical expression of polyps the determining factor in surgical decisions. [40] Despite rectal screening, the cumulative risk for secondary proctectomy to control polyposis or treat cancer in those with a remaining rectum was 0.70 at 40 years of follow-up in one study, although it was never necessary in patients with AAPC. [138] In my experience, some patients with AAPC can be managed for many years with colonoscopic polypectomy of millimeter-sized polyps and may possibly never need colectomy. In general, this approach should only be considered with AAPC patients who exhibit fewer than 5 to 10 1-mm sized adenomas at each examination and probably fewer than 30 cumulatively. Even in such patients, however, caution is important in view of cancer occurrence when colectomy is delayed. [139] Nonsteroidal antiinflammatory drugs (NSAIDs) have not been studied in this situation, and although they would be expected to reduce adenoma number, their effect on cancer risk is unknown. A number of studies have demonstrated that NSAIDs induce colonic adenoma regression in FAP. [140], [141], [142] and [143] It is presumed but not proven that cancer risk is also diminished. Equally important, polyp ablation is considerably easier in patients with a remaining rectum because NSAID therapy often minimizes the number of new adenomas encountered during follow-up examinations. A selective cyclooxygenase-2 inhibitor, Celebrex, has, in fact, been approved by the U.S. Food and Drug Administration for polyp regression therapy in FAP patients who have had a subtotal colectomy with a remaining rectum. [144] The published studies would suggest, however, that the effect of Celebrex is modest compared with sulindac. Developmental agents that would minimize the upper GI side effects of NSAIDs in different ways are now under study, including an agent that is the sulfone derivative of sulindac, exisulind. [145] This agent has no antiprostaglandin activity but appears to retain the polyp regression effect of the parent compound. The use of NSAIDs to prevent the emergence of adenomas in patients with a genetic diagnosis of FAP or to delay colectomy in those with polyposis is not yet recommended, although investigations addressing these issues are underway.

Upper gastrointestinal tract. Intervention for gastric polyps is unusual. Adenomas should be endoscopically resected if possible. The development of high-grade dysplasia in multiple fundic gland polyps can lead to the consideration of partial gastrectomy. Duodenal adenomas, particularly ampullary and periampullary ones, more often need therapy. [70] Possible therapies include endoscopic ablation or polypectomy, surgical polypectomy, endoscopic and surgical papillectomy, surgical duodenectomy, and the Whipple procedure. In view of their malignancy potential, removal of duodenal adenomas should be considered if they become large (probably at least 2 cm) or exhibit villous histology or advanced dysplasia. Single, large, pedunculated adenomas can usually be removed endoscopically, whereas larger ones, especially if they are sessile with advanced dysplasia, may require surgical duodenotomy for resection. Severe diffuse duodenal adenomatosis may require duodenectomy or the Whipple procedure, particularly if severe dysplasia is present. Unexpected cancers are often found in the surgical specimen, although radical surgery is still debated for benign lesions in view of possible complications and morbidity. Endoscopic papillectomy is indicated for ampullary adenomas that become symptomatic (including laboratory cholestasis) or develop villous change or advanced dysplasia. [70], [79], [146], [147] and [148] The recurrence rate is high, however, and multiple treatment sessions or surgical therapy may also be needed in selected cases. The Heidelberg Polyposis Register study is particularly demonstrative of the various options. [70] In that registry, endoscopic follow-up of the duodenum of FAP patients was accomplished in 135 patients with an average follow-up of 55.6 months (range, 6 to 172 months). One hundred and thirteen of the patients (83.7%) needed no therapy of the duodenum during the follow-up period, whereas 22 (16.3%) did. Endoscopic polypectomies were accomplished in four cases, whereas surgical duodenotomy was needed because of polyp size (large and sessile) in five. Endoscopic papillectomy was done in six cases because of symptomatic adenomas or severe dysplasia. Whipple procedures were needed in seven patients for severe diffuse duodenal adenomatosis, with cancer being unexpectedly found in four of these surgical specimens. Two of these involved the papilla, whereas two were in the distal duodenum. Other therapies are under investigation for duodenal adenomas, including photodynamic therapy and various NSAIDs. Trials of both have been inconclusive thus far. Studies with higher doses and longer duration NSAID therapy are now underway, however, planned because of the known affect of these agents on colonic adenomas and the need for effective chemoprevention in the duodenum.

Desmoid tumors. CT and magnetic resonance imaging are equally effective in following desmoid tumors. [149] Treatment is undertaken for symptoms, cosmetic issues, or functional involvement of or imminent risk to adjacent structures. Extra-abdominal and abdominal wall desmoids are best treated by surgery with adequate resection of margins. [98], [99] and [100] Less than half of tumors so treated recur, and further therapy with radiation and repeat excision is usually successful. Surgery is difficult, and sometimes impossible, in cases of intra-abdominal desmoids but remains as an important option in selected cases. [98], [150], [151] Because intra-abdominal desmoids often involve the mesentery or encase vessels or organs, medical therapies are often first attempted. The most consistent initial therapies for abdominal desmoids appear to be the NSAID sulindac and the antiestrogen tamoxifen. Both give a better than 50% response after 3 to 6 months of therapy for FAP. [152], [153] The response may be even better with a combination of the two. Chemotherapy can be offered for unresectable cases that fail to respond to this therapy. The protocol of doxorubicin and dacarbazine, followed by carboplatin and doxorubicin, has resulted in either complete remission or partial remission with stabilization of the tumor in

a high percentage of cases. [154] Other therapies have also been used with desmoids with variable success. A combination of low-dose methotrexate and vinblastine demonstrated stabilization of tumor growth or shrinkage in 60% of patients with sporadic desmoids at various stages. [97] This therapy has not yet been reported in FAP desmoid cases. Prednisolone was successful in one case [155] and hyperthermia in another. [156] Intestinal transplantation has now been used successfully in a number of cases of unresectable intra-abdominal desmoids. [157]

SYNDROMES WITH HAMARTOMATOUS POLYPS

Peutz-Jeghers Syndrome

Epidemiology and Clinical Characteristics Peutz-Jeghers syndrome (PJS) is an autosomal-dominant inherited syndrome of histologically distinctive hamartomatous polyps of the GI tract and characteristic mucocutaneous pigmentation. [158] Its incidence is estimated at 1 in 120,000 births. A high risk for both GI and non-GI cancers is now known to be part of this condition. [159] The mucocutaneous melanin pigment spots are seen in more than 95% of cases (Fig. 90-5). They are 1 to 5 mm in diameter and most commonly occur in the perioral and buccal areas (94%). Pigment spots on the lips are distinctive in that they cross the vermilion border and are often much darker and more densely clustered than common freckles. These spots also occur on the face, forearms, digits, palms, soles, perianal area, and rarely the intestinal mucosa. The pigment appears in infancy and may fade with age, but less so on the buccal mucosa.

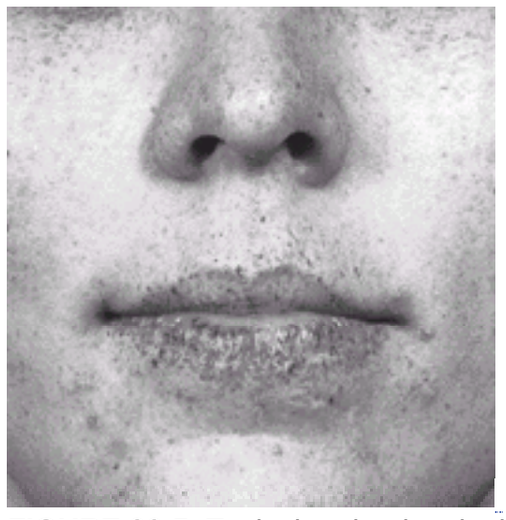

FIGURE 90-5. Typical perioral melanin pigmentation in Peutz-Jeghers syndrome.

The GI polyps occur in 88% to 100% of patients. Their frequency by segment is as follows: stomach, 24%; small bowel, 96%; colon, 27%; and rectum, 24%. [160] Between 1 and 20 polyps are usually found per GI segment. Polyps range from 0.1 to 3 cm in diameter and have a coarsely lobulated surface. Larger polyps are pedunculated, but smaller polyps are sessile, except in the stomach, where they are most often sessile regardless of size. Polyp growth begins in the first decade of life, but patients typically do not develop symptoms until the second or third decade. Symptoms arise from larger polyps, which may infarct, ulcerate, bleed, and cause intestinal obstruction and intussusception. Peutz-Jeghers polyps are histologically distinct. They are nondysplastic, have normal overlying epithelium specific to the GI site in which they are found, and exhibit an arborizing pattern of growth with muscularis mucosae extending into branching fronds of the polyp. Epithelial infolding may result in what is termed *pseudoinvasion* which can lead to an incorrect diagnosis of cancer. Adenoma and cancer may occur in Peutz- Jeghers polyps, exhibit monoclonality, and are thought to be the cause of intestinal cancer in this syndrome. [160], [161], [162] and [163] This is sometimes referred to as the hamartoma-adenoma-carcinoma sequence. Benign complications from the polyps predominate in the first three decades of life. The average age at diagnosis is 22 years in men and 26 years in women. [160] One third of patients experience symptoms in the first decade of life, and 50% to 60% occur before the age of 20 years. The clinical course of PJS is characterized in many patients by repeated surgeries for complications of small bowel polyps. This, together with related malignancies, leads to substantial morbidity and a decreased overall survival rate. [164] Malignant complications become the dominant cause of clinical problems after 30 years of age, [160] with an average age of 43 years for cancer diagnosis of any type. Both GI and non-GI cancers are common in PJS disease, with a combined frequency of all cancers being 93% by age 65 years. [159], [160], [162], [165] Cancer risks and average age of cancer diagnoses are shown in Table 90-6 and Table 90-7.

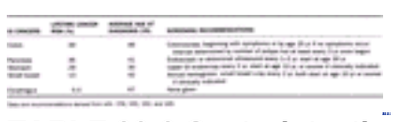

TABLE 90-6 Gastrointestinal Cancer Risks and Screening Recommendations in Peutz-Jeghers Syndrome

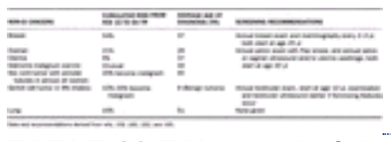

TABLE 90-7 Nongastrointestinal Cancer Risks and Screening Recommendations in Peutz-Jeghers Syndrome

Genetics and Pathophysiology PJS arises from mutations of the *STK11* gene (also called *LKB1*) on chromosome 19p. [166], [167], [168], [169] and [170] About 50% of patients with PJS belong to affected families, whereas 50% are isolated cases and may represent new mutations. [171] Germ-line, disease-causing mutations of the *STK11* gene are found in 60% of those with inherited and 50% of those with isolated PJS, [160] suggesting the possibility of other pathogenic PJS genes. Families with no *STK11* gene mutations exhibit a high incidence of biliary adenocarcinoma compared with families with mutations of this gene. [172] Loss of the wild-type allele of *STK11* by mutation, loss of heterozygosity, or promoter hypermethylation has been found in PJS polyps and cancers, verifying the central role of *STK11* as the disease-causing gene of PJS. [173], [174] Furthermore, the gene codes for a serine-threonine kinase that associates with the *p53* gene and regulates specific *p53*-dependent apoptosis pathways. [175] PJS polyps are devoid of STK11 protein staining and exhibit reduced apoptosis. Several types of germ-line *STK11* mutations have been found to be disease causing. [176] They include frameshift mutations, a 4–amino acid deletion, amino acid substitutions, and splicing errors but have in common the loss of kinase activity. Mutations of ß-catenin and *p53* but not *APC* appear to play a role in neoplasm development after STK11 inactivation. Genetic testing is now commercially available and is performed similar to testing in FAP. A person known to have the clinical syndrome is first tested. If a relevant mutation can be found in the *STK11* gene, other family members can be tested with near 100% accuracy.

Diagnosis, Screening, and Treatment Diagnosis is based on the finding of typical melanin pigment spots and characteristic GI polyps. Management involves screening as outlined in Table 90-6 and Table 90-7 and removal of all polyps larger than 0.5 or 1 cm in diameter to prevent both benign and malignant complications. Screening guidelines are empiric and based on the risk for GI complications and cancer. Colectomy is sometimes necessary to control colonic polyps and should be considered, especially if neoplastic change is found in the colon. When small bowel polyps become large or symptomatic, surgery is often necessary and includes careful examination of the entire small bowel to eliminate all significant polyps. Intraoperative endoscopy may be a helpful adjunct in this regard, and this is also an appropriate time to examine and remove gastric and duodenal polyps of significant size. [177]

Juvenile Polyposis

Epidemiology and Clinical Characteristics Juvenile polyposis (JP) is an autosomal-dominant inherited condition, with 20% to 50% of cases having a family history of the disease. [178] It is characterized by multiple juvenile polyps of the colon, although polyps may occur throughout the GI tract. [171], [178], [179], [180] and [181] There is also a very high risk for colon cancer; an increased risk for gastric, duodenal, and pancreatic cancers; and the frequent occurrence of certain benign extraintestinal features. The incidence of JP is about 1 in 100,000 individuals. The generally accepted clinical criteria for JP include the following: (1) at least five juvenile polyps in the

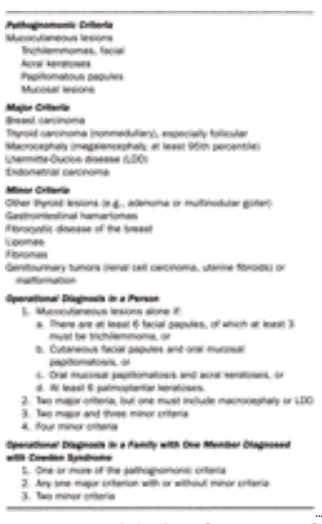
colorectum; (2) juvenile polyps throughout the GI tract; or (3) any number of juvenile polyps in a person with a known family history of juvenile polyps. [182] Inherited syndromes that exhibit the GI phenotype of JP must also be ruled out, including Cowden syndrome (CS), Bannayan-Riley-Ruvalcaba (BRR) syndrome, and Gorlin syndrome (see later). The polyps in JP vary in size from small sessile nodules to pedunculated lesions that are 3 cm or larger in diameter. Most large polyps are pedunculated, but small polyps, especially those in the stomach, are sessile. Grossly, most polyps exhibit a surface that is smooth, rounded, reddish-colored, and without fissures or lobulations, except for large polyps, which may appear to be multilobulated. A white exudate is often seen on the polyp surface. On cut section, there are cystic spaces filled with mucin. Microscopically, there is abundant lamina propria with benign but often elongated and cystically dilated glands and lack of a smooth muscle core. Excess chronic inflammatory cells are sometimes present. The epithelial lining of the surface and cysts is nondysplastic and reflects the area of the GI tract where the polyp is located. [183] The polyps of JP are most commonly found in the colon but may occur throughout the GI tract. [178] Polyps begin to appear in the first decade of life, and dozens to many hundreds of polyps are present in the fully developed syndrome. Most patients develop symptoms in the first two decades of life. The average age at diagnosis is 18.5 years. [184] Rectal bleeding with anemia is the most common presenting symptom, followed by abdominal pain, passage of tissue per rectum, and intussusception. A rare and often lethal form of the disease can be observed in infancy. It includes large numbers of juvenile polyps, GI bleeding, protein-losing enteropathy, and significant morbidity and even mortality. [185] Estimates of the risk for colon cancer vary from 9% to 68%. [171], [178], [182], [186], [187] More recent studies indicate the higher figures, and the latter figure is likely the most accurate because it represents the projected incidence of colorectal cancer by 60 years of age considering all JP cases in the St. Mark's Registry in London. The mean age of colon cancer is 34 years, with a range of 15 to 68 years. [181], [184], [187], [188] Although occasional isolated adenomas are observed in JP, the cancer risk is believed to arise from the occurrence of adenomatous tissue within the juvenile polyp. Up to 50% of juvenile polyps in JP contain areas of adenomatous change. Villous and malignant foci may be seen in larger polyps. [182], [186] Cancers of the stomach, duodenum, pancreas, and biliary tree have been reported in JP. [189] One study found that 6 (21%) of 29 JP patients from one large kindred had developed cancer of the stomach or duodenum. [187] The average age of upper GI carcinoma is 58 years, with a range of 21 to 73 years. [189] The precise phenotype of JP is somewhat in question because it was previously difficult to distinguish CS and BRR syndrome from JP, each exhibiting multiple intestinal juvenile polyps. Now that these syndromes can be defined genetically, a much more accurate clinical picture of each is emerging. Past reports, for example, found that congenital anomalies were present in 11% to 15% of JP cases. [189] Abnormalities included congenital deformities of the heart, CNS, soft tissues, GI tract, and genitourinary system and were primarily found in sporadic JP cases. A more recent evaluation found a higher incidence of congenital anomalies in JP, but mostly macrocephaly and hypertelorism once the other syndromes were separated. [190] Similarly, there has been an effort in the past to separate cases of JP involving just the colon from those involving the entire GI tract. A reexamination of each of these issues is clearly needed in the context of genetic diagnosis.

Genetics and Pathophysiology At least half of the families clinically affected with JP are found to have a disease-causing mutation of either the *SMAD4* gene (also called the *DPC4* gene) on chromosome 18, or the bone morphogenetic protein receptor 1A (*BMPR1A*) gene on chromosome 10, both tumor suppressor genes. [191], [192], [193] and [194] It was first estimated that *SMAD4* mutations would account for 35% to 60% of JP cases [192]; however, subsequent studies have suggested a smaller fraction, [195], [196] and a recent survey from Europe indicated that only 15% of JP families arise from germ-line mutations of the *SMAD4* gene, whereas 38% are from germ-line mutations of the *BMPR1A* gene. [194] Only a few families with JP appear to arise from mutations of the *PTEN* gene, [197], [198] although some maintain that these families are actually CS families. The *SMAD4* gene encodes a cytoplasmic mediator involved in the transforming growth factor-ß (TGF-ß) signal transduction pathway. Activation of the pathway leads to cell growth inhibition by way of regulating the transcription of genes involved in cell cycle and transcriptional regulation. [199] There are a number of additional *SMAD* genes in the pathway, but JP-associated mutations have not been found in them. [199], [200] and [201] The *BMPR1A* is a serine-threonine kinase type 1 receptor that also belongs to the superfamily of TGF-ß. It activates *SMAD4* independently of TGF-ß signaling, but the effector pathway, nuclear control, and transcriptional regulation are similar. The genetic etiology of JP in up to half of cases remains elusive, however, indicating that other genes may be involved in the etiology of the syndrome. It has been suggested that genetic events that give rise to JP affect stromal cells primarily and that epithelial cells acquire dysplasia only as a secondary event. [193] A recent investigation, however, demonstrated biallelic inactivation of the *SMAD4* gene in both the epithelium and stromal cells of JP polyps. [202] This observation would indicate that inactivation of *SMAD4* is a primary event in dysplastic transformation of epithelial cells in the polyps of JP.

Diagnosis, Screening, and Treatment Diagnosis is based on recognition of the disease characteristics and on genetic testing, especially in families. Commercial genetic testing has recently become available for JP, and clinical testing is approached as it is in FAP and PJS. Genetic testing is particularly important in JP, both to confirm the diagnosis in a proband and to test relatives. Testing is also important to separate JP from CS in view of the high risk for colon cancer in JP but not CS. Genetic testing has also been shown to increase markedly the screening compliance in relatives of those with JP. [203] It has been suggested that upper endoscopy and colonoscopy examinations begin in the late teens, or earlier if symptoms occur in those with a clinical or genetic diagnosis, or in those at risk if a genetic diagnosis is not possible. [181] Studies should be repeated every 3 years if no polyps are present but annually for endoscopic therapy if polyps are found. Colectomy is indicated if polyps are difficult to control endoscopically or if advanced neoplastic change or cancer is observed in polyps. Complete or partial gastrectomy may be necessary for cancer or advanced lesions that cannot be effectively controlled endoscopically. Screening recommendations have not been suggested for pancreatic cancer.

Cowden Syndrome

Epidemiology and Clinical Characteristics CS, also called *multiple hamartoma syndrome* is an autosomal-dominant inherited condition characterized by multiple hamartomas of the skin, mucous membranes, GI tract, and other organs and a high risk for cancer of the breast, thyroid, and perhaps other sites. [181], [204], [205], [206], [207] and [208] The disease occurs in about 1 in 200,000 individuals but is believed to be underdiagnosed. An international consortium has developed diagnostic criteria for CS [207] (Table 90-8). The hallmark of the syndrome is the presence of multiple facial trichilemmomas. Verrucous skin lesions of the face and limbs and cobblestone-like hyperkeratotic papules of the gingiva and buccal mucosa are common. [206] Biopsy examination has demonstrated facial lesions to most often be trichilemmomas, oral mucosal lesions to be fibromas, and all hand and foot lesions to be hyperkeratoses. [209] By the third decade of life, 99% of affected patients have developed mucocutaneous stigmata of the disease. [205]



Pathognomonic Criteria
Mucocutaneous lesions
- Trichilemmomas, facial
- Acral keratoses
- Papillomatous papules
- Mucosal lesions

Major Criteria
Breast carcinoma
Thyroid carcinoma (nonmedullary), especially follicular
Macrocephaly (megalencephaly, at least 95th percentile)
Lhermitte-Duclos disease (LDD)
Endometrial carcinoma

Minor Criteria
Other thyroid lesions (e.g., adenoma or multinodular goiter)
Gastrointestinal hamartomas
Fibrocystic disease of the breast
Lipomas
Fibromas
Genitourinary tumors (renal cell carcinoma, uterine fibroids) or malformation

Operational Diagnosis in a Person
1. Mucocutaneous lesions alone if:
   a. There are at least 6 facial papules, of which at least 3 must be trichilemmoma, or
   b. Cutaneous facial papules and oral mucosal papillomatosis, or
   c. Oral mucosal papillomatosis and acral keratoses, or
   d. At least 6 palmoplantar keratoses
2. Two major criteria, but one must include macrocephaly or LDD
3. Two major and three minor criteria
4. Four minor criteria

Operational Diagnosis in a Family with One Member Diagnosed with Cowden Syndrome
1. One or more of the pathognomonic criteria
2. Any one major criterion with or without minor criteria
3. Two minor criteria

TABLE 90-8 Diagnostic Criteria for Cowden Syndrome

Other common manifestations of the disease include multinodular goiter (50%), follicular (sometimes papillary) thyroid carcinoma (10%), [205] thyroid adenoma, fibrocystic breast disease and breast fibroadenomas (up to 75%), breast cancer (25% to 50%; median age at diagnosis, 41 years; range, 14 to 65 years), [209], [210] GI hamartomas (about 60%, although systematic study has not been undertaken), [206] multiple, early-onset uterine leiomyomas, macrocephaly (specifically, megencephaly), and mental retardation. Possibly related cancers include those of the endometrium (lifetime risk, 2% to 5%), kidney, colon, ovary, melanoma, lung, and retinal glioma. [206], [207] and [208] Male breast cancer has been reported in patients with CS. [208], [211] Additional benign soft tissue and visceral tumors that have been reported include hemangiomas, lipomas, lymphangiomas, neurofibromas, and meningiomas. Developmental or congenital abnormalities also occur and include hypoplastic mandible, a prominent forehead, and a high-arched palate. The GI hamartomas occur throughout the GI tract. A review of the reported cases in Japan found polyp distribution among 93 cases to be as follows: esophagus, 66%; stomach, 75%; duodenum, 37%; and colon, 66%. [212] Polyps of the esophagus are actually glycogenic acanthosis, which appear as whitish, flat elevations in the esophagus. [213] In the stomach, small bowel, and colon, a number of different types of hamartomas are observed, including juvenile polyps (by far the most common), lipomas, inflammatory polyps, ganglioneuromas, and lymphoid hyperplasia. Juvenile-like polyps that contain some neural elements are considered characteristic of this disease. GI cancer risk has generally been considered not elevated, although the study from Japan quoted previously found 9.6% of 93 patients to have colon cancer.

Related Syndromes

Lhermitte-Duclos disease. The rare occurrence of a benign hamartomatous overgrowth of ganglion cells in the cerebellar cortex (called *dysplastic gangliocytoma of*

the cerebellum) is called Lhermitte-Duclos disease. This same tumor is a known manifestation of CS. Recently, it has been found that virtually all cases of Lhermitte-Duclos occur as a part of CS. [214], [215] and [216]

Bannayan-Riley-Ruvalcaba syndrome. BRR syndrome, also previously called *Ruvalcaba-Myre-Smith syndrome* and *Bannayan-Zonanna syndrome* is characterized by the features of CS together with macrocephaly, delayed psychomotor development, lipomatosis, hemangiomatosis, and pigmented macules of the glans penis. [217], [218] Similar to CS, intestinal polyps are primarily juvenile polyps, and some contain ectopic ganglion cells. [219] It is now known that BRR syndrome and CS arise from mutations of the *PTEN* gene [220], [221] and that the identical mutation can lead to either phenotype. [221], [222] and [223] It has been suggested that CS and BRR syndrome be referred together as the *PTEN* hamartoma tumor syndromes.

Genetics and Management CS was recently found to arise from mutations of the *PTEN* gene. [224], [225], [226] and [227] *PTEN* is a ubiquitously expressed dual-specificity phosphatase, which acts as a tumor suppressor gene. [228] It regulates cellular processes, such as cell cycling, translation, and apoptosis by blocking activation of Akt, a serine-threonine kinase involved in cell growth and survival. [229], [230], [231] and [232] Up to 80% of patients who meet the diagnosis criteria of CS are found to have a *PTEN* mutation, [226], [233] whereas only 10% to 50% of people will have a *PTEN* mutation when the criteria are not fulfilled. [233], [234] and [235] Fifty percent to 60% of BRR syndrome patients exhibit a PTEN mutation. [221] Mutations are found in more than 90% of families that exhibit features of both CS and BRR. [207] One family with a CS-like phenotype was found to have a disease causing germ-line mutation of the *BMPR1A* gene. [194] Commercial genetic testing is now available for CS and BRR.

Surveillance Management of CS involves prevention of the associated cancers. [207] The specific risks and screening recommendations are given in Table 90-9. No recommendations have been given for the surveillance of GI areas, mainly because GI cancer risk is not increased in CS. Intervention is obviously needed whenever GI symptoms occur, especially rectal bleeding. It is now believed that most cases of CS are diagnosed because of either skin or GI findings. [206] Surveillance of the GI tract should probably be synthesized on the basis of polyp location, number, size and histology, once they are delineated. Finally, the finding of an increased risk for colon cancer in CS patients in Japan [212] indicates that better definition of the GI phenotype is needed in other populations.

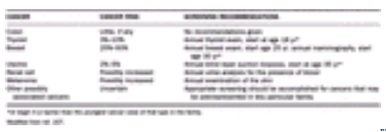


TABLE 90-9 Cancer Risks and Screening in Cowden Syndrome

Hereditary Mixed Polyposis Syndrome

Three families were described in which the polyposis phenotype links to a locus on chromosome 6. [236], [237] and [238] Affected patients exhibited primarily juvenile polyps but also adenomatous polyps and hyperplastic polyps and sometimes polyps of these histologies mixed.

Gorlin Syndrome

Gorlin syndrome, also called *nevoid basal cell carcinoma syndrome* is an autosomal dominant disorder with an occurrence of 1:55,600. [206] It accounts for about 0.5% of patients with basal cell cancer and occurs secondary to mutations of the *PTCH* gene on chromosome 9q. The primary clinical findings include multiple basal cell carcinomas, mandibular bone cysts, characteristic pits in the skin of the palms and soles, intracranial calcification, large head circumference, and congenital skeletal anomalies. Gastric hamartomatous polyps have been reported as a part of the disease.

POLYPOSIS SYNDROMES WITH NEURAL POLYP HISTOLOGY

Neural elements can be observed in the juvenile polyps of CS and BSS, and when found, are somewhat distinctive for those diagnoses. Multiple GI polyps with histologic neural elements can also be found in neurofibromatosis type I, in multiple endocrine neoplasia type IIB (MEN IIB) and independently in families without any known syndromes.

Neurofibromatosis Type I

Neurofibromatosis type I, also called *von Recklinghausen disease* is defined by the presence of more than five cutaneous café-au-lait spots together with frequent neurofibromas of the skin. [206] The incidence is 1 in 3000, and one third to one half of cases are new mutations. The condition is autosomal dominantly inherited and arises from mutations of the *NF1* gene on chromosome 17q. About 25% of affected patients exhibit multiple intestinal polypoid neurofibromas and less commonly ganglioneuromas. [239], [240] The small bowel is affected most commonly, followed by the stomach and then the colon. GI symptoms are unusual but may include GI bleeding, intussusception, or obstruction. [241], [242] Neurofibrosarcoma has only rarely been reported.

Multiple Endocrine Neoplasia Type IIB

Also called *multiple neuroma syndrome* MEN IIB is characterized by the presence of multiple tumors, including medullary thyroid carcinoma, pheochromocytoma, parathyroid adenomas (less common than in MEN IIA), enlarged and nodular lips (from ganglioneuromas), a marfanoid habitus, and ganglioneuromatosis of the GI tract. GI involvement in MEN II is common, with ganglioneuromatous polyps occurring throughout the GI tract, from lip to anus, but most commonly in the colon and rectum. [240], [243], [244] and [245] GI symptoms, including diarrhea and constipation, are common (more than 90% of cases) and arise from dysmotility of the GI tract secondary to the underlying ganglioneuromatoses because the lesions are often transmural. [240], [246], [247] Symptoms often begin in the first months of life and may present as megacolon. A single mutation at codon 918 in the tyrosine kinase domain of the RET receptor (of the RET protooncogene on chromosome 10q) has been associated with the MEN IIB phenotype. [244] About half of cases discovered are considered to be new mutations. Genetic testing is now available for this condition. [248]

Isolated Intestinal Neurofibromatosis of the Colon

Multiple colonic ganglioneuromas have been observed in families and isolated cases unrelated to von Recklinghausen disease or to MEN IIB. [243], [244], [249], [250] and [251] The observed ganglioneuromas are both microscopic and polypoid. There may be dozens of visible colonic polyps ranging up to 0.5 cm in diameter. The distribution of affected individuals in the one family described was typical of autosomal-dominant inheritance.

POLYPOSIS SYNDROMES OF UNCERTAIN ETIOLOGY

Cronkhite-Canada Syndrome

Cronkhite-Canada syndrome (CCS) is a noninherited condition characterized by generalized GI polyposis, cutaneous hyperpigmentation, hair loss, and nail atrophy. [252], [253] and [254] The syndrome has a worldwide distribution. [255], [256] Sixty percent of reported cases occur in men, and the average age at symptom onset is 59 years, with a range of 31 to 86 years. No familial occurrences have been observed. Nutritional, infectious, and immunologic associations have been discussed, but the cause of CCS remains elusive [257], [258]

The polyposis of CCS is present throughout the GI tract except for the esophagus. [253] Hundreds of polyps are observed, with polyp size ranging from a few millimeters to 3 cm in diameter. Colonic polyps are almost always sessile, even when large, which can often differentiate them from juvenile polyps. This is not, however, a reliable feature of the gastric polyps, which often become pedunculated. [257] Ulceration and friability are surface features of some of the polyps. Microscopically, the polyps are almost identical to juvenile polyps. In contrast to JP, however, the mucosa between polyps is also histologically abnormal, with edema, congestion, and inflammation of the lamina propria and focal glandular ectasia. Polyps may appear over several years or several months. They usually resolve after remission of symptoms, but they may persist for years.

Adenomatous change and colon cancer have been reported in the hamartomatous polyps of this syndrome. [255], [256], [259], [260] The overall incidence of colon cancer

appears to be about 12% to 15%. [253], [256], [260] Carcinoma of the stomach is also reported as a consequence of CCS. [261] It remains uncertain whether cancers of the GI tract arise from adenomatous change in the hamartomatous polyps, arise directly from the hamartomatous polyps, or both. [261]

A number of extraintestinal, ectodermal manifestations are observed in almost all patients with CCS. [253] Nails of the fingers and toes exhibit various degrees of dystrophy, described as thinning, splitting, and partial separation from the nail bed (i.e., onycholysis). Hair loss occurs over a few weeks on the scalp, eyebrows, face, axillae, pubic area, and extremities. Hyperpigmentation is described as dark, brownish macules, ranging from a few millimeters to 10 cm in diameter, and it occurs over the upper extremities, followed by the lower extremities, face, palms, soles, neck, back, chest, and scalp, in that order. The nail, hair, and pigmentation abnormalities are all reversible on remission of the disease.

Hypogeusia is the dominant initial symptom in most patients, which is soon followed by diarrhea, abdominal discomfort, anorexia, and weight loss. [253], [254] The diarrhea results from protein loss caused by excess mucous secretion by crypt cells. [257] Variable degrees of fat and disaccharide malabsorption also occur because of a somewhat decreased absorptive surface, but not from damage to the absorptive epithelium. Other common symptoms include fatigue, weakness, edema, nausea, and vomiting.

The disease often exhibits a fairly acute onset and a rapidly progressive course. [253] Weight loss and edema ensue, and ectodermal changes occur in a few weeks to a few months. GI bleeding also may occur and may be severe in some cases. Intussusception from small bowel polyps has been reported but is unusual. The diarrhea and protein-losing enteropathy may be extremely severe, resulting in profound malnutrition. Complications resulting from malnutrition are a major cause of morbidity and mortality in this syndrome. They include severe cachexia, anemia, congestive heart failure, and impaired immunity, resulting variously in pneumonia, sepsis, and septic shock. The disease may be fatal within a few months, although a more protracted course is also possible, especially if the patient responds to therapy or remits spontaneously.

A number of spontaneous remissions have been reported in CCS, and partial or complete remissions have resulted from several different interventions. [253], [256], [262], [263], [264], [265], [266] and [267] Therapies have included corticosteroids, antibiotics, colectomy, parenteral nutrition, and combinations of these. Each therapy has been successful in some cases but unsuccessful in others. Present recommendations are for aggressive supportive therapy, including enteral or intravenous alimentation. Corticosteroid therapy is undertaken if deterioration continues, and antibiotic therapy may be attempted, although its usefulness is questionable. Surgery is most often used to treat complications, including bleeding, malignancy, intussusception, and sometimes protein-losing enteropathy. Colonoscopy should be performed, if feasible, to consider the possibility of malignancy. Periodic examination of the colon and stomach seems to be indicated in long-term survivors with persistent polyps to screen for adenomatous change and colon cancer.

Hyperplastic Polyposis Syndrome

Rare patients are described with large numbers of hyperplastic polyps distributed throughout the colon. [268], [269] and [270] In such patients, polyps are most often sessile, 1 to 7 mm in diameter, but larger, sessile, or pedunculated hyperplastic polyps may be observed. [271], [272] Smaller polyps are distributed equally throughout the colon, whereas larger lesions often have a proximal colonic distribution. [269], [270] Colon cancer has often been reported with HP, but most of the cases were ascertained because of the cancer, so that the actual malignant risk remains unknown. In favor of a cancer association is the frequent finding of adenomatous polyps in patients with HP and even a description of serrated adenomatous polyposis. [273] Familial cases have been reported, but inheritance remains poorly defined. [270], [271] and [272], [274]

The most difficult issues with HP are to distinguish it from cases with multiple sporadic hyperplastic polyps and to determine appropriate management in view of the probable cancer risk, the frequent accompanying adenomas, and the large numbers of polyps with which the endoscopist must deal. Working criteria have been suggested to assist with diagnosis: (1) at least five hyperplastic polyps proximal to the sigmoid colon with two or more of them larger than 10 mm in diameter, (2) any number of hyperplastic polyps proximal to the sigmoid colon in an individual who has a first-degree relative with HP, or (3) more than 30 hyperplastic polyps of any size, but distributed throughout the colon. [269] A definition of more than 20 hyperplastic polyps has also been used. [270] Germ-line mutations for HP have not been identified, but chromosome 1p allelic loss has been observed in large polyps of HP patients. [270]

Management includes interval colonoscopic polyp removal, ablation, or both. I perform colonoscopy every 1 to 3 years, depending on the number of both hyperplastic and adenomatous polyps at each examination. Subtotal colectomy should probably be considered if HP with large numbers of polyps is found simultaneous to a colon cancer diagnosis.

POLYPOSIS SYNDROMES WITH INFLAMMATORY POLYPS

Inflammatory Bowel Disease

Multiple inflammatory polyps are frequently found in both ulcerative colitis and Crohn's disease. The polyps represent remaining normal tissue, with inflammatory elements that persist during the healing phases of the diseases. The polyps themselves have no malignant potential, although both ulcerative colitis and Crohn's disease have a colon malignancy risk that parallels the extent of colonic involvement and the duration of the disease.

Devon Polyposis

Devon polyposis, also known as *Devon family syndrome* was described in a family in which three generations of females were found to have multiple inflammatory fibroid polyps of the ileum. [275] The polyps varied in size from 0.5 to 8 cm, and each affected person experienced intussusception or small bowel obstruction. Similar polyps were found in the gastric antrum of one patient. Histologically, the polyps were benign proliferations of histiocytes.

Cap Polyposis

Cap polyposis is a rare syndrome of multiple inflammatory polyps in the rectosigmoid. Histologically, the polyps are inflammatory, with elongated tortuous crypts covered by a "cap" of granulation tissue. Clinically, patients may have diarrhea, rectal bleeding, and protein-losing enteropathy. [276] The authors of one case hypothesized mucosal prolapse as an etiology because they observed histological similarities to solitary rectal ulcer syndrome, in which multiple 1- to 3-mm–sized polypoid lesions in the distal rectum can also be observed. [276]

POLYPOSIS CONDITIONS ARISING FROM LYMPHOID TISSUE

Nodular Lymphoid Hyperplasia

Nodular lymphoid hyperplasia (NLH) is a rare polyclonal lymphoproliferative disorder of unknown cause that, in most cases, is not related to a distinct disease. [277] It is found in the terminal ileum of some patients with Gardner syndrome, in about 20% of patients with common variable immunodeficiency syndrome, [277], [278], [279], [280] and [281] as a rare association with intestinal lymphoma, [282], [283], [284] and [285] and in some otherwise healthy children. [286], [287] NLH also has been described in the small bowel of adults without immunodeficiency. [288], [289] It has been suggested that hyperplasia of the lymphoid nodules occurs as a local immune response to antigens in the gut lumen. It has been suggested that cellular immune dysfunction, as well as immunoglobulin deficiency, must be present for NLH to be present. [290]

The hyperplastic lymphoid nodules of NLH are most often found in the small bowel but also may occur in the stomach and colon. They are described as numerous, 3 to 6 mm in diameter, and exhibiting the same color as surrounding mucosa. Occasionally, nodules may reach 10 mm in diameter and even larger. The enlarged lymphoid follicles are morphologically indistinguishable from lymphoid follicles that occur normally in the GI tract. The nodules themselves do not usually cause symptoms, which are more likely related to the underlying conditions.

The primary clinical issue is to distinguish NLH from normal lymphoid tissue, where follicles range in size from 0.6 to 3 mm in diameter throughout the gut. Barium enema may reveal lymphoid follicles without evidence of disease in up to 50% of patients younger than 30 years of age and in up to 17% of those older. [291] Normal lymphoid nodules are less frequently detected by colonoscopy but become very apparent in melanosis coli. More recent endoscopic characterization of lymphoid

follicles, however, may show these normal structures to be more common. [292] Lymphoid hyperplasia of the terminal ileum is already found in almost half of patients examined by colonoscopy. [293] Follicles range in size from 1 to 10 mm or more and are larger, more numerous, and more frequent in younger individuals. Immunohistochemistry staining and tissue genotyping can now be used to distinguish malignant changes of lymphoid tissue and NLH. [294]

NLH as an entity does not require therapy.

Multiple Lymphomatous Polyposis

About 30% of primary extranodal lymphomas occur in the GI tract. Most of these present as a single lesion, although about 10% exhibit GI polyposis, including multiple lymphomatous polyposis (MLP) and immunoproliferative small intestinal disease (see later). [295], [296]

MLP is a rare intestinal malignancy characterized by the presence of numerous GI polypoid lesions of malignant lymphoma. It is a non-Hodgkin's B-cell lymphoma that is the GI counterpart of mantle cell lymphoma. [297], [298] and [299] MLP arises from a malignant transformation of lymphocytes that exhibit homing receptors for lymphoid tissue of the GI tract, thus giving rise to a diffuse polyposis presentation. [300] The polyps range from a few millimeters to several centimeters in size, involve the small and large bowel in 80% to 90% of cases and the stomach or duodenum in 50% of cases. [301] This condition occurs predominantly in men (88%), with reported cases ranging in age from 43 to 82 years at the time of diagnosis. [302] Symptoms are nonspecific, including weight loss, fatigue, diarrhea, abdominal pain, anemia, and occult GI bleeding. The condition often exhibits extra-abdominal dissemination, especially to peripheral lymph nodes. Chemotherapy is the treatment of choice, although the overall prognosis is poor. [299]

Mucosa-associated lymphoid tissue lymphomas, follicular lymphomas, and primary T-cell lymphomas have now also been described that are morphologically similar to MLP in that they exhibit a multiple polypoid appearance in the GI tract and are thus considered types of MLP. [303], [304], [305], [306], [307] and [308]

Immunoproliferative Small Intestinal Disease

Immunoproliferative small intestinal disease (IPSID), previously called both *Mediterranean-type lymphoma* and *a-heavy chain disease* can also exhibit multiple nodular lesions of the small bowel. [309], [310] IPSID most commonly occurs in people living in the Mediterranean region in the second or third decade of life. Patients present with a malabsorption syndrome lasting months to years that includes chronic diarrhea, weight loss, and abdominal pain. Small intestinal endoscopy may variously show thickened mucosal folds, diffuse nodularity, ulcers, a mosaic pattern, and nondistensibility from infiltration.

Histologically, IPSID begins as an intense proliferation of plasma cells in the lamina propria. It eventually proceeds to an overt malignant lymphoma with extension beyond the lamina propria and sometimes the occurrence of multiple nodular lesions. The process may remain in deeper intestinal layers, however, requiring full-thickness biopsy for diagnosis. The lymphoma is a plasma cell tumor or an immunoblastic sarcoma. An abnormal paraprotein is frequently resent, which represents the a-chain fragment of immunoglobulin A. IPSID is now thought in most, if not all, cases to be the late stages of a-heavy chain disease. [309] Unlike MLP, it is confined to the gut and is most often present in the small bowel.

MISCELLANEOUS NONINHERITED POLYPOSIS SYNDROMES

A number of reports have been made of leiomyomatosis of the colon and other segments of the GI tract. [311], [312] and [313] A multinodular submucosal tumor appearance is observed lumenally, which reflects single or multiple benign growths of smooth muscle of the bowel wall.

Lipomatous polyposis is also rarely observed. [314], [315] In one case, between 700 and 1000 lipomatous polyps were observed, but about 60 adenomatous polyps were also present. Polyps were 2 to 50 mm in diameter, were found throughout the colon, but were more dense in the left colon. [315] In another case, dense colonic lipomatous polyposis was observed together with lipomas of the peritoneum. [316] A third patient was found to have multiple lipomas throughout both the small and large intestine and a presentation of intussusception. [317]

Lymphangiomas are unusual solitary lesions in the colon, representing dilation or overgrowth of lymphatic channels. Clusters of elevated but apparent submucosal colonic polypoid lesions were observed colonoscopically in a recent case in which the lesions were found to be multiple lymphangiomas. [318]

Finally, pneumatosis cystoides intestinalis is characterized by multiple air-filled cysts of the wall of the GI tract that can have the appearance of polyposis by barium enema and colonoscopy. [319] The diagnosis is made by abdominal radiography or colonoscopic biopsy.

CHAPTER 91

C. Richard Boland

MALIGNANT TUMORS OF THE COLON

Colorectal cancer has been the focus of clinical and basic research since the early 1980s because of its importance in public health, and it has become the cancer most responsible for the explosive increase in our understanding of tumor biology. We know more about the biology and clinical characteristics of this tumor than any other digestive tract cancer and, possibly, any other tumor. This knowledge provides the gastroenterologist with a powerful array of diagnostic and prognostic tools for our patients and permits us to provide advice for patients who are concerned about their risk for this disease.

It is now clear that the development of colorectal cancer represents an interaction between the genome of the colorectal epithelial cell and its environment; both factors are essential for the development of a tumor. The likelihood of developing tumors is related to diet, which accounts for the striking international epidemiology of this disease. In certain instances, the genetic predisposition in a person is overwhelming, and the patient faces an extremely high risk for cancer. Several of the genes associated with these predispositions have been identified. In most instances, however, the risk factors are more subtle, and it is possible that the risk for cancer can be modified. Primary prevention, that is, dietary modification or the introduction of a chemopreventive drug, would appear to be the most appealing approach to this disease, but insufficient data are available to bring a quantitative estimate of the impact of any changes in diet. No chemopreventive drug is known yet to be sufficiently safe and effective that we can offer it to our patients. Secondary prevention, that is, colonoscopic surveillance and the removal of precursor lesions, is highly effective, and the physician is faced with implementing the most appropriate regimen for each patient. Progress in these areas has created a challenge to keep current with this disease.

Colorectal cancer is one of the most common potentially lethal gastrointestinal diseases encountered in clinical practice and is readily cured with proper management. Most of the neoplastic lesions in this organ are adenomas and adenocarcinomas, and the comments made in this chapter are directed toward these tumors, unless specifically stated otherwise.

Colorectal neoplasia is a multifaceted problem. The basic biology of gastrointestinal neoplasia has been discussed in Chapter 24 and includes discussion of concepts such as tumor genetics, multistep carcinogenesis, oncogene activation, inactivation of tumor suppressor genes, clonal expansion of neoplastic cells, and the generation of cellular diversity in tumor progression as a background for understanding colonic neoplasia. Additional details regarding the performance and interpretation of tests for occult fecal bleeding are found in Chapter 34. Small intestine tumors share some of the characteristics of colonic tumors, but this type of tumor is addressed specifically in Chapter 80. Benign colonic polyps and gastrointestinal polyposis syndromes are discussed here in the context of cancer but are described in more detail in Chapter 89 and Chapter 90, respectively. Management of malignant polyps is discussed in the context of adenomatous polyps in Chapter 149 of this edition. Carcinoma of the anus is not described in this chapter, but it is covered in Chapter 92. The use of colonoscopy in the diagnosis of colonic neoplasia is discussed here, but additional details regarding the mechanics of this procedure may be obtained from Chapter 140 and Chapter 142. Colonic lymphoma and carcinoid tumors of the colon are distinct from adenocarcinomas and are discussed separately at the end of this chapter, together with rarer pathologic forms of colon cancer.

Epidemiology

Cancer is considered an acquired genetic disease produced by exposure to environmental carcinogens; the damage caused by these carcinogens accrues over many years. Exposure to environmental carcinogens is a constant and cumulative process. Because colonic carcinogenesis is a multistep process, considerable time is required for these chance events to accumulate. Gut epithelia are dynamic tissues that constantly undergo proliferation and renewal. No single gene is so critical to the process that a mutation in it will result in cancer. Each mutation or genetic alteration involved in carcinogenesis produces a new cell that has a slight survival advantage over the previous ones. This growth advantage permits clonal expansion of the cells. Additional genetic events occur to cells within the clone, which then give rise to new clones that, in turn, overgrow their progenitors. A critical but currently undefined nuclear event eventually occurs that results in genomic instability, giving rise to the genetic diversity observed in tumor cell populations. After the onset of genomic instability, additional mutational changes continue spontaneously without the necessity for additional exogenous carcinogens. Eventually, clones emerge that are capable of forming metastatic colonies.

The likelihood of producing a neoplastic clone, that is, one that can free itself from homeostatic growth controls, increases with time and total carcinogen exposure (which is constant and perhaps inevitable), and the clinical result is that cancer incidence rises as an exponential function of age. [1] Deaths from colorectal cancers

typically begin to increase slowly in the fifth decade of life, rising steeply with advancing age. [2] In the Western world, incidence of cancers of the colon and rectum increases between 50 and 80 years of age as a function of the sixth power of age. [3] Any consideration of cancer epidemiology must therefore be corrected for differences of age in the study populations.

In the United States, in 2001 there were an estimated 135,400 new cases of colorectal cancer and 56,700 deaths from this disease (42% of the incidence rate). [4] In 2000, there were about 553,400 cancer deaths in the United States, and just more than 10% were caused by colorectal cancer. [4] Several countries around the world have incidence and mortality rates higher than those in the United States. Attack rates for colon cancer are considerably lower in Japan and in most developing nations.

Rectal cancer is a distinct disease from colon cancer in its epidemiology, in its pathogenesis, and in the way we treat it. Interestingly, the incidence of rectal cancer in Japan is similar to that in the United States. Mortality from rectal cancer in the United States appears to be slowly declining, even though incidence is slowly increasing. [5], [6] The divergence between incidence and mortality is associated with a shift to cancers with a more favorable stage, suggesting the impact of early detection of tumors and removal of premalignant lesions from the distal colon and rectum.

GEOGRAPHIC PATTERNS

An essential feature of colorectal cancer is the wide geographic variation in its incidence at the international level. As illustrated in Table 91-1, the age-adjusted incidence of colorectal cancer varies by as much as a factor of 4 between different population groups. [3] Industrialized nations are at greatest risk. These differences appear not to be caused principally by genetic factors because populations migrating from low- to high-incidence regions quickly experience an increase in their rate of colorectal cancer. [7] Also, there is a marked difference in risk between African Americans and black African populations. [8], [9] This is strong evidence for the impact of environmental factors on the incidence of colon cancer and is a source of optimism that the high rates seen in the Western world might be reduced by identifying and removing critical causative factors from the diet or environment. Conversely, changes in dietary practices are thought to be responsible for adverse changes in this disease in Japan. The age-adjusted incidences of cancer of both the colon and rectum have risen more than threefold from 1974 to 1991 in Japan, and these rates now approach those seen in the Western world. [10]

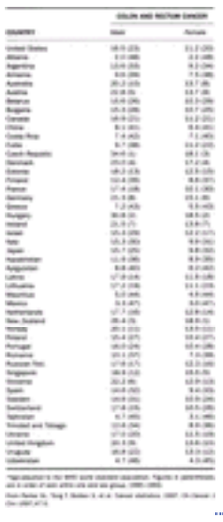

TABLE 91-1 Age-Adjusted International Colorectal Cancer Death Rates Per 10 [5] Population*

The estimated incidence rates of cancer vary widely, depending on the means of ascertainment used by the epidemiologist. It is often not possible to compare incidence rates estimated by different studies. In addition to considerations of accuracy in diagnosis and completeness of data retrieval, some studies do not correct the raw incidence figures for differences in age between populations. Only differences in disease incidence that have been determined using the same methodologies can be interpreted reliably. Accepting the inherent difficulties in collecting accurate data, it has been estimated that gastrointestinal cancers (i.e., colonic, gastric, esophageal, oral) account for four of the seven most frequently occurring cancer deaths observed worldwide and that lethal tumors of the colorectum rank just below cancers of the lung and stomach. [11] The rates are skewed in the United States, where colorectal cancer plays a more important role in cancer incidence and mortality, and stomach cancer is conspicuously low.

Whereas the incidence of colorectal cancers slowly drifted upward in the United States from 1950 to 1990, a slight downward drift in mortality occurred, suggesting that some introduced factor (perhaps the use of screening and colonoscopic polypectomy) resulted in better patient outcomes from this disease. [12], [13] One should keep in mind that incidence and mortality rates have not been constant over time.

No consistent observations of high-risk industries or occupations have been made, and smoking, for example, does not seem to play a role, despite the fact that tobacco use is associated with twofold to threefold increases in adenoma prevalence generally. Alcohol use, specifically beer drinking, is associated with a twofold to threefold increase in risk for colorectal adenomas and a significant increase in risk for colorectal cancer. [14], [15], [16], [17] and [18] The role of alcohol may be exacerbated by concomitant low intakes of methionine and folate. [19] There is a 2- to 3.6-fold elevated risk for colorectal cancers among women who have been irradiated for gynecologic cancer. [20] Asbestos exposure (either inhaled or ingested in the water supply) does not appear to increase the risk for colorectal cancer. [21], [22]

Physically active women have a relative risk for colorectal cancer of 0.54, [23] and virtually identical reductions in the risk for colorectal adenomas or carcinomas has been found in physically active men. [24] Increased total energy intake, which may complicate issues of physical activity, however, may reduce this benefit, [25] as discussed later.

DIETARY PATTERNS

Macronutrient Considerations

Investigators are most suspicious of the role of diet in the causation of colorectal cancer. [26] Dietary composition has been compared among populations with divergent incidences of colorectal cancer. The estimated risk for colon cancer increases by 2.3% for each 100 calories per day, and the total energy intake may be powerful enough to overwhelm other individual components of the diet. [27] Compelling epidemiologic leads have come from studies of the dietary intakes of fat, meat, and fiber, [28] and there is a strong dose-related association between per capita intake of total dietary fat or meat and the incidence of colorectal cancer (Fig. 91-1). However, dietary intervention studies over periods of 3 to 4 years have failed to reduce significantly the incidence of recurrent adenomas. [29], [30]

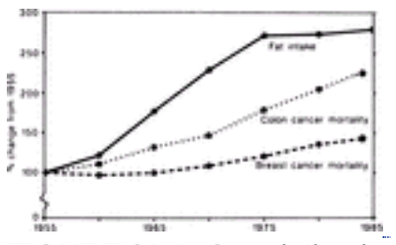

FIGURE 91-1. Correlation between changing fat intake and age-adjusted mortality from cancer of the colon and breast from 1955 to 1985 in Japan, during which time an increase in fat intake of 180% occurred. (From ref. [28].)

Meat and Fat Large epidemiologic studies have examined the role of diet in cancer. [31] In a study of more than 88,000 women, the intake of animal fat was positively associated with colon cancer incidence, with a relative risk of 1.89 for the highest quintile compared with the lowest, which is statistically significant but modest. The relative risk among daily eaters of beef, pork, or lamb compared with those reporting consumption less often than once a month was 2.49. Animal fat from dairy sources was not an independent risk factor because the relative risk for consumption of more than 18 g daily, compared with less than 7 g daily, was 0.91. There was no apparent risk for ingestion of vegetable fat or linoleic acid. Fat intake was not independent of total energy intake as a risk factor in this study. Eating fish or skinned chicken was associated with lower risk as well. Lower intake of fiber appeared to be a contributing dietary factor but was not independent of increased meat consumption. [32] In U.S. men, relative risks for colorectal cancer of 3.57 have been reported for those who ingest beef, pork, or lamb, [33] although other studies have not confirmed this finding. [34], [35] These nutrients may be part of the general phenomenon of a large total caloric intake, and it is not obvious whether these issues are separable. [36]

Serum Cholesterol Serum cholesterol is, in part, a reflection of total dietary intake of fat, and two large studies showed a direct relation between cholesterol levels and colon cancer. After excluding patients with colon cancer at the time of blood collection, a prospective study of 8000 Hawaiian Japanese men indicated that higher cholesterol values were significantly associated with later tumor development, particularly in the proximal colon. [37] A prospective study of more than 92,000 Swedish subjects revealed a positive association between serum cholesterol level and the risk for rectal cancer in men, with a relative risk of 1.65 for levels greater than 276 mg/dL. Similar trends were observed in women, although they were not statistically significant. [38] Decreased levels of high-density lipoprotein cholesterol and increased levels of low-density cholesterol have been reported in patients with colorectal adenomas. [39] Obesity in middle age is associated with increased colon cancer risk in men (relative risk for heaviest compared with lightest quintiles, 2.40); however, increased physical activity appears to eliminate the risk associated with obesity. [40] Women were not examined in this study. Curiously, studies from several countries have reported an inverse relation between serum cholesterol and colorectal cancer risk, [41], [42] and [43] and the Framingham Study reported a fourfold increase in risk for colon cancer among men who were both obese and had low serum cholesterol. [44] This finding may be explained, at least in part, by a case-control study that demonstrated an average decline of 13% in the serum cholesterol of colon cancer patients over a 10-year period compared with controls, who experienced a 2% rise during the same time frame. [45] Serum cholesterol may therefore reflect the increased risk associated with a high-fat diet but may fall by an unknown mechanism during the development of colorectal neoplasia.

How Does Dietary Fat Promote Cancer? The mechanism by which a high-fat diet enhances tumor production appears to be related to the role of bile acids on colonic epithelial proliferation. Increasing the intake of animal fat from 62 to 152 g/day produced a significant increase in total fecal bile acid and fatty acid excretion in humans, without affecting fecal weight, number of stools, transit time, fecal ß-glucuronidase, or fecal steroid degradation. [46] In rats, the intracolonic instillation of deoxycholic acid (DOC) increased cellular proliferation as measured by ornithine decarboxylase activity and new DNA synthesis. The proliferative response to DOC may be abolished by agents that destroy superoxide (such as superoxide dismutase) or inhibit lipoxygenase activity. DOC produces reactive oxygen radicals in the colon, and the generation of such molecular species can independently stimulate mucosal proliferation. [47] Because the oxidation of unsaturated fatty acids produces compounds that may stimulate cell proliferation, the generation of reactive oxygen may be the mechanism by which oxidized fatty acid residues are produced and colonic cell proliferation is stimulated, [48], [49] which could explain why unsaturated fatty acids are more effective in supporting tumor production in animal models and the coordinate role of bile acids and fat in the pathogenesis of colorectal cancer. It has been suggested that fish oil contains fats that protect against colorectal neoplasia. Marine fish oils are rich in unsaturated fatty acids, including n-3 or ?-3 fatty acids (which refers to the location of the double bonds being 3 positions from the end of the chain), in contrast to the n-6 or ?-6 fatty acids that predominate in unsaturated plant lipids. Geographic regions where people have large amounts of marine fish in the diet tend to have lower incidences of colorectal cancer. Furthermore, supplemental marine oils do not promote cancer in animal models. After treatment for 12 weeks with 4.1 g of eicosapentaenoic acid daily and 3.6 g of docosahexaenoic acid daily, subjects with adenomatous polyps showed a rapid contraction of the zone of proliferation into the lower portion of the colonic crypt, although no change in the total rate of proliferation was seen. [50] The mechanism by which ?-3 fatty acids suppress proliferation in the superficial portion of the crypt is not known, and the predictive value of this observation is not proven. Increased ingestion of dietary fat results in an elevation of fecal bile acids. [46] A significant elevation in fecal bile acid concentration has been reported in 82% of patients with large bowel cancer compared with 17% of patients with other diseases. [51] This observation has been confirmed in a wide range of population groups. [52] Patients with colorectal cancer have relatively high levels of unconjugated primary bile acids and neutral animal sterols and relatively low levels of esterified neutral sterols and saponifiable bile acids in their feces compared with a group of nonvegetarian patients without cancer. These differences are even more profound if cancer patients are compared with vegetarians, who have a lower risk for colorectal cancer than omnivores. [53]

Dietary Fiber The Western diet is relatively deficient in fiber compared with the diet of non-Western populations, and this may be important in the pathogenesis of colon cancer. [54] Countries with high fiber intake also tend to have lower intakes of fat and often a lower life expectancy, which introduces confounding variables. Although data obtained in laboratory animals have been somewhat confusing, the epidemiologic observations are more consistent. [55] Some case-control studies have demonstrated a protective effect of dietary fiber, [56] but other studies have failed to confirm this finding. [57] If the entire body of data accumulated on the subject is considered, most papers show a consistent protective effect of fiber, a small number of studies show no effect, and no study shows a deleterious effect of fiber on the incidence of colon cancer. [58] In a prospective questionnaire study of more than 760,000 people, the ingestion of a diet rich in vegetables and high-fiber grains was found to be significantly protective against fatal colorectal cancer, and the highest quintile of intake had relative risks of 0.62 (for women) and 0.76 (for men) compared with the lowest quintile. [59] A metaanalysis of 13 case-control studies that examined the impact of dietary fiber intake on colorectal cancer incidence revealed relative risks of 0.53, 0.63, 0.69, and 0.79 after comparing the four highest quintiles of fiber intake with the lowest ($P = 0.0001$). Although statistically significant, this is a relatively weak effect and not as powerful as the effect of family history, for example. After adjustment for fiber intake, relatively weak independent protective effects also were seen for vitamin C and beta carotene, which underscores the complexity of the role of diet in cancer causation. [60] The intake of nonstarch polysaccharides (i.e., fiber) correlates directly with fecal weight in studies from diverse international populations, and the incidence of colorectal cancer shows a significant inverse correlation with fecal weight (Fig. 91-2). Fecal weights in Great Britain were found to be about 106 g/day (corresponding to a fiber intake of 12.8 g/day). Based on the observation that high-risk Western nations have fecal weights in the range of 80 to 120 g/day, these investigators suggested that an increase in fiber intake to more than 18 g/day would increase fecal weights to more than 150 g/day and might reduce cancer incidence. [61] One trial demonstrated that the addition of 13.5 g of bran fiber to the diet (equal to a 1.5-ounce bowl of a commercially available all-bran cereal) resulted in a significant reduction in rectal epithelial proliferation in a group of high-risk patients with a past history of resected colorectal cancers. [62] Nonetheless, the projected impact on the incidence of colorectal cancer as a solitary intervention is not likely to be dramatic.

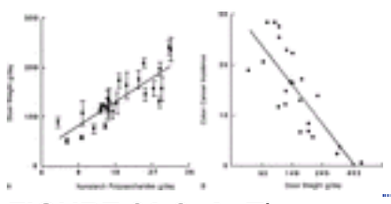

FIGURE 91-2. A: The mean stool weights ± standard error of the mean (*SEM*) in 11 groups of healthy subjects ($n = 206$) on controlled diets containing different amounts of dietary fiber. **B:** The relation between colon cancer incidence (age-adjusted cases per 100,000 population) from 23 population groups in 12 countries, plotted against stool weight in grams per day ($r = 0.78$). (From ref. [61].)

A number of mechanisms have been proposed for the protective effect of fiber against colorectal cancer. Fiber decreases fecal transit time and, by virtue of its sheer presence in stool, tends to dilute the concentration of other colonic constituents per g of stool. Both of these would tend to minimize contact between carcinogens and colonic epithelium. Second, fiber polymers may bind toxic substances and remove them from contact with epithelium. Third, fiber is neither digested nor absorbed in the small intestine but undergoes fermentation in the presence of the colonic flora, which reduces fecal pH and generates short-chain (volatile) fatty acids. [63] Certain short-chain organic acids derived from the fermentation of fiber can protect isolated colonic epithelial cells from DOC-induced injury in culture. [64] One of these, butyric acid, present in high concentrations in the colonic lumen, is thought to be an important energy source for colonic epithelium and has the ability to induce cellular differentiation in certain cultured cell lines.

Micronutrient Considerations

Calcium Cell proliferation normally takes place in the lower half of the colonic crypt. Early colorectal neoplasia has been associated with a shift of the proliferative zone from the lower to the upper portion of the crypt. [65] A generalized disturbance in the normal regulation of cell proliferation has been reported throughout the colons of patients with adenomatous polyps or cancers. [66] Groups at low risk for colorectal cancer, such as Seventh-Day Adventist vegetarians, [67] have low levels of colonic epithelial cell proliferation, and this has been used as an intermediate end-point biomarker for interventions in high-risk groups. Dietary calcium appears to participate in the regulation of colonic epithelial cell proliferation, although the mechanism of this control, and its interaction with bile acids, is not entirely clear. For example, colonic cell damage and epithelial proliferation may be stimulated by the addition of a bile acid, and both of these may be minimized by the supplementation of the diet with calcium. [68], [69] It has been hypothesized that the damaging and mitogenic effects of free fatty acids and bile acids could be reduced in the presence of supplemental calcium by precipitating free fatty acids as calcium soaps. [70] Correction of the hyperproliferative indices by supplemental calcium can also be achieved using epithelial explants in vitro, [71] which indicates that calcium may play an additional systemic role that is not explained by modification of the lumenal concentrations of fatty acids. Proliferative indices in the colons of a small group of patients at risk for familial colonic cancer have been studied with the patients on a conventional diet (assumed to contain about 700 mg of calcium per day) and then studied again after adding 1.25 g of calcium carbonate to the daily diet. Repeat study after 2 to 3 months indicated a reduction of the abnormal colonic proli-ferative indices to almost normal levels. [72] Although this result has been confirmed in another high-risk population, [73] contradictory results have been reported in other controlled trials. [74] The dose of calcium administered and the underlying proliferative activity of the epithelium may be important issues. Supplements of 1200 mg/day of elemental calcium did not reduce colonic epithelial cell labeling index in patients with adenomatous polyps, [75] but a daily dose of 2000 mg of calcium (i.e., 5 g of calcium carbonate) significantly suppressed rectal proliferation. [76] The mechanism by which supplemental calcium corrects the hyperproliferative states seen in patients at high risk for colon cancer has been questioned because of the ability to inhibit DNA synthesis with supplemental calcium in vitro. [71], [77] Although proliferation may be inhibited by supplemental calcium in normal tissues in vitro, growth inhibition is not observed in neoplastic tissues (i.e., adenomas and carcinomas). [77] No clinical trial has suggested more than a modest reduction in neoplasia with calcium supplementation, and large doses can be dangerous to some people, and may contain contaminants.

Selenium Low levels of selenium have been associated with an increased risk for colorectal neoplasia. [78] Selenium is a constituent of glutathione peroxidase, which prevents free radical damage to tissue and, by an independent mechanism, antagonizes toxicity caused by certain heavy metals. Attempts to assess interventions with supplemental selenium are in progress in geographic locations where the selenium content of soil and foods is poor. Excessive doses of selenium can be toxic to humans. Blood samples were obtained from a group of healthy subjects who were monitored prospectively for the development of cancer. This approach demonstrated significantly lower levels of serum selenium in patients who later developed gastrointestinal cancers, but no excess risk was found for patients with lower levels of serum retinoids, carotenoids, or vitamin E, all of which are potent antioxidants and were hypothesized to play a protective role against cancer. [79] Threshold limits for lower levels of these micronutrients are not known, and their roles in cancer prevention remain open questions. Selenium intake has been estimated in 27 countries and has been correlated with cancer incidence at various body sites. Significant inverse correlations were found between selenium intake and cancer of the colon and rectum. [78], [80]

Vitamins A, C, and E A number of vitamins may have anticancer effects. Vitamin A, beta carotene, and vitamin E are known to have powerful antioxidant activities, and retinoids function in certain laboratory models as differentiating agents. Also, a metaanalysis of five cohort studies suggested that those in the highest quartile for serum a-tocopherol (vitamin E) had a matched odds ratio of 0.6 for colorectal cancer compared with the lowest quartile (95% confidence interval [CI], 0.4 to 1). [81] Although it has long been suspected that people who have low serum levels of antioxidants would be at greater risk for certain cancers, prospective studies have been unable to confirm significant negative relationships between serum levels and subsequent risk for gastrointestinal cancer. [79] A 6-month chemopreventive interventional program using daily doses of 30,000 IU of vitamin A, 1 g of vitamin C, and 70 mg of vitamin E (D,L-a-tocopherol acetate) in patients with colorectal adenomas demonstrated a reduction in certain proliferation indices, but prevention of recurrent neoplasia has not yet been proved. [82] A small study of the effects of 400 mg of ascorbic acid and 400 mg of a-tocopherol per day has suggested a small reduction in the rate of colonic polyp recurrence over a period of 2 years. The minor benefit suggests that large numbers of people must be examined over a long period to detect significant benefits from this type of intervention. [83] In another study, a group of patients with familial adenomatous polyposis (FAP) was treated with 4 g of vitamin C plus 400 mg of a-tocopherol per day with or without 22.5 g/day of supplemental fiber from bran cereal. A modest regression of rectal polyps occurred among patients treated with vitamin C, vitamin E, and the high-fiber diet compared with patients given vitamins and a low-fiber diet or only placebo; however, this benefit did not quite reach statistical significance using rigorous analysis. [84] Unfortunately, a fairly large prospective, placebo-controlled clinical trial of antioxidant vitamins (including beta carotene, vitamin C, and vitamin E) failed to reduce the recurrence of adenomatous colorectal polyps. [85]

Dietary Folate and Hypomethylation of DNA Abnormal methylation of DNA has been proposed to play a role in carcinogenesis, and dietary folate and methionine are required for normal methylation. The actual role of this process in carcinogenesis is likely to be complex because some genes may be inappropriately expressed as a result of hypomethylation of its promoter site, whereas other tumor suppressor genes are silenced by hypermethylation of these regulatory sequences. Higher levels of dietary folic acid have been associated with lower risk for colorectal adenomas. [86], [87] A high level of alcohol intake may reduce levels of S-adenosylmethionine, which is required for methylation, and, as mentioned, alcohol intake has been correlated with risk for colorectal neoplasia. It remains to be seen how important dietary folate is in this process.

Other Micronutrient Anticarcinogens A growing list of dietary micronutrients and synthetic compounds have anticancer activity in animal models of cancer. [88] Many of these are blocking agents that prevent carcinogenesis by a variety of mechanisms. For example, benzyl isothiocyanate, a naturally occurring constituent of cruciferous vegetables, prevents the activation of certain procarcinogens. Organosulfur compounds from *Allium* species (i.e., garlic and onion families) also prevent procarcinogen activation, as do monoterpenes found in citrus fruits. A second class of blocking agents enhances the detoxification of carcinogens through phase 1 or 2 enzymatic pathways and are referred to as type A and B inhibitors, respectively. A third class of blocking agents is effective by inhibiting the increased cell proliferation that plays a role in promoting tumor formation, and they are effective inhibitors after carcinogen exposure. Many compounds share this activity, including phenols, flavones, tannins, curcumin, glycyrrhetinic acid, and glucarates. Other agents, referred to as suppressing agents, also act to suppress tumor development after carcinogen exposure but through poorly understood mechanisms distinct from those of the third class of blocking agents. This group includes protease inhibitors, terpenes, and other compounds. Some compounds have activities that both block carcinogens and suppress tumor formation. Many of these agents have been proposed as potential chemopreventive substances for human studies.

Role of Aspirin in Colorectal Cancer It has been appreciated by epidemiologists for some time that aspirin takers suffer fewer cancers than the rest of the population. In animal models of colorectal cancer, aspirin and non-steroidal antiinflammatory drugs (NSAIDs) inhibit the development of tumors. [89] Furthermore, patients with FAP experience a regression of their adenomas after treatment with the NSAID sulindac. [90], [91] and [92] Sulindac is a prodrug that is absorbed and reduced in the liver to the sulfide metabolite, which then is excreted in the bile and delivered to the colon. In 1991, a survey of more than 660,000 people sponsored by the American Cancer Society revealed a significant reduction in colon cancer deaths among aspirin users. Among those who used aspirin more than 16 times per month, the relative risk was 0.60 for men and 0.58 for women. [93] Risk reduction was seen even in people who reported aspirin use as rarely as once per month, raising interesting speculation regarding the mechanism and dose effects of this intervention. Subsequent studies of nearly 48,000 male health professionals confirmed a relative risk of 0.51 among those who used aspirin more than twice weekly; [94] however, a similar study of more than 500,000 nurses using this dose of aspirin incurred no measurable benefit unless they had used the drug consistently for 20 years or more. [95] A smaller, hospital-based case-control study of colorectal cancer patients estimated that the relative risk of cancer was 0.5 (95% CI, 0.4 to 0.8) among aspirin users, again suggesting that a longer duration of use is more protective, and indicated no protection for nonregular users or for subjects who had discontinued use more than 1 year before the study. [96] A significant reduction in adenoma recurrence (odds ratio, 0.52; 95% CI, 0.31 to 0.89) was found at the 1-year interval after initial colonoscopy among consistent aspirin users but not in the group of intermittent users; this result was independent of the number of initial polyps. [97] Significant reductions of about 40% for deaths from cancer of the rectum, esophagus, and stomach were reported recently from the large American Cancer Society survey. [98] The protection was greatest among long-time users (i.e., longer than 10 years) and was not found for tumors of nondigestive organs. The concept that NSAIDs may be of benefit in colorectal neoplasia came from the unexpected impact of sulindac on existing polyps in FAP (see Chapter 90). Unfortunately, reports on the use of this drug in patients with sporadic colonic polyps have provided divergent results, [99], [100] and no pharmacologic regimen can yet be recommended as an effective cancer-preventing intervention. The mechanism of action by which aspirin and NSAIDs protect against tumor formation in the digestive tract remains an issue of speculation and includes many possibilities. [101] It cannot be assumed that the antitumor effect is necessarily related to modifications in the production of prostaglandins in the gastrointestinal tract. In fact, an oxidized derivative of sulindac (sulindac sulfone) has the ability to inhibit polyp formation in the animal model even though it has no inhibitory effect on prostaglandin formation. There is growing evidence that NSAIDs may induce programmed cell death (apoptosis) in some early adenomatous cells but not in carcinoma cells. [102] One concept that initially challenged the prostaglandin-related hypothesis was the demonstration that NSAIDs increase the arachidonic acid in cells (due to inhibition of its conversion to prostaglandins), which stimulates the conversion of sphingomyelin to ceramide, a mediator of apoptosis. [103] Additional work has shown that NSAIDs may also inhibit some of the downstream effects that occur after disruption of the *APC* gene, which is an early event, mediating the appearance of the adenoma. [104] Also, combinations of NSAIDs with other agents have been found to be potent inhibitors of adenoma formation in the experimental model of FAP, raising novel therapeutic options for the future. [105]

Recommendations Although there are wide ranges in the international incidences of colorectal cancer, there is a fairly uniform, high rate of this disease in North

America, Western Europe, and much of the industrialized world. Groups migrating from low-risk into high-risk regions rapidly experience an increase in the incidence of colorectal cancer. It is a reasonable assumption that diet plays the greatest role in determining the incidence of colorectal cancer in the population. High fat intake and low fiber intake have been the most consistent associations with colorectal cancer, but the degree of risk attributable to these nutrients is modest. Unfortunately, interventions in which dietary fat has been reduced, fiber increased, and fruits and vegetables increased have not been able to reduce significantly the rate of recurrent adenomas over periods of 3 or 4 years among patients who have had adenomatous polyps removed. [29], [30] Several different interpretations are possible. First, it may be that 4 years of a new diet is not sufficient to alter the emergence of adenomas. It is possible that the intended intervention was not adequate and that insufficient changes were achieved in the diet. It is considered a reasonable recommendation that a healthy diet consist of less than 25% fat, include perhaps 25 g of dietary fiber, and be enriched with fresh fruits and vegetables, [106] but there is not yet any evidence that this will reduce the incidence of or mortality due to colorectal neoplasia.

ETIOLOGY

Colorectal Cancer Development through Multistep Carcinogenesis

Carcinogenesis in the colon and rectum initially was described in terms of the classic initiation-promotion model formulated more than four decades ago to explain carcinogenesis of the skin (see Chapter 24). According to this conceptual framework, the first step involved factors that directly damaged DNA, mutated the genome, and initiated the cells. The process was driven to completion by promotional factors that were not themselves mutagenic. It was thought that the two components of the process were strictly sequential in that promotional factors were effective only after the administration of initiating agent.

This model was replaced by a new model of multistep carcinogenesis driven by mutations at multiple loci. Colorectal neoplasia is best characterized as a process that begins with genetic mutations in critical growth-regulating genes that either enhance proliferation or prevent death, which provides growth and survival advantages for affected cells. As the cells expand their numbers, they accumulate additional mutations, some of which may be lethal but certain ones of which further enhance the ability of cells to proliferate. As the most advantageous genetic changes occur, these cells overgrow neighboring cells. Through successive waves of clonal expansion, the mutations appear to accumulate in the expanding clones. After the accumulation of sufficient genetic damage, and given a sufficient amount of time, the neoplastic phenotype is likely to occur, and the ability to invade and metastasize eventually emerges.

Caretaker and Gatekeeper Genes

The genetic events involved in carcinogenesis are typically inactivations of genes that have been characterized either as caretakers or gatekeepers, which helps to illustrate the functional nature of the genes involved. [107] This concept acknowledges two essential concepts of neoplasia: first, the genome of the neoplastic cell is unstable; second, mutations have occurred at critical growth-controlling genes. Loss of caretaker genes results in genomic instability, which increases the likelihood that mutations at other genes (including gatekeeper genes) will accumulate. Mutations tend to occur randomly, however, and most will have no effect on the growth potential of a cell; considering the demands of evolution, most mutations are likely to be deleterious. As illustrated by the fact that an entire metazoan organism may be created by cloning a somatic cell, it should be apparent that every cell has the theoretical capability of unlimited growth. A substantial number of our genes are expressed for the purpose of restraining this potential for growth, and these are called *tumor suppressor genes*. The inactivation of critical genes permits the cell to express normally forbidden behaviors, which is the basis for the gatekeeper concept. Each cell type appears to be controlled by a limited number of cell-specific gatekeepers. In a multistep process as occurs in the colon, the incremental changes in behavior gradually lead first to the formation of an adenoma and later to the evolution of carcinoma. Furthermore, some carcinomas may grow large without metastasizing, whereas others spread early in their course. The time required for these changes to occur depends on the degree of genomic instability and on chance. These issues are addressed in more detail in Chapter 24; the genes involved in colorectal carcinogenesis are discussed in the next section.

The Adenomatous Polyposis Coli Gene Is a Gatekeeper for the Colorectal Adenoma Much of what we know about colorectal carcinogenesis has been learned from studies of the familial syndromes FAP and hereditary nonpolyposis colorectal cancer (HNPCC). [108] FAP is caused by a germ-line mutation in the adenomatous polyposis coli (APC) gene, which is located on chromosome 5q. [109], [110], [111] and [112] Patients with FAP begin to develop adenomatous polyps in great number by early adolescence, and evidence has emerged that *APC* is the gatekeeper for the formation of adenomas. Furthermore, mutations in the *APC* gene are found in the smallest adenomas [113], [114] and do not appear to be responsible for later events in tumor progression. [114], [115] and [116] The alterations in the *APC* gene are almost always nonsense mutations, that is, those that result in a premature stop codon and consequently the production of a truncated *APC* gene product. Characteristically, adenomatous polyps also show loss of the nonmutated (or wild-type) *APC* alleles, called loss of heterozygosity (LOH, see later), as one would expect from the requirement for a two-hit mechanism at this tumor suppressor gene locus, in which both parental alleles must undergo inactivation. [114], [115] The APC protein appears to be involved in regulating cell death, which is discussed in Chapter 90.

K-*ras* Gene Mutations Are Associated with the Progressive Growth of Adenomas Most adenomas remain small and never progress beyond a benign stage. Growth and progression require additional disruption of growth controls. Mutations have been identified in the K-*ras* cellular protooncogene, and this has been demonstrated in larger adenomas, leading to the interpretation that this mutation may permit them to grow larger. [115], [116] and [117] The *ras* genes are highly conserved in nature; they encode for proteins located on the inner leaflet of the plasma membrane, bind guanine nucleotides, and are involved in signal transduction from the cell membrane to the nucleus. [118] Mutations located at critical positions in the gene alter the Ras protein in such a way that the signal transduction is constitutively activated, which leads to additional cell growth. A mutation at just one of three codons—12, 13, and 61 of the K-*ras* gene—is the mechanism by which *ras* is activated in many colorectal neoplasms. [119] For example, in one study of human tumors, mutations of K-*ras* were present in 10 of 27 colorectal cancers, and in 9 of these instances, the mutation occurred at codon 12 of the gene. [120] Mutation at codon 12 was found in 40% of 66 primary human colon cancers. The transforming mutations all occurred in the first or second of the three nucleotide positions of the codon but were not found elsewhere in the gene. [121] Not all colorectal cancers have K-*ras* mutations, and it is likely that mutations in genes encoding for other members of the signal transduction pathway occupied by K-*ras* may account for the constitutive activation of this signaling pathway in the absence of mutations in the K-*ras* gene itself. K-*ras* mutations appear to mediate a specific growth pattern and are associated with exophytic adenomas and carcinomas. [122]

The *p53* Gene Is a Gatekeeper for the Transition from Adenoma to Carcinoma Large adenomas are benign neoplasms, and despite the fact that they occasionally grow to a size of 6 cm or more in diameter, adenoma cannot invade the muscularis mucosae. The gene most responsible for malignant conversion appears to be the *p53* gene, which is activated by the two-hit mechanism characteristic of tumor suppressor genes. [115], [116] In the stepwise process, *p53* is the gatekeeper gene for the adenoma-to-carcinoma transition. [114] The *p53* gene serves as a cell-cycle checkpoint regulator and prevents nuclear replication after injuries that are likely to damage the DNA. [123] In the presence of damaged DNA, the p53 protein level rises in the cell, and progression into the cell cycle is prevented by G_1/S arrest. The cell either repairs the damage, or apoptosis (i.e., programmed cell death) ensues. Inactivation of the *p53* gene permits mutated DNA to be replicated and removes a level of restraint on abnormal cell behavior. Unlike what occurs in the *APC* gene, mutations in *p53* are usually missense; that is, they encode for a different amino acid somewhere in the protein chain. Truncating mutations do not occur commonly; rather, the aberrations tend to stabilize a nonfunctional p53 protein. The *p53* mutations tend to occur in hot-spot locations in colon cancers (codons 175, 248, and 273), and virtually all the mutations occur in one of four evolutionarily conserved regions of the gene located between codons 117 and 286. [124] This region of the p53 protein is responsible for DNA binding, and oncogenic forms of the protein lose the ability to bind DNA and activate gene expression. [125] Mutations in *p53* occur in a wide range of human tumors, [126] and this is perhaps the most common and most powerful tumor-causing genetic lesion. The mutational hot-spot region is where viral oncoproteins and at least one normally expressed regulatory protein bind and inactivate the function of *p53.* [123], [124], [127] In normal cells, *p53* is expressed at very low levels, has a short half-life, and is not readily detectable. Certain mutations in the *p53* gene result in the expression of a more stable but dysfunctional p53 protein that may be detected using standard immunohistochemistry. Overexpression of *p53*, as evidenced by observing the protein histochemically, may be seen in some colorectal adenomas, [128] but the biologic significance of a single mutated *p53* gene is uncertain if there is still a second, normal allele present in the nucleus because this is sufficient for normal cell growth. A second event occurs in which the normal or wild-type *p53* allele is lost, leaving the cell in the hemizygous, mutated state. As mentioned, the combination of a mutation in one allele, together with loss of the other allele, is the genetic combination responsible for the conversion of an adenoma to a carcinoma. [114], [129], [130] and [131] This conversion must occur in the context of an adenoma, which, as described, already has lost both copies of the *APC* tumor suppressor gene. The order of events appears to be critical in this instance because patients with a germ-line mutation in the *p53* gene (i.e., those with Li-Fraumeni syndrome) have only a modest increase in colorectal cancer. [132] Furthermore, mice who have had both copies of *p53* deleted from their genome have no tendency to develop gastrointestinal tract tumors but are at risk for lymphomas. [133] Overexpression of the p53 protein in colorectal adenomas is more prevalent in more highly dysplastic polyps and correlates with the proliferative activity of the lesion. [128] Increased expression of p53 and loss of the wild-type allele are associated with worse prognosis in colorectal cancer independently of other pathological features. [134], [135] There is evidence that loss of the wild-type allele is first seen in high-grade dysplasia (i.e., carcinoma in situ) and is associated with the onset of chaotic genomic instability, in which genetic material is randomly and rapidly deleted from the nucleus, resulting in LOH. [114]

Other Genetic Alterations in Colorectal Cancer Other genetic abnormalities occurring in colorectal neoplasia may participate in multistep carcinogenesis. For

example, although mutation in the *myc* oncogene has not been reported, this oncogene is amplified in some colon cancers. [136], [137] Although amplified expression of the *myc* RNA has been reported in more than two thirds of primary adenocarcinomas of the colon, levels of expression do not correlate with adverse patient prognosis. [138] Hypomethylation of DNA may lead to the altered expression of genes that are neither mutated nor amplified at the genomic level. This genetic modification has been reported in colorectal neoplasms and is found to a similar degree in benign adenomatous polyps. It may be one of the earlier genetic modifications in colorectal neoplasia. [139] The cellular protooncogene *src* is activated by mutation, resulting in increased tyrosine kinase activity, which is associated with increased cell proliferation, similar to that described for mutated K- *ras* genes. Increased protein kinase activity of activated *src* is an early event in the progressive neoplastic sequence and is seen in premalignant lesions such as adenomatous polyps. The activity of the enzyme is associated with the malignant risk for the polyp. [140] Several other oncogenes are mutated or otherwise abnormally regulated in colorectal cancer, but their roles in the overall scheme of colorectal carcinogenesis remain to be elucidated.

Genomic Instability in Colorectal Cancer

Colorectal cancers evolve by the accumulation of genetic alterations at loci involved in the control of cell growth. There is not one single human gene that, by itself, can cause cancer by virtue of mutation because of the redundancies that have evolved in the human genome. The fact that cancer occurs at all is best explained in the context of genomic instability and the progressive accumulation of mutations. First, a genetic caretaker function is lost that destabilizes the normally reliable process of DNA replication, resulting in genomic instability. Genomic instability, a genome-wide disorder, accelerates the accumulation of mutations throughout the nucleus. Many mutations are either neutral or deleterious and may not be relevant to the neoplastic process. A mutation eventually will occur that creates a growth advantage that is censored in normal cells, and this cell will overgrow its neighbors. Over time, additional mutations will accumulate that add to the growth advantage of the unstable clone. There are two types of genomic instability: one that results in loss of heterozygosity, and another that leads to microsatellite instability (MSI).

Chromosomal Instability Leads to Loss of Heterozygosity The type of genomic instability found in most colorectal cancers is characterized by aneuploidy, the loss of chromosomal segments throughout the genome, and LOH. [141], [142] In this poorly understood process, the nucleus no longer can symmetrically divide its chromosomes during mitosis. A variety of chromosomal rearrangements occur. In the case of LOH, one daughter cell receives more copies of a genetic segment, and the sister cell gets fewer. Increased numbers of lost genetic loci (expressed as the “fractional allelic loss”) are significantly associated with worse prognosis in colorectal cancer [141] because this increases the chance that LOH will occur at specific chromosomal locations such as 17p (the locus of the *p53* gene) and 18q (the locus of the several potential metastasis suppressor genes). [142], [143] Many of the lost genetic segments are random and may not be important for the malignant behavior of the cell, but in certain instances, LOH results in the loss of copies of tumor suppressor genes. If critical growth-restraining genes are lost, the altered cell gains an advantage in growth and survival over other cells, and undergoes clonal expansion. Widespread LOH events are characteristic of colorectal and other cancers, and the changing genetic background results in the generation of cellular diversity and, eventually, the metastatic phenotype with a primary tumor mass. Candidate genes have been proposed for various biologic characteristics of the metastatic phenotype, but the metastasis genes remain a complex and incompletely understood area.

Loss of DNA Mismatch Repair Activity Causes Microsatellite Instability At least two distinct pathways to colorectal neoplasia involve different mechanisms of genomic instability. In the first instance, which involves most colorectal cancers, there is the loss or gain of whole chromosomes or fragments thereof. [144] This has been called *chromosomal instability*. The existence of a second genetic pathway for colorectal cancer was discovered during the search for the gene for HNPCC or Lynch syndrome. This familial colon cancer gene was found using linkage analysis to map the phenotype to a specific genetic locus. This search required the use of genetic polymorphisms called *microsatellites*, which are short, repeated DNA sequences. Although the length of these sequences varies from person to person, they are stable and uniform throughout the cells of any individual. These sequences, which are interspersed more than 100,000 times throughout the genome, were found to be highly susceptible to mutation in HNPCC tumors, the phenomenon of MSI. [145], [146] This type of hypermutability also was found in about 12% of sporadic, nonfamilial colorectal cancers, particularly those in the proximal colon. [145], [147], [148] Tumors with MSI did not demonstrate the chaotic nuclear disorganization produced by LOH, and the two pathways with different types of genomic instability appear to be somewhat mutually exclusive. Furthermore, tumors with MSI are more likely to be diploid and are associated with a significantly better prognosis. [147], [149] Most of the tumors with MSI are not HNPCC but rather represent an acquired epigenetic lesion that mimics HNPCC but that tends to occur in older patients. [150]

Clinical Implications of Specific Genetic Lesions It is likely that many of the differences in clinical behavior of tumors are based on variations in the appearance and accumulation of specific genetic alterations. It has long been known that patients with HNPCC have a significantly better prognosis, when matched stage for stage against sporadic cancers. [151] Furthermore, when young patients (50 years of age or younger) have tumors with MSI, their survival is significantly better. [152] Also, HNPCC cancers are significantly more likely to be mucinous, to look poorly differentiated, and to have a Crohn’s disease–like lymphocytic infiltration, [153] features that are typically overrepresented in all tumors with MSI. In fact, the acquired form of MSI is almost always found in the proximal colon, where the majority of HNPCC tumors are. [154] As mentioned previously, tumors with MSI do not have chromosomal instability and, as a result, are usually diploid. [155] K- *ras* mutations are found rarely in tiny adenomatous polyps but are found increasingly with the larger sized polyps. K- *ras* mutations are found in about 50% of colorectal cancers and are significantly associated with exophytic adenomas compared with flat ones, and with polyploid cancers compared with cancers that arise de novo in flat mucosa. [122], [156]

Genetic Alterations in Cancers Complicating Ulcerative Colitis In specialized clinical situations, such as cancers complicating ulcerative colitis, different mechanisms may be operating. These tumors are significantly less likely to have K- *ras* gene mutations, [157], [158] but they show a high frequency of LOH, including the *p53* locus. [159], [160]

Aneuploidy

Because of the inability to identify histologic features of prognostic significance in most colorectal cancers, diagnostic approaches have been attempted to select patients at greatest risk for metastasis. Flow cytometry can be used to measure the DNA content of cell populations and to estimate the percentage of cells in different stages of the cell cycle. Resting cells are normally diploid. After the stage of new DNA synthesis is complete, the cells are briefly tetraploid, and after mitosis, they return to the diploid state. During the phase of DNA synthesis (S phase), the DNA content of a cell is transiently between the diploid and the tetraploid state. Aneuploidy is a state in which a population of cells has a stable but irregular DNA content, which appears as a spike of nondiploid, nontetraploid cells on flow cytometric analysis. About 80% of solid tumors contain aneuploid populations; several studies of colon cancers agree that about 65% are aneuploid. [161], [162] Furthermore, a smaller percentage (6% to 19%) of adenomatous polyps are aneuploid. [162], [163] and [164] Correlations between aneuploidy and state of differentiation or patient survival have been reported [165] but are on the whole inconsistent, and the studies in colorectal polyps add little to the current histopathologic classification of these lesions. Aneuploidy appears to occur early in the natural history of neoplasia (i.e., it is apparent in larger adenomas); however, as many as 40% of malignant tumors may never become aneuploid despite their ability to metastasize. [166] Although this remains an area of research interest, no clear clinical benefit is gained by measuring ploidy in colorectal tumors.

Mutagenesis

It is apparent that colorectal cancer begins with mutations in the nuclei of colorectal epithelial cells. The human diet contains a large number of naturally occurring mutagens and substances that may be metabolized into mutagens. Most of these mutagens are toxic chemicals synthesized by plants as a primary defense against attack by bacteria, fungi, insects, and other animals. The presence of these toxic compounds is so ubiquitous that an efficient and redundant network of protective mechanisms is present throughout the gut mucosa to detoxify these compounds. In fact, the ability of the enterocyte to metabolize certain xenobiotics is amplified by their presence in the diet. [167] The metabolic fate of procarcinogens is complex and may involve absorption from the gut, metabolism in the liver, secretion into the bile, and additional oxidative activation in the immediate vicinity of the target organ. [168], [169]

Animal Models of Colon Cancer

Much has been learned from rodent models of colonic carcinogenesis. The most commonly used model involves the administration of a member of the dimethylhydrazine family of carcinogens to rats or mice, which results in adenocarcinomas of the colon, small intestine, and other sites, depending on the carcinogen used, method of administration, and species of rodent. In the rat, adenocarcinomas occur throughout the proximal and distal large intestine, [170] although this may vary among rat strains. In certain inbred mouse strains, the tumors occur predominantly in the distal colon, and the characteristic adenoma-carcinoma sequence is seen. [171], [172], [173], [174] and [175]

Despite the conceptual limitations of the initiation-promotion model, these terms are referred to frequently in descriptions of the animal model. In this context, *initiation* refers to the period during which the carcinogen or mutagen is administered, and *promotion* refers to any manipulation that takes place in the postinitiation period. Tumorigenesis can be enhanced or reduced in experimental animals either by maneuvers that modify the generation of mutagen or by events that occur long after

administration of carcinogen, which either stimulate or inhibit the growth of dormant clones of mutant cells.

Role of Diet in Animal Carcinogenesis

The rodent model of colon carcinogenesis has been widely used for introducing dietary manipulations and observing their effects on tumor production. Increasing the total dietary fat from 5% to 30% of caloric intake produces a significant increase in the number of animals that develop cancers and the number of tumors per animal.[176],[177],[178] and [179] If rats are fed a high-fat diet more than 1 month after the last injection of carcinogen, significantly more tumors are produced than if the high-fat diet is given only during the period of administration of carcinogen.[176] This finding suggests that a high-fat diet mediates some aspect of neoplastic progression in the post-initiation period.

Polyunsaturated fats initially were thought to have greater tumor-enhancing effects than saturated fats for colonic as well as other tumors, such as mammary tumors. Differences between types of fat disappeared at the 20% level, however, at which a higher overall incidence of tumors was produced in all animals.[179] A diet supplemented with 4% to 22.5% menhaden oil, a lipid mixture derived from fish and seals that contains high amounts of polyunsaturated fatty acids of the n-3 or ?-3 series, had no tumor-enhancing effects compared with corn oil.

Bile acids also promote the development of tumors in the rodent model. The addition of cholic acid to the diet increased the number of rodents that developed tumors, the number of tumors per animal, and the fecal excretion of secondary bile acids.[180] Enhanced tumor production may result from other maneuvers designed to increase colonic exposure to bile acids, including ileal resection,[181] cholecystectomy,[182] and distal repositioning of the papilla of Vater.[183]

Fiber is a generic term and includes a wide variety of nondigestible soluble and insoluble forms of carbohydrate (e.g., cellulose, hemicelluloses, gums, mucilages, pectins) and other substances, such as lignins.[63] Bran is a heterogeneous preparation from the seed coats of cereal grains composed of fibers and other contaminating substances, some of which may have effects on epithelial proliferation. Cellulose is a ß-linked polymer of glucose found in virtually all plant tissues and is a common component of many forms of fiber.[184] Purified cellulose, in doses ranging from 4.5% to 15% of the diet, reduces tumor production in rats.[185],[186] and [187] Dietary cellulose decreases mitotic indices in the colon,[188] whereas virtually opposite effects are seen with pectin, which provides no protection against tumor production.[186] Dietary histories regarding fiber intake are difficult to estimate in humans, and the data are correspondingly confusing. The experimental model has permitted a dissection of the issues and has clarified the fact that certain components of fiber may be protective while others are not.

Administration of a 10% wheat bran diet inhibits tumor production and, in fact, can prevent the tumor-enhancing properties of bile salts.[189] Administration of a 20% wheat bran diet enhances cellular proliferation in the colon,[190] however, and either has no effect[191] or actually increases tumor production in the rat.[192] The tumor-enhancing effect is seen only if 20% wheat bran is administered during the initiation period, whereas a reduction in benign tumors is seen if this diet is administered after the administration of the initiating agent.[192] The administration of a 14% corn bran diet increases fecal bile acid excretion and enhances tumor production, reinforcing the conclusion that not all types or doses of fiber are equally protective against colon cancer.[193] The proliferative response elicited by 20% wheat bran[188] also can be produced by a diet of 10% guar, another fiber.[194] Two other fibers, 20% oat bran and 10% pectin, have no effect on colonic proliferation.[194]

The animal model also has permitted exploration of factors that may modify large bowel carcinogenesis, as summarized in Table 91-2[183],[192],[193],[195],[196],[197],[198],[199],[200] and [201] and Table 91-3.[186],[189],[193],[202],[203],[204],[205],[206],[207],[208],[209],[210],[211],[212],[213],[214],[215],[216],[217] and [218] Manipulations that increase the delivery of lipid and bile acids to the colon, such as the administration of cholestyramine[195] or neomycin,[200] small intestine resection,[201] and biliary diversion to the colon,[183] all increase the number of tumors occurring in experimental animals.

Cholestyramine
Suture material
Experimental colitis
Vitamin A deficiency
Neomycin
Small intestine resection
Diversion of bile to colon
Wheat bran, 20% of diet during initiation
Corn bran, 15% of diet

TABLE 91-2 Factors that Increase Experimental Large Bowel Cancers in Rodents

Indomethacin, aspirin, piroxicam, sulindac, most NSAIDs
Cyclooxygenase-2 inhibitors
Dietary fiber
Wheat bran, 10% of diet
Cellulose, 4.5%-9% of diet
Lignin, 7.5% of diet
Selenium
Vitamin C
Vitamin E
Retinoic acid
β-carotene
ε-Aminocaproic acid
Antibiotics
Dioctylsulfosuccinate
2-Difluoromethylornithine
β-Sitosterol
Butylated hydroxyanisole
Cabbage
Diallyl sulfide (garlic)
Disulfiram

TABLE 91-3 Factors that Decrease Experimental Large Bowel Cancers in Rodents

A large number of factors have been identified that inhibit colonic carcinogenesis, and in some instances, inhibition is specific to either the induction phase or the promotion phase. Antioxidants, such as vitamin C, vitamin E, vitamin A, butylated hydroxyaminisol (BHA), and butylated hydroxytoluene (BHT), do not prevent DNA damage and seem to exert their protective effects during the postinduction promotional period. Much of the current laboratory research of colon cancer has been performed on newer models in rodents of FAP or HNPCC, which develop through different types of genetic alterations and may require different types of preventive approaches.

Clinical Manifestations and Risk Factors for Colorectal Neoplasia

Clinical Presentation

Tumors of the colon and rectum grow at a slow, somewhat unpredictable rate. It is difficult to make any estimates of growth rates because colorectal tumors are rarely left in place for observation. Some information from the precolonoscopy era suggests that about 11.4 years may elapse before polyps with mild atypia become malignant, although polyps containing severe dysplasia become malignant in 3.6 years.[219] Colorectal neoplasms develop cellular heterogeneity with time because of genomic instability. As a result, some tumors grow more rapidly than others, and the rapidity of progression is not uniform. Colorectal neoplasms begin as adenomas and progress through stages of advancing degrees of dysplasia as they grow. *Hypothetical* modeling suggests that a tiny polyp requires about 2 to 3 years to reach a size of 1 cm.[220] The period from the mean appearance of adenomas to the mean diagnosis of cancer in FAP is 23 years.[221],[222] These estimates cannot be generalized to all neoplasms because they are based on selected lesions that have become malignant, and they fail to take into account the important consideration that many adenomas may never grow. These estimates serve to underscore the fact that most colonic tumors grow relatively slowly and tend not to give rise to dramatic or characteristic symptoms. Therefore, changes in bowel habits may be a sign of distal colorectal cancer, even if the symptoms have developed over a period as long as 1 year. The presence of symptoms for up to 1 year before diagnosis seems to have no adverse effect on survival.[223] Unsurprisingly, comparing colorectal cancer patients with controls in a retrospective case-control study, no significant differences were elicited in the historical frequency of bowel movements,

the presence of constipation, or the use of laxatives. [224]

As a colon cancer grows, it may give rise to one or more of four different groups of symptoms. First, the colonic lumen may be obstructed, relatively or completely, and produce corresponding symptoms. Obstruction may produce abdominal distention, pain, or, in its most extreme degree, nausea and vomiting. Most colon cancers grow as an expanding circular lesion; the traditional apple-core lesion occurs after the diameter of the tumor approaches the circumference of the bowel wall and obstructs the lumen. The colonic diameter is greatest in the cecum and ascending colon, where obstruction is much less likely to occur. The diameter is less in the transverse, descending, and sigmoid colons, which are more likely sites for obstruction. Gastrointestinal obstruction suggests the presence of a large tumor and is an ominous symptom; it is associated with a significant adverse effect on survival. [225]

Second, as colonic tumors expand into the bowel lumen, they tend to bleed, both because of the presence of abnormal vasculature and because of trauma from the fecal stream. Bleeding is likely to occur regardless of the location of the tumor, but it is usually not brisk. In fact, colon cancers typically lose considerably less than 6 mL of blood per day. [226] If a tumor is located near the anus, the blood may be deposited on the surface of the stool and may be grossly visible to the patient. More typically, the blood is mixed in with the stool and evades detection. Tumors in the proximal colon tend to grow larger without producing obstructive symptoms; thus, they may bleed longer and present with iron deficiency anemia. Tumors in the sigmoid colon or rectum are more likely to produce hematochezia or give rise to a positive fecal occult bleeding test (FOBT).

Obstruction and bleeding reflect complications of tumor growth into the lumen; however, an invasive tumor eventually penetrates the muscularis propria and invades adjacent tissues, which can lead to the third symptom complex of pain and other specific symptoms, depending on the organ invaded. Local invasion may produce tenesmus in the rectum, urinary symptoms (including pneumaturia) in the bladder, nonspecific symptoms in the pelvic organs, or an acute abdomen from colonic perforation. Invasion by rectal cancers into the perirectal fat may be associated with rapid extension and can produce ureteral obstruction. Invasion of other adjacent organs is less common, but the tumor may extend through the mesentery and compromise a vascular structure or, rarely, create a fistula between the colon and the small intestine or stomach. Manifestations of local extension all indicate invasion through the muscularis propria and are associated with an adverse prognostic implication. A metastatic lesion also may produce local symptoms because of its expansive or penetrating qualities. In these instances, the clinician may be drawn to the liver or bony site because of pain and later find a primary tumor in the colon that has produced a minimum of symptoms.

Finally, some tumors produce a wasting syndrome that is out of proportion to the size of the tumor, and normal resting energy expenditure, despite excessive metabolic activity of the tumor itself. Cancer cachexia is characterized clinically by a loss of appetite, weight, and strength. [227] Cancer cachexia is common in patients with any gastrointestinal malignancy, and affected patients may experience a more profound loss of subcutaneous fat than that caused by an equivalent degree of benign inflammatory disease, accounting for the characteristic general appearance of a cancer patient. [228]

Three of the four symptom complexes usually are indications of advanced stages of disease. The only exception is occult gastrointestinal bleeding. Of patients with colorectal cancer who present with symptoms at the time of diagnosis, most will have advanced disease and probably will die of their cancer. Therefore, strategies developed to reduce the morbidity and mortality of colorectal cancer have attempted to detect the excess bleeding caused by the neoplasm. Early forms of colorectal cancer lose blood at rates that are only minimally greater than normal rates of blood loss, however. Thus, it has been difficult to develop accurate and sensitive tests for early diagnosis. [226] This difficulty has placed additional emphasis on the improvement of tests for occult fecal blood and for the identification of subgroups of patients at greater risk for this disease. No substance has been detected in the serum that correlates with the presence of early cancer. Novel attempts are underway to look for altered genes shed from the tumor that can be measured in the stool. [229] The role of this type of testing in a clinical screening program is being evaluated.

Familiality and Colorectal Cancer

The principal feature used to identify higher-risk patients for co-lorectal cancer is the family history. This is not a straightforward issue because 5% of the U.S. population develops the disease, and depending on the number of relatives known, at least 10% of people report one first-degree relative who has developed colorectal cancer. Therefore, additional information is needed to determine increased risk based on family history. Key issues are the number of affected people in a family, the age at the time of tumor development, the number of first-degree relatives who *did not* develop cancer (a point often overlooked), and associated syndromic features. This issue is best understood first by considering syndromic familial cancer syndromes in which the genetic basis is understood, with the realization that much of the weaker forms of familiality may represent variations on these themes.

Familial Adenomatous Polyposis and Gardner Syndrome

The premier candidates to develop colorectal cancer are people who inherit a germ-line mutation (not to be confused with the somatic mutations that occur in sporadic tumors) at the *APC* locus and therefore have FAP or Gardner syndrome. These two conditions are variations on a single genetic disease and are described in detail in Chapter 90. FAP and Gardner syndrome patients develop adenomatous polyps at a median age of 16 years, [221] and virtually all of them progress to cancer, with a median age of 39 years for symptomatic malignancy. [222] This group of patients represents the extreme end of the spectrum and serves as a paradigm of the adenoma-carcinoma sequence. The sequence is terminated after the colon is removed or the patient dies of a complication of the disease; it is therefore not possible to know whether every adenoma would enlarge or undergo malignant degeneration with time. In older patients with this disease, it appears that many or most adenomas simply remain small. Genetic testing and counseling have now become a part of standard care for patients with these conditions. [231], [232]

It has now become apparent that the location of germline *APC* mutations correlates with FAP disease manifestations, thus giving clues to the functional domains of this gene. A mild form of FAP, called attenuated FAP, has now been described and is associated with mutations at the extreme proximal or distal end of the *APC* gene. [233], [234] and [235] Extremely dense polyposis correlates with mutations in the central portion of the gene, [236] whereas a trivial retinal lesion occurs when mutations are found distal to exon 8 through the midportion of exon 15. [237] A condition previously called *flat adenomas syndrome* is now known to be *attenuated FAP*, based on genetic testing. [238], [239], [240] and [241] Finally, an *APC* mutation that causes hypermutability of the allele on which it resides gives rise to a mild colon cancer susceptibility in about 6% of Ashkenazi Jewish people. [242]

Hereditary Nonpolyposis Colorectal Cancer or Lynch Syndrome

HNPCC is an autosomal-dominant disorder characterized by the occurrence, within a family, of multiple cases of colorectal cancer in the absence of gastrointestinal polyposis. [151], [243], [244] The population prevalence of this syndrome is not yet clear, but it accounts for 2% to 3% of all colorectal cancers. [245] Before the identification of the genetic basis of this syndrome, the disease could be recognized only by obtaining a history of the familial aggregation of colorectal cancers with an early age of onset, an excess of proximally located tumors, multiple primary tumors, and an excess occurrence of cancers in certain other organs, particularly the endometrium. The recognition of MSI in the tumor tissue, which is present in almost all cancers from HN PCC patients (and in about 12% of sporadic cases), led to a series of discoveries that linked this hypermutability to a defect in the DNA mismatch repair system. Independent investigators identified a small number of HNPCC-causing genes from a larger number of DNA mismatch repair genes, not all of which can cause HNPCC (Table 91-4). HNPCC can be linked to germ-line mutations in *hMSH2* and *hMSH6* (which are homologs of the prokaryotic DNA mismatch repair gene *mutS*) in *hMLH1*, and possibly in *hMLH3* and *hPMS2*. The last three of these are homologs of the prokaryotic DNA mismatch repair gene *mutL*. The *hMSH2* and *hMLH1* genes account for most classic HNPCC-causing mutations, but germ-line abnormalities in the other genes have been found in HNPCC. This has been better characterized for *hMSH6*, [246] which causes an attenuated form of the disease (see later), than for *hMLH3*, which is possibly associated with HNPCC, or for *hPMS2*, which may require homozygous mutations to create an increased risk for familial cancer. Given this complex situation, a major target for research in this area is the development of clinically practical screening tests for the genetic carrier state of HNPCC.

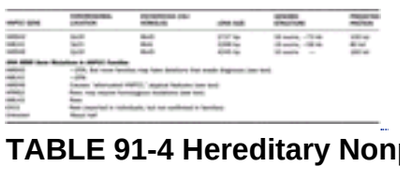

TABLE 91-4 Hereditary Nonpolyposis Colorectal Cancer (HNPCC) Genes

In HNPCC, there is a high risk for cancer but with features distinct from the polyposis syndromes. [247], [248] and [249] This syndrome is inherited as an autosomal dominant disease, and it produces colon cancers two to three decades earlier than in sporadic tumors. The syndrome was historically divided into two variants: [248] Lynch syndrome I, which included the early-onset colorectal cancers, and Lynch syndrome II, also called *cancer family syndrome*, [250] which included early onset of carcinoma at other sites, such as the endometrium, ovaries, upper urinary tract, small intestine, and stomach [251], [252] and [253] (Table 91-5). Identification of the genes responsible for this disease revealed that the variable expression of the tumor phenotype may be seen with mutations in any of the HNPCC genes, which obviates the necessity to subdivide the disease into these variants. Common tumors such as those of the lung, breast, and prostate are not more common in these HNPCC families. [251], [252] The extracolonic tumors are not uniformly distributed, and they tend to cluster in certain families, underscoring the necessity to obtain detailed information on tumor development. [249], [251] Most HN PCC families have some extracolonic cancers, most commonly in the endometrium. [253]

Autosomal dominant inheritance; high penetrance
Early-onset colon cancers (mean age ~40 y); risk begins in the 20s
Absence of multiple adenomatous polyposis
Multiple primary cancers
Multiple synchronous primaries in 18%
Metachronous tumors accrue at 3%–5% per year
Increased proximal tumors (60%–80% proximal to the splenic flexure)
Increased mucinous adenocarcinomas (35%–39%)
Linked to germ-line mutations in DNA mismatch repair genes
Increased number and early occurrence of other adenocarcinomas
Endometrium (20%–40% risk)
Stomach
Ovaries
Small intestine
Renal (pelvis and ureters)
Hepatobiliary system
Other sites (see text)
Muir-Torre syndrome
All the features of hereditary nonpolyposis colorectal cancer (most cases linked to germ-line mutations in hMSH2)
Unique skin tumors: multiple keratoacanthomas and sebaceous neoplasms

TABLE 91-5 Hereditary Nonpolyposis Colorectal Cancer

HNPCC was first recognized in 1895 by a University of Michigan pathologist named Aldred S. Warthin, and the index family was followed up in 1971 by Henry T. Lynch, who obtained data on 650 relatives over six generations. [250] This carefully studied family argued strongly for a genetic rather than an environmental cause of this disease because the progeny of each of the affected members of the initial kindred continued to show this characteristic, whereas the offspring of unaffected individuals did not. HNPCC has been reported from many countries throughout North America and Europe. It has been estimated that HNPCC is one of the most common forms of familial cancer and in some settings may account for up to 5% of cases of colon cancer. [254] Using rigorous criteria for the diagnosis, however, others estimate the incidence to be on the order of 2% to 3% of all colorectal cancer. [255], [256] Given the small family size typical in industrialized countries, it is difficult to establish familiality for common illnesses with variable presentations. A set of guidelines has been developed to assist in the use of molecular diagnostics for HNPCC. [257]

The principal difficulty in making this diagnosis is that the phenotype is not necessarily distinctive, and no definitive premorbid markers have been identified. For this reason, criteria for a working definition of HNPCC for clinical studies, developed by an international collaborative group, have been referred to as the Amsterdam criteria. The diagnosis is assumed if a family has all of the following: three or more relatives have a verified colorectal cancer, with one person being a first-degree relative of the other two; colorectal cancer involves at least two generations, and one or more cancers is diagnosed in family members younger than 50 years of age. Using databases collected in the United States—where the likelihood of colorectal cancer by age 74 years is 0.049 for men and 0.038 for women and 7% of the diagnoses are made in people younger than 50 years of age—the Amsterdam criteria would be met by chance alone in 0.08% of families of eight people, if all have lived to 74 years of age and if colorectal cancer had no familial clustering. [249] Because colorectal cancers are not randomly distributed among families, however, the number of such familial clusters is much higher. It is not necessary to meet all these criteria to make the diagnosis in clinical practice, however, because they are stringent and may exclude small affected families. The original Amsterdam criteria were revised in 1999 to account for the occurrence of noncolonic cancers, and it is clinically appropriate to consider endometrial cancer, and other cancers of the HNPCC spectrum, among the three cancers “required” by the initial Amsterdam criteria. [258]

One study of 19 European families with documented HNPCC gene mutations reported an estimated lifetime risk for co-lorectal cancer of 80% and a differential risk for endometrial cancer, depending on whether the germ-line mutation was in *hMSH2* (61%) or *hMLH1* (42%). Elevated risks for small intestinal cancer were found for both genes, and increased risks for cancers of the urinary tract, stomach, and ovaries were found among those with *hMSH2* mutations. [259] In a separate study using a population-based strategy and 67 known gene carriers whose disease outcome to age 70 years was known, an estimate has been made that the risk for any cancer in men was 91%, whereas in women it was 69%. Colorectal cancer occurred in 74% of men and in 30% of women, but women carried an additional 42% risk for uterine cancer. [260]

The penetrance of the HNPCC gene is high, but the age at presentation varies. Occasionally, patients develop tumors at very young ages (i.e., in their teens) and may have malignant disease before it develops in the parent, creating the erroneous initial impression of a skipped generation. Therefore, in considering this extreme degree of familiality, it is important to take family histories that include grandparents, aunts and uncles, and children.

In the general population, most colorectal cancers occur in the distal colon, and only 23% to 32% occur proximal to the splenic flexure; in HNPCC, 65% to 88% of the tumors occur in the proximal colon. [249] Significantly more mucinous carcinomas are seen in HNPCC than in control cases (35% to 39%). [261] A higher proportion of poorly differentiated tumors has been reported in HNPCC, but this may be a reflection of a large number of tumors with atypical cytologic features that have been overinterpreted. In fact, patients with these tumors are diagnosed at lower Dukes stages and have a better survival rate than controls. [249]

Although diffuse polyposis does not occur in these syndromes, these cancers develop from a discrete, small number of preexisting adenomas, and there is indirect evidence that they develop through an aggressive adenoma-carcinoma sequence in this disease. [262] In a colonoscopic screening program, 30% had polyps, and these were more likely to be multiple, large, and villous compared with those in the general population. [263] The prevailing opinion is that the HNPCC gene may predispose for rapid growth and malignant conversion in benign adenomas. In only 40% of these patients was a positive family history available before the diagnosis of the cancer, which is unfortunate because the level of suspicion of cancer is usually low in young patients. These patients have an extremely high likelihood of developing metachronous colorectal tumors, with mean annual cumulative rates reported to be 3% to 5%. [244] The mean age for developing the first tumor is about 40 years, and cancers occurring in patients in their 20s are not unusual. [239], [248] Because at initial diagnosis 18% have multiple synchronous tumors, it is inappropriate to treat this syndrome with a limited segmental colonic resection.

Muir-Torre syndrome is a rare variant of HNPCC characterized by multiple sebaceous gland neoplasms, including sebaceous adenomas, sebaceous carcinomas, and keratoacanthomas, in addition to all the features of HNPCC. MSI has been found in the skin and colorectal tumors in this disease, and nearly all of the families with this syndrome have been linked to mutations in the *hMSH2* DNA mismatch repair gene. [264], [265] The key clinical point is that a patient with a history of multiple sebaceous neoplasms (or keratoacanthomas) must raise the suspicion of HNPCC and the attendant risks for colorectal and other cancers.

Perhaps the most unique aspect of HNPCC is that it represents a separate pathway of tumor development in which the loss of DNA mismatch repair activity results in a cascade of inactivation of other tumor suppressor genes, including one of the tumor growth factor-ß receptors (TGF-ß1 RII), the apoptosis gene *BAX*, the insulin-like growth factor-2 receptor, and two of the DNA mismatch repair genes, *hMSH3* and *hMSH6*. [266], [267] and [268]

The diagnosis of HNPCC is first suspected on clinical grounds, but the management is sufficiently demanding for affected patients that it is clinically important to be more certain about the diagnosis. The first generation of diagnostic tests for HNPCC made use of the truncated protein test for the *hMSH2* and *hMLH1* genes, which is about 50% sensitive for families that met the Amsterdam criteria. [269] However, it is now possible to make the diagnosis by direct DNA sequencing from lymphocyte DNA, and databases are available, which can help distinguish common polymorphisms from disease-causing mutations. [270] An Internet database may be consulted for this purpose at the URL address: www.nfdht.nl/database/mdbchoice.htm. If a DNA sequence variation is found in a patient, one can determine whether this has

previously been seen in an HNPCC family or whether this sequence occurs at some frequency in the population without increasing the risk for cancer.

Germ-line mutations in *hMSH2* and *hMLH1*, which might be called the “major” DNA mismatch repair genes, account for most of diagnosed HNPCC; however, genetic testing is conclusive in fewer than 50% of cases, depending on how the families are ascertained and what genetic testing is used. [271] One explanation for this is that some of the mutations in the *hMSH2* genes are large genomic deletions that are not detected by either direct sequencing strategies or strategies based on the truncated protein test. [272]

Germ-line mutations in the “minor” DNA mismatch repair gene *hMSH6* accounts for a smaller proportion of the disease, where it produces an attenuated form of the disease. Mutations in this gene have been found in 8% of familial colon cancer families in which the phenotypes *did not* meet the Amsterdam criteria for HNPCC. The colon cancers occur somewhat later in life than in the *hMSH2* or *hMLH1* forms of the syndrome (at a median age of 61 years), the penetrance is reduced (i.e., not everyone with the mutation necessarily develops a cancer), and these families may have more endometrial cancer. [273], [274]

It is not entirely clear to what degree germ-line mutations in certain other minor DNA mismatch repair genes, that is, *hMLH3*, *hPMS2* and *hPMS1*, cause HNPCC, despite the fact that sequence variations have been found in some patients suspected of having HNPCC. After the initial reports that HNPCC could be linked to germ-line mutations in *hPMS1* and *hPMS2*, it was subsequently determined that there are no well-documented HNPCC families associated with *hPMS1* germ-line mutations and probably none with *hPMS2*. However, in the case of *hPMS2*, it is has been speculated that compound bi-allelic germ-line mutations at the *hPMS2* locus may rarely be associated with Turcot syndrome. [275] Likewise, germ-line sequence variations in the *hMLH3* gene have been found in a small number of patients with colon cancer, but large families with this have not been reported, and the most of the sequence variations are missense mutations, which are not necessarily disease causing. Until convincing, large families are found that confirm the inheritance of a colon cancer predisposition with these germ-line sequence variations, any conclusions remain subject to alternative interpretations. [276]

The diagnosis of familial colon cancer is a complex area. An Internet-based information site has been assembled and maintained by GeneTest at the Web site http://www.genetest.org/. Additional assistance can be obtained in interpreting mutations in a review of genetic testing for hereditary colon cancer. [277] Not all patients who are young with colon cancer or with modest degrees of familial involvement are candidates for undergoing genetic testing. One means of determining which patients should be tested for HNPCC is to perform microsatellite analysis on the excised tumor tissue, which can be done on an archival specimen embedded in paraffin. Tumors showing MSI suggest that one is dealing with HNPCC, and the absence of this makes the diagnosis quite unlikely. The guidelines for interpreting microsatellite analyses can be found in a workshop consensus statement published by the National Cancer Institute. [278]

Nonsyndromic Familiality for Colorectal Cancer

The risks conferred by a family history of colorectal cancer have been estimated in many studies by obtaining family medical data from patients who have developed a colorectal neoplasm; however, patients usually present with the family history and ask for an estimate of their risk for disease. [279] Nonetheless, the data provide reasonable guidelines for clinical decision making. This is not a trivial issue because about 10% of patients report a positive family history for colorectal cancer, and the increment of added risk is not uniform from patient to patient.

A prospective study of nearly 120,000 U.S. health care professionals led to the diagnosis of colorectal cancer in 463 individuals. The age-adjusted relative risk for colorectal cancer in patients with a first-degree relative with the disease was 1.72 (95% CI, 1.34 to 2.19). When there was more than one first-degree relative with colon cancer, the risk rose to 2.75 (95% CI, 1.34 to 5.63). If the affected individual was aged 30 to 45 years, the relative risk was 5.37 (95% CI, 1.98 to 14.6), and the risk to the family decreased significantly with increasing age of the proband. [280] Interestingly, the relative risk was close to 1.00 when the cancer occurred in a person older than 60 years of age. The implications are clearly that the general nonsyndromic familiality appears to be similar to the principles predicted from an understanding of FAP and HNPCC, in which the familial risk is associated with earlier age of disease. The genetic factors may represent milder variations of the syndromic diseases or other genetic diseases yet to be found. The key clinical issue is that when familiality is identified, the suspicion of disease and screening interventions must begin earlier than recommended for sporadic disease. Additional support for the observation that familial risk is proportional to the number of affected relatives came from a smaller Australian case-control study that found an odds ratio for colorectal cancer of 1.8 for one affected first-degree relative and 5.7 for two. [281]

The National Polyp Study, which enrolled nearly 1200 patients for familial analysis, found that the relative risk for colorectal cancer was 1.78 (95% CI, 1.18 to 2.67) for the parents and siblings of patients with adenomatous polyps. The relative risk rose to 2.59 (95% CI, 1.46 to 4.58) when the polyp-bearing patient was younger than 60 years old, and the risk increased significantly with an earlier age for diagnosis of the adenoma. Furthermore, the risk increased to 3.25 (95% CI, 1.92 to 5.52) for siblings of a polyp-bearing patient of whom a parent also had colorectal cancer. [282] This study underscores the fact that adenomatous polyps are important issues in the family history and that the age at onset and multiplicity of family member involvement should be taken into account while taking family histories.

A study from Utah screened a large number of individuals, their spouses, and first-degree relatives using a 60-cm flexible proctosigmoidoscope. This study demonstrated a significant impact of family history on the prevalence of distal colorectal neoplasia. [283] The investigators used pedigree analysis to identify whether any form of mendelian genetics would describe the inheritance seen. Their data supported dominant inheritance of a susceptibility to colorectal neoplasms (mostly adenomatous polyps) in the distal colon with a gene frequency of 19% in the general population. The expression of the phenotype (i.e., penetrance) among gene carriers increased with age, reaching 63% by age 80 years. Conversely, the penetrance for the nonsusceptible genotype was estimated to be zero (i.e., nonsusceptible families would develop no polyps).

This genetic model implies that a sizable segment of the population (19%) is susceptible to distal colonic neoplasia on a familial basis and that a large proportion of these people (i.e., 63%) will develop benign neoplasms by 80 years of age. Because about 5% to 6% of the population as a whole develop colon cancer, it could be further speculated that additional factors, presently unknown but possibly environmental, promote the development of malignant from benign neoplasms.

A very large twin study in Scandinavia indicated that 35% of colon cancer cases arose from inherited susceptibility, whereas 8% occurred on the basis of shared environmental factors in families. [284] The authors concluded that additional susceptibility genes for colon cancer should be sought. A number of such genes have been implicated and together with others are now under study as to their importance to the pathogenesis of familial colon cancer. [285]

Prior Polyps and Cancers Autopsy studies provide estimates that about 30% to 40% of colons contain adenomatous polyps, most of which are less than 1 cm in diameter. [286], [287] and [288] Patients with adenomatous polyps constitute the principal group identified as being at elevated risk for the development of cancer. Patients with adenomas have a 50% risk for developing a metachronous adenoma after 15 years of observation, with a risk of 1 in 12 (for men) or 1 in 20 (for women) for developing a cancer in that time frame. [289] Thus, individuals who develop one adenoma are at risk for developing more over time. Although the prevalence of adenomas is high, not all adenomas carry the same risk for recurrence to their host. A pair of retrospective studies reported that patients with small adenomas removed (i.e., those smaller than 1 cm) had a diminished risk for recurrent neoplasia, and their survival rate was not reduced compared with general risk estimates established for this community. [290], [291] On the other hand, those with adenomas larger than 1 cm had an increased risk for cancer of 2.7 times that estimated for the general population. [291] The relative risk for rectal cancer was found to be 0.6 for patients who had small (less than 1 cm) rectal adenomas removed with an average follow-up period of almost 14 years. In contrast, the removal of large adenomas was associated with a relative risk for rectal cancer 2.1- and 2.6-fold greater for lesions 1 to 2 cm in diameter and lesions larger than 2 cm, respectively. [292] Excess risk for rectal cancer was 3.8-fold after removal of villous adenomas and 5.1-fold after removal of adenomas containing severe dysplasia (i.e., carcinoma in situ). No increased risk followed the removal of multiple lesions. Risk for colon cancer (above the reach of the rigid sigmoidoscope) was increased 3.3-, 5-, and 5.9-fold after the removal of severely dysplastic, villous, and large (more than 2 cm) lesions, respectively, and a 4.8-fold increase was seen after the removal of two or more rectal adenomas. [292] Therefore, risk estimation depends on the size, number, and histology of the index lesions. Single, small (less than 1 cm) adenomas probably do not predict a significantly increased risk for recurrent neoplasia. It is more difficult to estimate the actual incidence of metachronous cancers from the literature, and the results are influenced by the amount of colon removed during the first operation and the duration of follow-up. The best estimate is that about 5% of patients will develop a second cancer after the removal of a primary colorectal cancer. [293] Because the average age to develop colorectal cancer is about 70 years, the risk for metachronous tumor development is likely to be higher in patients who are younger at the time of the first tumor. It may not be possible to refine this estimate because of the practice of removing all adenomas during surveillance colonoscopy of colon cancer patients.

Inflammatory Bowel Disease Patients with chronic inflammatory bowel disease are at increased risk for gastrointestinal cancer. The degree of risk, however, has been a subject of debate. A British study of 624 patients at a referral center indicated that 3.5% of their patients developed colorectal cancer, about seven times as many as expected in the general population. [294] The diagnosis of cancer in this condition was made at an average age of 41 years (range, 20 to 74 years). Relatively

fewer of these cancers occurred in the rectum (22%) compared with the expected rate in the general population (38%). Thus, there are important differences in clinical presentation in the setting of inflammatory bowel disease, the most important being age. The duration of inflammatory bowel disease is a critical factor in predicting the likelihood of developing adenocarcinoma of the colon. A retrospective study of 267 referral patients with ulcerative colitis revealed a 10% incidence of colon cancer. Cancer was more likely to occur among patients with pancolitis (13%) than among those with only left-sided disease (5%), and the latter group tended to develop cancer a decade later than the former. The incidence of colorectal cancer was less than 1% during the first decade of disease but progressively rose to 7% in the second decade, 16% in the third decade, and 53% in the fourth. [295] The high incidence of cancer complicating ulcerative colitis may be a reflection of bias in patient selection from referral centers. A review of the clinical courses of 258 patients treated for ulcerative colitis in a private practice revealed a cancer incidence of 7% after 26 years and 11% after 32 years of disease. [296] Most of these patients had less than universal colitis, and patients who were referred with known colon cancer were excluded from the analysis. Thus, the inclusion of a relatively small number of patients referred because of cancer could produce a large impact in the apparent risk for this disease. Geographic factors also may be important in influencing the risk for neoplasia in the setting of colitis. The incidence of cancer among children referred to a large referral center in the United States [297] was similar to that reported in Great Britain. [294] Cancer developed in 3% of the patients during the first 10 years after the onset of colitis, but the incidence increased by 20% in each of the next two decades and was estimated to be 43% 35 years after the onset of disease. In contrast, a center receiving referrals throughout Czechoslovakia reported a cumulative cancer risk of zero at 10 years, 5% at 20 years, 15% at 30 years, and 20% at 35 years, [298] even though the incidence of colorectal cancer is quite high in that country. [11] Although this was a large study consisting of 959 patients, only 32% of the patients had colitis of the entire colon, and most patients in this group (60%) had follow-up of less than 10 years. Thus, it is not clear whether the differences reported in the literature reflect geographic differences in the incidence of this complication or whether all of the increased risk is the result of greater extent and duration of disease. Patients with Crohn's disease are also at increased risk for colorectal cancer; however, the incidence is lower than that reported with ulcerative colitis. [299] It is not yet possible to estimate accurately the risk for cancer in this setting; however, an excess of carcinomas of the colon, small intestine, stomach, and anus, as well as an excess of lymphomas, has been reported. [299], [300] and [301] The survival rate of patients who develop cancers in the setting of ulcerative colitis is similar to that seen for noncolitic patients, [302] despite routine surveillance for cancer. However, a complicating carcinoma is unlikely to produce unique symptoms early in its natural history, and these tumors may be difficult to diagnose even if viewed colonoscopically in the setting of inflammation and mucosal distortion. In addition, the natural biology of cancers in ulcerative colitis may be different from that of sporadic ones. To improve the early detection and survival from colon cancer in colitic patients, attempts have been made to identify early neoplastic lesions. Dysplasia is currently the best marker for early cancer in this setting. Developing a standardized classification for dysplasia has been a major undertaking because inflammation and attendant repair can be easily confused for early neoplasia. [303] True dysplasia is an early benign neoplastic lesion, and biologically, it is analogous to adenomatous tissue in colonic polyps. Just as it is difficult to predict the clinical behavior of a small adenoma, low-grade dysplasia does not necessarily indicate the need for colectomy, and the predictive value for all grades of neoplasia has been controversial. [304] Low-grade dysplasia in a biopsy may reflect inflammation and be a transient change, it may reflect the presence of a higher-grade lesion (such as cancer) immediately adjacent to the biopsy site, or it may be a marker of a generalized problem in the colon, with additional neoplastic lesions elsewhere. Dysplasia in a plaque or elevated mass is especially ominous, and some have advocated total colectomy for this. [305] If low grades of dysplasia are found in random biopsies of flat mucosa, this is less likely to be associated with a synchronous cancer, and continued surveillance is the best option. High-grade dysplasia is a substantially more worrisome finding; if it is found in a colonic mass, total colectomy should be given serious consideration. After examination of the surgical specimens, most of these colons are found to have either confirmed high-grade dysplasia (which is the equivalent of carcinoma in situ) or a frank, invasive cancer.

Colon Cancer in Patients with Nonadenomatous Polyposis Syndromes

Juvenile Polyposis Syndromes and Peutz-Jeghers Syndrome Inherited syndromes that exhibit juvenile polyposis as a major phenotypic characteristic include the juvenile polyposis syndrome, Cowden syndrome, and Bannayan-Riley-Ruvalcaba syndrome. [306] They are all rare autosomal dominantly inherited conditions that give important clues to colon cancer pathogenesis. See Chapter 90 for a complete discussion of each of these. Juvenile polyposis syndrome gives rise to multiple juvenile polyps that exhibit benign complications in patients younger than 30 years of age but exhibit a high risk for adenomatous change in polyps and even cancer after that age. Cowden syndrome exhibits juvenile polyps and carries little colon cancer risk but a high risk for breast cancer and other hamartomatous growths. Bannayan-Riley-Ruvalcaba syndrome is similar to Cowden syndrome and adds the phenotypic manifestations of macrocephaly, delayed psychomotor development, and pigmentation of the glans penis to those of Cowden syndrome. Possibly explaining the phenotypic and cancer differences of these juvenile polyposis conditions is the recent elucidation of their genetic etiologies. Juvenile polyposis arises from germ-line mutations of the *SMAD4* [307], [308] and *BMPRA1A* tumor suppressor genes, [309], [310] both involved in the TGF-ß signaling pathway, whereas Cowden and Bannayan-Riley-Ruvalcaba syndromes are allelic and arise from germ-line mutations of the *PTEN* tumor suppressor gene. [311], [312] Peutz-Jeghers syndrome is characterized by perioral melanin pigment spots and histologically characteristic gastrointestinal polyps that are most common in the small bowel. [306] Similar to the juvenile polyp syndromes, benign complications of polyps predominate in the first three decades of life, whereas both gastrointestinal and extraintestinal malignancies become extremely common thereafter. [313] Peutz-Jeghers syndrome arises from germline mutations of the *STK11* gene, which appears to be a tumor suppressor gene because both alleles are found to be inactivated in neoplastic tissues. [314], [315]

Other Clinical Associations

Dietary History As mentioned in the initial section on epidemiology, more cancers would be expected in patients who ingest a high-fat, low-fiber, meat-rich diet, and obese, hypercholesterolemic patients would seem to be a target group for the disease. Nonetheless, the diet is relatively uniform within high-risk populations, and the individual variations in fat intake are too minor compared with the general characteristics of the diet to make dietary history valuable for selective screening. Other features have therefore been sought to identify high-risk patients, generally without success.

Colon Cancer and Cholecystectomy It has been suggested that patients who have undergone cholecystectomy may be at a greater risk for colon cancer, but the data on this issue have been inconsistent. Cholecystectomy has been implicated as a cause for an excess of cancers among women, [316] for an increased incidence of proximal colon cancers, [317] and for an increased incidence of adenomas. [318] It has been difficult to confirm the association between cholecystectomy and adenomatous polyps, [319] and other groups have suggested that the association with colon cancer is weak or absent. [320], [321] Several recent studies and one metaanalysis have demonstrated no excess in the risk for either adenomas or carcinomas after cholecystectomy. It is reasonable to disregard neoplastic risk when making decisions regarding gallbladder surgery, and there is no need for extra surveillance in patients who have had this operation. [322], [323] and [324]

Endocrine Abnormalities Acromegalic patients have a threefold excess of colon cancers. [325] The role of growth hormone has not been explored. Elevated serum gastrin levels are seen in patients with colorectal cancer, [326] and a postoperative reduction has been seen after surgery. [327] There is evidence that gastrin undergoes alternate processing in normal and neoplastic colon [328] and may function as an autocrine hormone to support the growth of tumor cells. [329] The total number of patients with these disorders is too small to permit an evidence-based recommendation for screening.

Skin Tags The presence of acrochordons (skin tags) suggests the simultaneous presence of colonic polyps. In a study of 94 men referred for colonoscopy, 48 had skin tags, usually located in the axilla, upper chest, or neck, and 46 did not. Among the group with skin tags, 77% had colonic polyps; in the subgroup without skin tags, 20% had colonic polyps. [330] In an attempt to confirm this finding in an unselected group of 492 men in a primary care clinic, skin tags were found in 46% of patients. Flexible sigmoidoscopy revealed polyps in 10% of individuals with skin tags, but 8% of those without skin tags also had polyps. [331] A review of the collected studies of this issue concluded that skin tags have prognostic significance only in symptomatic patients; therefore, this finding is of little practical significance. [332] Skin tags also do not correlate with carriage of the gene for FAP. [333]

Colon Cancer and *Streptococcus bovis* Patients with carcinoma of the colon occasionally present with septicemia or endocarditis caused by *S bovis,* [334], [335] which may be cultured from the feces of 10% to 16% of healthy subjects, but it is significantly more prevalent in the stools of cancer patients. In a study of 29 patients with *S bovis* septicemia, 16 had gastrointestinal neoplasms, and nearly half of the group did not undergo a complete diagnostic evaluation. [335] *S bovis* endocarditis also has been reported as the presenting symptom in one patient with FAP. [336] The presence of *S bovis* in the blood should prompt a complete gastrointestinal evaluation, beginning with the colon, and if this evaluation is negative, an evaluation of the esophagus and the stomach should be done. Septicemia produced by other members of the group D streptococcus family (*Streptococcus equinus*) also has been associated with colon cancer. [337]

Breath Methane Several laboratories reported that colon cancer patients are more likely to be breath methane excreters than the general population, presumably reflecting a difference in the anaerobic flora. [338] The elevated methane production falls to normal after the cancer is resected, suggesting that the presence of the tumor influences methane production and that increased methane production may be a result of colon cancer rather than a reflection of a fixed abnormality in the colonic flora. [339] Increased methane production also was reported in patients with familial polyposis and extensive ulcerative colitis in this study. Because there is a strong correlation between the methane excreter status of an individual and the status of other family members, these observations potentially have broad implications; however, breath methane measurements in more than 1000 people from South Africa from four population groups with wide differences in colon cancer risk demonstrated marked interethnic differences but no relation to cancer risk. [340] Furthermore, methane excretion is strongly affected by the use of laxatives or antibiotics and must be interpreted with caution.

Other Features Additional risk factors for colorectal cancers have been identified, but these generally are derived from exceptional circumstances. As previously mentioned, women who have been irradiated for gynecologic cancer have a 2- to 3.6-fold increased risk for colorectal cancer. [2C] Populations infected with

Schistosoma hematobium may develop colon cancers in the immediate vicinity of the polyps produced by the parasite eggs. [341] Patients who have undergone an implantation of the ureter into the sigmoid colon are at risk for carcinomas, adenomas, or severe dysplasia in the vicinity of the ureterosigmoidostomy. [342] In a study of 34 such patients, 29% had developed one of these neoplastic lesions at a mean interval of 22 years after their urinary diversion. Bloom syndrome is an autosomal recessive form of congenital dwarfism associated with unusual facies and hypersensitivity to sunlight. [343] This syndrome has been anecdotally associated with colorectal cancer; however, its rarity makes it difficult to document the actual incidence. The Bloom syndrome gene, *BLM,* is a helicase and is required for the orderly segregation of chromosomes during mitosis. Its inactivation leads to a type of genomic instability and predisposes to cancer. [343] Of interest, at least one individual with Bloom syndrome has been reported with multiple colonic polyps. [344] This genetic disorder is exceedingly rare, but one should keep in mind the possibility of a predisposition to colorectal neoplasia in this setting. It has been suggested that patients with Barrett esophagus may be at increased risk for colon cancer, [345], [346] and one small, prospective, controlled, colonoscopic study of 36 patients with Barrett esophagus revealed three cancers and nine adenomas; 2 of these patients had severe dysplasia. The authors suggested that such patients might benefit more from colonoscopic surveillance than screening of the esophagus. [347] This concept has not been confirmed in other studies. Patients with irritable bowel syndrome and diverticulosis [348] have no increased risk for colorectal cancer. Patients with these disorders have symptoms attracting attention to their lower gastrointestinal tracts; however, there is no need for extra surveillance for cancer among these patients.

Pathology

Most colorectal cancers are adenocarcinomas, and most cancers represent malignant conversion occurring in a preexisting adenomatous lesion. As a result, a spectrum of lesions may be found, ranging from the small adenomatous neoplasm containing no more than low-grade dysplasia and no immediate ability to invade or metastasize at one end of the spectrum, to the poorly differentiated adenocarcinoma with an unlimited capacity for local and distant spread at the other.

Gross Pathology

Colon cancers develop within preexisting foci of adenomatous tissue. This occurs usually, but not always, in a polypoid lesion. Adenomatous change may occur in flat mucosa, and a cancer may develop in this setting. Therefore, tiny cancers in flat mucosa are reported, but not commonly. [349], [350] and [351] These cases represent instances in which malignant conversion occurred early in the natural history of the neoplastic lesion, and they should be considered the exception to the rule.

Colon cancers characteristically begin as round mass lesions, but deviations from the ideal shape occur as a result of the asymmetric sloughing of cells and the emergence of clones with rapid growth capacity. If the resected colon is opened, a cancer typically has an elevated advancing edge, and the lumenal aspect usually is ulcerated and irregular. After the diameter of a cancer approaches the circumference of the colon, the opposite edges of the tumor converge, creating the characteristic apple-core lesion described by radiologists. This most often occurs in the sigmoid colon, which has the smallest circumference.

The older literature states that 75% of cancers are present in the rectum and sigmoid colon, making them accessible to detection by sigmoidoscopy. During the past several decades, a larger percentage of lesions have been found in the proximal colon. [352], [353], [354], [355], [356] and [357] This appears to be related, in part, to the fact that proximal colonic cancers are more common among people older than 65 years of age; as the population ages, a greater number of proximal colon cancers would be expected. Some have reported a decrease in rectal carcinomas, with corresponding increases in sigmoid cancers and proximal lesions, whereas others have observed an absolute increase in proximal cancers. [357] Even after correcting for age, however, investigators from several countries have reported a shift from a predominance of rectal tumors to those located more proximally, [354], [355] and [356] and in some registries, the decrease in the incidence of rectal cancer has been particularly dramatic. [357]

It has been estimated that about one fourth of cancers may be detected with a rigid sigmoidoscope, and this may be increased to about two thirds by the use of the 65-cm flexible sigmoidoscope, depending on the depth of the examination (Fig. 91-3). A substantial proportion of lesions (at least one third) is missed with limited examinations, and about one fourth of colorectal cancers are in the cecum and ascending colon, which is the most challenging part of the colon for imaging and visualization. [358] The changing location of colon cancers has obvious implications for clinical management. Although it has not been proved, environmental factors may be increasing the risk for colorectal cancer and that screening measures and polypectomy—which are more effective for the distal colon—have simultaneously decreased cancer incidence in the sigmoid colon and rectum.

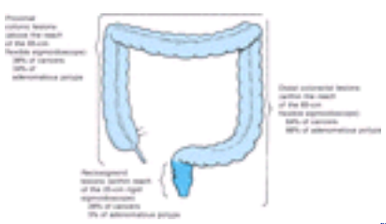

FIGURE 91-3. Distribution of neoplasms in the colon and rectum.

It is not rare to find multiple primary colorectal cancers. Multiple lesions generally are divided into those that occur simultaneously (synchronous lesions) and those that occur in different time frames (metachronous lesions). Synchronous colorectal cancers occur in 3% to 6% of de novo colon cancer diagnoses. [359], [360] and [361] The lesions may be either near one another or located in different portions of the colon. The incidence of multiple synchronous lesions is significantly higher in the setting of FAP or ulcerative colitis, in which it occurs in 21% and 18% of patients, respectively. [362] Synchronous adenomatous polyps are found in 36% of patients. [361] Multiple primary neoplastic lesions occur often enough that total colonoscopy is an essential part of the workup if a neoplastic lesion is found at a more limited examination. This permits the removal of synchronous polyps and the detection of synchronous cancers, which will modify the surgical approach.

Microscopic Pathology and Tumor Staging

Although most colorectal cancers are adenocarcinomas (Fig. 91-4), squamous cell carcinomas, adenosquamous carcinomas, lymphomas, and endocrine tumors such as carcinoids also occur in the colon. Most colonic adenocarcinomas are moderately or well-differentiated tumors, and there are few morphologic features of prognostic significance among them. About 20% of adenocarcinomas are poorly differentiated or undifferentiated tumors, and these two types are well known to be associated with a poorer outcome. Most adenocarcinomas secrete a small or moderate amount of mucin. About 10% to 20% of tumors may be described as mucinous or colloid carcinomas on the basis of a more prodigious production of mucin. These tumors are associated with a poorer 5-year survival rate than nonmucinous tumors. [363], [364]

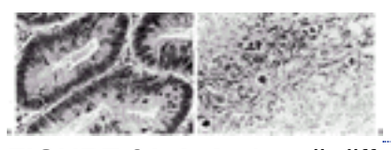

FIGURE 91-4. A: A well-differentiated adenocarcinoma of the colon demonstrates the characteristic glandlike formation. In each of these glands, the nuclei are large, the chromatin is poorly condensed, and the nuclei tend to drift away from the basal lamina. Mitoses are common. **B:** In a mucin-producing or colloid carcinoma, the cancer cells (*dark nuclei*) are suspended in pools of mucin, which is unstained in this section. The typical glandlike configuration is not seen. This microscopic appearance is associated with a more aggressive tumor.

The classification of tumor invasion was first undertaken by Dukes for rectal carcinoma. [365] The Dukes staging has undergone many modifications, and the stages

must be defined precisely for purposes of discussion because there is no standard classification. A system that is perhaps a consensus of most common use is as follows (Fig. 91-5):

Carcinoma in situ (also called high-grade dysplasia) is intramucosal carcinoma that does not penetrate the muscularis mucosae.
Stage A tumors invade through the muscularis mucosae into the submucosa but do not penetrate the next layer, the muscularis propria. (Note: Dukes was inconsistent here, as are other systems that include invasion of the muscularis propria in stage A, as illustrated in the figure.)
Stage B1 tumors invade into the muscularis propria, and B2 lesions completely penetrate the smooth muscle layer to the serosa but go no further. Some use B3 to describe a lesion that invades an adjacent organ.
Stage C lesions encompass any degree of apparent invasion but are defined by regional lymph node involvement. Some studies subdivide Stage C lesions based on the number of lymph nodes involved, with C1 lesions having one to three (or four) involved, and C2 having more positive nodes. The presence and number of involved lymph nodes, however, depend entirely on the number of nodes resected and examined pathologically, which may explain some of the inconsistencies in the literature.
Stage D lesions include all those with distant metastases.

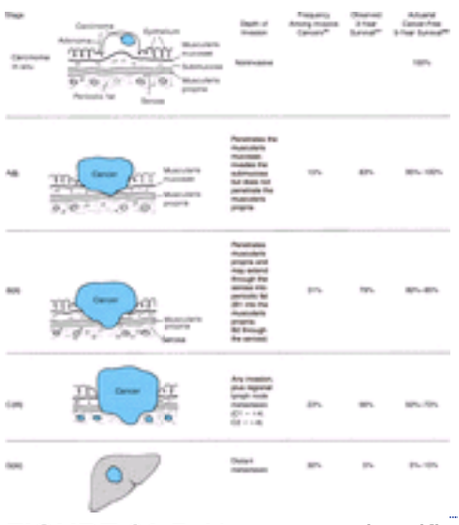

FIGURE 91-5. Numerous classifications have been proposed for colorectal cancer. Demonstrated here is the Dukes-Turnbull classification A through D (accompanied by the TNM stage in parentheses), but it is not the only classification currently in use. Of potential importance are subclassifications in classes B and C. Subclass B1 has been proposed to include invasion to the muscularis propria but not through the serosa. Subclass B2 includes tumors that penetrate the serosa to the pericolic fat but do not have regional lymph node or distant metastases. Patients with B1 lesions have a better prognosis and 5-year survival rate than patients with subtype B2 lesions. Class C lesions have been subdivided into C1, with four or fewer involved regional lymph node metastases, and C2, with more than four involved regional lymph nodes. Patients with subtype C1 lesions have a better outcome than patients with C2 lesions. The observed 3-year survival and actuarial cancer-free 5-year survivals are estimated for each stage. The actuarial survival estimates reflect excessive disease-related mortality from the cancer, and the crude survival rates are considerably lower because of co-morbidity.

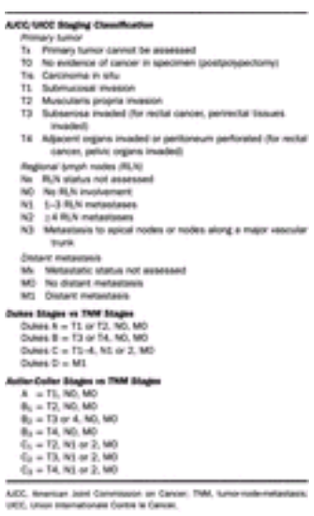
The relation between advancing stage and cancer mortality has been repeatedly demonstrated. [365], [366], [367] and [368] There is no important relation between the tumor size in the colonic lumen and clinical outcome. The aggressiveness of a colorectal tumor is reflected by its ability to invade, and growth into the colonic lumen is irrelevant to this biologic characteristic, except to the degree that it reflects the increasing probability that an invasive clone has had the opportunity to arise in a larger tumor.

In an attempt to create more uniform pathological categories for clinical studies, the American Joint Commission on Cancer and the Union Internationale Contre le Cancer have classified many tumors by a tumor-node-metastasis (TNM) system (Table 91-6). This classification is outlined as follows:

Tis refers to carcinoma in situ.
T1 indicates submucosal invasion (i.e., Dukes stage A), T2 indicates invasion of the muscularis propria (Dukes B1), T3 indicates invasion through the muscularis propria into the subserosa or perirectal tissues (Dukes B2), and T4 indicates invasion into adjacent organs or tissues (B3).
N0 indicates no involved lymph nodes; N1, one to three regional lymph node metastases (as in Dukes C1); N2, more than three regional lymph node metastases (Dukes C2); and N3, a nodal metastasis along the course of a major blood vessel.
Metastatic status is divided into M0 (no distant metastasis) and M1 (metastasis present). [369], [370]



AJCC/UICC Staging Classification

Primary tumor
- Tx Primary tumor cannot be assessed
- T0 No evidence of cancer in specimen (postpolypectomy)
- Tis Carcinoma in situ
- T1 Submucosal invasion
- T2 Muscularis propria invasion
- T3 Subserosa invaded (for rectal cancer, perirectal tissues invaded)
- T4 Adjacent organs invaded or peritoneum perforated (for rectal cancer, pelvic organs invaded)

Regional lymph nodes (R/LN)
- Nx R/LN status not assessed
- N0 No R/LN involvement
- N1 1–3 R/LN metastases
- N2 ≥4 R/LN metastases
- N3 Metastasis to apical nodes or nodes along a major vascular trunk

Distant metastasis
- Mx Metastatic status not assessed
- M0 No distant metastasis
- M1 Distant metastasis

Dukes Stages vs TNM Stages
- Dukes A = T1 or T2, N0, M0
- Dukes B = T3 or T4, N0, M0
- Dukes C = T1–4, N1 or 2, M0
- Dukes D = M1

Astler-Coller Stages vs TNM Stages
- A = T1, N0, M0
- B_1 = T2, N0, M0
- B_2 = T3 or 4, N0, M0
- B_3 = T4, N0, M0
- C_1 = T2, N1 or 2, M0
- C_2 = T3, N1 or 2, M0
- C_3 = T4, N1 or 2, M0

AJCC, American Joint Commission on Cancer; TNM, tumor-node-metastasis; UICC, Union Internationale Contre le Cancer.

TABLE 91-6 Colorectal Cancer Pathological Classifications

Figure 91-6 provides estimated 10-year survival rates for colon cancers according to the TNM staging system. [371]

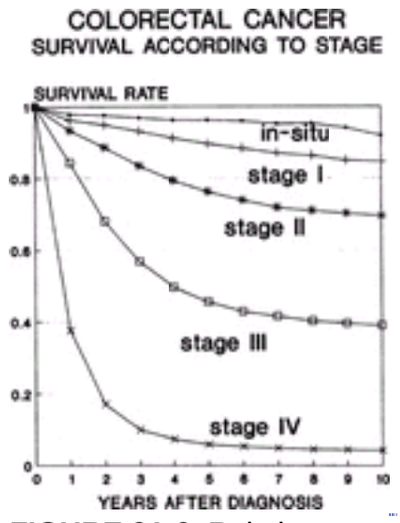


FIGURE 91-6. Relative rates of survival for patients with colon cancer, by stage of disease from a database of more than 110,000 patients using the tumor node metastasis (*TNM*) staging system. (*n* = 4841 stage 0; *n* = 19,623 stage I; *n* = 33,798 stage II; *n* = 29,615 stage III; *n* = 23,233 stage IV.) (From ref. [371].)

Additional microscopic features of rectal cancers defined by Jass and colleagues have been found to correlate with survival. This classification considers the observation that the following three factors correlated best with more aggressive tumors and reduced 5-year survival: spread through the bowel wall and lymph node metastasis (as noted by all other systems); absence of lymphocytic infiltration; and an assessment of whether the invasive margin of the tumor is infiltrating (i.e., more aggressive) or expanding (i.e., less aggressive). Numeric scores were assigned to each of these features, and a high degree of correlation with outcome was found by linear regression analysis. [372]

Several groups have used flow cytometry to measure the relative DNA content, or ploidy, of colorectal cancers. [373], [374], [375] and [376] Tumors with normal DNA content are diploid, and those containing cells with abnormal DNA content are aneuploid. There has been consensus agreement that diploid and near-diploid tumors have significantly better prognoses than aneuploid tumors and that this parameter is prognostic independent of Dukes or other stage (up to the point of distant metastases, after which all patients do poorly). The use of flow cytometry is not indicated in routine clinical practice because no prospective study has demonstrated that it can be used to direct therapeutic decision making.

Several investigators from Japan have recognized that some patients develop early cancers of the colon that appear to arise de novo in that they are lesions smaller than 1 cm and there is no evidence that they arose in a preexisting adenoma. [377], [378] It is not clear how commonly carcinoma arises directly from normal colonic tissue without an early adenomatous stage or whether this variant represents the early conversion of a microadenoma to carcinoma that fortuitously was detected as a small lesion.

One pathological variant bears mention because of the possibility for misinterpretation. Colitis cystica profunda represents the displacement of mucus-secreting cells beneath the normal epithelium, usually as a result of surgery, other trauma, or inflammation. This confers an abnormal, masslike configuration to the overlying mucosa. A biopsy reveals pools of mucus in the submucosa, and these pools may be mistaken for invasive colloid carcinoma. If this condition is seen in the head of an adenomatous polyp, it is referred to as *pseudoinvasion*. [379] This lesion also may occur at the site of a prior surgical anastomosis, and it can be difficult to identify correctly. In general, anastomotic recurrences are relatively uncommon, except at the site of a resection in the rectum or at the rectosigmoid junction, where the surgeon may have taken an inadequate margin of mucosa adjacent to the tumor in an attempt to preserve the rectum. Furthermore, recurrences are likely to be histologically similar to the initial tumor. Therefore, the pathologist should assess carefully the cytologic characteristics of the cells in the biopsy if this entity is being considered.

The colonic epithelium immediately adjacent to a colon cancer (transitional mucosa) is thicker than normal, is characterized by a distortion of the normal architecture, and shows an increase in sialomucin compared with normal tissues, in which sulfomucins normally predominate. [380], [381] Initially, it was suggested that this mucosa was a field of premalignant tissue from which tumors arise. Similar morphologic and histochemical changes are found adjacent to nonneoplastic colonic lesions [382] and lesions metastatic to the colon, however. The accumulated data suggest that transitional mucosa is hyperplastic epithelium that has developed in response to an adjacent tumor or other pathologic condition. [383] The presence of sialomucins in the mucosa at the margin of surgical resection predicts an anastomotic recurrence and is an adverse prognostic variable. [384]

Differential Diagnosis

Symptomatic colon cancers may present in several ways: as a partial or complete lower gastrointestinal obstruction; as overt gastrointestinal bleeding (i.e., hematochezia); as a locally invasive or expanding tumor with invasion of the perirectal tissue, bladder, or other pelvic organs; as a fistulous connection with another portion of the gastrointestinal tract; as a locally expanding metastatic lesion in the liver, bone, or other site; and, less commonly, as a systemic wasting disease (i.e., cancer cachexia).

All these symptoms carry a substantial list of possibilities in the differential diagnosis. If a patient presents with gastrointestinal obstruction, the first step is to determine the level of the obstruction, most typically with supine and upright abdominal radiographs. A tumor in the cecum may obstruct the ileocecal valve and produce a selective small bowel obstruction. Alternatively, an obstructing tumor may occur at any point throughout the colon. Diseases that most commonly produce this clinical picture are tumors, diverticulitis, inflammatory masses (either in the setting of inflammatory bowel disease or an acute infectious process), postinflammatory or ischemic strictures, and volvulus. A more complete differential diagnosis of lesions that may present as a colonic mass or obstruction and thereby mimic colon cancer is given in Table 91-7.

Mass Lesions
Benign tumors
Diverticulitis
Inflammatory masses
Ulcerative colitis
Crohn's colitis
Tuberculosis
Amebiasis
Fungal masses (e.g., mucormycosis)
Schistosomiasis
Viral lesions (CMV, LGV)
Cronkhite-Canada syndrome
Fatty ileocecal valve
Colitis cystica profunda
Surgical anastomoses
Feces (x-ray diagnosis)
Solitary rectal ulcer
Endometriosis
Appendectomy stump
Lymphoid polyps, lymphoma
Carcinoid tumors
Metastatic lesions
Kaposi sarcoma
Extrinsic compression
Submucosal mass
Submucosal hematoma
Extrinsic mass
Obstructing Lesions
Strictures
Late sequelae of inflammation
Radiation
Ischemic colitis
Volvulus
Extrinsic compression
Endometriosis
Pancreatitis

CMV, cytomegalovirus; LGV, lymphogranuloma venereum.

TABLE 91-7 Lesions that May Mimic Colon Cancer

Colorectal neoplasms begin to lose blood early in their natural history, but most patients are unaware of this blood loss. Most colon cancers lose less than 10 mL of blood per day, and patients are not likely to notice this bleeding unless it is deposited on the surface of a formed stool from a lesion in the distal colon or rectum. If a patient observes bright rectal bleeding, it may represent bleeding from hemorrhoids or an anal fissure. Patients with inflammatory bowel disease commonly experience rectal bleeding, and so it is not a reliable sign of early neoplasia. Bleeding from ischemic bowel disease or a diverticulum is usually more brisk than that

seen from a neoplasm.

Sometimes, a locally invasive carcinoma is difficult to differentiate from an inflammatory process, even if visualized endoscopically or surgically. A mass produced by a perforated diverticulum can be bulky and indurated, suggesting a neoplastic process, but biopsy specimens from an inflammatory mass may not be diagnostic. Furthermore, certain entities may give rise to an ambiguous biopsy, including colitis cystica profunda, which may occur at a surgical anastomosis, and endometriosis.

Diagnostic Approaches to Colon Cancer

Several distinct issues associated with the diagnosis of colorectal neoplasia overlap to some degree and are confused frequently. The first of these involves the workup of the patient with symptoms of colonic obstruction, bleeding, or a locally invasive disease. Closely related to this is the workup of a positive test for occult fecal bleeding in a patient without other symptoms. Finally, there is the controversial issue of how to screen the asymptomatic patient.

Symptomatic Patients

In the symptomatic patient, colonic disease may be strongly suspected, but cancer is only one item in the differential diagnosis. The presence of a guaiac-positive stool increases the suspicion of colorectal neoplasia, but a negative test does not exclude it. [385] If the patient is not obstructed and there is no suspicion of perforation, the patient's colon should be cleansed, and colonoscopy is the diagnostic procedure of choice. Colonoscopy is the most accurate and sensitive diagnostic modality available, and it permits the biopsy of suspicious mucosal lesions. The complication rate (including perforation and hemorrhage) is less than five cases per 1000 patients. The barium enema is a less sensitive diagnostic procedure, and removal of the administered barium is required for colonoscopic verification of any suspected lesions. Nonetheless, a barium enema may provide important complementary information not available using colonoscopy, especially if there is a colonic stricture or obstruction or when an extrinsic lesion is involved. In evaluating a patient for specific colonic symptoms, the absence of blood in the stool should not exclude evaluation by colonoscopy or barium enema.

Estimating Risk for Colorectal Cancer In determining the appropriate evaluation in a patient with symptoms that may be referable to the colon, it is helpful to focus on risk factors that make the presence of colorectal cancer more or less likely. Patients younger than 40 years of age are relatively unlikely to have cancer unless they have ulcerative colitis, have an FAP variant (i.e., attenuated FAP), or come from an HNPCC kindred. The incidence of colorectal cancer begins to rise after the age of 40 years, but it remains relatively low until 50 years of age and older, when the risk rapidly accelerates. The risk for colorectal cancer continues to rise relentlessly with each decade thereafter, and age is the greatest single risk factor for colorectal cancer. [386] Genetic factors play a special role in co-lorectal cancer, but most patients do not have any genetic risk factors that are currently identifiable. A more important issue to consider is a history of adenomatous polyps because these are the precursor lesions for cancers. Particular attention should be given to patients with multiple adenomas, large adenomas, or adenomas containing villous features or carcinoma in situ. Genetic testing should be reserved for young patients with colorectal neoplasia in the setting of multiple family members with cancer.
Diagnostic Workups It is important not to overlook the visual inspection and digital examination of the anus and distal rectum, even if additional studies are planned. This permits the diagnosis of anal neoplasms and the occasional adenoma or carcinoma present on the rectal side of the anal verge that can be missed on an incomplete endoscopic examination. Furthermore, stool is obtained during this procedure to test for the presence of occult bleeding. Anoscopy and proctoscopy using a rigid instrument may be used to examine the rectum and anus, and therapeutic procedures may be performed using these instruments. The rigid sigmoidoscope is not used in the routine diagnosis of cancer except for special instances to evaluate the rectum. It is painful to advance this instrument into the distal sigmoid colon, and even in the best of hands, this is an insensitive test compared with flexible instruments. Flexible fiberoptic proctosigmoidoscopy may be performed using instruments of virtually any length. Instruments measuring 60 cm are widely available, and rectosigmoid examinations also may be performed with the standard colonoscope. A rigorous preparation is not required because examination of the sigmoid colon and rectum is usually undertaken after cleansing enemas. No sedation is required, and patient acceptance of the procedure is much higher than for the rigid instrumentation. The use of the 60-cm instrument may be mastered by general internists and endoscopic technicians with appropriate training. The barium enema is largely of historical interest in the diagnosis of polyps and cancers of the colon. The single-contrast barium examination is inadequately sensitive to exclude polyps and cancers and should be replaced by the double-contrast study. Preparation for a barium enema varies from center to center; most frequently, a clear liquid diet, a combination of saline cathartics and stimulant cathartics, and cleansing enemas are requested by the radiologist. Sedating medication is not required. About 0.03 Gy is delivered to the abdomen during this study, and patient acceptance is lower than it is for flexible sigmoidoscopy or colonoscopy; however, the entire colon may be examined by this technique. Overlapping loops of bowel in the sigmoid colon and the flexures are areas of particular difficulty in interpretation. The presence of extensive diverticulosis or residual fecal material can present additional diagnostic difficulties. There is difficulty in excluding lesions in the rectum because of the presence of the obstructing balloon required for this procedure. Thus, proctosigmoidoscopy is suggested as an adjunctive study to improve the sensitivity of a barium enema. The sensitivity of the barium enema is directly related to the patience and diligence of the radiologist. One retrospective analysis suggested that barium enemas detected 83% of colon cancers, whereas colonoscopy performed by a gastroenterologist detected 97% of colorectal cancers. Cancers detected using colonoscopy were substantially more likely to be Dukes class A (25% versus 10%). [387] One small, uncontrolled study of a series of patients who underwent single-contrast barium enema surveillance after the removal of an index large (greater than 1 cm) adenomatous polyp reported that half of the patients who developed cancers (median size, 4.5 cm) had had a negative barium enema within the past 3 years. [388] As an adjunct to the National Polyp Study, the use of barium enema was found to be inadequate for surveillance after an initial polypectomy. Only 32% of diminutive (5 mm or smaller) colonic adenomas were detected by barium enema—which is understandable and not necessarily a problem, but the radiologic approach missed 53% of adenomas 6 to 10 mm in size and 48% of those larger than 1 cm. [389] It may be most accurate to refer to the barium enema as a screening rather than as a diagnostic test because the results are not diagnostic, and abnormal findings require colonoscopy and biopsy to diagnose a neoplasm. The 180-cm colonoscope is the most widely used diagnostic instrument to study the colon. The entire colon can be examined in at least 90% to 95% of studies, and this approach has the highest diagnostic sensitivity of all available tests. Preparation of the colon is achieved using a nonabsorbable gastrointestinal lavage solution. Intravenous sedation and analgesia are administered during the examination; therefore, patient acceptance is high. However, this is the most expensive and invasive of examinations and carries with it a low (0.1% to 0.3%) incidence of severe complications, such as hemorrhage and perforation, which can require surgical intervention. A valuable aspect of this procedure is the fact that mucosal biopsy and endoscopic polypectomy may be undertaken. Thus, definitive diagnosis and even treatment may be accomplished. The performance of tandem, back-to-back colonoscopy on the same day has provided data on the minimal rate of false-negative examinations. The "miss" rate for adenomatous polyps was inversely related to size and was 6% for polyps larger than 1 cm, 13% for adenomas measuring 6 to 9 mm, and 27% for adenomas smaller than 5 mm. [390]
What Is the Definitive Diagnostic Test for Colorectal Neoplasia? If the initial diagnostic procedure is a barium enema, a negative result may create a diagnostic dilemma. In a study of 97 patients who had persistent large bowel symptoms and a negative air-contrast barium enema, colonoscopy revealed 4 carcinomas and 24 adenomatous polyps not detected by the radiologic approach. [391] In a similar study of 76 patients with symptoms of colonic disease, the diagnostic evaluation began with rigid sigmoidoscopy, after which all the patients underwent flexible sigmoidoscopy, double-contrast barium enema, and then colonoscopy. The double-contrast barium enema alone reached a final diagnosis in 67% of patients, whereas colonoscopy was successful in 91%. The addition of flexible sigmoidoscopy to double-contrast barium enema improved the diagnostic yield to 76%, [392] suggesting that colonoscopy is the preferred diagnostic procedure for the initial workup of a patient with symptoms of colonic disease and, moreover, indicates that colonoscopy should be used to evaluate colonic symptoms or bleeding even if the air-contrast barium enema is negative. A review of 31 colon cancers overlooked on double-contrast barium enema revealed that half of the lesions were missed as a result of perceptive errors; that is, the lesions were visualized on the x-ray film and recognized in retrospect, but they could not be identified as neoplasms on the initial reading. [393] Another third of the lesions were missed because of perceptive error complicated by technical factors obscuring the lesion; the tumor was not visible even on respective viewing in 10%, and in 6%, the lesion was seen but misinterpreted. In addition, almost one third of barium enemas in patients older than 65 years of age are technically inadequate because of inability of the patient to obtain a suitable preparation or to cooperate with the procedure. [394] Clearly, the figures obtained are highly dependent on the skill and persistence of the radiologist and endoscopist, and it must be emphasized that some neoplastic lesions may be missed by the colonoscopist. A second prospective study of tandem colonoscopy on 90 patients who had a total of 221 lesions demonstrated that an experienced colonoscopist missed about 15% of neoplastic lesions smaller than 10 mm but no lesions larger than 10 mm. [395] Colonoscopy is the current gold standard for the diagnosis of colorectal neoplasia, and it would appear unlikely that any indirect approach, such as radiography or ultrasonography, can approach this technique for sensitivity.

Screening Asymptomatic Individuals for Colorectal Cancer

Because colorectal cancer produces few symptoms while the tumors are small and most readily curable, screening of asymptomatic patients has been advocated (see Chapter 34). In this context, *screening* refers to testing patients in the absence of specific symptoms. Screening for colorectal cancer can reduce the mortality from this disease. There is still disagreement regarding which screening approach is optimal, the costs of the program, and how much screening can be afforded.

A good screening test must improve the lives of those screened, either by prolonging life or by improving its quality. To be effective, the test must be sensitive (i.e., it should detect all diseased individuals), specific (i.e., it should not detect nonmalignant lesions), and acceptable (i.e., it should not subject nondiseased individuals to excessive anxiety or extra testing) and affordable by those tested. Two modalities have been evaluated for efficacy as screening tests for colorectal cancer: testing of

feces for occult blood and endoscopic examination of the bowel. Both modalities are effective in reducing cancer mortality, but each has limitations.

Fecal Occult Bleeding Tests: Technical Considerations In a typical stool (150 g), the following rule of thumb may be used: Each 1 mL of blood results in about 1 mg of hemoglobin per gram of stool. The detection of tiny blood losses into the gastrointestinal tract seems like a simple task, but, in fact, this test is fraught with complexities. The normal gastrointestinal losses of blood may be estimated by the intravenous administration of ^{51}Cr-tagged erythrocytes, followed by measurement of the excretion of radioactivity in the stools. This has been done by several laboratories, and there is agreement that normal losses are about 0.5 to 1 mL/day. [396], [397] During its transit in the gastrointestinal tract, the blood is dispersed throughout the stool and undergoes degradation. Moreover, there are natural inhibitors of peroxidase activity in feces. It had previously been noted that the guaiac test was less sensitive if the stool had dried out on the filter paper; therefore, a drop of water often was added to the back of the Hemoccult II card (Beckman Coulter, Fullerton, CA) to rehydrate the stool before development of the test. In one study, 156 normal subjects were given a diet restricted in red meat, fruits, and vegetables; none of 310 of the guaiac tests done on subjects given the low-peroxidase diet was positive, and only 2 (0.6%) of 310 were positive after rehydration of the slides. [398] If the slides were rehydrated, as many as 6.6% of the tests became positive. Dietary peroxidase was principally a problem for the guaiac test after the ingestion of beef, but not with poultry, fish, or pork. [399] The standardized guaiac test is therefore reliably negative in control subjects on restricted diets, and less than 1% of tests are falsely positive on low-peroxidase diets. The test becomes unreliable if performed with rehydration unless the diet is strictly regulated, diminishing the value of this maneuver. The next critical issue in the development of a screening test was to understand how much colorectal neoplasms bleed. Mean blood loss (fecal ^{51}Cr-rbc) from a cohort of symptomatic tumors of the cecum and ascending colon was 9.3 mL/day (range, 2 to 28 mL/day) but was much less for lesions located distal to the hepatic flexure, from which the mean blood loss was less than 2 mL/day. [226] Despite the sensitivity of the guaiac test, a false-negative rate of 31% was encountered using this test, which was reduced to 9% if the guaiac slides were rehydrated. As previously mentioned, however, rehydration is a problem if the diet has not been strictly regulated with regard to foods containing peroxidase. A single guaiac test was falsely negative 50% of the time in patients with cancer. The false-negative rate fell to 31% with 3 consecutive days of testing and then to 13% after 10 days of continuous testing. The sensitivity improved with rehydration, and the false-negative rate was only 5% after 5 days, but again, rehydration may be accompanied by sharp loss in specificity depending on the diet. The proportion of positive guaiac tests is closely related to the amount of blood in the stools. The tests are usually negative if the stool hemoglobin concentration is less than 2 mL/g of stool, and they are more likely to be positive with increasing fecal hemoglobin. [226] Colonic polyps also may be detected by the tests for occult bleeding, but benign lesions lose less blood, and the sensitivity of the test is much lower. [226], [400] The mean blood loss from an adenomatous polyp is about 1.3 mL of blood per day, regardless of its location. Polyps in the distal colon (descending colon, sigmoid colon, and rectum) produce 54% positive tests, whereas those in the proximal colon produce positive tests only 17% of the time. [226] Gastrointestinal bleeding from polyps is usually detected only when polyp size exceeds 20 mm. [226] A positive guaiac test is more likely if a polyp is located in the distal rather than proximal colon. [398] Numerous attempts have been made to develop a better FOBT. The manufacturers of Hemoccult II developed a more sensitive slide test, called Hemoccult SENSA (Beckman Coulter, Fullerton, CA), which seems to provide sensitivity similar to that seen with rehydrated Hemoccult slides. The same manufacturer also developed an immunochemical test for fecal hemoglobin called HemeSelect (Smith Kline Diagnostics, Palo Alto, CA), which uses a specific antibody for human hemoglobin but is performed in the laboratory, and a result is not available immediately in the clinic, as are the guaiac-based slide tests. The antibody-based test has the theoretical advantage of not cross-reacting with nonhuman hemoglobin, and it also should not detect bleeding from an upper gastrointestinal site because of degradation of the intact molecule. Both Hemoccult SENSA and HemeSelect are much more sensitive than Hemoccult II, detecting 94% and 97%, respectively, of the symptomatic colorectal cancers, compared with 89% for Hemoccult II. The sensitivity for silent cancers, which are obviously more difficult to detect and are the target lesions, is uncertain. For adenomatous polyps larger than 1 cm, Hemoccult SENSA was positive in 76%, HemeSelect in 60%, and Hemoccult II in 42%. The Hemoccult SENSA and HemeSelect were positive in 5% and 3% of screened subjects, respectively, and most of these positive tests were not associated with colorectal neoplasia. [401] Therefore, the price for increased sensitivity is the need to perform a large number of definitive workups (i.e., colonoscopy) because of false-positive tests. A combination of these tests may be more economical and a clinically reasonable compromise. When a highly sensitive screen (i.e., the Hemoccult SENSA test) was positive and then the positive stools retested with a more specific (and expensive) test (i.e., HemeSelect), a sensitivity of 65.6% for cancers and a specificity for predicting carcinoma of 97.3% was found. [402] The combined approach had the most favorable positive predictive value of the strategies analyzed. The HemoQuant test (Mayo Medical Laboratories, Mayo Clinic, Rochester, MN) provides a quantitative measure of fecal heme and can detect the tiny increments of bleeding that occur in the setting of colorectal neoplasia. [403] The test is not influenced by dietary peroxidase and should be superior to Hemoccult as a diagnostic test. [404] Unfavorable performance characteristics and high cost considerations are such that this test has not gained popular use.

Fecal Occult Bleeding Tests: Factors Modifying Results The Hemoccult card test has been developed so that patients can take it home, modify their diets, collect two samples per day from a stool on each of 3 consecutive days, and return the cards for developing. Thus, some or all the specimens will have undergone changes because of storage. Using early-generation Hemoccult cards, less sensitive than Hemoccult II, about 8 mg of hemoglobin per gram of stool was required to produce a positive test. After stool samples had been stored on Hemoccult cards for 4 days, the intensity of the reaction diminished, and it became negative in 8 days. Therefore, low levels of fecal hemoglobin become undetectable, with a longer delay between the collection of the stool and the development of the test. [405] An inexperienced processor of Hemoccult cards can overread the result, thus seriously affecting the outcome of a screening project. [406] The effect of iron preparations on the guaiac test has been somewhat controversial. A study of 1700 guaiac tests concluded that oral iron does not result in positive guaiac reactions. [407] A small study suggested that ferrous sulfate and ferrous gluconate produced false-positive reactions in more than half of 10 patients tested, and that an aqueous solution of iron could produce a positive guaiac test. [408] However, the black pigment in stools of patients on iron supplements may have been misinterpreted as the blue color characteristic of a positive guaiac test, confirming that oral iron supplements do not produce true-positive guaiac tests. [409] Although ferrous sulfate dissolved in water produces a positive Hemoccult II test, at the pH of the stool (pH > 6.o), the iron precipitates out of solution and does not produce a positive test. Ferrous (Fe^{2+}) iron produces a positive reaction only after the addition of hydrogen peroxide, which oxidizes Fe^{2+} to Fe^{3+}. The black iron pigment in stool is insoluble ferrous sulfide, and no Fe^{2+} or Fe^{3+} is elutable into water from the black stools. [409] It is unlikely that oral iron therapy contributes appreciably to false-positive guaiac reactions, and, furthermore, it does not appear to cause occult gastrointestinal bleeding. [410] Because the basis of the guaiac test is the oxidation of an indicator substance (guaiac), the presence of strong antioxidants (e.g., 1 to 2 g/day of ascorbic acid) produces a spuriously negative guaiac test. [411]

Screening Asymptomatic Populations for Occult Fecal Bleeding Several studies illustrate the benefits and limitations of screening for colon cancer. More than 54,000 FOBT kits were sent on request to asymptomatic people [412]; only 26% of the tests were completed, of which 4.4% were positive. More than one third of those with positive tests failed to respond to repeated inquiries for follow-up, and another 20% had an incomplete diagnostic workup after referral to a physician. Among all those with positive tests, 5% had cancers detected, nearly two thirds of which were Dukes stage A or B lesions. Another 30% of the patients had abnormalities other than cancer, including adenomatous polyps. Thus, compliance is an issue in a community-screening program. In a large controlled trial, a cohort of patients aged 40 years or older was screened on a meat-free, high-bulk diet. The slides were not rehydrated, and there was a 4-day storage interval between slide preparation and testing. [413], [414] The Hemoccult tests were positive in 1.7% of the group, and results were strongly age dependent. The first-generation tests were positive in 1%, compared with 3.7% using the more sensitive version (Hemoccult II). The first-generation Hemoccult slides were predictive for neoplastic lesions in 50% of patients, including 12% cancers and 38% adenomas. The more sensitive Hemoccult II slides had a predictive value of 44% for any neoplastic lesion. Modifications intended to make the test more sensitive gave a higher proportion of positive tests, found more neoplasms, and generated many more false-positive results. Although the entire group of patients was offered at least one rigid 25-cm sigmoidoscopic examination, a 43% reduction in cancer mortality was reported in the half of the group randomized to receive the FOBTs. [414] A large (20,000 patients) controlled prospective trial studied the impact of screening for colon cancer on the detection of colon cancer subsequent to symptoms. Half were encouraged to have FOBT, and half were advised to consult their physicians if they developed colonic symptoms. [415], [416] Only 38.5% of patients who were offered screening returned their slides. Of the group returning slides, 4.1% had a positive test, and 36% of these had neoplastic disease on air-contrast barium enema and flexible sigmoidoscopy. Of the group with a positive test, 8.5% had cancer, and 28% had one or more adenomas, 30% of which were larger than 2 cm in diameter. Among the 17 invasive carcinomas detected, 13 were Dukes stage A, 2 stage B, and 2 stage C. One patient among the 4716 patients with an initial negative screen developed a stage C carcinoma of the ascending colon during the year after screening, suggesting that there had been a false-negative test. Among the subjects randomized to the screening group in the initial study, there were 384 who either refused the test or failed to reply; in this group, 11 developed symptomatic neoplastic disease within the following year, including 8 with cancer (5 stage B and 3 stage D), and 3 patients presented with large adenomatous polyps. Among the initial 10,000 patients randomized to the screening arm, a total of 24 had cancers diagnosed. Among the 10,000 control subjects, 10 patients presented with symptomatic carcinomas of the colon, 4 of which were stage B, 4 stage C, and 2 stage D. This study clearly indicated that a substantial number of asymptomatic cancers could be detected using the FOBT, and early-stage lesions were often diagnosed. [415], [416] The initial group of compliant subjects were offered rescreening; 85% were compliant, and 2.8% of those patients had positive tests. [416] Of the 80 patients with positive tests, 4 (5%) had cancers, 3 of which were stage A. In the original control group of more than 10,000 unscreened patients, 7 patients presented with symptomatic colorectal cancer during the second follow-up year (in addition to the 10 detected during the first year). No tumor was stage A; 47% (8) were stage B, 35% (6) stage C, and 18% (3) stage D. This group has updated their study after accruing more than 100,000 subjects, and the results are essentially unchanged. [417] A summary of the five published controlled studies of screening for colon cancer is provided in Table 91-8. Asymptomatic populations have about 1% to 2.4% positive tests. If more than 1% to 2% of tests are positive, it suggests that dietary restrictions have not been adequately followed, that the clinicians have used rehydration of the guaiac test, or that a more sensitive version of the test has been used. It is recommended that beef be eliminated from the diet during the lead-in period. In addition, antiinflammatory agents and antioxidants such as vitamin C should be avoided. Furthermore, the physician or technician should develop the slide as soon as possible, should not rehydrate the slides, and should be aware of the potential for misinterpretation of the slides in patients taking iron supplements. These measures minimize the number of false-positive FOBTs, which would increase the cost of a surveillance program. By limiting the sensitivity of the test, at least one third of colorectal cancers are missed.

TABLE 91-8 Controlled Trials of Fecal Occult Blood Testing in Screening for Colorectal Neoplasms

Early-stage cancers can be detected using FOBTs, and co-lorectal cancer mortality is reduced by finding these tumors. A case-control study demonstrated an odds ratio of 0.69 for colorectal cancer mortality in patients who had had their stools screened for occult fecal blood within the previous 5 years. [418] The odds ratio was lowest for the first year after screening but increased to 1 (i.e., no benefit) 3 years after screening. The impact of FOBT screening, therefore, has a time limit. The most important study of FOBTs was reported from the University of Minnesota and involved the use of Hemoccult cards, 83% of them rehydrated, on more than 46,000 patients studied prospectively for an average of 13 years. [419] In this three-armed study, annual FOBTs resulted in a 33% reduction of colorectal cancer mortality. This reduction was achieved largely through stage shift, in which there was a 50% reduction in the number of Dukes stage D tumors in the screened group, which in turn had a profound effect on survival. A substantial reduction in mortality was demonstrated in this large, credible, carefully controlled study, and the magnitude was similar to that predicted by the previous studies. [414], [418] The use of the rehydrated Hemoccult cards raised the positivity rate among screened individuals from 2.4% (their rate without rehydration) to 9.8%, necessitating diagnostic evaluations in a large proportion of the study population. In fact, 38% of the annually screened group underwent at least one colonoscopy during the study. As a result, only 2.2% of those with a positive test were found to have colorectal cancer, compared with 5.6% when the nonrehydrated tests were used briefly in the middle of the study. Although the number of adenomatous polyps removed from this group was not reported, this intervention may have added to the large and highly significant reduction in mortality seen only in the annually screened group. A follow-up analysis of the Minnesota trial demonstrated that the biennially screened group had a 21% reduction in mortality, suggesting a narrow window of opportunity for annual FOBT screening. [420] Two more prospective randomized clinical trials of the effects of FOBT screening on colorectal cancer mortality were published from Denmark and Britain. [421] and [422] Both used nonrehydrated Hemoccult cards, a practice representative of common standards, and biennial screening. The Danish study of 140,000 people aged 45 to 75 years had a 67% completion rate for screening, and the group offered biennial screening had a colorectal cancer-specific mortality ratio of 0.82 ($P = 0.03$) compared with the group offered standard care without screening. [421] The British study involved more than 152,000 people aged 45 to 75 years, about 60% of whom completed at least one screening, and a 15% reduction in cumulative colorectal cancer mortality was observed ($P = 0.026$). In the Minnesota and Danish studies, similar numbers of cancers were found in the screened and unscreened groups, whereas 4.3% more cancers were found in the screened group from Britain. In the British study, the reduction in colorectal cancer mortality among patients found in the first screen was 39% of that in the control group. It appears that the benefits from FOBT screening occur primarily by virtue of diagnosing early-stage tumors, and there is an important benefit of offering annual rather than biennial screening. Using a rehydrated Hemoccult card results in many more positive tests but substantially affects the overall costs of the program because of the need for a definitive diagnostic workup for each positive FOBT.

Role of Sigmoidoscopy in Screening for Colon Cancer Screening with FOBTs is insensitive and often nonspecific, and about two thirds of colorectal neoplasms are within reach of the flexible sigmoidoscope. A large, uncontrolled observation of the effects of screening by rigid sigmoidoscopy suggested that frequent inspection of the rectum and removal of all premalignant lesions would reduce the incidence of invasive rectal cancers to a low number and even could eliminate the occurrence of advanced-stage disease. [423] The development of flexible instruments that could reach from the anus to the cecum raised the obvious issue of how far to take the examinations and how frequently they should be repeated. Two studies have suggested a significant reduction in mortality from screening sigmoidoscopy. A case-control study examined the use of screening sigmoidoscopy among 261 patients who died of cancer of the rectum or distal colon, compared with case-matched controls. Only 8.8% of the cancer patients had undergone screening sigmoidoscopy, compared with 24.2% of the controls. The authors estimated that screened subjects had only 30% of the risk for fatal cancers of the rectum and distal colon, compared with the unscreened cohort. Furthermore, the data suggested that screening sigmoidoscopy might provide risk reduction for as long as 10 years. A similar number of fatal colon cancers were above the reach of a sigmoidoscopic examination in both the screened and unscreened groups, suggesting that the two groups were evenly matched for colorectal cancer risk. [424] This observation was confirmed by another case-control study. [425] A history of at least a single screening sigmoidoscopy over a 10-year period of study was present in 10% of those who died of colorectal cancer but in 30% of case controls. The estimated risk for death from colorectal cancer was reduced by 79% after a single examination, and the adjusted odds ratio for death from cancer in the rectum or distal colon was 0.05. Case-control studies have features similar to both prospective and retrospective studies, but they do not represent the most convincing evidence of clinical effectiveness. No large, controlled, prospective trial has been published that tests the efficacy of endoscopic screening with either sigmoidoscopy or colonoscopy. Nonetheless, there is strong and compelling evidence for a protective effect of sigmoidoscopy and, presumably, the removal of premalignant lesions. Endoscopic screening appears to bring with it a protective effect that lasts substantially longer than the 1–2 year protection of FOBTs. The magnitude of protection is substantially greater than that derived from FOBTs, presumably because it is possible not only to detect early-stage lesions but also to remove premalignant lesions and interrupt neoplastic progression early in its long natural history. Unfortunately, the costs of endoscopic screening will be considerable, depending on the protocol chosen, and the demand for this testing will compete for other health care resources.

Role of Colonoscopy in Screening for Colon Cancer The case-control studies predicted a powerful impact for screening sigmoidoscopy on mortality rates for distal colorectal cancer. Several groups have investigated the diagnostic yield of screening colonoscopy in asymptomatic adults. To date, there have been no controlled prospective trials of mortality reduction due to colonoscopic screening; hence, the actual impact of this modality still remains speculative. In a study by the Veterans Affairs Cooperative Study Group on the diagnostic yield at screening colonoscopy, more than 3000 patients underwent colonoscopy, and these were nearly all men with a median age of just under 63 years. Of the individuals who underwent colonoscopy, 37.5% had one or more neoplastic lesions, and 1% had an asymptomatic, invasive cancer. Of the individuals who had no polyps in the colon distal to the splenic flexure, 2.7% had a neoplasm in the proximal colon that was either large (10 mm or larger) or had an advanced histology. More than half of patients with advanced proximal neoplasms had no distal adenomas that may have been detected at sigmoidoscopy and triggered additional workup. [426] The major limitation of the study is that it involved virtually all men, exclusively U.S. veterans. However, a similar study undertaken in 1994 consecutive asymptomatic adults aged 50 years or older, including both men and women, with a median age of 60 years, reported similar findings to the Veterans Administration study. Twelve cases of cancer were detected (0.6% of the total); 3.1% of subjects had advanced lesions in the distal colon, and 2.5% had advanced lesions in the proximal colon. The risk for an advanced proximal lesion in the absence of distal polyps (i.e., those that would be missed with a complete sigmoidoscopy) was 1.5% of the total and represented 46% of all the patients with advanced proximal neoplasms. The relative risk for an advanced proximal neoplasm increased with the severity of lesions found in the distal colon and sequentially rose as the distal colon showed a hyperplastic polyp (relative risk, 2.6), tubular adenoma, or an advanced neoplasm (relative risk, 6.7). [427] A follow-up to the Veterans Administration study demonstrated that performing one-time screening with a rehydrated FOBT and sigmoidoscopy would fail to detect advanced colonic neoplasia in 24% of those patients. [428] These findings indicate that screening only the distal colon will miss some proportion of advanced proximal neoplasms and that using an index lesion in the distal colon to determine the need for full colonoscopy will miss some advanced lesions; however, that proportion is relatively small and represents about 1.5% to 2.7% of the entire group. Additional strategies are being explored to detect cancers and other advanced neoplasms in the proximal colon without the risks and expenses involved with total colonoscopy. The term *virtual colonoscopy* refers to the use of an imaging procedure such as a computed tomography (CT) or magnetic resonance imaging of the colon. These techniques are still in development. One study of 100 patients documented that a complete exam could be performed in 87% by virtual colonoscopy compared with 89% using conventional colonoscopy. However, virtual colonoscopy fails to detect 9% of lesions 10 mm or larger, 18% of lesions 6 to 9 mm, and 45% of diminutive polyps. There was also a 19% false-positive report of polyps, all of which will lead to a second diagnostic procedure. [429] The use of noninvasive imaging studies is promising; however, they will require additional technical improvements before they will be instituted widely.

Screening Recommendations for Asymptomatic Populations The published data indicate that mortality from colorectal cancer can be reduced by annual FOBT programs by as much as a 33% but that biennial FOBTs (which may more accurately reflect actual practice) reduce mortality by only 15% to 21%. A greater degree of prevention is achieved with screening sigmoidoscopy, which may provide a reduction in cancer mortality of about 80% for that portion of the bowel screened. Programs that use FOBTs are complicated by the variables involved in the techniques used, the need for annual testing, and the need for follow-up colonoscopy in all patients with a positive screening test. If FOBTs are used in a screening program, they should be done annually, and all positive tests must be pursued vigorously. Screening sigmoidoscopy is substantially more effective in preventing cancer mortality, but only the distal bowel is examined. The American Cancer Society, the National Cancer Institute, and several other advisory panels have recommended that screening for colorectal cancer in average-risk individuals begin at 50 years of age and consist of annual FOBTs plus flexible sigmoidoscopy every 10 years. Positive screening examinations should be followed by colonoscopy or, alternatively, double-contrast barium enema, preferably in combination with flexible sigmoidoscopy. Consensus statements have been developed for screening asymptomatic patients and surveillance of high-risk populations. [430] Although conclusive empiric data are not available to support it, colonoscopy has been recommended as a screening test every 10 years, [431] and U.S. Medicare began paying for this in 2001.

Surveillance for Colorectal Cancer among High-Risk Groups

Surveillance is not the same as screening. It refers to the periodic follow-up testing—usually colonoscopic—of individuals who are at high risk for colorectal cancer and who have previously had negative screening examinations. Each clinical situation should be considered individually.

Familial Adenomatous Polyposis All first-degree relatives of FAP patients are at 50% risk for the disease and should have annual flexible sigmoidoscopy beginning

at age 10 to 12 years because adenomas begin to appear at an average age of 16 years (see Chapter 90). [221], [277] Genetic testing can now be used to guide screening in families and is informative in more than 80% of families. [277] If a family has attenuated FAP, annual colonoscopy should be employed, probably beginning in the late teens. [277]

Hereditary Nonpolyposis Colorectal Cancer HNPCC is more complex than FAP because there is no distinctive premalignant phenotype, and the diagnosis is often suspected only because of a strong family history. Patients at risk for HNPCC develop a small number of adenomas at an early age, and these have a high propensity to become malignant. Most polyps and cancers occur above the reach of the sigmoidoscope; hence, the only acceptable screening technique is periodic total colonoscopy. The time required for the progression of adenomas to carcinomas is unknown for this disease, but it is thought to be more rapid than for sporadic tumors, and a cautious approach is necessary. Colonoscopy is recommended, beginning at about 25 years of age or 5 years before the earliest colorectal cancer developed in that family, and it should be repeated every 2 years if negative. A trial of colonoscopy every 3 years has demonstrated a 62% reduction in cancer incidence, and no cancer deaths occurred in 133 examined individuals over 15 years, compared with 9 deaths in 119 unscreened controls. [432] If adenomatous polyps are found, it is not unreasonable to repeat the examination in 1 year. If a cancer is found, subtotal colectomy is the appropriate surgery, followed by annual sigmoidoscopic examination of the residual bowel. [151] The availability of diagnostic genetic testing has a great impact on the management of HNPCC because it will permit the patient to consider prophylactic subtotal colectomy on the basis of a firm diagnosis and can free many first-degree relatives of affected patients from the anxieties of uncertainty about this disease.

Positive Family History of Colorectal Cancer After the autosomal dominantly inherited familial cancer syndromes (i.e., FAP and HNPCC) have been ruled out, many patients remain with one or more relatives who have had co-lorectal cancer (Fig. 91-7). The recognition of attenuated phenotypes adds to the possibilities of genetic factors in older patients with limited family histories. Given the possibility that this disease is susceptible to environmental influences, it follows that not all of these people are necessarily at an increased risk for cancer.

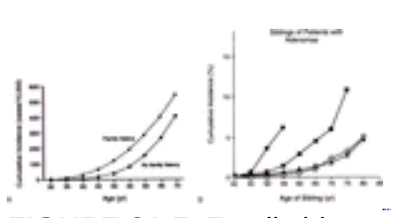

FIGURE 91-7. Family history and colorectal neoplasia. **A:** The influence of any family history of colorectal cancer on cumulative incidence of the disease. **B:** The influence of a history of colorectal cancer in siblings and the age at diagnosis on the cumulative incidence of colorectal adenomas. Filled circles: <60, parent with colorectal cancer; filled squares: =60, parent with colorectal cancer; filled triangles: <60, no parent with cancer; open squares: spouse controls. (**A** from ref. [280]; **B** from ref. [282].)

The following information may be used to target surveillance measures, but this area remains controversial. A family history of colorectal cancer in a first-degree relative (i.e., parents, siblings, children) increases the risk by about 75% to 80% over those with no family history, and variables such as multiple affected relatives or young affected relatives affect this risk sharply, as described earlier. [279], [281] Colonoscopy in first-degree relatives of those with colon cancer are found to exhibit adenomatous polyps twice as often as controls. [431], [432] Individuals with a single, elderly affected relative are not necessarily at increased risk for colorectal cancer, but the risk increases if there are two or more affected relatives or if the tumors have occurred in young people (i.e., younger than 55 years of age). Patients with any family history of cancer should enter a routine surveillance program that involves annual FOBTs and periodic sigmoidoscopy, perhaps every 3 to 5 years. Patients with multiple affected family members or with first-degree relatives who developed colorectal cancer before the age of 55 years need more surveillance, but it is not clear how much more is justified. One should perform a colonoscopic examination perhaps 5 years earlier than the earliest cancer in the family because of the tendency for familial cancers to occur above the range of the sigmoidoscope. If this is negative for neoplasia, follow-up surveillance should consist of annual FOBTs and sigmoidoscopies every 3 to 5 years unless the family history is more worrisome and suggests attenuated FAP or HNPCC, in which case colonoscopy every 2 to 3 years may be necessary. Genetic screening is valuable for the expanding group of syndromes related to FAP and is in evolution for HNPCC; referral to a geneticist is an important option for confusing histories or worried patients.

Prior History of Adenomatous Polyps Many patients have adenomas discovered through screening examinations, workups of colorectal symptoms, or other evaluations. The recommended surveillance of such patients has undergone an important change in light of new data, and a degree of restraint is appropriate for certain patients. Most adenomatous polyps (or flat adenomas) are small, do not produce symptoms, and have been discovered serendipitously by colonoscopy. The presence of solitary adenomas with diameters less than 1 cm does not predict an increased likelihood of recurrent neoplasia. [290], [291] and [292] Therefore, the detection of a solitary, small, low-grade adenomatous polyp, especially in an elderly patient, does not mandate colonoscopic follow-up. Patients who have had more advanced lesions, such as larger adenomas (more than 1 cm), villoglandular or villous adenomas, multiple adenomas, or adenomas containing high-grade dysplasia, require follow-up colonoscopy. For this group, there is no need for a repeat examination at the 1-year time interval after the colon has been cleared of lesions by a technically optimal examination. The National Polyp Study Group indicated that a 3-year interval is adequate for follow-up colonoscopy. [433] The detection of adenomas was common at the 1- and 3-year points, with polyps found in 32% of the patients examined once and 41.7% of those examined twice during the 3 years of follow-up; however, the incidence of advanced lesions (large or higher pathologic grade) was only 3.3% in both groups, and cancers were rare and discovered at an early stage. [433] Thus, patients who have had small, solitary adenomas removed do not need colonoscopic follow-up, and those with larger lesions can wait 3 years after the colon has been cleared of lesions for follow-up, if not longer, given the relatively small number of advanced lesions at 3 years. Subsequent studies suggest that for many average-risk patients, a 5-year surveillance interval may be suitable. [434] These intervals might require modification for issues such as a incomplete removal of neoplasia at first colonoscopy, a personal history of rapidly growing neoplasms, or the presence of multiple neoplasms.

Prior History of Colorectal Cancer Follow-up colonoscopy after the resection of a cancer is frequently overdone, and the objectives of such examinations should be clear to the examiner. Patients who have had sporadic cancers removed are not necessarily different from those who have had highly dysplastic adenomas removed; the principal difference between a cancer patient and a high-grade adenoma patient is the timing of discovery of the lesion. Cancer patients need an examination of the anastomotic site within the first 3 to 6 months after surgery, and perhaps again at 1 year, but the effectiveness of this approach has never been rigorously tested. In the absence of an anastomotic recurrence, the rationale for continued colonoscopic surveillance is to remove recurrent adenomas and to detect metachronous cancers. New lesions develop through the adenoma-carcinoma sequence, which typically evolves over a period of a decade or more. Colonoscopic examination every 3 years is recommended, just as for patients with advanced adenomas. If no lesions are found in a surveillance exam, the interval may be expanded to 5 years. [434]

Inflammatory Bowel Disease Patients with ulcerative colitis are at increased risk for developing cancer. The risk is lowest in the first decade of disease, but 9% develop cancer each decade thereafter. [435] Patients with colitis limited to the distal colon are at much lower risk. It is recommended that patients undergo screening colonoscopy after 8 to 10 years of disease, during which time biopsies should be done of all suspicious lesions and from multiple regions throughout the colon. If high-grade dysplasia is found in the colon, the patient should undergo repeat colonoscopy immediately, with careful inspection of the site of dysplasia and collection of multiple biopsies to exclude an adjacent cancer. Although the optimal intervals for periodic examination have not been determined, colonoscopic surveillance appears to reduce significantly colorectal cancer mortality in this setting by detecting cancers at earlier stages. [436] Barium enemas play no role in the screening for cancer in these patients because of the abnormalities produced by inflammation and scarring. Alternatively, if the patient's disease is sufficiently severe, a colectomy should be considered at this time. Such a decision should take into account the adverse effects of chronic disease as well as the risk for cancer. Patients who have no dysplasia on multiple biopsies are at relatively low risk for neoplasia during the next 1 to 2 years, and these patients should undergo surveillance colonoscopy about every 2 years. If no dysplasia is found on follow-up colonoscopy, a longer interval between surveillance studies may be appropriate. Patients with milder disease and disease limited to the distal colon are also candidates for increased intervals between surveillance studies because of the relatively lower incidence of new dysplasia among patients initially free of this abnormality. Low-grade dysplasia is more difficult to interpret, especially in the setting of acute inflammation. It is not clear whether the diagnosis of low-grade dysplasia should increase the threshold for a consideration of colectomy; however, these patients should be studied with colonoscopy at annual intervals to detect the evolution of higher grades of neoplasia. Low-grade dysplasia is not sufficiently predictive to suggest the need for colectomy. Patients with Crohn's disease are at increased risk for gastrointestinal cancer, including carcinoma of the colon. There is inadequate information to recommend how frequently patients with Crohn's disease of the colon should undergo routine screening colonoscopy. Crohn's colitis involving the entire colon should be considered in the same risk category as ulcerative colitis and should be screened the same way.

Clinical Course and Complications

The clinical course of colorectal neoplasia includes two major considerations: First, what determines the behavior of a colon cancer? Second, if a primary tumor is removed, what determines the behavior of the rest of the colon?

Natural History of Colorectal Neoplasia

The pathological stage of colorectal cancer is the best clinical predictor of outcome. Pathological stage is principally a reflection of depth of invasion. Tumor diameter

and total tumor mass are not strong independent predictors of clinical outcome. It is not unusual to find a large, bulky tumor that neither penetrates the muscularis propria nor metastasizes, and it is also not unusual to find a small, 2- to 3-cm tumor that invades and metastasizes to distant sites. This latter situation presumably represents the temporal compression of tumor progression events resulting in the early appearance of a biologically aggressive tumor. In fact, as a group, Dukes stage B tumors may be larger than stage C lesions. The relative distribution of cancers by stage is listed in Table 91-9. Actuarial age-adjusted 5-year survival rates for colorectal cancers are about 99%, 85%, 67%, and 14% for stage A, B, C, and D tumors, respectively. [365] The best prognostic indicator is the depth of invasion; crude 5-year survival rates for modified Dukes stage A tumors range from 81% to 84%; for stage B, 62% to 65%; for stage C, 36% to 40%; and for stage D, 0% to 3%. [436], [437] Five-year survival data corrected for anticipated age-related mortality are higher. Of patients presenting with large bowel cancer, about 70% will appear resectable for cure, but one third of that group (45% of the original sample) will experience recurrent disease. Only 11% of those presenting with advanced disease (30% of the group) or those with postoperative recurrence (25%) will be cured by additional surgery. [438]

STAGE*	ESTIMATED DISTRIBUTION (%)†	DETECTION BY SCREENING (%)‡
A	10	60
B	50 (± 10)	20
B1	15	
B2	35	
C	25	10
C1	13	
C2	13	
D	15	10

*Pathological stage varies by the investigator.

† These are estimates drawn from several reported studies that used differing methods to recruit and exclude patients.

‡ From Boland CR. Diagnosis and management of primary and metastatic colorectal cancers. Semin Gastrointest Dis 1992;3:33; in several large studies, 65%–90% of cancers were stage A or B when detected by screening.

TABLE 91-9 Distribution of Colorectal Cancer Patients by Pathological Stage

Metastatic Disease

It is a tenet of tumor biology that cancers are relentlessly progressive. Rarely, a patient can survive for 20 or 30 years despite an unresected primary tumor. The median survival period for patients who have hepatic metastases diagnosed at the time of surgery is only 4.5 months. [439] The clinical objective is to detect colorectal tumors early in their natural histories and to intervene with appropriate surgical therapy. Five-year corrected survival rates have been reported to range from 40% for all colorectal cancers [440] to 67% for patients who are candidates for potentially curative surgery for rectosigmoid tumors. [441] About 25% of all these patients are diagnosed with stage D tumors. In general, metastatic disease is disseminated when first detected and is only infrequently localized. One group of patients, perhaps 15% to 40%, do not have grossly detectable metastatic disease at the time of surgery but eventually succumb to recurrent disease within 5 years. It has been difficult to identify these patients prospectively to assess the impact of adjuvant treatment on their outcome.

It has long been appreciated that circulating tumor cells may be found in the mesenteric and systemic circulation of patients with colorectal cancer, and curiously, this is of no prognostic significance. [442] It is therefore not surprising that K-*ras* mutations are found in the plasma of patients with colorectal cancer, [443] but it is not clear whether any prognostic significance can be attached to this finding. More than 80% of co-lorectal adenocarcinomas are well or moderately differentiated tumors, and few prognostic features can be found to predict tumor recurrence in this group. Poorly differentiated and colloid (or mucinous) tumors make up the remainder of the adenocarcinomas, and the 5-year survival rate in these instances is somewhat worse than for their better differentiated counterparts. The primary adverse prognostic indicators are the depth of invasion and the presence of metastasis at the time of surgery. Tumor size is not an independent predictor of outcome. [444]

About three fourths of patients presenting with colorectal cancer undergo a resection that appears to be curative. The expected location of metastatic disease is related, to some extent, to the location of the primary tumor (Table 91-10). One third of these patients develop recurrent disease. About 60% of this group die with recurrences in multiple sites, one fourth develop a local recurrence at the site of the primary tumor, and a small residual number develop isolated metastases in a single organ. [438] Among patients who underwent surgical exploration for their primary tumor, 6 (14%) of 43 had overt hepatic metastases, and the other 37 (86%) had follow-ups at 3-month intervals for the development of recurrent disease. During 2 years of follow-up, 11 (30%) of the 37 developed overt hepatic metastases. Among these 11 patients with occult metastases, CT was most sensitive in detecting silent recurrences. [445] Only 1 of these 11 patients with an occult hepatic metastasis survived 3 years. [446] Colorectal cancers may metastasize to sites other than the liver or regional lymph nodes, but these tend to occur with symptoms of colonic or metastatic disease.

METASTATIC SITE	PRIMARY TUMOR SITE (%)		
	Right Colon	*Sigmoid Colon*	*Rectum*
Liver	67	68	48
Lung	31	43	52
Pelvis	9	27	41
Regional lymph nodes	49	57	59

Summarized and adapted from Welch JP, Donaldson GA. The clinical correlation of an autopsy study of recurrent colorectal cancer. Ann Surg 1979;189:496. From Boland CR. Diagnosis and management of primary and metastatic colorectal cancer. Semin Gastrointest Dis 1992;3:33.

TABLE 91-10 Distribution of Metastases from Colorectal Cancer at Autopsy

In a study of 302 consecutive autopsies on patients with early metastatic cancer from an unknown primary site at the time of presentation, only 3.6% came from the colon or rectum. [447] Similarly, only of 3% of 62 patients who presented with cerebral metastases had a colorectal primary tumor. [448] Therefore, a colonoscopy or barium enema is a low-yield procedure in the absence of colorectal symptoms in the workup of a metastasis of unknown origin.

Treatment

Colon Cancer

Primary Surgical Treatment for Cure of Colon Cancer The preoperative workup in a patient ound to have colonic cancer requires an inspection of the entire colon, preferably with colonoscopy, because of the 5% risk for a second primary cancer, which modifies the surgical approach. An air-contrast barium enema may suffice if there is difficulty advancing the colonoscope proximal to the index lesion. Additional preoperative workup includes a CT scan of the abdomen to search for metastatic neoplastic disease, particularly in the liver. If a CT scan is performed, there is no need to perform an additional radionuclide or ultrasonographic imaging procedure of the liver. Radionuclide scanning with a monoclonal antibody directed against co-lorectal tumor antigens is available [449] but does not routinely add to the information gained from a CT scan. This modality is more valuable in localizing pelvic or abdominal recurrence, which may be difficult to find on CT. A chest radiograph is part of the routine preoperative evaluation, but a CT scan of the thorax is not recommended as a routine preoperative assessment. An imaging procedure of the central nervous system is also a low-yield procedure, and the cost is not commensurate with the probable benefit. A complete blood count is needed because of the possibility of iron deficiency anemia and its correction before surgery. In the absence of detectable metastatic disease, a measurement of serum carcinoembryonic antigen (CEA) should be done. The CEA should be drawn before removal of the primary tumor because not all cancers produce this glycoprotein, and if the preoperative value is not elevated, the test is not informative in the postoperative period. If the CEA is elevated, and if the operative assessment is that all tumor has been removed, the CEA measurement should be repeated about 1 month after surgery, assuming the physician and patient are prepared to undertake repeat surgery for any evidence of tumor recurrence. The upper limit of normal for plasma CEA is 5 ng/mL. Because CEA is excreted in bile, levels are difficult to interpret in the face of biliary obstruction or hepatic dysfunction. CEA measurement is not useful as a primary screening test because of the large number of patients with nonneoplastic conditions who have minor elevations, and it is not useful in locating the source of metastatic lesion. Serial measurements of CEA may be of value in detecting early recurrences in the postoperative patient; however, this test should not be undertaken unless the patient is prepared to accept exploratory laparotomy for an elevated

result. If this course of action is unacceptable to the patient, it may be best not to measure it. The primary modality for treatment for colonic cancer is surgical resection. The surgical approach is directed by the location of the tumor and the desire to remove not only wide margins of resection (a minimum of 5 cm proximal and distal to the edges of the tumor) but also regional lymph nodes. A cancer in the cecum, ascending colon, hepatic flexure, or transverse colon is treated with a right hemicolectomy, including a dissection of the mesenteric lymph nodes. Examination of the liver for gross metastatic disease helps predict the postoperative outcome. Tumors from the splenic flexure to the sigmoid colon are treated with a left hemicolectomy and primary colonic anastomosis preserving the rectum. Lesions in the sigmoid colon are treated with a segmental (low anterior) resection with an end-to-end primary colonic anastomosis. Every attempt is made to treat cancers in the rectosigmoid region with a low anterior resection, which permits preservation of the rectum and obviates the need for colostomy. Rectosigmoid lesions, however, require the dissection of hypogastric lymph nodes in addition to the standard mesenteric dissection. [450] The skill of the surgeon is an important prognostic factor that should be considered because the operative mortality and complication rates vary significantly among surgeons. [451] Every patient with colon cancer who is an acceptable surgical candidate should undergo resection of the primary lesion, if possible. Colonic cancers have a tendency to produce intestinal obstruction late in the clinical course, when the patient may no longer be a surgical candidate. Patients who present with obstruction are best managed with a primary resection of the tumor rather than a multistage procedure leading to delayed resection of the tumor; however, technical considerations may require tumor resection and diverting colostomy, with a delayed anastomosis. The operative mortality rate for colon cancer surgery is about 5%, [437], [451] but it may be as high as 17% for emergency operations [437] and as low as less than 3%. [452] In planning treatment, it is important to realize that this disease tends to occur in older patients with comorbid conditions.

Cancer in an Adenomatous Polyp A situation in which a segmental colonic resection may be avoided is that in which in situ or invasive carcinoma is found in a pedunculated adenomatous polyp. This subject is discussed in more detail in Chapter 149. If the endoscopist and pathologist agree that the cancer has been removed, for example, by snare cautery, additional surgery is not necessary. [453] A margin of 2 mm between the deepest extension of cancer, and the resection line is predictive of a favorable outcome with regard to tumor recurrence. [454], [455] An exception to this policy is the case in which poorly differentiated cancer is encountered.

Adjuvant Chemotherapy of Colon Cancer After Surgery for Apparent Cure The postoperative prognosis for patients who undergo primary resection of colonic cancer is based on the surgical stage of disease; about 70% appear to have received curative surgery (i.e., all tumors Dukes stage A, B, and C), and yet about one third of this group eventually develop recurrent disease. [438] The administration of chemotherapy to patients who have undergone a complete surgical resection with curative intent is referred to adjuvant therapy, which is distinct from treating known metastatic disease. Numerous chemotherapeutic regimens have been used in an attempt to reduce the recurrence rate of metastatic disease. [456] Before 1989, no regimen had been shown to improve survival in this disease. The first step forward was demonstration of a significant survival benefit with levamisole plus 5-fluorouracil (5FU) as adjuvant therapy in patients with Dukes stage C colon cancer. [457] This study included 401 patients with Dukes stage B or C colorectal cancer, excluding those with stage A cancer (in which the predicted outcome is too good to justify adjuvant therapy) and those with stage D cancer (who, by definition, have advanced disease). The patients were randomized to receive either no additional therapy or 1 year of treatment with levamisole (50 mg every 8 hours for 3 days, repeated every 2 weeks) plus 5FU (450 mg/m ^{2} daily intravenously for 5 days, followed on day 28 with single weekly injections of 450 mg/m ^{2}). Separate arms were randomized to receive only levamisole or to receive no adjuvant treatment. Stage B patients were those with tumor that had invaded the serosa, pericolonic or perirectal fat, or adjacent organs by direct extension, without lymph node metastasis (stage B2 according to some classifications). Stage C patients had involvement of regional lymph nodes but no distant metastases. The median length of follow-up was longer than 7 years, and the minimum was longer than 4 years. A significant reduction (31%) in tumor recurrence rate was found for levamisole plus 5FU, and a reduction of borderline significance (27%) was found for levamisole alone. Combination therapy also produced a delay in the time to tumor recurrence. Considering patients of both stages eligible for analysis, no improvement in survival was seen for any treatment regimen compared with controls. The patients in this study were analyzed separately by tumor stage. No improvement in the recurrence interval or survival was found for patients with stage B tumors, but a significant improvement in recurrence-free interval and survival was found in stage C tumors for the combination of levamisole plus 5FU compared with control patients. No benefit was found for levamisole alone. The authors concluded that substantial benefits would be achieved if stage C patients were treated with adjuvant therapy. These results were confirmed in a larger study of 1296 patients with either locally invasive (stage B2) or stage C colon cancers; rectal tumors were excluded, and median follow-up time was 3 years. [458] No benefit for tumor recurrence or survival was found among the patients with stage B2 disease. A 41% reduction in tumor recurrence was found in patients with stage C disease treated with levamisole plus 5FU ($P > 0.0001$), and the death rate was reduced by 33% in this group (Fig. 91-8). No benefit was found with levamisole alone. A final report on this study confirmed the durability of the initial findings, [459] and a cost analysis suggests that adjuvant therapy for stage C (III) colon cancer is very cost-effective. [460] Although patients with stage B2 cancers are considered for adjuvant therapy by some oncologists, their relatively good 5-year prognosis (77% 5-year survival rate) suggests that it may be difficult to provide significant improvement with acceptable toxicities. [461]

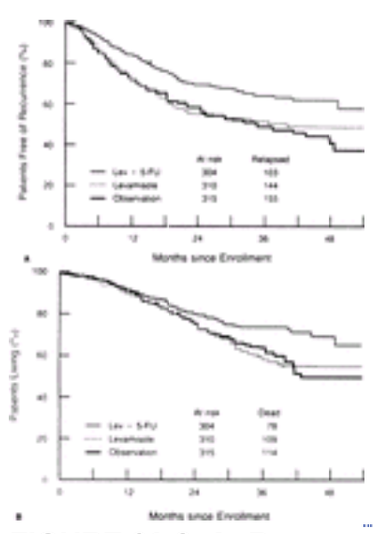

FIGURE 91-8. A: Recurrence-free interval after adjuvant treatment of stage C colon cancer with levamisole (*Lev*) and 5-fluorouracil (*5-FU*). There was a significant improvement in recur-rence-free status from 47% to 63% among treated patients at 42 months ($p < 0.0001$; **top**). The reduction in recurrence was greatest for sites outside the abdomen. **B:** Survival after adjuvant treatment of stage C colon cancer with Lev and 5-FU. There was a reduction in the death rate by about 33% in the treated group compared with controls ($p = 0.006$; **top**). (From ref. [458].)

Patients should be advised that considerable toxicity probably will be encountered with chemotherapy, but that significant improvement in disease-free survival may be expected for patients with stage C cancer of the colon. No benefit has been demonstrated for any adjuvant regimen applied to patients with stage A or B colorectal cancer. More than half of patients experienced nausea, 47% experienced diarrhea, and 17% experienced vomiting during the maintenance phase of treatment, although the side effects have been described as mild by the authors. [458] Stomatitis, dermatitis, and alopecia each were observed in about one fourth of the patients. Mild leukopenia (2000 to 4000 leukocytes) was encountered in 38% of patients. Numerous neurologic symptoms were experienced by 18% of patients; these resolved after therapy was discontinued. Fully 30% of patients discontinued their therapy prematurely because of toxicity, most commonly because of nausea. The current standard of practice in the community for stage III colorectal cancer consists of 5FU weekly and levamisole given 3 days every 2 weeks for a year. Leucovorin plus 5FU for a year is equally efficacious, and leucovorin has largely replaced levamisole in many communities. [462] 5FU, levamisole, and leucovorin given together for only 6 months also reduces mortality, whereas 5FU plus levamisole for only 6 months is not as efficacious.

Follow-up of Patients After Surgical Resection Although about 70% of patients appear to have complete excision of all malignant disease, more than one third of this group suffer later recurrences. In a small proportion of these patients, timely therapy may prolong survival. Several approaches have been developed to detect early recurrences and to treat them effectively. Colonoscopy should be performed once between postoperative months 3 and 6 and again 12 months postoperatively to detect recurrences of the primary tumor and the development of metachronous or missed synchronous tumors. Recurrences of primary tumor occur at the anastomotic site and may or may not be detectable using colonoscopic surveillance because some occur on the serosal aspect of the bowel. Anastomotic recurrences most often develop after rectal or rectosigmoid resections, and the likelihood is strongly dependent on the Dukes stage of the resected cancer. Most appear within 2 years of the initial operation, and 90% are heralded by persistent symptoms. It is important to diagnose local recurrences and to be aware that some of these are submucosal because there is a 49% 5-year survival rate after resection of such disease. [463] Measurements of serial CEA levels at 2-month intervals and CT scans at 3- to 6-month intervals have been evaluated as means for detecting early metastatic disease. There is little sense in measuring serial CEA levels unless the patient and physician are prepared to undertake additional surgery for an elevated level. CEA measurements vary among laboratories; therefore, a reference laboratory with careful quality control is essential. Recurrent tumor was found at a second-look operation in 56 (93%) of 60 patients operated on solely because of serial elevations of CEA. Recurrent tumor was later identified in 3 of the remaining 4 patients, and 1 had a spurious elevation of CEA as a result of liver disease. About half of these patients had resectable tumor, and more than one third have had long-term disease-free survival times. [464] Another group reported recurrent disease in 33 (89%) of 37 laparotomies performed for elevations of CEA in asymptomatic patients, with a 43% resectability rate, evenly split between local recurrences and liver metastases. [465] Others have reported that the use of serial CEA values to direct laparotomy for recurrent disease may result in long-term, disease-free survival in only 3% of a group of patients who had follow-up after colorectal surgery. [465], [466] Furthermore, the cost of follow-up per resectable tumor has been estimated at about $25,000, exclusive of the cost of CT scanning; the added cost of the radiologic procedure, if it is used on all patients, could triple this cost. [467] Therefore, the willingness of the patient to

undergo additional procedures and operations as well as the impact of total cost must be considered in planning an appropriate follow-up schedule in light of the minor impact on patient outcome provided by this surveillance.

Radiation Therapy for Colon Cancer Radiation therapy has been evaluated as an adjuvant therapy for colon cancer and as treatment for metastatic disease. There is no benefit with the use of radiation therapy as an adjunctive agent for colon cancer outside the rectum. Adenocarcinomas of the colon tend to be relatively radioresistant, and the toxicities from abdominal radiation are considerable.

Rectal Cancer

Surgical Therapy The approach to the treatment of rectal carcinoma is dictated by the fact that most of this organ is located beneath the peritoneal reflection and is surrounded by perirectal fat. Any degree of invasion greater than Dukes stage A requires a wide excision, usually consisting of a combined abdominoperineal resection and subsequent colostomy, which is not required for resections of carcinoma in the colon. Lesions located high in the rectum (more than 6 cm from the anus) may be treated with a low anterior resection without total proctectomy, but this approach brings with it a higher likelihood of local recurrence. Invasive cancers in the distal 6 cm of rectum are best treated with an abdominoperineal resection and hypogastric lymph node dissection. If the degree of invasion is not clear on physical examination, endorectal ultrasound may help to provide important staging information. [468] A patient with a small rectal neoplasm, even in the distal 6 cm, may refuse a proctectomy and colostomy because of the possible complications and changes in lifestyle that accompany this operation, or the patient may not be a suitable operative candidate for this procedure. In this instance, a local excision of the tumor may be considered. The preferred lesions for this approach should be small (less than one third the circumference of the rectum); they should be readily mobile, indicating only early or localized invasion of the submucosal tissues; and they should not be mucinous or poorly differentiated carcinomas, which carry a more ominous prognosis. Abdominoperineal resection was once standard treatment for many rectal cancers, but surgeons with interest and expertise in this tumor are able to perform successful local resections with a sphincter-sparing operation on a growing proportion of these lesions. A study of 57 patients with distal rectal cancer treated with full-thickness local excision demonstrated an overall 5-year survival rate of 83%, and the cancer-specific mortality rate was 11%. [469]

Rectal Polyps Pedunculated polypoid lesions in the rectum can be removed using snare polypectomy. Sessile polyps, which may create a therapeutic dilemma elsewhere in the colon, often can be treated more aggressively in the rectum, because of the additional margin of safety provided by the subperitoneal location of the rectum. Transanal local excision may be elected for mobile cancers that do not penetrate the bowel wall and are not poorly differentiated adenocarcinomas, especially for the patient who is not a surgical candidate or who refuses abdominoperineal resection and colostomy. Current standards of care would suggest that the resectability of a questionable rectal lesion should be confirmed with endorectal ultrasound.

Other Therapies Because of the relatively encouraging outcome after local excision in patients with small rectal cancers, other nonsurgical modalities have been evaluated. Neodymium:yttrium-aluminum garnet (Nd:YAG) laser photocoagulation has been safely applied for the removal of adenomatous polyps that cannot be removed by standard snare polypectomy. [470] Laser ablation also may be used as palliative treatment for symptomatic rectal cancers in patients who are not candidates for surgical resection. [471], [472]

Radiation Therapy to Improve Operability in Rectal Carcinoma The role of preoperative radiation therapy is often overlooked in the management of rectal cancer. A retrospective review indicated that 20 (80%) of 25 patients with initially unresectable rectal cancer were converted into surgical candidates by preoperative radiation therapy, and 16 (80%) of 20 patients underwent resection for cure, with 2- and 5-year survival rates of 56% and 43%, respectively. [473] Other groups confirmed the value of preoperative radiation for rectal cancer. [474] As many as 50% of patients with a fixed rectal cancer can be operated on with apparent long-term benefit after radiation therapy. [475] A subsequent prospective study indicated that postoperative radiation therapy (or radiation therapy plus adjuvant chemotherapy) for rectal cancer prolonged survival in treated patients compared with untreated controls. [476] Additional experience in a controlled study suggests that some of the benefits achieved by preoperative radiation therapy also may be achieved using postoperative radiation. [477] Most surgeons prefer not to delay surgery for preoperative radiation; therefore, postoperative radiation is more commonly used. Nonetheless, a prospective trial of preoperative short-term radiotherapy (25 Gy delivered in five fractions over 1 week) for resectable rectal cancers demonstrated that the therapy did not adversely affect postoperative mortality and was associated with a 58% 5-year survival rate and 74% cancer-specific survival at 9 years. Outcome measures such as recurrence rates and survival significantly improved for most of the subgroups and were diminished in none. [478] The use of preoperative radiation may be of benefit and is probably an underused therapeutic option.

Adjuvant Therapy for Rectal Carcinoma The incidence of local recurrence in rectal cancer is dependent on the pathological stage; local recurrence is found in 8% of Dukes stage A, 31% of Dukes stage B, and 50% of Dukes stage C patients, and the unadjusted 5-year survival rates are 77%, 44%, and 23%, respectively. [479] Effective adjuvant therapy must take into account both local and systemic disease. A regimen of intravenous 5FU in combination with external-beam radiotherapy, significantly prolonged the time to tumor recurrence, but not overall survival, in a multiinstitutional study of patients with Dukes stage B and C tumors of the rectum. [480] In another large study, patients with stage B and C rectal cancers showed some benefit from chemotherapy with 5FU, semustine, and vincristine, but improvements in survival or disease-free intervals with radiation alone were not seen. [481] Newer regimens involving radiation and combination chemotherapy are used for pre- and postoperative regimens.

Combined Radiation and Chemotherapy for Rectal Cancer Combined postoperative adjuvant treatment consisting of chemotherapy and radiation is of benefit in patients with locally invasive (Dukes stage B2) or Dukes stage C rectal cancer. [482] Combined therapy consisted of an oral dose of semustine plus 5FU, followed by external-beam radiation. The radiation therapy consisted of a total of 4500 cGy and was delivered in divided doses 5 days a week for a period of 5 weeks. This form of therapy reduced pelvic recurrences by 46%, distant tumor spread by 37%, and patient deaths by 27%. Estimated 5-year recurrence rates in patients receiving radiation only was about 63% and was reduced to 42% in patients receiving the combination therapy (Fig. 91-09). Toxicity of this treatment may be considerable. The acute side effects include bone marrow suppression and diarrhea, and late complications of radiation include proctitis, strictures, and bowel obstruction (occurring in 6.5% of all patients). Combined radiation and chemotherapy constitutes an appropriate adjuvant therapy to offer patients who have undergone apparently successful resections of Dukes stage B2 and stage C rectal cancers. A randomized study of 660 patients with TNM stage II or III rectal cancer demonstrated that the use of semustine did not add to the increased survival time provided by 5FU alone, and dropping semustine avoids the potential problem of introducing secondary neoplastic complications. Protracted infusions of 5FU during pelvic irradiation produces delays in relapse times and results in improved survival. [483]

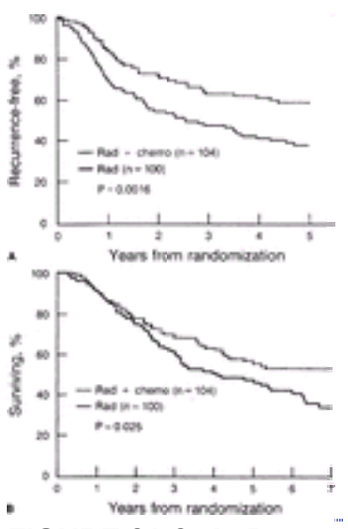

FIGURE 91-9. A: Recurrence-free intervals in patients with stage B2 or C rectal cancer treated by postoperative radiation therapy with or without chemotherapy. Patients receiving chemotherapy had 34% fewer recurrences. **B:** Survival rates in patients with stage B2 or C rectal cancer treated by postoperative radiation therapy with or without chemotherapy indicated a significant improvement in survival with adjuvant chemotherapy. (From ref. [482].)

Patients with rectal cancer who appear to be good operative candidates at the time of presentation should undergo immediate operative therapy, either abdominoperineal resection or local excision with mesorectal resection. Patients with Dukes stage A and B1 lesions have a relatively favorable 5-year prognosis and need no further therapy. Patients with stage B2 and C lesions should undergo resection and postoperative combined adjuvant radiation and chemotherapy. Patients who appear to be inoperable at the time of presentation should undergo radiation therapy first and then should be evaluated for the possibility that the tumor has been rendered operable. Newer combinations of chemotherapeutic agents are continuously being investigated.

Metastatic Colorectal Cancer

Resection of Metastatic Disease Anastomotic and other local recurrences of cancer may occur after resections in the colon but are more likely to occur in the pelvis after a rectal or rectosigmoid resection. Most patients with recurrences present because of symptoms, and it is reasonable to consider surgical resection of the metastatic disease. The use of CEA measurement and CT scanning has resulted in the identification of an increasing number of patients with isolated metastatic

disease in the liver. If a single hepatic metastasis or a cluster of lesions in a single lobe is discovered without other evidence of extrahepatic disease, surgical resection should be considered the primary approach because it is the only treatment that may provide a long-term, disease-free clinical course. The median survival time for an untreated solitary hepatic metastasis is about 10.6 months. [484] The operative mortality rate for this procedure is less than 5% in experienced hands, and 25% to 35% of operated patients are reported to experience a 5-year, disease-free survival. [485] Tumors recur in the liver in about one third of these patients, but a larger number of recurrences develop in extrahepatic organs. Solitary resected lesions that are smaller, that have wide margins of resection, and that are unassociated with extrahepatic disease are more likely to be resected for cure. [486] Up to three resectable metastases and a preoperative CEA level of less than 5 ng/mL are also factors that are predictive of a better outcome. [487] The limiting factor in successful resection of metastatic disease is the identification of patients who are suitable for resection because they represent fewer than 10% to 15% of all patients with follow-up after initial colonic surgery with curative intent. A useful application of positron emission tomography (PET) is the detection of foci of metastatic disease. PET can detect intrahepatic foci of tumor that are not apparent by conventional imaging, but it can be particularly helpful in detecting extrahepatic foci. [488] The outlook is less promising for resection of isolated pulmonary metastases. A series of 62 patients reported 5-year survival rates of 42% and 10-year rates of 22% after thoracotomy, with a mean overall survival time of 24 months. A solitary pulmonary metastasis less than 3 cm in diameter should be considered for a surgical resection, but the impact of this on survival and cure rates is undetermined. [489], [490]

Chemotherapy for Metastatic Colorectal Cancer Fewer than half of all colorectal cancer patients eventually develop metastatic disease, either at a local site or in a distant organ. Only a small proportion of metastatic disease is amenable to surgical resection. Hence, many forms of medical therapy have been tested in an attempt to manage this complication effectively. Several systematically administered cytotoxic therapies can shrink measurable metastatic disease. A wide range of objective responses have been reported in the literature, but a partial response rate of 15% to 20% is a reasonable estimate of efficacy. Although patients whose tumors shrink in response to 5FU live longer than patients whose tumors are resistant to treatment, there is no evidence that a group of patients treated with chemotherapy experiences prolonged survival, nor is it possible to know whether patients whose tumors respond to treatment live longer than if they had not been treated at all. Attempts have been made to enhance the effectiveness of 5FU for metastatic (stage D) colorectal cancer by adding leucovorin or methotrexate. Trials suggest that combined therapy may increase the number of responses, although the improvement is modest. [491], [492] and [493] The added agent often enhances toxicity more than the response rate because of the inherent limitations of the antimetabolites used to treat colorectal cancer. Any claims of treatment efficacy must be documented in the setting of a prospective, controlled clinical trial. The drug irinotecan (Camptosar), a topoisomerase I inhibitor, has been tested in a clinical trial to treat metastatic co-lorectal cancer in combination with 5FU and leucovorin. The use of three drugs resulted in a significantly longer progression-free survival, and a median survival time of 7.0 months was observed, compared with 4.3 months in patients treated with 5FU and leucovorin alone. In addition, a higher rate of confirmed response (39% versus. 21%) and a longer overall survival (14.8 versus 12.6 months) was observed with the three-drug combination. However, although statistically significant differences in outcome were confirmed in these trials, the benefits collapse in the period 12 to 24 months after treatment, and the clinician must discuss with the patient whether 1 week of infusion therapy every 4 weeks for 6 months is an acceptable strategy to gain a few months of disease-free survival. [494] Some patients will find this to be a reasonable form of therapy; however, others will refuse.

Chemotherapy for Localized Hepatic Metastases More than 80% of patients who die with metastatic colorectal cancer suffer hepatic involvement, a fact that has prompted interest in developing effective therapies to control the growth of tumor in this organ. Surgical resection should be considered for isolated hepatic metastases; unfortunately, these are uncommon. Because 95% of the blood flow to metastases is delivered by the hepatic artery, attempts have been made to intensify cytotoxic therapy while limiting systemic toxicity by administering the drug through the hepatic artery. The initial experiences with the intraarterial hepatic artery infusion chemotherapy used a percutaneous access port and reported complete disappearance of tumor in 15% of patients, 50% reduction in tumor sizes in 39%, and 25% shrinkage of tumors in another 21%. [495] Systemic drug toxicity was minimized, but a number of complications occurred, including displacement of the catheter tip and arterial thrombosis. A totally implantable intraarterial infusion pump was introduced in 1979 in an attempt to improve the uniformity of drug delivery. A group of 93 patients were treated with hepatic arterial infusion of 5-fluorodeoxyuridine (FUDR), of whom 45% had failed prior systemic chemotherapy. Significant reductions in tumor size were seen in 83% of patients, with a median response of 13 months and a median survival of 25 months after diagnosis of the liver metastasis. Extrahepatic tumor did not respond to the therapy. [496] Unfortunately, the study included no control group. In a similar study, 65 patients were treated in a prospective randomized trial of surgery (if possible) plus continuous hepatic artery chemotherapy, and no significant improvement in survival was seen with FUDR. [497] In a follow-up study, toxicity was reported in more than 80% of the patients, including mucosal damage in the stomach and duodenum, cholestatic liver disease, and strictures of the bile ducts. [498] These investigators subsequently reported the results on 162 patients after gaining additional experience with the technique and limiting the complications. Intrahepatic arterial FUDR produced a significant improvement in response compared with systemic FUDR, with response rates greater than 50%. [499] A randomized study of 100 patients with liver metastases treated with continuous hepatic arterial floxuridine reported a prolongation of survival with improved quality-of-life measures among the treated patients. [500] A metaanalysis of this approach suggested that the overall benefit is modest. [501] Unfortunately, this therapy requires an operation, it still has a considerable number of serious complications, and a significant prolongation of survival has never been demonstrated. [493] A growing number of patients will undergo resection of hepatic metastases from colorectal cancer, and there is a modest body of evidence suggesting that the actuarial survival may be improved if these patients are treated with hepatic arterial infusions of 5FU and FUDR, with or without leucovorin in six cycles. This treatment provided a modest but statistically significant increase in survival free of hepatic progression compared with surgery and systemic therapy alone. [493]

Emerging Therapies for Colon Cancer Several groups have attempted to manipulate the immune system to improve outcomes in patients with locally advanced or metastatic colorectal cancer. To date, neither vaccine-based approaches nor the use of tumor-infiltrating lymphocytes have been shown to have an impact on colon cancer. The treatment of colon cancer with 5FU produces modest benefits but with relatively modest toxicity compared to other forms of cytotoxic chemotherapy. One major drawback is the need for infusion therapy. Patients who are dealing with what is likely to be a lethal disease may be reluctant to sacrifice high quality of life to the infusion center receiving treatment when they are feeling well. Thus, oral fluoropyrimidine therapy is now being tested for colorectal cancer, including tegafur (UFT), capecitabine, eniluracil, and others. [462] The clinical benefit in terms of tumor regression is likely to be modest; however, the new approaches to giving the drug may improve the quality of life for patients with metastatic colorectal cancer who wish to take some therapy for their disease.

Other Tumors of the Large Intestine

A variety of cancers other than adenocarcinoma also occur in the large intestine and enter into the differential diagnosis of a colonic mass discovered because of symptoms or an abnormal screening test. Lymphomas and carcinoid tumors are neoplasms that arise from cells intrinsic to the colon. Much less commonly, sarcomas may arise from the smooth muscle or adipose tissue of the submucosa. Adenoacanthomas, squamous cell carcinomas, and undifferentiated carcinomas appear to represent variant types of differentiation that may have originated from the colonic epithelium. Additionally, primary tumors from other sites occasionally may metastasize to the colon. These tumors are so rare that it is difficult to generalize about their clinical characteristics.

Colonic Lymphomas

Primary colonic lymphomas constitute a relatively small proportion of all colonic malignancies (less than 0.5%) but are important because of the substantial differences in treatment and prognosis. [502], [503] A study of 117 patients with gastrointestinal lymphoma indicated that 48 (41%) occurred in the stomach, 37 (32%) in the small intestine, 13 (11%) in the ileocecal region, 2 (2%) in the appendix, and 11 (9%) in the colon. [502] Using Rappaport's classification, 60% were diffuse histiocytic lymphomas, and the remainder were divided among multiple categories. The clinical features of ileocecal and large intestinal lymphomas are presented in Table 91-11. The symptoms are nonspecific and include abdominal pain, gastrointestinal bleeding, and constipation. Ileocecal lymphoma tends to occur in a younger group of patients than does lymphoma in the rest of the large intestine. About half of gastrointestinal lymphomas have regional lymph node involvement or widespread dissemination at the time of diagnosis. The 2-year actuarial survival rate was about 40% but was related to the stage of disease; patients with stage IE or IIE lymphomas had 2-year actuarial survival rates of 82% and 71%, respectively, whereas no patients with stage IV disease survived 2 years.

	LOCATION OF LYMPHOMA	
	Large Intestine	*Ileocecal*
Number of patients	8	13
Average age (range) in years	58 (52–77)	37 (7–70)
Gender (M:F)	0.6:1	3.3:1
Presenting features (%)		
Abdominal pain	50	100
Anorexia	12	23
Diarrhea	50	38
Constipation	0	7
Weight loss	12	31
Gastrointestinal bleeding	62	29
Abdominal mass	25	29
Two-year actuarial survival	38%	41%

From ref. 502.

TABLE 91-11 Colonic and Ileocecal Lymphomas: Clinical Features

An increased likelihood of gastrointestinal lymphoma is seen in a variety of autoimmune diseases, including rheumatoid arthritis, Sjögren syndrome, systemic lupus erythematosus, Wegener granulomatosis, congenital immune deficiency syndromes, and acquired immunodeficiency syndrome (AIDS). Patients who receive organ transplants and are treated with immunosuppressive drugs have a greatly increased likelihood of developing secondary malignancies, including gastrointestinal lymphomas. The gross and microscopic pathology of these lesions is highly variable, but they are more likely to produce single or multiple discrete lesions than diffuse colonic involvement, which may be found in about 10% of cases. Although rectal lymphoma has been reported in the setting of chronic ulcerative colitis, this complication of inflammatory bowel disease is rare. [504]

Isolated colonic non-Hodgkin lymphoma is rare, occurring mostly in the cecum, and immunosuppression is a common risk factor. [505] A report of eight rectal lymphomas also showed few unifying characteristics. Patients presented with a variety of symptoms, including a change in bowel habits, lower abdominal pain, and rectal bleeding, and the lesions ranged from small submucosal nodules to diffuse friable abnormalities. [506]

Treatment of colonic lymphomas has included the use of surgery, radiation, and chemotherapy. Most treatment regimens include chemotherapy; however, the optimal form of treatment and its impact on survival remain to be established.

Kaposi Sarcoma in the Colon

Before the emergence of the AIDS epidemic, Kaposi sarcoma was a rare neoplasm largely confined to the skin, with infrequent systemic involvement. It appears, however, that Kaposi sarcoma as a complication of AIDS includes gastrointestinal involvement in 75% of patients. [507]

The stomach and duodenum are involved more frequently, but about one third of these patients also have colonic involvement, and subcutaneous nodules and infiltrative lesions may be demonstrable using radiographic studies. [508] /SUP>In a study of 50 patients with Kaposi sarcoma, characteristic lesions were visualized using a 60-cm flexible sigmoidoscope in 28% of patients. Gastrointestinal Kaposi sarcoma lesions are dark-red macules, plaques, or nodules with the appearance of a submucosal hemorrhage, and they are recognizable to those familiar with the cutaneous lesion. These lesions are submucosal, and the biopsy confirms the visual impression in only 36% of cases. The lesions tend to be multiple but are rarely symptomatic, and no adverse clinical sequelae of these lesions have been identified. Visceral involvement of Kaposi sarcoma in AIDS patients is associated with a significantly poorer prognosis, and only one of nine patients with follow-up for 2 years after the diagnosis of gastrointestinal Kaposi sarcoma was still alive. [509]

Carcinoid Tumors of the Colon and Rectum

Carcinoid tumors are neoplasms derived from cells capable of synthesizing a wide variety of hormones and autacoids. Carcinoid tumors begin as small submucosal nodules and tend to be asymptomatic until the overproduction of a functionally active peptide produces a paraneoplastic syndrome such as flushing, wheezing, or diarrhea. Carcinoid tumors may occur anywhere throughout the gastrointestinal tract, but they are most common in the appendix, ileum, and rectum (Table 91-12). More than half of these tumors occur in the appendix or ileum, and 17% may be found in the rectum. Whereas carcinoid tumors originating from the stomach or small intestine can give rise to a variety of systemic syndromes, rectal carcinoids do not produce the carcinoid syndrome. Most are asymptomatic, and about one fourth present with rectal bleeding. In a series of rectal carcinoid tumors, 23 (61%) of 38 were less than 2 cm in diameter, only one of these was malignant, and none had distant metastases. Therefore, most carcinoid tumors are amenable to local excision. Among the 15 (39%) of 38 tumors 2 cm or more in diameter, 14 were malignant, but only one gave rise to distant metastases. [510] These larger lesions should be treated aggressively, like adenocarcinomas. Carcinoid tumors of the distal colon often are diagnosed incidentally during the biopsy of a polypoid lesion, and the key to their management is to ensure their complete removal and to consider the possibility of multiple lesions. Carcinoid tumors in the proximal colon, appendix, and ileum have a somewhat different behavior: they may be locally invasive; stimulate desmoplasia in the retroperitoneal or mesentery, giving rise to a variety of mechanical complications such as intestinal obstruction; and may metastasize to the liver with symptoms such as abdominal pain, cramps, diarrhea, flushing, fixed cutaneous changes, and wheezing. A carcinoid tumor confined to the intestinal tract does not produce the characteristic features of carcinoid syndrome, which is actually a manifestation of metastatic disease. [511] and [512]

ORGAN	PERCENTAGE OF TOTAL	PERCENTAGE WITH METASTASIS
Stomach	3	18
Duodenum	1	16
Jejunum	2	35
Ileum	28	35
Appendix	47	3
Colon	2	60
Rectum	17	12

CHAPTER 92

Jeffrey L. Barnett

ANORECTAL DISEASES

ANORECTAL EXAMINATION

The anorectal examination is an important part of the gastrointestinal evaluation and not merely a means of obtaining stool for occult blood testing. It must be performed with particular care and thoroughness in anyone with anorectal complaints (Table 92-1). The anorectal evaluation is usually reserved for the terminal portion of the examination after the patient-physician relationship has at least been partially established. Step-by-step explanation, reassurance, and gentle technique help to minimize patient embarrassment and discomfort. The patient should be placed in the left lateral decubitus position with the buttocks protruding just beyond the edge of the examining table. The hips may be slightly raised with a sandbag or a folded sheet. The prone jackknife position is ideal for examination of the anorectum, although it requires a specialized examining table and places the patient in a somewhat unfamiliar position. After the patient is adequately draped and the instruments are at hand but out of direct patient view, examination begins with inspection of the perineum. The buttocks, sacral region, and thighs are observed for signs of pilonidal disease, dermatologic conditions, and infections. The buttocks are then firmly retracted with both hands to permit inspection of the perianal region. Fistulous openings, fecal or mucus soiling, and excoriations or chronic skin changes give clues to underlying disease processes. Anal pathology such as tumors, skin tags, anal fissures, and prolapsing hemorrhoids are often best identified at this time. Lesions should be described with regard to their anatomic location.

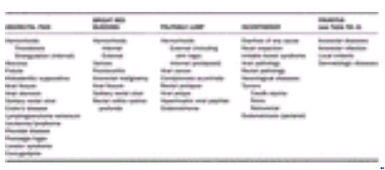

TABLE 92-1 Differential Diagnosis of Primary Presenting Symptoms of Anorectal Diseases

Clock-face descriptions are confusing unless patient position and orientation are specified. Digital examination begins with palpation of the perianal area. Induration, tenderness, or the cord of a fistulous tract may be appreciated. The examining finger is well lubricated and slowly, gently inserted into the anus. Palpation begins away from the area of suspected pathology. Anesthetic lubricant may be necessary in those with painful lesions. Occasionally, adequate examination is impossible except under anesthesia. External hemorrhoids, thrombosed internal hemorrhoids, fissures, and fistulous tracts should be sought. Sphincter tone and the posterior puborectalis impression should be appreciated with the patient at rest, during squeeze, and when bearing down. The presacral area, the prostate, and even the cul-de-sac region may be palpated. Anteriorly, the impression of the cervix or an indwelling tampon should not be confused with pathology. During the examination of the rectal mucosa, the presence of polyps, tumors, feces, and foreign bodies is ascertained.

Anoscopy is the best means of examining the anal canal. It should be performed only if the patient has specific anal complaints. Fistulous openings and anal canal lesions are noted. Internal hemorrhoids may be seen arising just above the dentate line. Their true magnitude is best appreciated if the patient bears down and the hemorrhoids are seen to bulge into the lumen. Fissures and perianal lesions may be appreciated as the instrument is withdrawn to below the dentate line. Rigid proctosigmoidoscopy is performed for full evaluation of the distal colon and rectum. The rigid instrument is particularly useful for preoperative documentation of the position of a rectal cancer, large-bite rectal biopsy specimens for diagnosis of Hirschsprung disease, removal of foreign bodies, and evaluation of the mucosa if fiberoptic or video equipment is unavailable. For most other indications, the flexible instrument is preferred.

HEMORRHOIDS

Hemorrhoids result from dilation of the superior and inferior hemorrhoidal veins. These veins form a hemorrhoidal plexus, or cushion, in the submucosal layer of the lower rectum. Because the hemorrhoidal cushion is a normal anatomic structure, all adults are candidates for the development of symptomatic hemorrhoids. In the United States, estimates of prevalence range from 4.4% to as high as 50% of the adult population. [1], [2] Although it is widely believed that constipation is an important

risk factor for hemorrhoids, recent studies suggest that diarrheal disorders are more frequently associated with hemorrhoidal disease. [3], [4]

Anatomic Considerations

Hemorrhoids may be either external or internal, and often both types are present in the same individual. Internal hemorrhoids arise from the superior hemorrhoidal cushion above the mucocutaneous junction of the anorectum, or dentate line. Internal hemorrhoids are lined with rectal mucosa and occur in three primary locations: right anterior, right posterior, and left lateral, although anatomic variability is common. The end branches of the superior and middle hemorrhoidal arteries terminate in the submucosa above the dentate line with an anterior and posterior branch on the right and a single lateral branch on the left, corresponding to the three primary hemorrhoid locations. The right posterior and left branches give off two end branches to potentially form secondary hemorrhoids. External hemorrhoids arise from the inferior hemorrhoidal venous plexus below the mucocutaneous junction and are lined by perianal squamous epithelium. The perianal squamous epithelium of the anus contains numerous pain receptors, so that thrombosis of external hemorrhoids causes significant pain. Internal and external hemorrhoidal plexuses freely communicate to drain the lower rectum and anus. Internal and external hemorrhoids drain into the inferior vena cava through the internal pudendal veins.

Pathogenesis

Elegant histological studies have shown that hemorrhoids are normal features of the human anatomy. They have three important parts: the lining (rectal mucosa or anoderm), the stroma (blood vessels, smooth muscle, supporting connecting tissue), and the anchoring connective tissue (which secures the hemorrhoids to the sphincter mechanism). Hemorrhoidal tissue has anatomic similarities to erectile tissue such as the corpora cavernosa. [5] With age or other aggravating factors, the anchoring and supporting connective tissue deteriorates, causing the hemorrhoids to bulge and descend, leading eventually to symptoms. [6] This theory is supported by the increased incidence of hemorrhoids in patients with chronic constipation, diarrhea, pregnancy, or pelvic tumors—conditions that increase pelvic venous pressure. In certain individuals, the internal sphincter becomes hypertrophic and the anal outlet becomes functionally narrowed. At straining, the fecal bolus acts as an obturator forcing the hemorrhoidal cushions to descend through the hypertrophic sphincter, enlarge, and become symptomatic.

Definitions

External skin tags are redundant folds of skin that arise from the anal verge. External hemorrhoids arise from the inferior hemorrhoidal plexus below the dentate line and are covered by anal squamous epithelium. Internal hemorrhoids arise from the superior hemorrhoidal plexus above the dentate line and are covered by columnar epithelium of the rectum. They may be classified according to their degree of protrusion or prolapse. First-degree hemorrhoids bulge into the lumen of the anorectal canal on anoscopy but do not protrude out of the anus. Second-degree hemorrhoids prolapse out of the anus with defecation or straining but reduce to a normal anatomic position spontaneously. Third-degree hemorrhoids prolapse out of the anus with defecation or straining and require digital reduction. Fourth-degree hemorrhoids are irreducible and are at risk for strangulation. The clinical presentation and recommended therapy for the various degrees of hemorrhoids are different and are discussed later. Anorectal varices are not hemorrhoids; they occur as a consequence of portal hypertension and are discussed separately.

External Skin Tags After thrombosis of an external hemorrhoid, the overlying skin becomes redundant, and this excess skin remains long after the underlying clot resolves. External skin tags may also arise after formal hemorrhoidectomy or de novo in cases of inflammatory bowel disease. Primary symptoms, if present, are complaints of a palpable growth near the anus and difficulty with anal hygiene. Skin tags are relatively easy to distinguish from more serious pathology such as anal cancer or condyloma acuminata by their gross appearance as normal skin and their soft, fleshy texture on palpation. Treatment is conservative whenever possible, and surgical excision is only necessary in cases of poor hygiene or patient anxiety.
External Hemorrhoids Thrombosis of an external hemorrhoid can be an extremely painful event. Distention of overlying perianal skin and inflammation associated with the process of thrombosis may cause severe patient discomfort. Bleeding usually occurs late in the course of thrombosed external hemorrhoids after the overlying perianal skin ulcerates and the resolving, liquefied hematoma necessitates. External hemorrhoids should be distinguished from strangulated internal hemorrhoids and anorectal varices. Strangulated internal hemorrhoids tend to be larger and more circumferential, encompassing the entire anus. Anorectal varices should be considered in any patient with a history of cirrhosis or portal hypertension. Many thrombosed external hemorrhoids can be treated with warm sitz baths two to three times per day. Stool softening agents such as psyllium seed preparations, synthetic mucilloids, and the sodium or calcium salts of dioctyl sulfosuccinate can minimize straining at stool and prevent aggravation of the pain and thrombosis. Topical therapy with anesthetic ointments and witch hazel–impregnated pads may provide additional relief. One must temper the attribution of clinical improvements to medical therapy with the knowledge that the natural history of thrombosed external hemorrhoids is resolution after 48 to 72 hours. If the pain is severe and the patient is seen within 48 hours of symptom onset, surgical evacuation or excision of the thrombosed external hemorrhoid should be performed. After the thrombus has organized, it cannot be evacuated. This can usually be done in the clinic setting and provides prompt relief.
Internal Hemorrhoids Internal hemorrhoids may be asymptomatic or associated with discomfort, pruritus ani, fecal soiling, or prolapse. Bleeding, however, is the typical complaint that brings the patient to the physician and hemorrhoids are the most common cause of rectal bleeding. Such bleeding is described as bright red spotting on the toilet tissue or dripping into the toilet bowl. It most often occurs at the end of defecation and is separate from the stool. It does not usually occur apart from defecation. Rarely, acute severe bleeding requires transfusion and, occasionally, ongoing chronic losses cause iron-deficiency anemia. [7] However, hemorrhoids should not be considered the source of hematochezia until other potential bleeding sources in the colon and rectum have been investigated. With the possible exception of a young patient with a bleeding pattern typical of hemorrhoids, a flexible sigmoidoscopy or, if clinically appropriate, a full colonoscopy should be performed. Occult bleeding should not be attributed to hemorrhoids. Occult blood in the stool deserves a complete evaluation regardless of the presence of hemorrhoids. Prolapse of the hemorrhoidal tissue is another common complaint. Prolapse may manifest itself anywhere along a continuum of symptoms from difficulty with anal hygiene to painful strangulation. Prolapsed tissue may also be a presenting symptom of rectal prolapse, rectal polyps, or rectal cancer. Sigmoidoscopic evaluation with biopsy of suspicious lesions should be carried out if appropriate. Anal condyloma and anal cancer are easily differentiated from prolapsing hemorrhoids, and thrombosed external hemorrhoids tend to cause pain as a presenting symptom. All degrees of internal hemorrhoids may be associated with mild discomfort, but only strangulated hemorrhoids cause significant pain. Strangulated hemorrhoids usually possess an external and internal component and occur secondary to prolapse with subsequent lack of blood supply. Progression to gangrene with resultant infection is life threatening and will occur if immediate surgical therapy is not instituted. In contrast to complete rectal prolapse, strangulated hemorrhoids lack concentric mucosal folds and are irreducible.

Treatment

Conservative Therapy Dietary counseling, behavior adjustment, and topical agents are effective for most first-and second-degree hemorrhoids. A high-fiber diet and adequate fluid intake should be prescribed to promote passage of soft, bulky stools to prevent straining. Some patients may require the addition of hydrophilic bulk-forming agents such as psyllium extracts or mucilloids. Excessive and prolonged defecatory straining should be discouraged. Many patients benefit from warm sitz baths twice daily and attention to proper anal hygiene. A number of proprietary agents such as suppositories, ointments, and medicated pads (witch hazel and glycerin) may provide topical astringent relief. Hydrocortisone or anesthetic-containing preparations (benzocaine, lidocaine, pramoxine, dibucaine) offer short-term relief of pruritus, burning, and soreness, although firm efficacy data are lacking. If conservative therapy does not suffice, a definitive procedure is necessary (Table 92-2). The available treatment modalities can be broadly classified into one of two categories: those that involve loss of redundant mucosa and those that do not. In general, first- and second-degree hemorrhoids can be treated without removal of redundant hemorrhoidal tissue. Third- and fourth-degree hemorrhoids usually require a form of therapy that results in both thrombosis of the hemorrhoid and removal of redundant tissue.

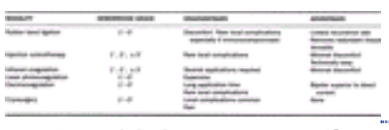

TABLE 92-2 Nonoperative Procedures to Treat Internal Hemorrhoids

Rubber Band Ligation Barron [8] first described a rapid, simple, effective device for the treatment of internal hemorrhoids in the office or outpatient setting. In a large office-based practice, 21,000 patients were treated and 44.8% required rubber band ligation. [9] Band ligation is associated with both thrombosis of the hemorrhoid and removal of redundant mucosal tissue. By inducing submucosal scarring, development of new hemorrhoidal tissue is prevented. Rubber band ligation is a good treatment for refractory first-degree hemorrhoids as well as all second- and selected third-degree hemorrhoids. Fourth-degree hemorrhoids are not well treated by this method. Because it is an outpatient procedure, no special preparation is needed for the majority of patients. After anorectal evaluation is performed, the anoscope is inserted and a hemorrhoidal cushion is selected for band application. No anesthetic is required if care is taken to place the band at least 0.5 cm above the dentate line. Some authors recommend banding of only one column per session to minimize tissue necrosis, but up to four ligations have been performed with acceptable morbidity. [10], [11] Rubber band ligation allows a controlled removal of tissue rivaled only by formal hemorrhoidectomy. Complications are rare but serious. In a series of

512 patients treated with rubber band ligation, 2.5% required hospitalization. [12] Migration of the band onto the anoderm is associated with excruciating pain requiring immediate removal of the band. Persistent severe pain, fever, urinary retention, or foul-smelling rectal drainage may herald the presence of a rectal infection. A number of case reports of necrotizing infection and death as a result of band ligation have appeared in the literature. [13], [14] Significant discomfort lasting for days occurs in some patients and mucosal slough with potential for bleeding occurs 5 to 7 days after band application. Results of rubber band ligation are generally excellent. Long-term patient satisfaction is about 90%. [15] No requirement for anesthesia and the ability to perform band ligation in the clinic setting continue to make this a popular treatment option for patients with hemorrhoids. Novel methods to perform banding have also been employed. A band ligator cap device attached to the tip of a flexible endoscope allows excellent visualization of band placement. [16] Inexpensive plastic single-handed ligators have been developed that employ suction to capture the hemorrhoidal tissue for band placement. [17], [18]

Injection Sclerotherapy The use of a sclerosant solution such as sodium morrhuate or 5% phenol is an accepted treatment for first- and second-degree hemorrhoids. The sclerosant is injected with a special hemorrhoidal needle into the submucosa around, but not into, symptomatic hemorrhoids. An intense inflammatory reaction results in fixation of the mucosa to the underlying muscle thus obliterating the submucosal layer where hemorrhoids form. Injection of sclerosants is a less controlled and therefore less popular technique than rubber band ligation. Known complications are mucosal slough, prostatic infection, contact hypersensitivity, and rectal infection. A refinement of injection sclerotherapy for hemorrhoids uses a flexible endoscope to inject 23.4% saline through a sclerotherapy needle into the hemorrhoidal cushion. In a small preliminary series of patients with grade I, II, or III hemorrhoids, success rates were similar to those seen with other, more conventional therapies. [19]

Cryosurgery Special cryoprobes activated by liquid nitrogen, carbon dioxide, or nitrous oxide have been developed. Local tissue destruction is caused by freezing and subsequent necrosis. All symptomatic hemorrhoids are treated in one session. If deep freezing of the submucosal hemorrhoidal cushions does not occur, symptoms persist. Tissue damage is uncontrolled, and wound healing is accompanied by prolonged anal drainage, late bleeding, and pain. [20] Compared with rubber band ligation, patient satisfaction is less and local complications more frequent with the cryosurgical technique. [21], [22]

Electrocoagulation Electrosurgical units have been adapted for use in the outpatient therapy of internal hemorrhoids. [23] Application of direct electrical current is less precise than with band ligation or formal hemorrhoidectomy and requires several minutes of contact time. Excess electrical current is grounded through the patient's body, and occasionally discharges occur that cause injury at sites distant from the area of intended tissue destruction. Bipolar electrocoagulation is as efficacious as the direct current technique and is performed more rapidly. [24], [25] It may be easier to perform and less painful than rubber band ligation. [26]

Photocoagulation Both infrared light and lasers have been used to treat symptomatic hemorrhoids. [27] Photocoagulation stimulates fibrosis of the submucosal layer by first causing tissue coagulation and necrosis. Advocates of photocoagulation point to the lack of electrical contact with the patient's body and a more controlled application of destructive force compared with electrofulgeration. [28] Infrared devices are hand-held and much less expensive than laser devices. Equipment for both forms of photocoagulation is more expensive than equipment for rubber band ligation or injection sclerotherapy. The incidence of discomfort and complications compare favorably with those of rubber band ligation and injection sclerotherapy. Rubber band ligation therapy produces more posttreatment pain than injection sclerotherapy or infrared photocoagulation, but fewer patients are likely to need re-treatment because of symptomatic recurrences. [29] Laser photocoagulation is an additional, albeit expensive, alternative. Using a carbon dioxide laser, 1816 consecutive patients were treated with success rates approaching those of more established therapies. [30]

Hemorrhoidectomy Fewer than 10% of symptomatic hemorrhoids require surgical hemorrhoidectomy. [9] It is the treatment of choice for most third-degree hemorrhoids, all fourth-degree hemorrhoids, strangulated hemorrhoids, and hemorrhoids that have persisted despite other forms of therapy. Advantages of the surgical approach include precise removal of all internal and external hemorrhoids, control of bleeding, and rapid wound healing. Disadvantages include the need for regional anesthesia, postoperative pain, risk of postoperative urinary retention, and expenses incurred from both hospitalization and lost time from work. A number of procedures have been developed, but all incorporate three basic principles: removal of all symptomatic diseased tissue, preservation of wide intervening skin bridges to prevent anal stenosis, and avoidance of damage to the anal sphincter mechanism. Some surgeons advocate primary closure of the entire hemorrhoidectomy wound, but others close the rectal mucosal wound only to the dentate line and leave the anoderm open to allow drainage. Using primary closure of the entire wound, Ferguson and colleagues [31] reported excellent results 5 years after hemorrhoidectomy in 95% of patients and a wound infection rate of 0.20%. In a more recent trial [32] however, the open technique led to faster and more reliable wound healing with a similar rate of pain and complications. Even with careful attention to perioperative fluid management, acute urinary retention requiring Foley catheterization may occur in 10% of patients. [20] The incidence of transient bacteremia may approach 8% even in uncomplicated cases. [33]

Ablation of the Internal Anal Sphincter Two strategies have been employed to decrease the abnormally high resting anal pressure found in some patients with hemorrhoids. Lord [34] advocated forceful anal dilation under general anesthesia, but the procedure causes variable and uncontrolled damage to the anal sphincters with resulting fecal incontinence. Good results occur in 80% of patients, but some of the efficacy of this procedure may reflect submucosal hemorrhage and subsequent scar formation. A more controlled disruption of the internal sphincter is achieved with lateral internal sphincterotomy (see section " Anal Fissure"). A metaanalysis of randomized controlled trials assessing at least two treatment modalities for symptomatic hemorrhoids found that rubber band ligation was superior to sclerotherapy and patients undergoing ligation were less likely to require future therapy than those treated with sclerotherapy or infrared coagulation. [35] Hemorrhoidectomy resulted in a better response than rubber band ligation, but the surgical group had significantly more pain and a higher incidence of complications. Based on these findings, it seems reasonable to suggest band ligation or a similar treatment as first-line therapy for grades 1 to 3 hemorrhoids, reserving hemorrhoidectomy for large grade 3 and grade 4 hemorrhoids and for those failing other techniques.

Anorectal Varices Meticulous histological study has shown that anorectal varices and hemorrhoids are unrelated. [5] Hemorrhoids are vascular cushions of ectatic venular-arteriolar connections of the hemorrhoidal plexus and they have no direct connection to the portal system. They occur independently of anorectal varices and the presence or degree of portal hypertension. [36], [37] Alternatively, rectal varices represent enlarged portal-systemic collaterals which correlate with the presence of portal hypertension. They develop as a result of hepatofugal portal venous flow through the inferior mesenteric vein to the superior hemorrhoidal veins. The varices represent the communication between these superior hemorrhoidal veins (portal circulation) and the middle and inferior hemorrhoidal veins (systemic circulation) which, in turn, flow into the femoral vein and then to the inferior vena cava. The distinction of anorectal varices from external hemorrhoids may be difficult. Often patients with anorectal varices have other known manifestations of portal hypertension such as esophageal varices and ascites. Anorectal varices are usually discrete, serpentine, submucosal veins. In contrast to external hemorrhoids, varices are compressible and refill rapidly. They extend from the squamous portion of the anal canal across the dentate line and into the rectum proper. Nearly 45% of patients with cirrhosis will be found to have anorectal varices by careful endoscopic examination and the prevalence increases to 75% using rectal endosonography. [36], [37] and [38] In one series, 5% of patients with bleeding as a manifestation of portal hypertension bled from anorectal varices. Bleeding may occur from either the anal or rectal portion of the varix and can be massive and life threatening. [39] The optimal management of anorectal varices is not known. Injection sclerotherapy, cryotherapy, rubber band ligation, and hemorrhoidectomy have all been associated with torrential, occasionally fatal bleeding. [40], [41] Treatment by underrunning the variceal columns with absorbable suture achieves primary control in a majority of cases and has a very low rate of morbidity. [39] Rubber band ligation has also been advocated but must be done in a controlled environment with full resuscitation capabilities. Inferior mesenteric vein embolization or ligation has been reported. [42] Ultimately, surgical or transjugular intrahepatic portosystemic shunting may be required. [43]

ANORECTAL ABSCESS AND FISTULA

Suppurative anorectal infection can be divided into two categories—anorectal abscess and anorectal fistula. Anorectal abscess may be defined as an undrained collection of perianal pus. Anorectal fistula is an abnormal communication between the anorectal canal and the perianal skin. Abscess is the acute manifestation and fistula the chronic manifestation of suppurative anorectal infection. In most cases, the underlying pathophysiology is thought to be the same and the treatment for each is essentially surgical.

Epidemiology, Etiology, and Differential Diagnosis

In a series of 1023 patients treated for anorectal abscess or fistula, the male-to-female ratio was 2:1. The age distribution was from 10 to 82 years, with the majority in the third and fourth decades of life. The most common associated medical diseases were hypertension, diabetes, heart disease, and inflammatory bowel disease. [44] The incidence of perirectal infection in patients with acute leukemia is approximately 8%. [45]

Current evidence suggests that infection of the anal glands is the most common cause of anorectal abscess and anorectal fistula. The most common bacterial isolates are *Escherichia coli, Enterococcus* species, and *Bacteroides fragilis*. [46] Histological specimens from patients with anorectal fistula revealed infected anal glands 70% to 90% of the time. Anal glands arise from the anal canal at the level of the crypts of Morgagni. At least half of the glands are observed to penetrate into the intersphincteric space. [47] Obstruction of the anal glands may occur in the presence of trauma, anal eroticism, diarrhea, hard stools, or foreign bodies, with resultant stasis and secondary infection. This cryptoglandular origin of anorectal abscess and fistula is further supported by the fact that the primary internal orifice is found at the level of the dentate line.

Specific diseases may cause anorectal abscess and anorectal fistula in the absence of primary cryptoglandular infection. These include Crohn's disease, anorectal

malignancy, tuberculosis, actinomycosis, lymphogranuloma venereum, radiation-induced proctitis, leukemia, and lymphoma. Other disease states that may cause a similar clinical picture and should be included in the differential diagnosis of suppurative anorectal conditions are infected presacral epidermal inclusion cysts, hidradenitis suppurativa, diverticulitis, pilonidal disease, and Bartholin abscesses.

Anatomic Considerations

Anorectal abscesses may be classified by anatomic site of origin and potential pathways of extension. Abscesses that are inferior to the puborectalis and levator ani muscles are classified as low intermuscular abscesses, and those that extend above these muscles are classified as high intermuscular abscesses. Low intermuscular abscesses are subclassified as perianal, submucosal, intersphincteric, or ischiorectal. High intermuscular abscesses are described as pelvirectal, retrorectal, or rectovesical. Proper surgical management is guided by correct anatomic identification of the type of anorectal abscess.

Anorectal fistulae are described based on pathogenesis of the disease (e.g., Crohn's disease, hidradenitis suppurativa) and classified according to the normal muscular anatomy of the pelvic floor. All anorectal fistulae are anatomically divided into one of four groups (Fig. 92-1). The most common type of anorectal fistula is the intersphincteric fistula, in which the fistula ramifies only in the areolar tissue between the internal and external anal sphincters. Transsphincteric fistulae pass from the intersphincteric plane through the external sphincter and into the ischiorectal fossa. Suprasphincteric fistulae pass upward in the intersphincteric plane, over the puborectalis muscle, and into the ischiorectal fossa. Extrasphincteric fistulae pass from the perianal skin through the ischiorectal fat and levator muscles into the rectum. Division of the entire tract of either suprasphincteric or extrasphincteric fistulae results in total division of the muscles of continence. [48] Anal endosonography and magnetic resonance imaging (MRI) have emerged as useful modalities for determining the position of an anorectal abscess or fistula relative to the anal sphincter complex. [49], [50] MRI has been shown to predict clinical outcome based on the initial severity of fistulous disease better than surgical exploration. [51]

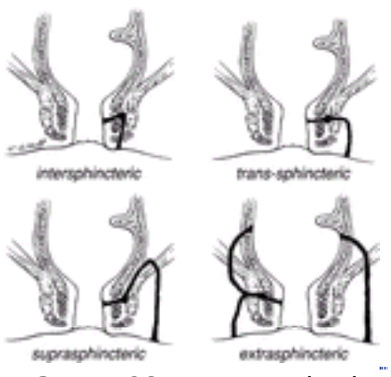

FIGURE 92-1. Anatomic classification of anorectal fistulae.

Clinical Manifestations

Acute pain and swelling are the most common complaints in the patient with anorectal abscess. Pain may occur in the absence of swelling, especially with small intersphincteric or pelvirectal abscesses. Sitting, movement, and defecation exacerbate pain. Antecedent history may reveal a bout of constipation, diarrhea, or minor trauma. Constitutional symptoms include malaise and fever. The presence of foul-smelling drainage means that the abscess has necessitated, or is discharging through the primary anal orifice.

Inspection of the perineum of a patient with perirectal abscess reveals the cardinal signs of inflammation: redness, heat, swelling, and tenderness. Drainage may be observed from the infected crypt orifice. An intersphincteric abscess may manifest only as localized tenderness. Rectal examination is often difficult because of pain, so evaluation under anesthesia is indicated if a complete examination is otherwise impossible. Delay in making the diagnosis of anorectal abscess leads to extension of the infection into previously uninfected spaces and also increases the subsequent risk of overwhelming sepsis.

Chronic, purulent drainage is the chief complaint of patients with anorectal fistula. A history of prior anorectal abscess is frequently elicited. Discomfort or pain often occurs with defecation but is not as severe as that associated with anal fissure or anorectal abscess. The perianal skin may be pruritic or excoriated. Bleeding is usually minor and caused by granulation tissue at the orifice of the primary or secondary anal orifice.

Anorectal fistulae can usually be diagnosed by the presence of a red, granular papule from which pus is expressed. The primary orifice is the fistulous opening at the level of the dentate line, which is thought to be the original site of the infected anal gland. The secondary orifice is the fistulous opening anywhere else on the perineum. Multiple secondary openings should alert one to the possibility of either Crohn's disease or hidradenitis suppurativa. It is often possible to palpate a fistulous tract as a firm cord just beneath the perianal skin. Attempts to pass metal probes are best made in the operating room. Anoscopy and sigmoidoscopy are performed to identify the primary orifice and to determine the presence of proctocolitis.

Patients who are neutropenic as a result of hematologic malignancy are particularly susceptible to serious anorectal infection. [52] Mortality rates from anorectal infection in patients with acute leukemia, if untreated, may be more than 45%. [46] Early diagnosis and aggressive surgical drainage may be life-saving in these individuals, with improvement in mortality rates to below 10%. [45] Point tenderness and poorly demarcated induration are the most frequent findings. Frequent reexamination may allow detection of an abscess if initial findings are equivocal. Because of the profound granulocytopenia, fluctuant masses are not usually seen. Necrosis and tissue breakdown may proceed quite rapidly, with extension into the genitalia and pelvis. If spontaneous drainage has already occurred, pain rapidly subsides and further surgical drainage may be postponed. *Pseudomonas aeruginosa* is a common wound isolate, and appropriate perioperative intravenous antibiotics should be administered if it is found. [53]

Treatment

Because of the risk of extension of pus into adjacent spaces and the potential for the development of necrotizing anorectal infection, the treatment of anorectal abscess is a surgical emergency. In one series, the time interval from onset of primary anorectal abscess to necrotizing anorectal infection was from 0.5 to 5 days, with a mortality in excess of 50%. [54] If one chooses to temporize waiting for an abscess to point or become ripe, it must be with the realization that the risks of necrotizing infection and extension into previously uninfected spaces rise dramatically.

In healthy patients with superficial abscesses in the perineal or ischiorectal location, drainage can be performed in the outpatient setting with local anesthesia. All other abscesses should be drained in the operating room with adequate anesthesia, lighting, and surgical instrumentation. If a primary fistula tract is identified and is not thought to encompass a large proportion of the sphincter mechanism, fistulotomy may be done in selected cases. In general, the patient should be counseled as to the possibility of persistent drainage from a retained or unidentified fistula which may require a second operation. [55] An abscess may also recur if the underlying fistula has not been definitively treated.

Antibiotics are usually not necessary, and they may temporarily mask the underlying suppurative infection and delay surgical therapy. Only in occasional cases does a perianal cellulitis resolve with antibiotic therapy alone. In otherwise healthy individuals with minimal infection of the surrounding tissues, incision and drainage of the abscess is all that is required. Patients with significant underlying disease, such as diabetes, acute leukemia, valvular heart disease, or extensive soft tissue infection, benefit from perioperative antibiotics. The choice of antibiotics should be directed by the clinical situation and culture results but, in general, both gram-negative aerobic and anaerobic bacteria should be covered. Ticarcillin/clavulanate, piperacillin/tazobactam, or a broad-spectrum cephalosporin are recommended for empiric coverage, but a particular clinical situation may mandate antibiotics with specific anaerobic, enterococcal, or pseudomonal coverage. The most common wound isolates are polymicrobial with *Escherichia coli, Proteus vulgaris, Bacteroides* species, streptococci, and staphylococci predominating. [56] A high proportion of necrotizing anorectal infections contain *Clostridium* species. [54] Immunosuppressed patients often demonstrate *Pseudomonas aeruginosa*. [45]

Postoperative management consists of frequent wound inspection, warm sitz baths, attention to stool consistency, and judicious analgesia. The wound should be

observed to heal from the base up so that skin bridges do not form, allowing the abscess to recur. If persistent drainage occurs, a second operation for fistulotomy is necessary. Warm baths improve hygiene and offer some symptomatic relief. Narcotic analgesics and perirectal pain both predispose to constipation, so a high-fiber diet, bulk-forming agents, or laxatives should be prescribed.

The presence of an anorectal fistula is an indication for operation. The operative approach depends on the location of the fistulous tract in relation to the sphincteric mechanism. Anorectal manometry has been used to improve the clinical and functional results of surgery for fistula-in-ano. [57] The basic prerequisites for successful therapy of a fistula include removal of the primary orifice, identification and opening of the entire extent of the fistula, and conservation of as much external sphincter as possible. Postoperative care is similar to that for anorectal abscess. In a series of 624 patients undergoing anal fistula surgery the fistula recurred in 8%, and 45% complained of some degree of postoperative incontinence. [58] A novel fibrin sealant has been touted as a less invasive method to heal fistulae. Further refinement is needed to improve the healing rates and lessen the chance of recurrences. [59]

Anorectal disease as a manifestation of Crohn's disease requires special consideration. In addition to standard therapy with 5-aminosalicylate derivatives and immunosuppressives, the use of metronidazole or ciprofloxacin is modestly beneficial in the healing of perineal Crohn's disease. Unfortunately, the required long-term therapy with metronidazole is associated with several side effects, most notably paresthesias. Also, discontinuation of therapy is often associated with flaring of disease. [60] Conservative surgical techniques are usually adequate to drain abscesses, reduce inflammation, and provide relief of symptoms. [61] In one study, proctectomy—once widely practiced—was necessary in only 12% of patients with complicated perianal Crohn's disease. [63] Surgical diversion of the fecal stream, usually in conjunction with resection of diseased intestine or a local anorectal procedure, may be necessary for perianal disease. [62] Infliximab, a chimeric monoclonal antibody to tumor necrosis factor, has emerged as an agent with impressive effectiveness for persistent Crohn's perianal fistulous disease. A controlled trial using 5 mg/kg at 0, 2, and 6 weeks improved (68%) and healed (55%) of patients compared to those receiving placebo (26% and 13%, respectively). [63]

RECTAL PROLAPSE

Rectal prolapse is simply protrusion of the rectum through the anal orifice. Complete rectal prolapse, or procidentia, is the classic situation in which all layers of the rectum visibly descend through the anus. Occult rectal prolapse refers to internal intussusception of rectal tissue without visible protrusion at the anus. Mucosal prolapse is a common condition in which only distal rectal tissues and not the entire rectal circumference protrude through the anus.

Rectal prolapse in children is an uncommon problem usually seen in infancy. It may be idiopathic, associated with congenital defects, such as spina bifida or myelomeningocele, or associated with cystic fibrosis. Prolapse occurs with defecation and usually reduces spontaneously. Treatment is conservative, and the condition is often self-limited.

Rectal prolapse in adults occurs at least 3 to 10 times more often in women than men and is not associated with multiparity. Men may develop prolapse at any age, but in women, the peak incidence is in the sixth and seventh decades. It is associated with poor tone of the pelvic musculature, chronic straining at stool, fecal incontinence, and, sometimes, neurological disease or traumatic damage to the pelvis.

Pathogenesis

Anatomic defects that have been described with rectal prolapse include a weakened endopelvic fascia and diastasis of the levator ani, loss of the normal horizontal rectal position in the sacrum, an abnormally deep pouch of Douglas, a redundant rectosigmoid colon, and a weak anal sphincter. [64] Most authors support the view that prolapse is caused by the intussuscepting rectum and that most of the anatomic defects described occur secondarily. Weakening of the fascial attachments of the rectum to the presacral fascia allows lengthening of the rectosigmoid and its mesentery. The normal positioning of the rectum in the sacral hollow is lost. The subsequent vertical orientation of the rectum enhances the ability of the rectum to intussuscept. Chronic straining in a misguided attempt to evacuate the internally prolapsing rectal tissue only serves to exacerbate the problem. Signs of pelvic neuropathy and anal sphincter dysfunction are common in patients with rectal prolapse. Many patients complain of partial or major fecal incontinence. On manometric evaluation, incontinent patients have low basal and voluntary contraction pressures. [65] Denervation of striated musculature on electromyogram, perineal descent, and absence of the anocutaneous reflex are also common findings. The presence of disturbed sphincter function and pelvic denervation may explain the disappointingly high incidence of persistent incontinence after surgical correction of the prolapse. Manometric findings associated with a higher risk of postoperative fecal incontinence include a resting anal pressure of less than 10 mm Hg and a maximal voluntary contraction pressure of less than 50 mm Hg. [66]

Clinical Manifestations

Patients complain of prolapse of tissue with defecation. As the condition progresses, rectal prolapse may occur with straining or even upright posture alone. Common accompanying symptoms include straining at stool, the sensation of incomplete evacuation, tenesmus, and fecal incontinence. Protrusion of the rectum through the anus is a striking clinical sign. Complete rectal prolapse is signaled by the presence of red concentric mucosal folds with a palpable double thickness to the rectal wall tissue. The protruding rectum may extend many centimeters, and usually the lumen tip points slightly posteriorly. The patient is asked to sit and strain to produce prolapse if it is not immediately obvious. Endoscopic or barium examination is performed on all patients with rectal prolapse to exclude tumors and mucosal lesions. Sigmoidoscopy may reveal changes consistent with solitary rectal ulcer. A voiding defecogram is the best way to identify occult prolapse (internal intussusception).

Complete rectal prolapse must be differentiated from mucosal prolapse, prolapsing internal hemorrhoids, anorectal varices, anal polyps, benign and malignant anorectal tumors, and hypertrophic anal papillae. Mucosal prolapse is characterized by a short segment of mucosa with disordered or radially arranged (not concentric) mucosal folds. Internal hemorrhoids usually have a varicose appearance and are separated into discrete cushions.

Every attempt should be made to manually reduce a persistently prolapsed rectum to avoid potential complications such as strangulation, ulceration, bleeding, and perforation. Some form of intravenous sedation may facilitate manual reduction. Placing granulated sugar on the prolapsed mucosa often eliminates edema and allows reduction. [67] Gangrene of the anterior rectal wall, a surgical emergency, is occasionally associated with evisceration of small bowel onto the perineum.

Treatment

Mucosal prolapse may be treated with procedures designed to remove redundant tissue and induce local fibrosis (see previous discussion of treatment of internal hemorrhoids). There is controversy over the appropriate treatment for occult rectal prolapse. To oversimplify, occult prolapse may be best treated surgically if fecal incontinence or chronic solitary rectal ulcer is present and conservatively if defecation difficulties or lesser symptoms predominate. [68] One study [69] suggests that sclerotherapy is successful if there is only a small associated rectocele and short perineal descent but that transanal excision of prolapsing mucosa is necessary if the rectocele and perineal descent are more prominent.

To avoid complications and ongoing damage to the pelvic floor and sphincter muscles, complete rectal prolapse should be surgically corrected. Perineal muscle exercises and buttock strapping offer palliation in the patient who refuses or is unable to undergo surgery. There are many surgical options advocated for the treatment of rectal prolapse, but they can be simply summarized as follows. Management in healthy patients involves replacement of the rectum into the sacral hollow with or without resection of redundant rectosigmoid colon. The two intra-abdominal operations that have been popularized in the United States are the anterior sling rectopexy (Ripstein procedure) and abdominal proctopexy with or without sigmoid resection.

Ripstein operation involves mobilization of the rectum to the tip of the coccyx and attachment of the rectum to the presacral fascia by means of a band of nonabsorbable plastic such as Teflon or Marlex mesh. Abdominal proctopexy as a sole procedure can be performed with very acceptable recurrence rates and function. Constipation is common in patients who are continent, and continence is not assured in others. Internal anal sphincter pressures and continence usually improve after rectopexy but not to normal values. [70] A laparoscopic approach has been used to further decrease operative morbidity. [71]

Abdominal proctopexy and sigmoid resection as a combined procedure eliminates two of the theorized causes of rectal prolapse by fixing the rectum directly to the sacral hollow by means of nonabsorbable sutures and removing the redundant sigmoid colon. Prosthetic materials, such as Marlex, are generally not placed in the peritoneal cavity if sigmoid resection is performed because of the risk of contamination of the mesh and resultant sepsis. In a series of 102 patients with abdominal proctopexy and sigmoid resection, 80% had good to excellent results, no mortality, and improved morbidity, compared with those treated with the Ripstein procedure. [72] Abdominal proctopexy and sigmoid resection is physiologically the most demanding procedure and should be used only in patients in good general physical

condition. These procedures have continued fecal incontinence as the major postoperative complaint. Patients who continue to have incontinence 6 to 12 months after definitive correction of the rectal prolapse often benefit from a Parks postanal repair or a plication sphincteroplasty. [73], [74] A systematic review suggested that residual fecal incontinence was less common after abdominal (vs. perineal) approaches and that division (vs. preservation) of the lateral ligaments during rectopexy was associated with less recurrent prolapse but at the price of more constipation. [75]

In the elderly or debilitated patient, a perineal or extra-abdominal approach is associated with acceptable morbidity and mortality rates. An elegant study of perineal rectosigmoidectomy for complete prolapse in 114 elderly patients demonstrated a recurrence rate of 10% with no mortality and good functional results. [76] A diverting colostomy may be also be an appropriate alternative for this group of high-risk patients.

ANAL FISSURE

Anal fissure is a painful linear ulcer in the anal canal. Primary anal fissures are usually found in young and middle-aged adults and occur equally in males and females. Primary fissures are located in the posterior midline more than 90% of the time. The remainder are found in the anterior midline. Fissures may occur secondary to an underlying disease such as inflammatory bowel disease (especially Crohn's disease), proctitis, leukemia, carcinoma, and, rarely, syphilis or tuberculosis. These lesions, in contrast to primary fissures, are usually found in a more lateral position.

Etiology

The elliptical arrangement of the anal sphincter fibers offers less muscular support to the anal canal posteriorly. This deficient support predisposes the posterior anal canal to traumatic tears during passage of a large, hard stool. Fissures may become chronic because of high resting anal sphincter tone and repeated trauma during passage of fecal boluses. Rectal distention normally causes a transient internal anal sphincter relaxation. Patients with anal fissure have an abnormal overshoot contraction following the normal relaxation. The overshoot contraction may explain the reflex spasm and pain seen after defecation. This phenomenon disappears after successful treatment of the fissure. [77] Preoperative maximal resting pressure and maximal contraction pressure are also elevated in patients with fissure. [78], [79] A histopathological study documented the presence of fibrosis throughout the anal sphincter in patients with anal fissure. [80] Recent studies have emphasized the potential role for ischemia in fissure disease. Vascular perfusion of the anoderm is lower in the posterior midline than in other locations and measurements performed are particularly low in patients with anal fissure. Measurements before and after lateral sphincterotomy in patients with chronic anal fissure demonstrated the inverse relationship between anal sphincter pressures and posterior anoderm perfusion pressures. [81], [82]

Clinical Manifestations

Severe pain associated with scant, bright red rectal bleeding is the hallmark of anal fissure. The pain occurs during and after defecation ("like passing a piece of glass") and usually seems out of proportion to the clinical findings. Severe pain may make anoscopy impossible, and even digital examination is difficult without topical anesthesia. The fissure is best identified by simple inspection after spreading the buttocks. Acute fissures are small, linear tears oriented perpendicular to the dentate line in the posterior midline. Fissures located in a lateral position should prompt a search for a secondary etiology. If an acute anal fissure does not heal promptly, certain characteristic secondary features develop. The classic triad of chronic anal fissure includes the fissure, a proximal hypertrophic papilla, and a sentinel pile or fibrotic nubbin of skin found at the anal verge (Fig. 92-2).

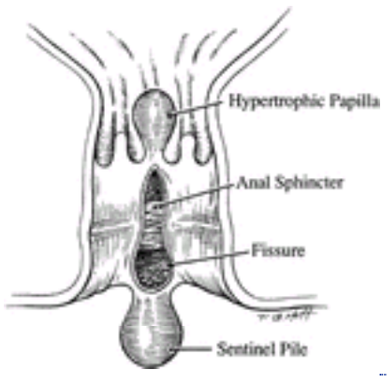

FIGURE 92-2. The classic triad of chronic anal fissure: hypertrophic papilla, anal fissure, and sentinel pile.

Treatment

Prescribing a high-fiber diet and adequate fluid intake should soften stools. Hydrophilic bulk agents or salts of dioctyl sulfosuccinate are important aspects of therapy because many fissures are precipitated by the traumatic passage of hard, dry stools. The temporary use of topical anesthetic preparations containing agents such as benzocaine or pramoxine hydrochloride provides symptomatic relief. The use of these medications, in addition to warm sitz baths two to three times daily, acts to decrease sphincter spasm to provide additional relief. [83] A combination of bran supplements and sitz baths was shown to be superior to a topical anesthetic or hydrocortisone cream with respect to symptoms and healing. [84] With such a conservative regimen, most acute fissures heal in 4 to 6 weeks. Occasionally, patient anxiety, severe pain, or other considerations may rule out such a prolonged trial of conservative therapy.

Chronic fissure usually requires some form of surgical therapy to reduce internal sphincter tone. Reduced sphincter tone permits easier passage of the fecal bolus through the anal canal. Repetitive injury is avoided so that the traumatic tear may finally heal. The beneficial effects of sphincterotomy on internal sphincter spasm and healing of anal fissure have been well documented, and surgical cure rates on the order of 95% can be expected. [77] Midline sphincterotomy with fissurectomy also offers definitive therapy for chronic anal fissure. However, in a retrospective study of 300 patients, a higher rate of postoperative complications was seen compared with the lateral sphincterotomy. [85] Also, an unfortunate complication of posterior midline sphincterotomy and fissurectomy is development of a residual keyhole deformity of the anus, which predisposes to long-term leakage of feces and mucus. Another approach to treating sphincter spasm is manual dilation. The anus is dilated to six fingers under regional anesthesia. A metaanalysis of operative techniques concluded that internal anal sphincterotomy was superior to manual dilation for both fissure healing and the occurrence of incontinence to flatus. [86]

Chemical methods may also be used to lower sphincter pressures to allow healing. Topically applied nitroglycerin heals fissures by reducing maximum resting pressure and by increasing anodermal blood flow. [87] Several open and controlled trials [88], [89] have demonstrated the efficacy of 0.2% nitroglycerin ointment although a large, controlled trial [90] failed to confirm this. Headaches are a frequent adverse effect of even a pea-sized application of nitroglycerin. For this reason, other topical smooth muscle relaxants have been investigated. A controlled trial of nearly 300 patients found that nifedipine gel healed 90% of fissures at 3 weeks and more recently, diltiazem ointment healed 75% of patients after 2 to 3 months of therapy. [91], [92] Headaches were not seen. Botulinum toxin injected into the sphincter muscles directly through the perianal skin heals the majority of fissures (>80%), a finding confirmed in a controlled trial (73% vs. 13% healing at 2 months). [93] Temporary mild fecal incontinence appears to be rare. In a direct comparison, botulinum toxin healed 96% of fissures versus 60% using 0.2% nitroglycerin ointment. [94] A randomized trial found surgical sphincterotomy to be more effective than nitroglycerin. [95] However, sphincterotomy may cause fecal incontinence in approximately 8% of patients. [96] A reasonable, but not yet evaluated, strategy to treat chronic anal fissure disease is to use a topical muscle relaxant or botulinum toxin initially and reserve surgical sphincterotomy for those who fail to respond.

ANAL STENOSIS

Anal stenosis is an abnormal narrowing of the anal canal associated with a variety of underlying diseases. Patients may complain of narrow stools, painful or resistant defecation, and bleeding from recurrent anal tears. The clinician is typically unable to perform a digital rectal examination. Malignant causes of anal stenosis include anal and rectal cancer and, less commonly, transmural invasion of the anorectum by a urogenital malignancy. Common causes of benign anal stenosis are prior rectal

surgery, trauma, and inflammatory bowel disease. Postsurgical stenosis of the anal canal is most often a result of injudicious excision of anal skin during hemorrhoidectomy. [97] Laxative abuse and chronic diarrhea are also associated with anal stenosis because lack of a solid fecal bolus to intermittently dilate the anus causes hypertrophy and narrowing of the anal sphincters. [98] Other causes of anal stenosis include radiation injury, tuberculosis, actinomycosis, lymphogranuloma, and congenital abnormalities.

Treatment is based on the severity and location of the anal stenosis. Mild strictures respond to periodic dilation and a high-fiber diet. Severe stenosis usually requires some form of anoplasty to increase the amount of perianal skin. [99] Lateral internal sphincterotomy is often used in conjunction with anoplasty. Cure rates in excess of 90% are usually seen. [97]

SOLITARY RECTAL ULCER

Solitary rectal ulcer is a chronic benign disorder related to abnormal defecation. The usual presenting symptoms are the passage of mucus and blood, altered bowel habits, anorectal pain, a feeling of incomplete evacuation, and straining at defecation. Classically at sigmoidoscopy, a shallow, discrete, 1-cm punched-out ulcer with a hyperemic margin is seen 7 to 10 cm from the anal verge on the anterior wall. However, ulcers range from 0.5 to 4 cm in diameter, are located a few centimeters to 13 cm from the anus, and are occasionally found on the posterior wall. Furthermore, there may be multiple ulcers or no ulcer at all. Sometimes only a localized erythematous or nodular area of mucosa is noted. Initial misdiagnosis is common and the lesion may be mistaken for inflammatory bowel disease or neoplasia. [100] Characteristic histological changes seen on biopsies taken from abnormal mucosa or ulcer margins include fibrous obliteration of the lamina propria, disorientation and thickening of the muscularis mucosae and regenerative changes in the crypt epithelium. [101]

Pathogenesis

The pathogenesis of solitary rectal ulcer is related to prolonged straining at stool and difficulty initiating defecation. Digital evacuation is frequently practiced in these patients, but trauma caused by self-digitation probably plays a minor role. Although clinically apparent rectal prolapse through the anal orifice is only occasionally seen with solitary rectal ulcer, careful observation during sigmoidoscopy or defecography demonstrates subtle forms of mucosal prolapse and delayed evacuation during defecation in 90% of these patients. [102], [103] However, patients with solitary rectal ulcer syndrome have higher sphincter pressures and thicker rectal walls (primarily muscularis propria) than patients with complete rectal prolapse. [104], [105] Womack and colleagues [102] have shown that rectal prolapse coupled with high transmural pressures during defecation is probably responsible for the mucosal trauma that causes ulceration. The anterior wall mucosa, 7 to 10 cm proximal to the anal margin, is often the first and largest part of the intussusceptum as it descends downward into the anal canal. This corresponds to the usual location of ulceration seen clinically.

Treatment

Complications of massive bleeding, rectal stricture, and even ulcer penetration into the prostate gland have been reported but are so rare that the patient should be reassured as to the benignity of the syndrome. [106], [107] Because solitary rectal ulcer is caused by repeated mechanical trauma of the prolapsing mucosa during defecation, it is appropriate to begin treatment by eliminating straining and improving bowel habits. Beneficial results should not be expected for months, and relapses are common. [108] Sulfasalazine, antibiotics, and enemas of steroids or 5-aminosalicylic acid are of no use, but sucralfate retention enemas may be beneficial. [109] Symptoms refractory to conservative management may respond to surgical rectopexy. [110], [111] Biofeedback therapy may be helpful as a primary therapy and may also decrease postsurgical symptomatic recurrences. [100], [112]

FECAL INCONTINENCE

Fecal incontinence is the release of rectal contents against one's wishes. It is perhaps the most embarrassing and socially disabling of all gastrointestinal problems. Prevalence rates vary, but it is clear that the elderly and institutionalized persons are particularly victimized. More than 16% of elderly persons living in residential homes are incontinent of stool at least twice a month, and 10% are incontinent on at least a weekly basis. [113] Risk factors in the elderly include a history of urinary incontinence, neurological disease, poor mobility, cognitive decline, and age older than 70 years. [114] Random surveys of the general population identify 18% who admit to at least one episode of fecal incontinence and 4% with symptoms more than once a week. [115], [116] The complaint of fecal incontinence is not readily volunteered because of the social stigma attached to it, and instead the initial complaint may be "diarrhea." [117] Clinically, incontinence must be placed in the context of surrounding circumstances. The frequency of fecal soiling in an individual with urgency may simply reflect availability of a toilet. Fecal soiling in a mentally disabled or demented person might relate directly to a communication or recognition problem.

Pathophysiology

Anal Canal and Sphincters The anal canal is 3 to 4 cm long and represents the distal outlet of the gut. It normally remains closed as an anteroposterior slit by tonic contractions of the surrounding musculature. Spongy vascular tissues within the canal are distensible and play a minor, fine-tuning role in fecal continence by assisting with anal closure. Minor degrees of seepage after hemorrhoidectomy may be caused by partial excision of this tissue. The circular smooth muscle layer of the rectum terminates in the thickened, rounded internal sphincter muscle. The internal sphincter is under autonomic control and is responsible for the majority of resting anal canal tone. The external sphincter is a surrounding sleeve of striated muscle that blends into the puborectalis and levator ani muscles proximally and extends to just below the internal sphincter margin distally. It is a voluntary muscle with somatic innervation from the pudendal nerve (sacral branches S2, S3, and S4). Although it is a striated muscle, the external sphincter maintains a degree of tonic neural activation and thus contributes to resting anal tone (approximately 30%). However, it assumes a major role in maintaining continence by contracting in a reflex manner during times of sudden rectal distention or increased abdominal pressure (i.e., coughing, lifting). Voluntary contraction of the external sphincter approximately doubles the normal resting tone of the anal canal. Traumatic obstetrical and surgical injuries, prolapsing rectal and hemorrhoidal tissues, and various neuropathic diseases are examples of processes involving the anal canal and sphincters that may cause incontinence.
Puborectalis Muscle The puborectalis muscle attaches to the symphysis pubis and wraps around the posterior aspect of the anorectal junction effectively forming a sling. Tonic contraction of this muscle produces an acute angle of approximately 80 degrees between the axes of the rectum and anal canal, forming an important mechanical kink or barrier to the passage of stool. The action of the puborectalis may also contribute to an as yet unproven flap-valve effect that produces an occlusion of the upper anal canal by the anterior rectal mucosa. [118] Sudden increases in intra-abdominal pressure accentuate the anorectal angle to reduce transmission of pressure into the anal canal so that, in concert with the external sphincter, continence is maintained. The anorectal angle formed by the puborectalis muscle is arguably the most important structure in the preservation of gross fecal continence. [119], [120] Any traumatic or neuropathic injury to this muscle causing persistent straightening of the anorectal angle leads to major fecal incontinence.
Anal Sensation Although the rectum itself is sensitive only to stretch, the anal canal epithelium is endowed with a rich network of nerve endings sensitive to touch, pain, and temperature. Together, these sensory inputs make up an important part of so-called anal sampling, which allows differentiation between solid, liquid, and gas contents in the rectum. After material enters and distends the rectum, a transient reflex relaxation of the internal sphincter occurs (the rectoanal inhibitory reflex) to permit the rectal contents to come into contact with the sensitive anal canal mucosa. Using tactile and perhaps thermal properties, anal sampling differentiates flatus from solid or liquid stool to allow selective passage of these materials. [121] Simultaneously, the external sphincter reflexively contracts to maintain continence until voluntary contractions consciously take over. Within a short time, rectal accommodation to the new volume deactivates stretch receptors, and the sensation of urgency dissipates.
Rectum The motility, compliance, and sensation of the rectum are important features of fecal continence. Baseline rectal contractions are of higher frequency and amplitude than are those in the sigmoid colon. This reverse peristalsis acts as a subtle barrier to fecal flow. The rectum has the ability to accommodate different fecal volumes presented to it. This reservoir function maintains continence and allows for appropriate timing of defecation. In a similar manner, the sampling reflex and a normal call to stool depend on intact rectal sensation. Neuropathies caused by diabetes and other diseases impair rectal sensation and therefore interfere with continence. [122] Poor distensibility of the rectum in ulcerative colitis, radiation proctitis, and chronic rectal ischemia may lead to fecal urgency and incontinence. [123] Similar symptoms in those with irritable bowel syndrome are probably caused by hypersensitivity to distention and abnormal motility patterns in the rectum.
Stool Volume and Consistency Nearly everyone has experienced fecal urgency and perhaps incontinence during an acute diarrheal illness. Large volumes of liquid stool pose a special challenge to even healthy mechanisms of continence. Some persons are incontinent of stool only if stressed with a liquid bolus; others are continent of stool but cannot retain flatus. Any disease that causes diarrhea, especially if it is associated with large volumes and rapid transit, may produce fecal incontinence.
Defecation The process of normal defecation depends on intact mechanisms of continence. The sequence of events leading to defecation is initiated when material from the sigmoid colon enters the rectum. Rectal distention causes reflex relaxation of the internal anal sphincter, exposing the rectal contents to the anal mucosa so

that sampling may occur. External sphincter contraction maintains continence until the rectum can accommodate to the bolus. After feces fills the rectum to a sufficient degree, the urge to defecate is experienced. If a conscious decision to initiate defecation is made, a squatting or sitting position is assumed. This position straightens the anorectal angle in preparation for passage of stool. If the urge is strong and the individual is exerting conscious resistance to passage of stool, simply relaxing voluntary control allows defecation to proceed. Otherwise, a Valsalva maneuver is performed to increase intra-abdominal pressure and push the feces toward the anal canal. The pelvic floor descends, the rectum contracts, external sphincter activity is inhibited, and the fecal bolus is expelled out of the rectum. Stool is passed piecemeal with episodic straining or, alternatively, propulsive contractions may empty portions of the left colon in a single motion.

Clinical Manifestations

It is clinically useful to categorize fecal incontinence as either partial or major. [115] Partial incontinence is defined as minor soiling of loose stools and poor control of flatus. The elderly and those with internal sphincter deficiencies and prolapsing hemorrhoidal or rectal tissues are particularly prone to minor soiling. Fecal impaction also predisposes to partial incontinence. A rectum chronically distended with feces continuously induces internal sphincter relaxation, allowing leakage of stool in those with weakened sphincter mechanisms. Major incontinence refers to frequent loss of control of even solid stools. Neurological diseases, traumatic injuries, and surgical damage to the puborectalis or sphincter muscles may cause major incontinence. One may also consider the category of “leakers” characterized by the loss of small amounts of liquid or solid stool smears. These patients typically remain continent of flatus and stool and have near normal sphincter pressure and innervation. Many, but not all, have identifiable pathology such as hemorrhoids or fistulae on physical examination. [124] A comprehensive list of the causes of fecal incontinence is provided in Table 92-3. Many incontinent patients have no obvious predisposing history of major trauma, anorectal disease, or neurological disease. Careful studies using electromyography and other neurophysiological techniques have identified striated muscle denervation damage in most of these patients with idiopathic incontinence. [125] Perineal descent associated with chronic straining at stool may cause stretch injury and subsequent denervation of the pudendal nerve. [126], [127] Pudendal nerve injury and occult sphincter disruption commonly occur during vaginal delivery of childbirth. [128] Approximately 30% of women will have occult sphincter defects detectable by endosonography after their first vaginal delivery and more than 10% will complain of urgency or incontinence. [129] Multiparity, high birth weight, forceps delivery, and third-degree perineal tears are important risk factors. It is not surprising that more than one mechanism of continence may be disturbed in those with neuropathic incontinence. [130] Careful testing has found that motor neuropathy of the external sphincter and pelvic floor is associated with damage to the internal sphincter and a sensory deficit of the anal canal. [131]

Diarrhea
Fecal impaction
Irritable bowel syndrome
Anal pathology
Anal carcinoma
Congenital abnormalities
Protruding internal hemorrhoids
Rectal prolapse
Perianal infections
Fistula
Injury

Cauda equina lesions
“Idiopathic” (primary neurogenic)
Childbirth injury
Chronic constipation
Descending perineum
Old age

TABLE 92-3 Causes of Fecal Incontinence

An important cause of fecal incontinence not associated with pathology of the pelvic nerves or sphincter muscles is irritable bowel syndrome. The incontinence of irritable bowel syndrome commonly occurs in those with diarrhea-predominant symptoms associated with fecal urgency and cramping relieved by defecation. Physiological or emotional stressors lead to rapid delivery of loose stools and flatus into a hypersensitive rectum. This produces occasional soiling even in the individual with an intact sphincter mechanism.

Clinical Evaluation After the existence of incontinence has been established, the clinical evaluation begins with an assessment as to the frequency, severity, and circumstances surrounding the incontinent episodes. Does the patient suffer from partial or major incontinence? How acute are the symptoms? Are the episodes associated with urgency, or is there no prior warning? Does incontinence occur on a background of constipation or diarrhea? Does the patient require assistance to reach the toilet? After incontinence has been characterized, detailed questions concerning childbirth, prior anorectal surgery, rectal prolapse, hemorrhoids, and straining at stool should be addressed. A history of central or peripheral nervous system diseases, diabetes mellitus, prior pelvic irradiation, or diarrheal disease should be elicited. Perianal inspection and digital examination provide clues to the cause of incontinence. Anal deformities, tumors, perianal infections, fistulae, and prolapsing hemorrhoids may be visually apparent. Absence of the anal wink (contraction of the subcutaneous portion of the external sphincter) in response to a perineal pin stroke suggests a neuropathic process. Digital examination allows a crude assessment of anal resting and voluntary squeeze tone. A rough estimate of the anorectal angle and puborectalis function can be made by palpation of this muscle in the posterior midline at the proximal edge of the external sphincter during rest and voluntary squeeze. The presence of fecal impaction, rectal prolapse, and perineal descent can also be determined.

Clinical Testing Several tools are available to evaluate the mechanisms of continence. The extent of investigation depends on local expertise and the patient’s clinical presentation.

Anoscopy and sigmoidoscopy. Inspection of the distal colon is a minimum requirement in the evaluation of incontinence. Discovery of tumors or mucosal inflammation (infectious, ulcerative, ischemic, or radiation proctitis) directs treatment and probably eliminates the need for further evaluation.

Manometry. Sphincter function is determined by measuring resting and maximal squeeze pressures of the anal canal using balloons, miniaturized transducers, or perfused catheters. Rectal balloon inflation is performed to measure the reflex relaxation of the internal sphincter and contraction of the external sphincter muscles. Sophisticated techniques can determine spatial sphincter defects by cross-sectional mapping of the whole sphincter. [132] The techniques of dynamic manometry and prolonged anal manometry using a sleeve sensor may offer more information than standard static anal manometry. [133], [134]

Tests of rectal compliance and sensation. Estimates of rectal sensation are made by inflating a balloon in the rectum and measuring various subjective thresholds such as first volume sensed, volume producing urgency, maximum tolerated volume, and the delay in sensation. [135], [136] Rectal compliance is determined by obtaining concurrent balloon volume and pressure measurements so that pressure-volume curves can be generated.

Neurophysiological tests. External sphincter and puborectalis muscle activity can be measured using conventional concentric needle electromyogram (EMG) or more sophisticated single-fiber EMG. These techniques measure muscular denervation and reinnervation characteristic of neuropathy and allow sphincter mapping but require considerable expertise and are uncomfortable for the patient. Nerve dysfunction can be more directly characterized by measuring pudendal nerve terminal motor latencies and pudendal evoked potentials. [125], [137] Pudendal nerve terminal motor latency can be easily measured using a simple digitally placed electrode. Abnormal nerve conduction, especially bilaterally, may predict a poor surgical outcome. [138]

Imaging modalities. Muscle thickness and defects in both the internal and external sphincter can be mapped in patients with traumatic or idiopathic incontinence without radiation or the discomfort of EMG needle electrodes. Anal endosonography offers an exciting new way to image the anorectal angle and sphincter musculature with high resolution. [139] Endosonography after vaginal delivery may detect clinically inapparent sphincter tears that may be associated with subsequent incontinence. [140] Endosonography may also predict the response to nonoperative treatment in men with incontinence. [141] Using surgical anatomy at the time of repair as a gold standard, endoanal MRI may be even more accurate than sonography. [142]

Anal sensory tests. Miniature probes can now measure thermal and electrical sensitivity of the anal canal. [121], [143] Information from these novel tools may offer insights into the anal sampling reflex and anal sensory abnormalities identified in incontinent patients. [144]

Defecography. Defecography radiographically evaluates defecation by video fluoroscopic imaging during actual voiding of a simulated barium stool. [145] It is well tolerated and easy to perform. Static and dynamic measurements of the anorectal angle, pelvic floor, and puborectalis function are made during rest, squeeze, and attempted defecation. Pathology best recognized during defecation, such as perineal descent, rectal prolapse, enterocele, and rectocele, can be diagnosed, although symptoms may not correlate well with these defects. [146]

Continence testing. Several tests have been devised to challenge the integrated mechanisms of continence. These tests quantitate continence by measuring

leakage of rectally infused saline or resistance to passage of a solid object. [147] They offer only an approximation of the clinical symptom and cannot tease out specific pathologies. However, continence tests standardize the measurement of incontinence and require no expensive equipment or particular expertise. They may be useful for comparing groups of patients or assessing an individual's response to therapy over time. The strategy employed to evaluate fecal incontinence depends on the patient's clinical presentation, the availability of investigative tools, and the likelihood of altering future therapy. Soiling associated with an acute diarrheal illness probably requires no specific anorectal evaluation other than evaluation of the diarrhea itself. In a similar vein, the discovery of ulcerative proctitis by proctosigmoidoscopy requires no further anorectal studies, and treatment may be instituted immediately. For the majority of cases that are less clear-cut, anorectal manometry, combined with a balloon inflation estimate of rectal sensation, is an important functional study. It also allows for future treatment in the form of anal biofeedback if necessary. Endosonography, or perhaps MRI, offer the best anatomic testing. Defecography, rectal compliance tests, and nerve conduction measurements are useful adjunctive tools depending on local expertise.

Treatment

Fecal incontinence often responds well to a combination of relatively simple interventions. Therapy is at least partially dependent on the underlying cause. As a first priority, diarrheal stools, if present, must be treated. Solid stools are much easier to retain than liquid stools, so this simple measure alone may eliminate all symptoms. If possible, the underlying cause of diarrhea should be corrected, but, if not, empiric therapy with fiber agents or antidiarrheals is appropriate. Loperamide and diphenoxylate are effective in producing solid stools and reducing stool frequency in those with chronic diarrhea and incontinence. [148], [149] However, loperamide does this more effectively than diphenoxylate and also appears to improve continence to a standard saline load test. [149], [150] Seepage of liquid stools around a fecal impaction should, of course, not be treated as diarrheal stools. Instead, the impaction must be cleared with enemas and a treatment plan for constipation instituted. Incontinent debilitated patients or those with nervous system injuries usually respond best to a bowel program of regular defecation. Such a program should take advantage of the gastrocolonic response and judiciously use constipating agents or enemas and suppositories as appropriate. Fiber is useful for the frequent, low-volume, loose stools of irritable bowel syndrome but may need to be restricted for diseases with poor rectal reservoir capacity in order to decrease fecal volume. Anticholinergics should be tried to blunt the gastrocolonic response in patients with irritable bowel syndrome with urgency-associated incontinence after meals. Practice of sphincter exercises several times daily to improve both the tone and the awareness of the pelvic diaphragm and sphincter muscle is a useful adjunct to treatment in the incontinent patient.

If incontinence persists despite the measures outlined and the patient is motivated, sensitive to rectal distention, and able to contract the external sphincter, anal biofeedback should be attempted. [151], [152] This technique applies simple operant conditioning to the anal sphincter. Similar techniques can be used to gradually lower sensory thresholds to rectal distention in those with impaired rectal sensation caused by diabetes or other neuropathies. [122], [135] A report of biofeedback using a simple anal plug to record external sphincter contractions argues against the need for a rectal balloon, although a recent controlled trial suggests that enhancement of rectal sensitivity is important. [153], [154] Large well-designed studies are needed to confirm the approximate 70% success rates of biofeedback therapy. [155], [156] Conditions that may predict a poor response to biofeedback therapy include severe neuropathy causing poor rectal sensation and near absent external sphincter contraction during squeezing, irritable bowel syndrome, anterior resection of the rectum, and the surgical keyhole deformity of the anal canal caused by previous posterior sphincterotomy. [152], [153], [157] Urgency incontinence responds better than passive leakage. [158]

Patients with major fecal incontinence unresponsive to medical management are the most appropriate candidates for surgery. Surgical correction of rectal prolapse or third-degree hemorrhoids should be performed to improve the fecal soiling associated with these conditions. Several operations have been advocated for intractable symptoms. Incontinence caused by trauma, anal surgery, or obstetrical injury may respond to simple external anal sphincter apposition or overlapping repair. [159] Postanal repair is the procedure of choice for complex sphincter injuries or for neuropathic damage to the pelvic floor (often idiopathic) and loss of the normal anorectal angle. [74], [119] More than two thirds of patients can expect good results, although reduction of the anorectal angle cannot be demonstrated. [120], [160] Gracilis muscle transposition (graciloplasty) is a technically demanding procedure that may benefit patients with a destroyed sphincter or congenitally poor pelvic floor development. [161] The addition of an implantable device to electrically stimulate the neoanal sphincter (dynamic graciloplasty) provides additional benefit. [162], [163] More than 60% have satisfactory results but complications requiring reoperation are common. [164] Implantation of an artificial sphincter may be considered for those with nonreconstructable sphincters or severe neurogenic incontinence. Modifications of the device have reduced mechanical complications, but infectious complications still occur and long-term results are adequate in only 50% of patients. [165] Finally, as a last resort, placement of a colostomy should be considered. Substituting management of a stoma for unremitting fecal incontinence may significantly improve the quality of life for selected patients.

PRURITUS ANI

Pruritus ani is an annoying itchy sensation of the anus and perianal skin. It may be temporary or chronic, unrelenting, and difficult to treat. Pruritus is often associated with burning and soreness. Periods of intense itching vary in frequency but are characteristically most disturbing at night after daytime distractions are removed. It affects 1% to 5% of the population with a male-to-female predominance of 4:1. [166]

Etiology

Pruritus ani may occur as a symptom of a specific disease affecting the perianal skin or, more commonly, as an idiopathic condition possibly related to residual fecal material (Table 92-4). A number of anorectal diseases, including fissures, fistulae, and hemorrhoids, produce pruritus ani because of fecal soiling and contamination of the perianal region. These lesions make local hygiene especially difficult, and irritated, macerated skin may develop. Pruritus, discomfort, and mucus drainage are more common in those suffering from hemorrhoids than in a control population and often resolve with treatment of the hemorrhoids. [167] Anal malignancies, including Bowen disease, epidermoid cancers, and extramammary Paget disease, may rarely present as pruritus ani and should not be discounted without careful anal inspection, even if symptoms have existed for years. [168]

Anorectal diseases and fecal contamination
Diarrhea
Anal incontinence
Hemorrhoids
Fissures
Fistulae
Rectal prolapse
Malignancy: Bowen disease, epidermoid cancer, perianal Paget disease
Infections
Fungal: candidiasis, dermatophytes
Parasitic: pinworms, scabies
Bacterial (nonvenereal): Staphylococcus aureus, erythrasma
Venereal: herpes, gonococcal, syphilis, condylomata acuminata
Local irritants
Moisture: obesity, excessive perspiration
Soaps: hygiene products
Toilet paper: perfumed, dyed
Underwear: irritating fabrics, detergents
Anal creams, suppositories
Dietary: coffee, beer, acidic foods
Drugs: mineral oil, ascorbic acid, hydrocortisone sodium succinate, quinidine, colchicine
Dermatologic diseases
Psoriasis
Atopic dermatitis
Seborrheic dermatitis

TABLE 92-4 Causes of Pruritus Ani

Candida albicans and dermatophyte infections appear as characteristic localized erythematous rashes but may also be cultured from the perianal area even if skin lesions are not present. *C albicans* is more likely to be identified if random cultures are obtained, but dermatophyte infections, if present, are more likely to be associated with pruritus ani. [169] Pinworm (*Enterobius vermicularis*) causes pruritus ani that is characteristically nocturnal. Children are most commonly affected, but adults, especially those exposed to children, may occasionally become infected. Diagnosis is best made by applying adhesive cellophane tape to the perianal skin early in the morning in an effort to detect eggs. Scabies (*Sarcoptes scabiei*) and pubic lice (*Pthirus pubis*) can also cause pruritus ani. Itching in the genital region and identification of organisms or eggs on pubic hair lead to the proper diagnosis.

Perianal bacterial infections have been implicated in pruritus ani. Separate reports have identified *Staphylococcus aureus* and erythrasma (*Corynebacterium minutissimum*) as pathogens in patients with pruritus ani. [170], [171] However, a controlled study has failed to provide a bacteriologic basis for this condition. [172] A number of sexually transmitted diseases have been associated with pruritus ani. These include herpes simplex, gonorrhea, syphilis, condyloma acuminatum, and molluscum contagiosum. [166] Dermatologic conditions, such as psoriasis and eczema, must also be considered. One series of patients referred to a combined colorectal and dermatologic clinic had a dermatosis, particularly psoriasis, as the most common cause of pruritus ani. [173] A variety of local irritants, allergens, and chemicals that contact the perianal skin may cause pruritus. Perfumes and dyes present in toilet paper and soaps, personal hygiene products, irritating fabrics, laundry detergents, and even well-intentioned medications in the form of topical anal creams or suppositories are examples. Even intravenous steroids and chemotherapies have been implicated. [174], [175] Clinical experience and elimination diets implicate certain dietary products such as coffee, cola, beer, tomatoes, chocolate, tea, and citrus fruits in the production of anal pruritus, although the mechanism is unknown. [176], [177] Any food product that causes diarrhea in a patient may lead to pruritus simply because of frequent fecal contamination of the perianal region.

Idiopathic pruritus ani is usually caused by a combination of perianal skin fecal contamination and trauma. Ambulatory monitoring has shown exaggerated transient internal sphincter relaxation which likely predisposes to subtle fecal leakage in idio-pathic pruritus ani. [178] Not surprisingly, feces and colonic mucous secretions are irritating to perianal skin. [179], [180] Acute diarrhea in an otherwise healthy person may lead to irritation of the perineum because of frequent wiping. Tiny amounts of feces repeatedly contaminate the sore perianal skin, leading to further irritation. Soon the itch-scratch cycle develops, serving to perpetuate skin trauma. Patients with chronic pruritus ani often suffer from frequent loose stools or some degree of fecal incontinence or seepage. This hostile environment is repeatedly traumatized from vigorous wiping or scratching, and adequate healing can never occur. Pruritus is further exacerbated by inadequate perianal hygiene or excessive moisture caused by perspiration, airtight clothing, severe obesity, or a particularly deep-set anus.

Treatment

With patience and time, most causes of pruritus ani are successfully treated. Dermatologic diseases and infectious causes of pruritus ani are uncommon but, if identified, should be treated in the usual manner. Anorectal disorders that confound attempts at good perianal hygiene, such as prolapsing internal hemorrhoids or painful anal fissures, should be corrected. Fecal leakage or incontinence must be aggressively managed to avoid soiling of perianal skin. For the same reason, frequent loose stools should be minimized with antidiarrheals and fiber agents if appropriate. Foods or beverages that produce diarrhea or pruritus symptoms in a particular individual may be discontinued. Blanket recommendations to discontinue or curtail coffee, beer, citrus fruits, and other foods reported to cause pruritus ani lack firm support, but elimination diets may be appropriate in particular cases. The key to management of pruritus ani is to keep the anal area clean and dry while minimizing trauma caused by wiping and scratching. [181] The patient should be instructed to gently cleanse the anal skin with a premoistened pad or tissue after defecation. Witch hazel preparations or soothing lanolin-containing lotions are useful for this purpose. This always removes more residual feces than dry wiping alone. The area should be dried with a blow dryer or a soft tissue using a gentle dabbing, not rubbing, motion. Those with unpredictable small amounts of fecal discharge are instructed to wear a thin cotton pledget. This is barely perceptible when applied to the anus and should be changed frequently throughout the day. Excessive perspiration is corrected with application of baby powder and avoidance of tight, nonporous clothing. Irritating fabrics, greasy salves, perfumed toilet paper, hygiene products, and soaps should be avoided. A 1% hydrocortisone cream may be applied sparingly twice daily during the acute phase of pruritus ani but should not be used for longer than 2 weeks to avoid skin atrophy. Applying a protective ointment (zinc oxide) over the antiinflammatory agent may facilitate healing. For severe nocturnal symptoms, a nighttime dose of a systemic antipruritic such as diphenhydramine is appropriate. Long-standing, intractable pruritus ani has responded very well to intracutaneous injections of methylene blue and other agents. [182], [183]

RECTAL FOREIGN BODIES AND TRAUMA

An astonishing hodgepodge of foreign bodies can become incarcerated in the rectum. [184] These include thermometers, enema tips, tools, bottles, light bulbs, pieces of food, and sexual devices inserted for purposes of medical treatment, concealment, assault, or, most commonly, eroticism. In an attempt to cope with an embarrassing situation, patients may claim the object was inserted to obtain relief from a particular discomfort or symptom. Frequently, the patient may complain of pain or bleeding without admitting to a foreign body insertion. [185] A directed interview and careful abdominal and rectal examination of an often sheepish patient are necessary to identify the foreign body and the potential risk of rectal trauma. Anteroposterior and lateral radiographs should be obtained to determine the object's outline and location and to detect pneumoperitoneum if present. Alternatively, a patient may unknowingly swallow a toothpick or piece of bone that later impacts in the anal canal and may mimic an abscess or fissure. [186]

Nearly all objects can be removed transanally without resorting to surgery. Even if the object is easily palpable, removal under direct vision is the best way to avoid iatrogenic injury. [187] Foreign bodies may be classified by position as low-lying if in the rectal ampulla or high-lying if at or proximal to the rectosigmoid junction. [187] Small, low-lying objects are retrieved transanally using an operative anoscope. Removal of larger objects, such as vibrators or rubber phalluses, may require regional anesthesia, anal dilation, and a grasping forceps. Large, bulky objects, such as glass bottles and light bulbs, require special care. After adequate anesthesia, several Foley catheters are inserted past the object. Air insufflation through the catheters relieves the proximal vacuum effect that may occur during attempted withdrawal. Gentle manipulation coupled with slow traction using the inflated Foley balloons successfully extricates the bulbous object in most cases. An obstetrical vacuum extractor has also been used to remove a glass foreign body. [188] If a glass object is broken accidentally during attempted removal, laparotomy is required. High-lying foreign bodies are managed using spinal anesthesia and the lithotomy position. By palpating the abdomen, the object is pushed distally and then simultaneously grasped with forceps through the sigmoidoscope to coax it into the rectal vault, from which it may be removed as a low-lying object. If the object cannot be delivered to within reach of the rigid sigmoidoscope manually or after 12 hours of observation, or if abdominal distress develops, laparotomy is indicated. Proctosigmoidoscopy should be performed after all foreign body retrievals to rule out retained objects, lacerations, hematomas, and perforations.

Other causes of rectal trauma include penetrating injuries (usually gunshot wounds), blunt trauma (motor vehicle accidents), impalement injuries (criminal assaults), homosexual activities (fist fornication), and iatrogenic injuries (endoscopy, enemas, surgical procedures). [189] Surgical management of major rectal trauma usually includes a diverting colostomy, presacral drain placement, distal rectal irrigation, and maximum preservation of sphincter musculature. [190]

ANAL CARCINOMA

Anal carcinomas are relatively rare, comprising only 1% to 2% of all colonic cancers. A variety of histological types have been described, including squamous cell (70%–80%); basaloid, also known as transitional cell or cloacogenic (20%–30%); mucoepidermoid (1%–5%); and small cell anaplastic type (<5%). [191] All can be broadly classified as epidermoid carcinomas for purposes of clinical discussion. The mean age at presentation of patients with anal cancer is approximately 60 years. [192] Perianal and rectal carcinoma are more common in men, but the occurrence of anal canal tumors is nearly twice as common in women. [192]

Etiology

Although the cause of anal cancer is unknown, several risk factors have been identified. These tumors are strongly associated with homosexual behavior and receptive anal intercourse in men and with a history of sexually transmitted diseases, especially genital warts, in both sexes. [193] These data, immunohistological studies, and polymerase chain reaction techniques suggest a causal role for human papillomavirus infection, particularly type 16. [194], [195] Smoking, human immunodeficiency virus (HIV) infection, multiple sexual partners, cervical neoplasia, and immunosuppression after organ transplantation are other important risk factors. [196] Anal cytology screening may be cost-effective in homosexual and bisexual men. [197]

Clinical Manifestations

Bleeding, pain, and sometimes pruritus are presenting symptoms of anal cancer. However 25% of patients are symptom-free, and it is not unusual for the lesion to be discovered incidentally at routine examination. Almost 2% of surgical specimens for benign anorectal disease are reported to contain previously unsuspected tumor, although a survey of hemorrhoidectomy specimens suggests a much lower incidence. [198], [199] Benign anal lesions are temporally associated with, but do not appear to cause anal cancer. [200] High-grade dysplasia identified by screening cytology must be confirmed by biopsy and may be present even before visible lesions exist. [201] Rarely, a palpable metastatic inguinal lymph node is the sole presenting manifestation. Because symptoms are usually mild and nonspecific and easily confused with those of common benign anorectal lesions, the tumor is discovered late in more than 60% of patients. At presentation, 15% to 30% of patients have metastases to

pelvic or inguinal lymph nodes, and 10% have distant spread to the liver or lungs. [191]

Diagnosis is made by biopsy (under anesthesia, if necessary), and the local extent of disease is determined by palpation, anoscopy, and sigmoidoscopy. Lesions originating from the anal canal tend to be undifferentiated and more aggressive, whereas those arising from the anal margin are more differentiated and less malignant. [202] A poor prognosis is portended by squamous cell tumors greater than 2 cm in size (especially those >5 cm), basaloid or anaplastic carcinomas, sphincter muscle invasion, or spread to regional pelvic or inguinal lymph nodes. [191]

Treatment

The standard therapy for small, noninfiltrating anal cancer has been wide local excision in an attempt to preserve normal anal function. [191], [192] Split-thickness skin grafts may be required to cover large denuded surfaces. Large or infiltrating lesions require an abdominoperineal resection for radical excision of structures, including the sphincters, levator muscles, and rectum. Prophylactic inguinal lymph node resection is not indicated.

The advent of supervoltage radiotherapy alone or combined with surgery or chemotherapy has changed the approach to this neoplasm. Studies by Nigro and others [203], [204] and [205] suggest that radiotherapy (external beam or interstitial) plus chemotherapy with 5-fluorouracil and mitomycin causes complete tumor regression in most cases and is superior to radiotherapy alone. Cisplatin-based regimens may prove to be superior to those with mitomycin. [206] Subsequent abdominoperineal resection is unnecessary if follow-up biopsies document eradication of tumor. This combined approach minimizes local tumor recurrence while retaining normal anal function. The 5-year survival rate exceeds 70%. [1] Abdominoperineal resection for combined chemotherapy radiation therapy failures has a poor prognosis. [207]

Nonepidermoid Anal Malignancies

A variety of uncommon neoplasms of the anus and perianal skin make up the nonepidermoid tumors of the anal region. Adenocarcinoma of the anal canal is a rare tumor often arising in anorectal fistulae. [192] This lesion may also arise from other anal glands or may be confused with distal extension of a primary rectal carcinoma. Despite radical abdominoperineal resection, recurrences are typical. Extramammary Paget disease is a perianal glandular tumor that tends to spread along the epidermis and to eventually metastasize. [192] It typically appears in the seventh decade of life as an erythematous, well-demarcated eczemoid plaque with ulcerations. Perianal Paget disease is frequently associated with an underlying colonic malignancy. [208] Wide total excision is indicated for localized disease. [208] More advanced lesions require a radical abdominoperineal resection with ipsilateral groin dissection if inguinal node involvement is seen. Anal melanoma accounts for 1% of all anal tumors and 1.6% of all melanomas. Typical lesions are 4 cm in diameter, nonpigmented in one third, and tend to metastasize early with 5-year survival rates of only 15% to 20%. [209] Radical resection offers no clear advantage over wide local excision. [210], [211] Basal cell carcinoma of the perianal skin is a very rare lesion that produces rolled skin edges with central ulceration. The prognosis is quite good after adequate local excision or radiotherapy. [212] Bowen disease is a slow-growing, cutaneous squamous cell carcinoma in situ. Lesions occur as reddish-brown scaly or crusted plaques that may resemble a patch of psoriasis or dermatitis. Treatment ranges from simple observation alone in lesions found incidentally in hemorrhoidectomy specimens to wide local excision. [213]

PROCTALGIA FUGAX AND THE LEVATOR SYNDROME

Proctalgia fugax and levator ani syndrome are types of functional anorectal pain that differ based on the duration, frequency, and quality of discomfort. Limited evidence suggests that the former may be caused by smooth muscle spasm and the latter by striated muscle tension. [214] Proctalgia fugax (literally “fleeting rectal pain”) is an obscure condition characterized by sudden, brief episodes of severe rectal pain. Rome diagnostic criteria require at least 3 months of the recurrent episodes of pain localized to the anus or lower rectum lasting from seconds to minutes and no pain between episodes. [214] The true incidence of the disorder is unknown, although surveys of healthy people reveal attacks of rectal pain in approximately 15%. [215] Most people do not seek medical advice, probably because the pain typically lasts less than 1 minute (84%) and occurs fewer than 6 times per year (72%). [216] Modern surveys identify no consistent gender predominance. [215], [216]

Attacks are described as an intense stabbing or aching midline pain above the anus, lasting several seconds to many minutes. Pain may be variably associated with an urge to expel flatus, a desire to lie on one side with hips flexed, and, rarely, cold sweats, syncope, and priapism. Occasionally, attacks are exclusively nocturnal. Stress, fatigue, heat, cold, and sexual activity have all been reported to induce pain, but usually no clear precipitant is identified.

Not surprisingly, proctalgia fugax has been associated with irritable bowel syndrome and a variety of psychogenic disorders such as anxiety and hypochondriasis. [217], [218] The cause of proctalgia fugax is unknown. Unsubstantiated theories include rectosigmoid intussusception, vascular migraine equivalent, accumulation of rectal gas, or spasm of the anal sphincter, rectosigmoid colon, or pelvic musculature. The diagnosis is made on the basis of a characteristic history alone. Anorectal examination and sigmoidoscopy are normal. A familial internal anal sphincter myopathy causing proctalgia fugax and difficulty with rectal evacuation has been reported. [219]

Of primary importance in the treatment of proctalgia fugax is reassurance as to the benign nature of the disorder. This advice in conjunction with treatment of irritable bowel syndrome or psychogenic disorders, if present, often suffices. A number of specific remedies have been proposed for more refractory symptoms. Their efficacy is difficult to determine given the transient nature of symptoms and the lack of even uncontrolled trials. Local therapies include rectal massage, firm manual pressure to the perineum, and application of warm soaks or baths. One author [220] claims good results if the patient spreads the buttocks while in a knee-chest position to allow expulsion of rectal gas. Pharmacological intervention should be reserved for those with particularly frequent, severe, or disabling symptoms. Anecdotal reports claim success with a variety of drugs to reduce spasm, including amyl nitrate, sublingual nitroglycerine, salbutamol, clonidine, and diltiazem. [221], [222] and [223] One controlled trial [224] found that salbutamol aerosol significantly shortened painful attacks.

The levator syndrome refers to an aching rectal pain caused by tenderness and spasm of the levator ani muscle group (ileococcygeus, pubococcygeus, and puborectalis). It is perhaps best thought of as a variant of proctalgia fugax, although the two disorders are frequently confused in the literature. The pain is more chronic, aching, and pressure-like than that of proctalgia fugax and is most commonly seen in middle-aged women. [225] Rome diagnostic criteria require at least 3 months of chronic or recurrent rectal pain or aching, episodes lasting at least 20 minutes, and absence of other causes of rectal pain. [214] Defecation, prolonged sitting, and precipitants of proctalgia fugax have been described as precipitants of levator syndrome pain. The key diagnostic finding is palpable tenderness and spasm of the levator muscles as the examining finger sweeps 180 degrees from the coccyx to the pubis posteriorly to anteriorly. [225] For unknown reasons, findings are more frequently localized to the left side. Treatment consists of variable combinations of reassurance, local heat, vigorous digital rectal massage of the levator musculature, and muscle relaxants. In those with persistent symptoms, several groups have reported beneficial results using biofeedback training or electrogalvanic stimulation. [226], [227], [228] and [229]

MISCELLANEOUS CONDITIONS

Coccygodynia refers to pain in the coccyx. The discomfort is sharp or aching in quality and may radiate into the rectal region or to the buttocks. Traumatic arthritis, dislocation or fracture as a result of injury, or difficult childbirth can all cause organic coccygodynia. [1] Prolonged sitting has been suggested to cause functional coccygodynia. In both cases, manipulation of the coccyx reproduces pain and muscular spasm. Many patients respond to symptomatic treatment with warm soaks and analgesics. Local injection of steroid with or without coccygeal manipulation is usually beneficial in those with persistent symptoms. [230] Rarely, coccygectomy is required.

Unusual causes of rectal pain include cauda equina tumors, pelvic tumors, perianal endometriosis, intermittent enteroceles, a variety of rare retrorectal tumors and cysts, and rare genetic syndromes. [1], [231], [232] Other idiopathic, presumably functional, perineal and rectal pain syndromes remain poorly understood. [233]

Pilonidal (“nest of hair”) disease is a common skin lesion of the gluteal cleft seen most frequently in young men. Family history, obesity, and local trauma are risk factors. [234] Patients complain of recurrent drainage, swelling, or pain. Once thought to be a congenital lesion, pilonidal abscess is now recognized to be an acquired condition of the midline coccygeal skin region, often secondarily invaded by hair. Definitive treatment is usually surgical. [235], [236]

Hidradenitis suppurativa is a chronic suppurative condition of the apocrine glands most often involving the axillary and inguinoperineal skin regions. Apocrine glands

are activated at puberty, so the disease is not seen before adolescence and rarely occurs initially after middle age. Axillary hidradenitis suppurativa is most common, but perineal involvement is seen in nearly one third of those with the disease, especially in men. [237] The best recognized risk factors are obesity and acne, although perspiration and mechanical trauma to the skin and hair of the anogenital region may also predispose to perianal hidradenitis. Warm wet compresses and antibiotics are appropriate for early disease but surgical treatment is usually necessary. [238]

CHAPTER 93

Diane M. Simeone and Michael W. Mulholland

PANCREAS: ANATOMY AND STRUCTURAL ANOMALIES

Cross-sectional imaging techniques have greatly increased the understanding of pancreatic anatomy, and the ability to manipulate the pancreas surgically, endoscopically, and percutaneously has made it necessary for a wide variety of physicians to be familiar with pancreatic anatomic variations. The anatomy of the pancreas has been described in many standard texts, but the functional and therapeutic implications of its anatomic relations often are underemphasized.

Diseases of the pancreas are often more difficult to manage medically or surgically than those of other abdominal viscera. The pancreas lies hidden in the deeper recesses of the retroperitoneal space of the upper abdomen, is largely protected by the lower rib cage anteriorly, and is almost completely covered by the stomach, transverse colon, and transverse mesocolon. At laparotomy, the pancreas cannot be properly visualized or palpated without extensive dissection, mobilization, and retraction.

The central position of the pancreas provides for lymphatic drainage along several major routes, namely, the splenic, hepatic, and superior mesenteric nodal systems as well as the aortocaval and other posterior abdominal wall lymphatics. Moreover, the intimate anatomic association of the pancreas with vital major vessels of the epigastrium at once limits the extent of any surgical procedure and also dictates what must be removed. Thus, when a tumor spreads a short distance to involve the superior mesenteric vein, the portal vein, or the celiac axis, it usually becomes incurable. Similarly, if the gland is removed in radical fashion, the need to excise the vessels and lymph nodes associated with it frequently makes necessary the removal of the duodenum, gallbladder, distal bile duct, spleen, upper jejunum, and part of the stomach. Finally, the vascular nature of the pancreas and the adjacent organs makes it easy to understand why the most common intraoperative and postoperative complication of pancreatic resection is hemorrhage.

EMBRYOLOGICAL DEVELOPMENT

The pancreas develops from two primordial outpouchings of the duodenum and is first apparent at 4 weeks' gestation. The dorsal pancreatic bud grows more rapidly than the ventral pancreas and by 6 weeks extends into the dorsal mesentery. The ventral pancreas remains smaller and is carried away from the duodenum by the development of the hepatic rudiment into the biliary system. Differential growth of the duodenum and axial rotation of the gut result in the dorsal pancreas being carried to the left and the ventral pancreas being carried to the right of the duodenum (Fig. 93-1). Migration of the distal common bile duct behind and to the left of the duodenum causes the ventral pancreas to lie below the dorsal pancreas, forming the uncinate process of the pancreas. The common bile duct lies posterior to the dorsal pancreatic duct. Fusion of the two parts of the pancreas occurs during the seventh week of gestation. Fusion of the ventral duct with the dorsal duct results in the formation of the main pancreatic duct. The proximal end of the dorsal pancreatic duct usually does not communicate with the main duct and forms the accessory pancreatic duct.

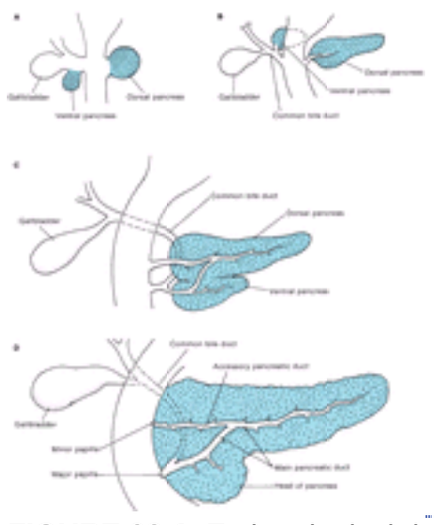

FIGURE 93-1. Embryological development of the pancreas. The various stages of intrauterine pancreatic growth are shown at 4 weeks' gestation (**A**), 6 weeks (**B**), 7 weeks (**C**), and birth (**D**). (Adapted from Arey LB. Developmental anatomy, 7th ed. Philadelphia: WB Saunders, 1974:259.)

The pancreatic acini and the first zymogen granules appear at 12 weeks' gestation. Groups of endocrine cells develop from multipotential stem cells in the ductular epithelium (nesidioblasts) at 9 weeks' gestation. Discrete islets of Langerhans' cells can be identified at 12 weeks. Most of the islet cells develop within the tail of the pancreas and the dorsal pancreas. The first cells to produce granules are the alpha cells, soon followed by the beta and delta cells. Complete maturation of the pancreatic gland does not occur until sometime after the end of gestation. The smooth muscle of the sphincter of Oddi develops independently of the duodenal musculature, and only later does it become incorporated into the duodenal wall.

Most recent evidence indicates that islet cells arise from stem cells that appear in pancreatic ducts during the third month of gestation. Insulin-containing granules may be demonstrated immunocytochemically by the end of the third month. Islet cells migrate away from the ducts in which they arise and move into the interlobular connective tissue. Mature islet morphology is established before birth.

GROSS ANATOMY

The pancreas is a soft, flattened, elongated gland, 12 to 20 cm long in the adult, that lies behind the peritoneum of the posterior abdominal wall and is obliquely rather than transversely oriented (Fig. 93-2; see also Fig. 93-1). The pancreas has a lobular structure and, although totally invested in fine connective tissue, does not have a true fibrous capsule. The adult gland weighs 85 to 95 g. Because of its oblique orientation, a transverse section or computed tomography scan normally does not pass through the entire length of the gland. The head of the pancreas is on the right side and lies within the C-shaped concavity of the duodenum at the level of the

body of L2. The tail of the gland is to the left; the tail lies between the two layers of peritoneum that form the lienorenal ligament and is located at the level of the body of L1. The first portion of the duodenum is suspended in front of the head of the gland. The lesser curvature of the second part of the duodenum and the upper aspect of the third part of the duodenum intimately invest the head of the pancreas. Superiorly, the head is related to the gastroepiploic foramen and the structures that form the contents of the free border of the lesser omentum. Anteriorly, the first portion of the duodenum covers the superior part of the pancreatic head, and below this the right side of the transverse mesocolon is attached transversely. Posteriorly, the head of the pancreas contacts the right renal hilum, both renal veins, the inferior vena cava, and the termination of the right gonadal vein as well as the right side of the aorta. [1]

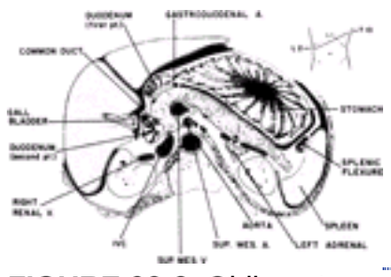

FIGURE 93-2. Oblique transverse cross-section of the upper abdomen viewed from below. The section passes through the long axis of the pancreas at approximately the level indicated in the inset. The disposition and relations of structures shown approximate those seen on oblique transverse ultrasonic scanning.

The distal end of the common bile duct passes behind the upper border of the head of the pancreas. The bile duct grooves the posterior aspect of the head of the gland before passing through the substance of the head to reach the duodenal papilla of Vater. From the posterior aspect of the head, a tongue of pancreatic tissue of variable size, the uncinate process, extends to the left to occupy the concavity formed by the third and fourth part of the duodenum. The uncinate process lies anterior to the inferior vena cava and aorta and is covered superiorly and anteriorly by the superior mesenteric vessels as they emerge below the neck of the pancreas.

From the head of the pancreas, a constricted part of the gland, the neck of the gland, extends toward the left. It is 3 to 4 cm wide and joins the head of the gland to the body of the gland on the left. The pancreatic neck lies behind the posterior peritoneum of the lesser sac, and attachments of the transverse mesocolon and the root of the small bowel mesentery cover its inferior border. The neck of the pancreas lies anterior to and is closely related to the confluence of the superior mesenteric and splenic veins. These form the lowest part of the portal vein.

In front of the aorta in the midline, the body of the pancreas continues its retroperitoneal course toward the left side, held securely against the aorta and the posterior parietes by the posterior peritoneum of the lesser sac. The antrum and the body of the stomach contact the body of the pancreas anteriorly. The left renal vein, passing between the aorta and the pancreas, is separated posteriorly by the latter from the first part of the superior mesenteric artery. At a slightly higher level, elements of the celiac and superior mesenteric plexus ramify between the pancreas and the aorta. The midline part of the body of the pancreas is pushed anteriorly by the bodies of L1 and L2 and, therefore, lies closest to the anterior abdominal wall. Because of its prominence and fixity in this region, this area of the pancreas is most vulnerable to blunt abdominal injuries. In addition, a tumor in this region may be palpated as a mass that does not move with respiration and that strongly transmits the aortic pulsation. The celiac axis, surrounded by the celiac plexus, divides into its major branches between the superior border of the body of the pancreas and the crura of the diaphragm.

The body of the pancreas passes laterally, posteriorly, and slightly cephalad behind the posterior peritoneum of the lesser sac and merges imperceptibly with the tail of the gland. The exact junction of the body and tail is not discernible anatomically. The posterior relationships of the body and tail of the pancreas include the posterior attachment of the left crus of the diaphragm, the left suprarenal gland, the upper pole of the left kidney, and hilum of the spleen. The splenic vein above and the left renal vein below lie close to one another behind the body and tail of the gland.

At the upper border of the body and tail of the pancreas, the splenic artery courses to the left from its origin at the celiac axis. The transverse mesocolon is attached to the anterior part of the lower border of the gland. The splenocolic ligament attaches the splenic flexure of the colon to the hilum of the spleen and brings it adjacent to the tail of the pancreas.

The shape and disposition of the pancreas varies, as demonstrated by pancreatography. In 57% of people, the bulk of the head of the gland is to the right of the spinal column. In about 38% of cases, it lies directly over the spine, but only rarely (5%) does the head of the pancreas lie to the left of the spine. There is a tendency in older adults for the pancreas to be ptotic. The duodenal opening of the main pancreatic duct lies at the level of L2 to L4 in 92% of cases, but, rarely, it has been described at a lower level.

SURGICAL EXPOSURE

Although the pancreas is located retroperitoneally, it must be approached by way of an anterior laparotomy incision. Little of the gland can be seen or palpated at laparotomy without dissection. In a thin patient, small areas of the head may be seen directly behind the peritoneum of the supracolic and right infracolic compartments, and the inferior border of the body and tail may be seen from the left infracolic compartment at the root of the transverse mesocolon. These limited views, however, usually are obscured by omental, mesocolic, and retroperitoneal fat. By passing a finger through the gastroepiploic foramen of Winslow, the neck of the pancreas may be felt from above.

The head of the pancreas may be inspected and palpated more closely by performing two maneuvers. [2] First, the hepatic flexure of the colon is mobilized downward and medially, dividing the attachments of the transverse colon to the front of the duodenum and pancreatic head as far as the origin of the middle colic vessels. In addition, the attachments of the right side of the greater omentum to the transverse colon are divided. Thus, the lesser sac can be widely exposed on the right side of the middle colic vessels. Second, the peritoneum lateral to the second part of the duodenum is incised, and the duodenum and pancreatic head may be elevated and swept to the left by blunt dissection, exposing the right renal vein, the inferior vena cava, the right gonadal vein, the origin of the left renal vein, and the retroduodenal and retropancreatic portions of the distal common bile duct. After this mobilization (Kocher maneuver), the head of the pancreas may be palpated anteroposteriorly between the thumb and fingers. The mesenteric vessels are obscured from view by the uncinate process.

Limited visualization of the superior part of the body of the pancreas may be obtained by opening an avascular part of the lesser (gastrohepatic) omentum and retracting the lesser curvature of the stomach inferiorly. This maneuver also brings the celiac axis into view. A much more adequate visualization of the body of the pancreas may be obtained by widely opening the lesser sac, which can be achieved by dividing the gastrocolic omentum at its attachment to the transverse colon. Extending this opening to the right into the subpyloric region allows visualization of the anterior aspect of the head and neck of the pancreas, especially if the right gastroepiploic vessels are ligated and divided. Extending the opening to the left and dividing the short gastric (gastrosplenic) vessels in the gastrosplenic ligament superiorly and the relatively vascular splenocolic ligament inferiorly will give complete visualization of the anterior surface of the body and tail of the pancreas. The spleen, splenic vessels, and tail of the pancreas may be mobilized medially and anteriorly en bloc, allowing inspection of the posterior aspect of the tail and body of the gland. All these surgical maneuvers may be carried out quickly and safely with little risk of damage to vital structures or troublesome bleeding. By this means, all except the region of the neck and uncinate process of the pancreas may be evaluated fully.

ARTERIAL BLOOD SUPPLY

The pancreas derives its blood supply from the celiac axis and the superior mesenteric artery (Fig. 93-3; see also Color Fig. 93-3). These major vessels and their branches also provide the blood supply to other vital organs adjacent to the pancreas.

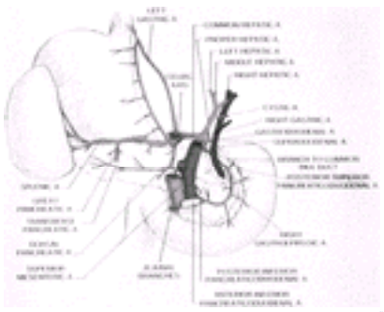

FIGURE 93-3. (See Color Figure 93-3.) Blood supply of the pancreas. The pancreas, duodenum, stomach, and spleen are viewed from their posterior aspects.

Typically (in 90% of people), the celiac axis divides into the common hepatic, splenic, and left gastric arteries. The common hepatic artery passes to the right, anterior to the portal vein, to reach the free border of the lesser omentum and usually lies to the left of the common bile duct. After giving off the gastroduodenal artery, the hepatic artery turns upward toward the porta hepatis and divides into the left and right hepatic arteries. The middle hepatic artery, supplying the caudate lobe of the liver, is usually a branch of one of these two vessels. This arrangement of the hepatic arterial blood supply, however, occurs in only 55% of people. Replaced or accessory hepatic arteries are frequent, occurring in as many as 30% of people. The most frequent variation from normal is the right hepatic artery branching off from the superior mesenteric artery and coursing behind the uncinate process and the head of the pancreas to reach the free border of the lesser omentum. [3]

The gastroduodenal artery usually originates from the hepatic artery. The gastroduodenal artery courses from its origin behind the first part of the duodenum and, after giving off the posterosuperior pancreaticoduodenal artery, lies on the anterior surface of the head of the pancreas. At the lower border of the first part of the duodenum, it branches into the right gastroepiploic artery and the anterior superior pancreaticoduodenal artery.

For the most part, the head of the pancreas and the duodenum have a common blood supply: the anterior and posterior pancreaticoduodenal arcades. The anterior arcade gives off the only arteries that enter the head of the gland from its anterior aspect. This arcade is formed by the anastomosis of the anterosuperior pancreaticoduodenal artery, which is a terminal branch of the gastroduodenal artery, and the anteroinferior pancreaticoduodenal artery, which is usually a branch of a common inferior pancreaticoduodenal artery, arising from the superior mesenteric artery.

The posterior pancreaticoduodenal arcade is formed by the anastomosis of the posterosuperior pancreaticoduodenal artery, usually a branch of the gastroduodenal artery, and the posteroinferior pancreaticoduodenal artery, which arises in a way analogous to the anterior pancreaticoduodenal artery. Of surgical importance is the relation of the posterosuperior pancreaticoduodenal artery to the common bile duct. Typically, this vessel arises from the gastroduodenal artery and passes to the right, anterior to the common bile duct, contributing the major source of the structure's blood supply. The supraduodenal portion of the common bile duct also may be crossed anteriorly by the right hepatic artery, the right gastric artery, and the supraduodenal artery, making mobilization of the lower end of the common bile duct more difficult.

Because of the shared blood supply of the duodenum and pancreatic head, extensive interference with the pancreaticoduodenal arcades in the course of a 95% pancreatectomy may compromise the blood supply of the duodenum. [4] In addition, because the duodenojejunal flexure and the first part of the jejunum may derive their blood supply from branches of the inferior pancreaticoduodenal artery or the pancreaticoduodenal arcades, ligation of these vessels in the course of a resection may render the proximal jejunum ischemic.

The body and tail of the gland derive their blood supply chiefly from branches of the splenic artery. This vessel, the largest branch of the celiac axis (5–11 mm in diameter), courses laterally at the upper border of the pancreas; its characteristic marked tortuosity appears to be related to age: it is often absent in infants and is most marked in the elderly. The splenic artery gives multiple side branches to supply the neck, body, and tail of the pancreas. The termination of the splenic artery passes between the layers of the lienorenal ligament and, at the hilum of the spleen, four or five branches enter the splenic hilum separately.

VENOUS DRAINAGE

The general pattern of veins draining the pancreas is the same as that of the arterial blood supply (Fig. 93-4). Blood from the pancreas ultimately drains into the portal vein, which is formed by the junction of the superior mesenteric vein and splenic vein behind the neck of the gland. The close relationship of the portal and superior mesenteric veins to the head, neck, and uncinate process of the pancreas is of vital surgical importance; in determining the resectability of a pancreatic lesion, a key step is assessment of involvement of these veins. The portal vein originates from behind the neck of the pancreas as a continuation of the superior mesenteric vein after it becomes confluent with the splenic vein. The portal vein passes upward to the right to gain access to the free border of the lesser omentum, where it lies posterior to the hepatic artery and the common bile duct. At the porta hepatis, it divides into a short, broad right branch and a longer, narrower left branch. In adults, the portal vein is about 8 to 10 cm long and 8 to 14 mm wide. Its average length is about 8.4 cm. [5]

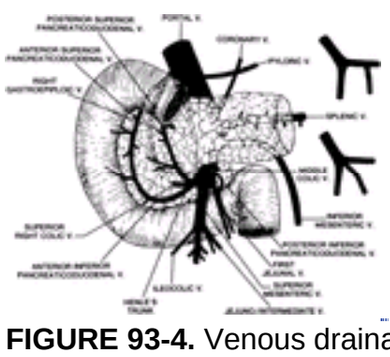

FIGURE 93-4. Venous drainage of the pancreas. The pancreas and duodenum are viewed from their anterior aspects. **Insets:** Normal variations in the termination of the inferior mesenteric vein.

The splenic vein originates at the hilum of the spleen by the confluence of five or six tributaries draining the spleen. It receives the basal brevia (short gastric veins) and left gastroepiploic veins at the hilum. It passes through the lienorenal ligament behind the tail of the pancreas and below the splenic artery and is the large, straight vein that courses to the right in contact with the posterior surface of the pancreas. It receives many tributaries from the tail, body, and neck of the gland.

Below the pancreas, the ileocolic vein passes directly, and usually without tributaries, from the ileocecal region to join the right side of the superior mesenteric vein in the midline just above the inferior border of the third part of the duodenum. At about the same level on the left side, the jejunointermediate vein joins the superior mesenteric vein. The confluence of these three veins forms the lower limit of what has been termed the surgical trunk of the superior mesenteric vein. Above this point, about two thirds of the superior mesenteric vein lies below the inferior border of the neck of the pancreas, with the remaining one third being retropancreatic. The superior jejunal vein joins the left side of the superior mesenteric vein. The middle colic vein usually joins the superior mesenteric vein immediately below the inferior border of the pancreatic neck.

The inferior mesenteric vein typically joins the splenic vein vertically behind the body of the pancreas. The latter passes horizontally and combines with the superior mesenteric vein at a right angle to form the portal vein, which turns obliquely to the right to pass into the free edge of the lesser omentum. Small veins draining the head of the pancreas pass directly into the portal vein. Similarly, small veins draining the uncinate process terminate in the right and posterior aspects of the retropancreatic superior mesenteric vein. The anterior aspects of the major veins are usually free from tributaries. From the left side, the coronary vein joins the retropancreatic portal vein, and the pyloric vein joins the suprapancreatic portal vein. The superior and posterior pancreaticoduodenal veins drain into the portal vein from the right side, deep to the first part of the duodenum and opposite the pyloric vein. The coronary vein (also known as the left gastric vein) usually (in 60% of cases) drains into the left side of the retropancreatic portal vein, but it may have a high termination well above the neck of the pancreas.

The close anatomic relationship of the splenic vein with the pancreas often leads to splenic vein occlusion in inflammatory or neoplastic diseases involving the body

and tail of the gland. Retrograde venous drainage toward the splenic hilum and then by way of the short gastric veins and the left gastroepiploic vein creates the syndrome of left-sided portal hypertension and gastric varices.

LYMPHATIC DRAINAGE

The lymphatic vessels of the pancreas conform to the general pattern of deep lymphatic drainage and accompany the arterial supply (Fig. 93-5; see also Color Fig. 93-5). The duodenum and head of the pancreas have a common lymphatic drainage; lymph from the foregut and midgut structures, including the pancreas, liver, stomach, spleen, small bowel, and proximal large bowel, eventually flows into the celiac and superior mesenteric groups of paraaortic nodes and into the cisterna chyli. [6] The lymphatics of the tail of the pancreas pass to the splenic nodes at the hilum of the spleen, and those of the body of the pancreas pass upward to the pancreaticosplenic nodes lying along the superior border of the gland. These nodes, along with the retropancreatic nodes, drain into the celiac nodes. Lymphatics of the upper anterior part of the head of the pancreas pass through the subpyloric nodes lying behind the first part of the duodenum. Obstruction of these pancreatic lymphatic drainage pathways by tumor may result in the shunting of lymph through local collateral channels, resulting in the involvement of nodes primarily concerned with hepatic or gastric drainage. Inferiorly, the retropancreatic and antepancreatic group of nodes drain into the superior mesenteric nodes, and lymph from the latter also may pass into nodes in the root of the transverse mesocolon. The absence of fascial or retroperitoneal coverings on the posterior aspect of the pancreas allows easy communication between lymphatics of the pancreas and those of neighboring retroperitoneal tissues and organs. The lymphatic network is so rich that a thorough lymphadenectomy en bloc with a pancreatic resection frequently produces a profuse postoperative chylous leakage. [7]

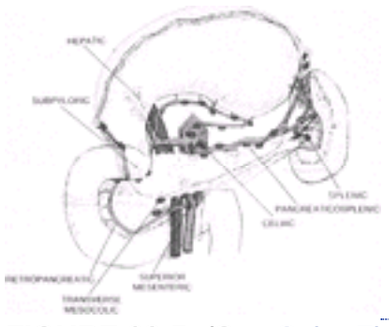

FIGURE 93-5. (See Color Figure 93-5.) Lymphatic drainage of the pancreas. The pancreas is viewed from its anterior aspect. The gastrocolic ligament has been divided along the greater curvature of the stomach, which has been retracted anterosuperiorly. The transverse mesocolon has been detached from the peritoneum of the posterior abdominal wall. Labels indicate representative lymph nodes in the major regional nodal groups.

NERVE SUPPLY

The sympathetic efferent innervation of the pancreas is derived from the greater, lesser, and least splanchnic nerves. The bodies of the preganglionic sympathetic neurons originate in the lateral gray matter of thoracic spinal segments 5 through 10. After transversing the sympathetic trunks, presynaptic nerve fibers synapse with postganglionic sympathetic neurons within the celiac plexus, although there is some minor distribution to the pancreas through the hepatic and superior mesenteric plexuses. The celiac ganglion consists of two masses that lie on either side of the aorta, anterior to the crura of the diaphragm and close to the adrenal glands. The right celiac ganglion is partly covered by the inferior vena cava, and the left celiac ganglion is covered by the peritoneum of the lesser sac close to the upper border of the pancreas. The cell bodies of afferent sympathetic neurons are located in dorsal root ganglia. Afferent fibers often cross the midline in celiac ganglia before projecting centrally so that sympathetic afferent innervation is bilateral.

The parasympathetic innervation of the pancreas is derived from the vagal nerves. The cell bodies for efferent vagal fibers are located in the medulla in the dorsal motor nucleus. Efferent fibers pass to the pancreas by way of the celiac division of the posterior vagal trunk. No synaptic connections are made within the celiac ganglia; postsynaptic neurons are located within the pancreatic parenchyma. Afferent vagal fibers also pass through the celiac ganglia; afferent cell bodies are located within the nucleus ambiguus. [8]

The ultrastructure of pancreatic innervation has been studied extensively in several animal species in addition to humans. Myelinated fibers usually are not found within the parenchyma. Intrapancreatic ganglion cells are seen within the interlobular tissues, with nonmyelinated fibers passing to both exocrine and endocrine portions of the gland. The sites of nerve termination may be generally grouped as blood vessels, pancreatic acinar cells, ductal cells, and pancreatic islets. Functional correlates suggest that pancreatic nerves may modulate the function of each of these pancreatic elements. In addition to the classic cholinergic and adrenergic neurons, evidence suggests that a large number of peptide-containing neurons also exist within the pancreas. Immunocytochemical methods have demonstrated the presence of fibers or cell bodies containing vasoactive intestinal polypeptide, substance P, cholecystokinin-8, gastrin-releasing peptide, enkephalin, galanin, neuropeptide Y, and calcitonin gene-related peptide. [9], [10] The physiological actions of many of these peptidergic nerves within the pancreas remain to be defined, but anatomic studies suggest that modulation of release of acetylcholine and catecholamines from autonomic nerve terminals within the pancreas may be important. Regulation of pancreatic secretion and blood flow is also an important function of intrapancreatic neurons.

Pain fibers from the pancreas travel through the celiac ganglia and by way of the sympathetic splanchnic nerves and the thoracic sympathetic chain to reach the spinal root ganglia. Pain from the head of the pancreas tends to be broadly localized in the midepigastrium, and pain from the body and tail tends to be localized in the left upper quadrant. Visceral pain from the pancreas usually is sensed as a severe, constant discomfort in the epigastrium. Because the pancreas does not contact the somatically innervated parietal peritoneum, sharply localized pain usually does not occur. Radiation of pancreatic pain to the back in the area of the lower thoracic vertebrae is common.

Recent studies suggest that pancreatic innervation may be altered in disease states such as chronic pancreatitis. In patients with chronic pancreatitis, the number and diameter of intralobular and interlobular nerve bundles have been reported to be increased relative to normal numbers. Pancreatic nerves in these patients demonstrated increased immunostaining for substance P and calcitonin gene-related peptide. [11] Because these peptides are known to be expressed in afferent neurons, the changes have been postulated to be responsible for the pain syndrome associated with chronic pancreatitis. Alterations in peptidergic pancreatic innervation also have been reported in animal models of chronic pancreatitis. [12] The cellular mechanisms responsible for these abnormalities are unknown; interactions of nerves with pancreatic inflammatory cells have been proposed as a cause. [13]

DUCTAL SYSTEM

The main pancreatic duct of Wirsung extends from the tail of the pancreas to the major duodenal papilla or ampulla of Vater (Fig. 93-6 and Fig. 93-7). The average diameter of the duct in the adult tapers from 4 to 2 mm, and it is widest in the head of the gland. [14] The main duct is close and almost parallel to the distal common bile duct for 2 to 3 mm before combining to form a common duct channel before opening into the duodenum. The accessory pancreatic duct of Santorini, which is present in 40% to 70% of people, usually communicates with the main duct and passes transversely to the right in the upper part of the head of the pancreas. The duct of Santorini lies anterior to the intrapancreatic common bile duct and usually opens into the proximal portion of the second part of the duodenum at the minor papilla, proximal to the ampulla of Vater.

FIGURE 93-6. Terminology variously applied to describe the pancreatic duct system. One system indicates an understanding of ductal embryology, particularly with

regard to the development of the more unusual variations (**left**). For clarity and practicality, however, the terms given on the right are preferred.

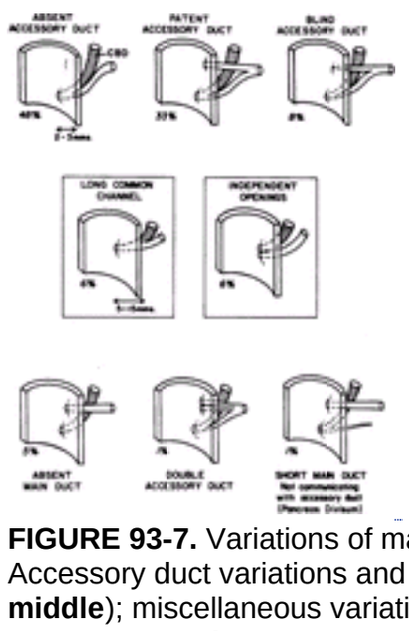

FIGURE 93-7. Variations of main and accessory pancreatic ducts, and their relation to the common bile duct (CBD) from a series of 143 postmortem preparations. Accessory duct variations and usual short common channel for CBD and main pancreatic duct (**top**); variations of CBD and main pancreatic duct terminations (**middle**); miscellaneous variations (**bottom**). (Adapted from Berman LG, Prior JT, Abramow SM, et al. A study of the pancreatic duct system in man by use of vinyl acetate casts of post mortem preparations. Surg Gynecol Obstet 1969;110:391.)

This “typical” ductal anatomy actually may be present in as few as 33% of people. [15] Important variations include nonpatency of the accessory duct (8%), independent openings of the common bile duct and the main pancreatic duct (6%), an absent main duct (5%), and patent double accessory ducts (1%). Noncommunication between the main duct and the accessory duct, with the body and tail of the gland draining exclusively by way of the duct of Santorini, results in the anatomic variant known as *pancreas divisum,* which occurs in 2% to 6% of otherwise healthy people.

The sphincter of Oddi consists of circular smooth muscle that surrounds the common channel of the common bile duct and the main pancreatic duct at the ampulla of Vater. The muscle fibers of the sphincter of Oddi extend around the common bile duct just distal to the latter’s oblique entry into the wall of the duodenum to form the choledochal sphincter. A short region of circular smooth muscle also surrounds the pancreatic duct just before its termination to form the pancreatic duct sphincter.

ULTRASTRUCTURE

The pancreas is a mixed endocrine and exocrine gland. The glandular constituents by weight are 80% exocrine tissue, 18% ductular system, and 2% endocrine tissue. The pancreas is a lobulated organ with lobular subunits composed of acini. The acini are rounded or have a short tubular form and consist of single rows of epithelial cells lying on a basal lamina. Lining the lumen of the acinus are pyramidal acinar cells and pale-staining centroacinar cells, which are unique to the pancreas. The acinar lumen connects with the intralobular ducts to form the interlobular ducts, which, in turn, coalesce to form the main pancreatic duct. Lining the ductules are columnar cells, goblet cells, and occasional argentaffin cells. Thick layers of connective tissue and elastic fibers surround the large ducts.

In the resting state, the basal portion of the acinar cell contains a centrally located spherical nucleus lying within a highly basophilic cytoplasm secondary to the large number of ribosomes in the rough endoplasmic reticulum. The abundant ribosomes attest to the high protein-synthesizing capacity of the acinar cells. A clear region containing the Golgi complex separates the nucleus from numerous eosinophilic zymogen granules, each about 1 µm in diameter, lying at the apex. The acinar cell has short microvilli, averaging 0.2 µm in length, which protrude into the acinar lumen. At the apical portion, the cells are held together by tight junctions, which prevent reflux of lumenal contents. Laterally, the cells are connected by gap junctions, which permit intercellular communication.

The thin basal lamina on which the acini rest is supported by collagen fibers. A rich capillary plexus surrounds the acinus in this connective tissue and is penetrated by numerous nerve fibers, which reach the acinar cells. [16]

The endocrine portion of the pancreas consists of about one million islets of Langerhans, which are distributed throughout the gland but are relatively concentrated in the tail of the pancreas. The islets are about 200 µm in diameter, and each is associated with a prominent capillary plexus. The islets contain several cell types. About 75% to 80% of islet cells are beta or B cells, which secrete insulin, and 10% to 20% are alpha or A cells, which contain glucagon. Delta or D cells constitute about 5% of the islets and contain somatostatin. [17] The B cells occupy the center of the islets, whereas the perimeter is lined by A cells. D cells are dispersed between these groups. Other peptide-secreting cells that may be associated with the islets include enterochromaffin (EC) cells containing 5-hydroxytryptamine and pancreatic polypeptide (PP) cells containing pancreatic polypeptide.

CONGENITAL ANOMALIES

Agenesis or Hypoplasia of the Pancreas

Agenesis of the pancreas is a rare and, at one time, universally fatal condition. [18] Failure of the pancreas to develop may occur as an isolated anomaly, or it may be associated with other congenital defects, such as absence of the gallbladder. [19] Although the cause is not known, pancreatic agenesis has been associated with retarded intrauterine growth, presumably resulting from failure of the endocrine pancreas to produce insulin. [20] Partial agenesis of the pancreas results from incomplete formation of either the dorsal or ventral pancreas and has a more favorable outcome than complete agenesis. Involvement of the dorsal segment appears to be more common than involvement of the ventral pancreas. These glands possess normal exocrine and endocrine function.

Hypoplasia of the pancreas is a congenital disease involving exclusively the exocrine pancreas and has been referred to as *lipomatous pseudohypertrophy of the pancreas*. [21] Pathologically, the gland appears enlarged and of normal shape but of a fatty consistency. The major pancreatic ducts are developed, and islets of Langerhans are present; however, secondary pancreatic ducts and acinar lobules are absent or underdeveloped, and fatty tissue replaces normal acinar cells. [22] The finding that the gland is of normal shape, but missing differentiated cellular components, led investigators to postulate that embryological development is normal in this condition. It is proposed that an intrauterine insult occurs, such as infection, causing hypoplasia of the exocrine gland. [23] Although this disease usually is diagnosed in infants, it has been reported to occur in adults. [21], [22] Manifestations result from severe pancreatic exocrine insufficiency.

Annular Pancreas

Annular pancreas is an unusual complication of disturbed embryological development in which the head of the pancreas surrounds the duodenum, often resulting in duodenal obstruction. Annular pancreas frequently is associated with other congenital defects, including Down syndrome, Meckel diverticulum, malrotation of the intestine, duodenal atresia and bands, intestinal webs, tracheoesophageal fistulae, imperforate anus, absence of the gallbladder, and certain types of cardiac defects. [24], [25], [26], [27] and [28] Annular pancreas has been described in association with pancreas divisum (see section “ Pancreas Divisum”). [29] Men appear to be affected more commonly than women. The occurrence of annular pancreas is usually sporadic, although several reports describe a familial association and apparent autosomal dominant transmission. [30], [31] and [32]

Typically, the annulus is a band of pancreatic tissue completely encircling the second portion of the duodenum (Fig. 93-8). The ring usually lies proximal to the major papilla, and in a few cases the annulus involves the first or third portion of the duodenum. Histologically, pancreatic tissue frequently invades the muscularis layer of the duodenum. [33]

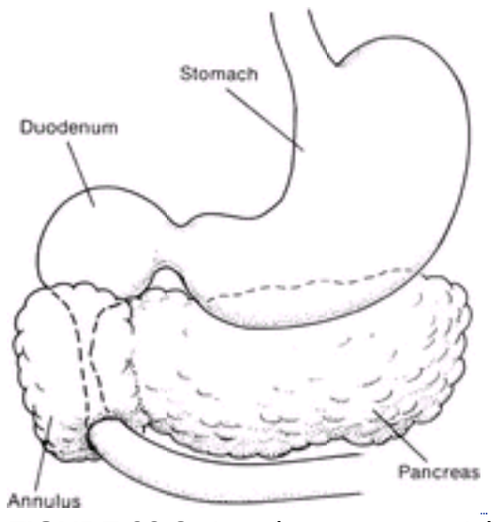

FIGURE 93-8. Annular pancreas. A band of pancreatic tissue surrounds the midportion of the duodenum.

The most popular etiologic theory suggests that the ventral pancreatic bud becomes fixed; as the pancreas and duodenum rotate, a band of pancreatic tissue is left encircling the duodenum. [34] Supporting this theory is the report that a high concentration of pancreatic polypeptide cells, which is characteristic of the ventral pancreas, was found in annular tissue. [35] Other theories propose that hypertrophy of the dorsal and ventral ducts or ectopic pancreatic tissue causes the annulus. [36]

More than half of all cases are diagnosed in the first year of life. Severe duodenal stenosis is usually apparent within the first few days of birth. Because pancreatic tissue encircles the duodenum, causing obstruction, newborns and infants are intolerant of oral feedings and have vomiting, often of bilious material. Upper abdominal distention and visible peristalsis are often present on physical examination. [37] Although vomiting is the usual presenting symptom in children, adults often complain of postprandial colicky abdominal pain, bloating, and fullness that also may be associated with nausea and vomiting. [38], [39], [40] and [41] Upper gastrointestinal bleeding and duodenal ulcer disease occur in one third of adults, and acute pancreatitis is a common associated finding in this disorder.

Radiographic signs of annular pancreas are those of duodenal obstruction. Plain radiographs of the abdomen often show a “double-bubble” sign resulting from dilation of the duodenum and stomach. With high degrees of obstruction, a duodenal cutoff sign also may be seen. In infants, these findings are the only necessary radiographic tests. Radiographic findings are not specific in older children and adults, and it is usually necessary to document duodenal obstruction by upper gastrointestinal contrast studies. Constricting bands, 0.8 to 5 cm long, around the duodenum have been detected radiographically. [42] Other signs include dilation and reverse peristalsis of the proximal duodenum. Endoscopic evaluation of annular pancreas usually is not helpful. The mucosa usually is normal, and it is difficult to appreciate mild narrowing of the duodenum. In severe cases, concentric narrowing of the duodenum or stenosis and associated peptic ulcer disease are suggestive of the diagnosis. Endoscopic retrograde cholangiopancreatography (ERCP) has been used to visualize the ductal system in annular pancreas and is diagnostic of the disorder. [43], [44], [45] and [46] Magnetic resonance (MR) pancreatography is being used with increasing frequency as a noninvasive alternative to diagnostic ERCP in the evaluation of pathological conditions of the pancreas such as annular pancreas and pancreas divisum. [47] Characteristic features can also be determined by computed tomography. [48] In symptomatic patients, treatment of annular pancreas is surgical alleviation of the obstruction. Division of the annulus is not recommended because of the high incidence of pancreatitis and pancreatic fistulae complicating that procedure, and bypass of the obstructed intestinal segment is preferred. [49]

Heterotopic Pancreas

Aberrant localization of pancreatic tissue, also known as heterotopic pancreas or pancreatic rests, refers to segments of pancreatic tissue not in continuity with the main body of the pancreas. The condition is usually asymptomatic, and therefore its true incidence is difficult to determine. Heterotopic pancreas has been identified in one of every 500 laparotomies, and autopsy studies have reported frequencies ranging from 0.6% to 15%. [50], [51] Seventy percent of such rests are found along the upper gastrointestinal tract, with the stomach (25.5%), duodenum (27.7%), and jejunum (15.9%) representing the most frequent locations. Other intra-abdominal locations include the gallbladder, liver, small intestine, colon, appendix, omentum, and Meckel diverticulum. [52], [53] and [54] In the stomach, pancreatic rests are found primarily in the prepyloric region along the greater curvature. Extra-abdominal sites include the lung and umbilicus. [55], [56] and [57] Histologically, heterotopic pancreas can contain acinar tissue, islets, ducts, or any combination thereof. Seventy-five percent of rests are located in the submucosa of the stomach or intestine and appear as firm, yellow nodules 2 to 4 cm in diameter underlying the mucosa. These often have a central mucosal depression, thought to represent the presence of a vestigial duct, which may be recognized endoscopically or by radiographic contrast studies. The origin of heterotopic pancreas is not known, and it is likely that several abnormalities of embryological development account for the locations in various sites. As pluripotential cells, pancreatic rests may represent abnormal differentiation of endodermal stem cells. Conversely, disturbances in migration of the pancreas as it rotates around the gut may account for some heterotopic locations. [58]

Heterotopic pancreas is usually an asymptomatic condition that is an incidental finding at surgery or autopsy. Symptoms attributed to this disorder include abdominal pain, nausea, vomiting, and gastric outlet obstruction. [59], [60] Peptic ulcer disease and upper gastrointestinal bleeding also have been described. Because of the varied locations of pancreatic rests, involvement of other organs can occur. Pancreatitis, biliary obstruction with jaundice, intestinal obstruction, and intussusception all have been associated with heterotopic pancreas. [61], [62], [63], [64], [65], [66] and [67] As a result of the combined exocrine and endocrine function of the pancreas, any pathological change in the normal pancreas also can occur in ectopic tissue. [68] Therefore, malignant degeneration, cyst formation, and islet cell tumors also may be found in pancreatic rests. [69], [70], [71], [72] and [73]

Pancreatic rests involving the upper gastrointestinal tract often are detected initially by contrast radiography or endoscopy by the presence of a submucosal bulge with central umbilication. [74], [75] These lesions are covered by normal mucosa, making routine endoscopic biopsy impossible. Heterotopic pancreas may be difficult to differentiate from leiomyomas, fibromas, carcinoid tumors, or other malignant tumors. Over the last several years, endoscopic ultrasound (EUS) has become an increasingly useful modality in the evaluation of these submucosal gastrointestinal masses. EUS not only can distinguish between an intramural lesion and compression from an extralumenal mass, but it also allows identification of the wall layer from which the mass originates. For example, pancreatic rests, located in the submucosal layer, can be differentiated from leiomyomas, the most commonly encountered submucosal masses, which are located in the layer of the muscularis propria. [76] In other cases in which a definitive diagnosis cannot be made based on EUS appearance, EUS-guided fine-needle aspiration may be used to obtain a histological diagnosis. [77]

Treatment of ectopic pancreatic tissue is indicated only for those who have significant symptoms or complications, such as recurrent upper gastrointestinal bleeding, biliary or intestinal obstruction, or malignant degeneration. Definitive treatment is surgical removal of the ectopic tissue. Asymptomatic people with incidental discovery of heterotopic pancreas do not require further evaluation or treatment. [68] If unsuspected pancreatic rests are found at surgery, excision prevents the possible complication of malignant degeneration and eliminates confusion if subsequent symptoms develop. [68], [78]

Pancreas Divisum

Pancreas divisum, the most common congenital anomaly of the pancreas, is caused by failure of the ducts of the dorsal and ventral anlagen to fuse during the fifth and sixth weeks of gestation. Normally, the proximal one third of the dorsal pancreatic duct regresses as it fuses with the ventral duct, forming the main pancreatic duct. In pancreas divisum, the ventral duct of Wirsung empties into the duodenum through the major papilla but drains only a small portion of the pancreas. Secretions from the tail, body, neck, and remainder of the head of the pancreas drain into the duodenum through the minor papilla by way of a persistent duct of Santorini. In 2% to 3% of cases in which the ducts do not fuse, the ventral duct may not be demonstrable. Normally, drainage of the pancreas can occur by either duct, depending on fusion of the two ductal systems and the degree of patency of each. Most pancreatic drainage is through the duct of Wirsung, and although some drainage occurs through the duct of Santorini, this volume is relatively small. Occasionally, the duct of Santorini ends blindly in the duodenal wall.

Although pancreas divisum is a long-recognized entity, only with the advent of ERCP has its clinical significance become apparent. In autopsy series, pancreas divisum has an incidence of 5% to 10%; [79] as an ERCP finding, its incidence is 4%. [80], [81] and [82] In a series of patients with pancreatitis, however, there was a 16% incidence of pancreas divisum, and the incidence of the abnormality increased to 25% in idiopathic pancreatitis. [80] Therefore, it appears that pancreas divisum is associated with pancreatitis. It has been postulated that pancreatitis may result from a combination of pancreas divisum and stenosis at the level of the accessory papilla, with impediment of pancreatic secretory flow. As a congenital defect, clinical manifestations of pancreas divisum may occur at any age but are uncommon in childhood. Symptoms may be mild with only occasional epigastric pain occurring postprandially, but more often episodes of severe acute pancreatitis occur. Chronic pancreatitis also may develop, with all of its associated sequelae. Changes in the pancreatic ducts characteristic of chronic pancreatitis may be detected on ERCP.

Pancreas divisum is diagnosed by pancreatography (Fig. 93-9). On ERCP, the major papilla is often difficult to cannulate, but on injection with contrast fluid, the duct of Wirsung appears shortened and of small diameter. There is rapid filling of small accessory ducts, and too much contrast can be injected before it is realized that the duct of Wirsung is not in communication with the main pancreatic duct. As a result, the patient may experience sudden pain, and pancreatitis of the ventral pancreas can develop. What appears as an abrupt cutoff of the duct of Wirsung must not be confused with a mass lesion such as a malignancy or pancreatic pseudocyst. The delicate nature on the pancreatogram of the accessory ducts is a helpful indicator of pancreas divisum. If possible, the accessory papilla should be cannulated, which should reveal a duct of Santorini running the entire length of the pancreas that is not in communication with the duct of Wirsung. While ERCP remains the gold standard for diagnosis of pancreas divisum, MR pancreatography is an emerging, noninvasive radiographic technique that is being used to define ductal anatomy (see " Annular Pancreas"). If stenosis of the papilla is not demonstrated radiographically, pancreatic manometry and secretin ultrasound scanning may be useful in identifying patients who may benefit from endoscopic or surgical intervention. [83], [84]

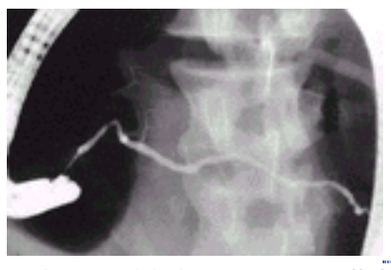

FIGURE 93-9. Pancreas divisum. An endoscopic retrograde pancreatogram performed through the accessory papilla shows the dorsal duct in pancreas divisum. (Courtesy of Peter B. Cotton, M.D., Durham, NC.)

Patients with mild symptoms can be managed conservatively. Patients with recurrent episodes of acute pancreatitis or chronic pain require intervention to alleviate accessory ductal stenosis. Surgical accessory duct sphincteroplasty has been successful in treating patients, with the best results observed in patients with recurrent episodes of acute pancreatitis. [85], [86] and [87] Endoscopic therapy with a combination of minor duct sphincterotomy and stenting has achieved similar rates of success; however, the follow-up period in these patients has been less than in the surgical groups, [88], [89] and [90] and long-term stenting of the pancreatic duct has been reported to result in chronic ductal changes. [91] Determination of which patients with acute recurrent pancreatitis would be served best by surgical or endoscopic treatment awaits further studies. Patients with chronic pancreatitis have a poor response to both surgical and endoscopic treatment modalities. In cases in which sphincterotomy has failed or the ductal involvement is more extensive, direct ductal drainage or resection of the involved pancreas is necessary. [92], [93]

Congenital Cysts

Cysts of the pancreas are distinguished from more common pseudocysts by the presence of an epithelial lining. Pseudocysts often follow bouts of acute pancreatitis, with trauma being a major precipitant. Identification of true columnar or cuboidal epithelium in congenital cysts may be difficult, and it is not always possible to distinguish a congenital cyst from a pancreatic pseudocyst. In cysts located in the peripancreatic space, identification of pancreatic enzymes in the cyst fluid is helpful in determining that it is of pancreatic origin; however, not all pancreatic cysts contain fluid rich in pancreatic enzymes. Solitary congenital cysts are rare. [94] They are more commonly diagnosed in early childhood but may remain asymptomatic and undetected into adulthood. Although other congenital anomalies have been reported with pancreatic cysts, these are more often isolated defects. [95]

The most common presentation of a solitary pancreatic cyst is as an abdominal mass, which may be associated with abdominal pain or complications resulting from expanding size, such as gastroduodenal obstruction. Encroachment on the intrapancreatic or extrapancreatic common bile duct may cause biliary obstruction. [96] Subcutaneous fat necrosis and osteolytic lesions secondary to pancreatic enzymes leaking into the circulation from a developmental pancreatic cyst have been described. [97]

A plain radiograph of the abdomen or an upper gastrointestinal radiographic series demonstrating a mass displacing a portion of the stomach, duodenum, or colon may suggest the presence of a pancreatic cyst. The best diagnostic test is computed tomography, which demonstrates a fluid-filled cystic lesion in the pancreas and its relationship to surrounding structures. In considering the differential diagnosis, it is important to consider other possible cystic lesions of the pancreas, including pancreatic pseudocysts, cystadenomas, and cystadenocarcinoma.

Cystic neoplasms of the pancreas are rare, representing about 10% of pancreatic cysts and 1% of pancreatic carcinomas. [98] Abdominal or back pain, the most common symptom, is present in about half of patients. One third of patients have an abdominal mass or weight loss. One third of patients are asymptomatic, with the cyst discovered during evaluation of other complaints. There is a clear predilection for women, with a female-to-male ratio of 8:1. Computed tomography is the most useful diagnostic modality and typically reveals a multiloculated lesion, 3 to 6 cm large, located in any region of the pancreas. Two major histological variants exist: serous cystadenomas and mucinous cystic neoplasms. Mucinous cystic neoplasms of the pancreas have clear malignant potential. Serous cystadenomas, in contrast, are almost invariably benign. Preliminary experience with biochemical and cytologic analysis of cyst fluid to distinguish serous and mucinous neoplasms has been reported. [99] The differentiation of congenital cysts, acquired pseudocysts, and cystic neoplasms is crucial. The operative therapy for chronic pseudocysts is nonresectional, whereas therapy for cystic neoplasms requires resection. [100]

Symptomatic congenital cysts should be removed whenever possible, which can be done by enucleation of the cyst if it is located in the body or head of the pancreas or by resection of the cyst with adjacent pancreatic tissue if it is confined to the distal pancreas. If the location of the cyst precludes either of these approaches, such as a cyst in the head of the pancreas, drainage into the stomach or jejunum can be performed. With surgical drainage of the cyst, pathological examination should be done to exclude malignancy.

Multiple Cysts

Multiple congenital pancreatic cysts are rare and usually are associated with other congenital anomalies. In particular, polycystic kidney disease and cystic fibrosis are frequently associated with pancreatic cysts. Other clinical syndromes involving multiple pancreatic cysts include von Hippel-Lindau syndrome, Ivemark syndrome, and Bruber syndrome, in which cysts of the lung, liver, and central nervous system also are found. [101], [102] Many of the associated anomalies are lethal, although patients may have no symptoms referable to the pancreatic cysts. Because of the numerous cysts and the involvement of several organ systems, no treatment is necessary unless specific symptoms or a particular complication, such as infection of a cyst, dictates surgical excision or drainage.

CHAPTER 94

Mark Topazian and Fred S. Gorelick

ACUTE PANCREATITIS

Acute pancreatitis is a clinical syndrome defined by a discrete episode of abdominal pain and elevations in serum enzyme levels. There is inflammation of the pancreas with varying amounts of injury to adjacent and distant organs. In the United States, more than 80% of the cases are related to biliary stones or alcohol use. Although there are many factors that may precipitate acute pancreatitis, it is rare for any but alcohol, hyperlipidemia, or genetic disorders to lead to chronic pancreatitis.

The first reports of pancreatitis may date to the 1700s, but the first systematic analysis of pancreatitis was published by Reginald Fitz in 1889. [1] In this landmark study, the clinical and pathological findings in 53 patients were presented. Fitz's analysis of the patterns of abdominal pain, fever, and jaundice, along with physical findings, established the criteria for diagnosing pancreatitis. Etiologic factors such as gallstones, alcohol, penetrating ulcers, and trauma were mentioned. Pancreatic pseudocyst, splenic vein thrombosis, disseminated fat necrosis, and abscess were also described. Fitz's report established the framework for studies and treatments of pancreatitis that have spanned more than a hundred years.

INCIDENCE

The incidence of acute pancreatitis ranges from 1 to 5 per 10,000 per year. This value is approximate and may vary widely among populations for several reasons. First, histological confirmation of pancreatitis is unavailable in most patients and the diagnosis must rely on clinical assessment, biochemical tests, and radiologic evaluations, which are limited in their sensitivity and specificity. Second, the incidence of precipitating factors such as alcoholism and gallstones varies among populations. Finally, some patient groups may be systematically excluded; for example, those with mild disease may not come to a hospital.

CLASSIFICATION

Pathology, etiology, and clinical presentation and course may all be used to classify acute pancreatitis. The existence of various groupings reflects the different goals of such classifications. Some are useful in establishing a differential diagnosis or understanding disease mechanisms, and others may provide prognostic information or guide intervention.

A sensible classification system based on a number of clinical parameters has been described by Bradley. [2] The most important feature of this classification is that it defines a common nomenclature for describing acute pancreatitis. It separates pancreatitis into mild and severe disease based on physiological findings, laboratory values, and diagnostic imaging tests, which are discussed in this chapter. Mild pancreatitis is not associated with organ dysfunction or complications, and recovery is usually uneventful. Severe pancreatitis is associated with impaired pancreatic function, local and systemic complications, a complicated recovery, and significant mortality rates. Bradley's classification makes several important distinctions by defining pancreatic fluid collections, pseudocysts, and necrosis, and separating infected pancreatic necrosis from pancreatic abscesses. This classification does not provide the criteria for establishing prognosis early in the patient's course, as discussed later in this chapter (see section " Clinical and Physiological Assessment "), but does provide a clear framework for discussing acute pancreatitis using a

defined set of terms.

PATHOLOGY

Detailed histological studies of pancreatic tissue are available from a limited number of cases of human acute pancreatitis. A histological spectrum of acute pancreatitis is recognized ranging from mild, interstitial disease to coagulation necrosis. [3] Interstitial pancreatitis may lead to local and systemic complications but is rarely fatal; necrotizing pancreatitis may be fatal in up to 30% of cases.

Interstitial

In interstitial pancreatitis the gland is edematous, but its gross architecture is preserved. Parenchymal inflammatory cells are present together with interstitial edema. Disruption of the normal acinar cell architecture is common and may contribute to the reduced enzyme secretion characteristic of acute pancreatitis. Zymogen granules are displaced from their fusion site in the apical domain of the cell and become dispersed throughout the cell, and the apical membrane appears contracted and microvilli disappear. [4] Zymogen granules fuse with each other instead of the apical membrane. Similar to animal models of pancreatitis, a distinct form of cell necrosis is observed in which the apical domain of the acinar cell is shed into the lumen, resulting in intact zymogen granules within the lumen. This pattern of partial cell necrosis may allow the acinus to regenerate rapidly after injury.

Necrotizing

Macroscopically, marked tissue necrosis and hemorrhage are apparent. Surrounding areas of fat necrosis are also prominent. These chalky areas of dead adipose tissue are found within the peripancreatic tissue and throughout the abdomen. Large hematomas often are located in the retroperitoneal space. The microscopic appearance of the pancreas parallels the gross changes, with marked fat and pancreatic necrosis. Vascular inflammation and thrombosis are common.

PATHOPHYSIOLOGY

Pancreatitis is triggered by a variety of mechanisms, including pancreatic duct obstruction, pancreatic ischemia, and toxic, immunologic, or metabolic factors. These various insults activate three major pathological processes within the acinar cell that initiate pancreatic injury (Fig. 94-1). First, inactive digestive zymogens are converted into active enzymes. Second, pancreatic exocrine secretion is inhibited and third, the pancreas generates proinflammatory mediators. The relative importance and sequence of these processes may vary with the clinical setting. Once injury has been initiated, it is perpetuated and amplified by other processes, including the inflammatory cascade and vascular damage. The importance of thinking about the steps in acute pancreatitis, especially the latter ones such as the release of damaging cytokines, neutrophil recruitment, platelet activation, and formation of free radicals, lies in the potential to target future therapeutic interventions.

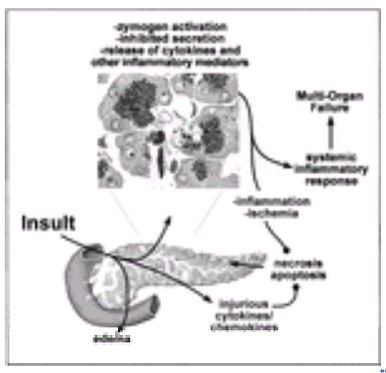

FIGURE 94-1. Initiation of acute pancreatitis. Various forms of insults initiate a cascade of events that result in acute pancreatitis. The pancreatic acinar cell responds to a variety of insults with activation of zymogens, inhibition of secretion, and release of proinflammatory substances. Inflammatory cells are activated. Expression of adhesion molecules promotes retention of inflammatory cells within the pancreas. Pancreatic blood flow may decrease because of capillary leaks, compression by edema, and vascular damage and occlusion. Toxic factors produced by pancreatic cells and inflammatory cells cause pancreatic cell death. Generalized activation of inflammatory cells may lead to the systemic inflammatory response syndrome and multisystem organ failure.

Activation of Pancreatic Zymogens

Active pancreatic enzymes have been detected within the pancreas in experimental and clinical pancreatitis. Further, a marker of trypsinogen activation, the trypsinogen activation peptide (TAP) increases within 1 hour of the onset of experimental pancreatitis. [5] A mutation in the trypsinogen molecule that is predicted to amplify trypsin activity causes at least one form of familial pancreatitis. [6] Further, mutations in the pancreatic trypsin inhibitor (SPINK 1) appear to predispose to developing pancreatitis. [7], [8] Finally, pretreatment with the protease inhibitor gabexate may reduce endoscopic retrograde cholangiopancreatography (ERCP)-induced pancreatitis. [9] Premature activation of zymogens may be the first step in a process that leads to pancreatic autodigestion and induces other pathways that lead to pancreatic injury.

Although premature zymogen activation may take place within pancreatic ducts or the interstitial space, the earliest activation site is within the acinar cell. Treatment of isolated pancreatic acini with concentrations of cholecystokinin (CCK) that generate pancreatitis in vivo leads to intracellular zymogen activation. [10] Two mechanisms have been proposed to account for intracellular activation of trypsinogen and the zymogen cascade: trypsinogen autoactivation, and trypsinogen activation by the lysosomal enzyme cathepsin B. The contribution of each potential pathway to zymogen activation remains unclear. However, the finding that genetically deleting cathepsin B from mice dramatically reduces trypsin activation in a model of pancreatitis suggests that cathepsin B plays a major role. [11] Although the site and cellular mechanism of the activation remain unclear, pathological increases in intracellular calcium may be required for zymogen activation. Alcohol, a common cause of pancreatitis, has been shown to sensitize the acinar cell to the enzyme-activating effects of CCK and to stimulate the release of CCK from the small intestine.

The potential consequences of zymogen activation are manifold, and include damaging local effects, attack on other tissues, and promotion or activation of additional pathways leading to tissue injury. Once released from the acinar cell, active digestive enzymes undoubtedly attack normal tissue structures; however, potent enzyme inhibitors are present in circulation and play an important role in limiting tissue damage. The major serum protease inhibitors include a2-macroglobulin, a1-antitrypsin, antichymotrypsin, serum trypsin inhibitor, and C1 esterase inhibitor. After these inhibitors bind to activated enzymes, the resulting complex is cleared by the reticuloendothelial system. Decreased amounts of circulating protease inhibitors and delayed clearance of serum protease-inhibitor complexes by the reticuloendothelial system have been associated with more severe forms of pancreatitis. [12]

Inhibition of Secretion

A feature common to several models of pancreatitis is the inhibition of enzyme secretion from the pancreas. Although increased paracellular permeability may contribute to this decrease, reduced acinar cell secretion from its apical membrane is likely to play a major role. Disruption of the acinar cell cytoskeleton may play a role in blocking secretion. [13] This inhibition leads to the retention of active enzymes within the acinar cell instead of their secretion into the pancreatic duct. The inhibition of secretion is likely to play a central role in the initiation of disease.

Generation of Inflammatory Mediators

Several major classes of inflammatory mediators are generated and released during acute pancreatitis. [14] These agents act by stimulating recruitment of inflammatory cells, enhancing the activation and adherence of inflammatory cells to the vascular wall, or cause direct cell injury. Soluble inflammatory mediators are known as

cytokines. Some, such as tumor necrosis factor-alpha (TNF-a) and platelet-activating factor (PAF), are generated by both the pancreatic acinar cells and inflammatory cells. Chemokines are a family of low-molecular-weight cytokines that attract particular subsets of inflammatory cells. For example, interleukin-8 (IL-8) attracts neutrophils and monocyte chemotactic protein-1 (MCP-1) attracts monocytes. Substance P is released from nerve endings and appears to mediate inflammation and particularly lung injury in experimental pancreatitis.

Substances that either directly injure acinar cells and endothelium or mediate the inflammatory response play an important role in both the early and late phases of acute pancreatitis. Higher circulating levels of proinflammatory cytokines are associated with more severe disease. Not all cytokines exhibit a harmful effect. Indeed, in one study but not another, inteleukin-10 (IL-10) has been shown to prevent ERCP-induced pancreatitis. [15], [16] The concept of treating clinical acute pancreatitis with cytokine inhibitors has promise, but has not yet succeeded in clinical trials.

Perpetuation of Disease

Inflammation Recruitment of inflammatory cells into pancreatic blood vessels and later into the pancreatic parenchyma is an early feature of acute pancreatitis. Increased expression of intercellular adhesion molecule-1 (ICAM-1) during pancreatitis leads to enhanced adhesion of activated neutrophils to the vascular endothelium. Trypsin activation of the alternate complement pathway may play a role in neutrophil recruitment. The influx of inflammatory cells may be so great as to form white cell emboli and plug small blood vessels. Activation and the influx of lymphocytes may also be an important component of injury in some forms of pancreatitis. Fibrinolysis and complement activation correlates with disease severity. Prominent generation of proinflammatory mediators can lead to the systemic inflammatory response syndrome (SIRS). Marked leukocyte activation can lead to distant organ injury and the development of multisystem organ failure. SIRS and associated multisystem organ failure is one of the two major causes of death from acute pancreatitis (the other being pancreatic infection).
Vascular Damage, Edema, and Ischemia Vascular damage and ischemia probably play an important role in many forms of acute pancreatitis. Kinins released by inflammatory cells make capillary walls permeable and promote tissue edema and fluid losses. Pancreatic edema may indirectly compromise pancreatic blood flow and increase tissue ischemia. Increased capillary permeability in other organs may contribute to organ failure. The pancreas and inflammatory cells release TNF-a, which mediates cell death, inflammation, and plays a major role in the development of shock. Oxygen free radicals also promote pancreatic injury and may be generated by a number of mechanisms. They are formed soon after acute ethanol ingestion by its oxidative metabolism. Free radicals may also be generated during vascular reperfusion and are released by neutrophils. Levels of free radicals correlate with both decreased pancreatic protein and nonprotein sulfhydryl groups and the severity of pancreatic injury. [17] Free radical damage may involve both abnormal peroxidation and depletion of thiol donors such as glutathione. Attempts to prevent pancreatic injury using free radical scavengers have been only partially successful in experimental models, and are largely untested clinically.

Protective Mechanisms

The acinar cell has a number of cellular mechanisms to limit the effects of zymogens activated within the acinar cell. Potentially active enzymes are packaged within a secretory granule membrane that is impermeable to proteins. Breakdown of the zymogen granule membrane may allow enzymes to be released into the cell. The pancreatic trypsin inhibitor is packaged together with trypsinogen in the secretory granule. Although the inhibitor is efficient, the zymogen granule contains quantities sufficient to inhibit only a small portion (10%–20%) of activated zymogen. Thus, large-scale zymogen activation might easily overwhelm the cellular protease inhibitors. Relative deficiencies of the pancreatic trypsin inhibitor have been found in some forms of recurrent pancreatitis. [18] In addition to trypsin inhibitor, proteases are also present in the zymogen granule that can degrade activated enzymes. Finally, active enzymes can be secreted from cells.

Experimental Models

Animal models of acute pancreatitis have been developed to aid in the understanding of the disease and evaluate potential therapy. Many models induce an injury that closely resembles interstitial pancreatitis, but models of severe necrotizing pancreatitis have also been established. A common shortcoming of animal studies that evaluate therapy for acute pancreatitis is timing of intervention; most treat at or before the onset of pancreatitis in a time frame that would not be clinically feasible.

Hyperstimulation One hundred years ago, Mouret [19] observed that excessive cholinergic stimulation was associated with pancreatic injury. Mouret speculated that the activation of trypsin might play an important role in this injury. In subsequent experimental models, infusions of the CCK analog, cerulein, were shown to generate pancreatic injury in a time- and dose-dependent manner. [4] Pathological changes within the first hour of hyperstimulation include inhibition of secretion into the pancreatic duct, pancreatic edema, and margination of neutrophils. Within 3 to 6 hours, inflammatory cells invade the interstitium and vacuoles form within acinar cells. Isolated pancreatic acini are often used to examine organ function at the cellular level. Recent studies have demonstrated that similar to in vivo models of pancreatitis, hyperstimulation of isolated acini by CCK causes intracellular zymogen activation. [10] Moreover, this treatment results in inhibition of secretion from the acinar cells and generation of proinflammatory mediators such as TNF. [20] The advantage of using this system is that it can be easily manipulated and examined without the confounding factors of hypoxemia and inflammation found in vivo. Thus, isolated acini appear to be a useful model for examining some of the earlier pathological events in acute pancreatitis.
Other Models A number of other models of experimental pancreatitis have been developed. It has been demonstrated that obstruction of the opossum pancreatic duct alone results in pancreatitis; [21] this model may be useful for examining the mechanism of gallstone pancreatitis. The diet-induced model is based on the observation by Lombardi and associates [22] that a choline-deficient diet supplemented with the synthetic amino acid analog of methionine, DL-ethionine, induced a fatal hemorrhagic pancreatitis in young female mice. One possibility raised by the diet model is that abnormal metabolites may contribute to pancreatitis under certain conditions such as refeeding.

SPECIFIC ETIOLOGIES

It is important to review the differential diagnosis of acute pancreatitis in each patient. Many patients have an easily identifiable and treatable cause such as hyperlipidemia or gallstones. Less common causes should be considered in those with no obvious precipitant, especially in patients with recurrent, unexplained bouts of pancreatitis. An overview of the prevalence of various etiologies is shown in Fig. 94-2.

FIGURE 94-2. Etiologies of acute pancreatitis.

Obstructive

Many forms of pancreatic duct obstruction have been associated with pancreatitis, including gallstones, pancreas divisum, sphincter of Oddi dysfunction or stenosis, ampullary or pancreatic tumors, duodenal diverticula, and parasites, clots, or foreign bodies lodged in the ampulla. Gallstones are the commonest cause of acute pancreatitis in many parts of the world.

Gallstones Although gallstones are etiologically linked to pancreatitis, this condition develops in only a small percentage of patients with gallstones. For example, in a cohort from Minnesota with gallstones, the incidence of acute pancreatitis was 0.17% per year. [23] The presence of gallstones, however, increases the relative risk for acute pancreatitis 14- to 35-fold in men and 12- to 25-fold in women. [24] Small gallstones, less than 5 mm in size, increase the risk of acute pancreatitis. A contributing factor that places men at greater risk may be larger cystic ducts favoring the migration of stones into the common duct. Anomalous union of the pancreatic and biliary ducts or a long common channel in the ampulla may also predispose to pancreatitis, possibly by promoting reflux of bile into the pancreatic duct. [25] Metabolic factors also may increase the risk for development of pancreatitis from gallstones. For example, underlying hyperlipidemia manifest by delayed chylomicron clearance may

make patients more susceptible to gallstone pancreatitis. [26] Many models have attempted to reproduce the pancreatitis generated by stones in the ampulla. A century ago, on the basis of autopsy findings, Opie proposed that a gallstone lodged in the papilla would obstruct the ampullary orifice and allow reflux of bile into the pancreatic duct via the common channel. Several observations have challenged that theory: patients without a common channel can have gallstone pancreatitis, [27] and retrograde flow of bile into the pancreatic duct at physiological pressures does not induce pancreatitis. [28] Although addition of increased intraductal pressure to bile infusion results in severe pancreatitis, pressures of such magnitude are not thought to occur under physiological conditions. Opie also proposed that pancreatic duct obstruction alone might be the mechanism by which stones cause pancreatitis. In general, simple obstruction of the pancreatic duct in animals has not generated pancreatitis. In the American opossum, however, pancreatic duct obstruction alone generates acute pancreatitis. [29] This supports the "ductal obstruction theory," as does the occurrence of human pancreatitis in other forms of pancreatic duct obstruction. It seems likely that most biliary pancreatitis is precipitated by the transient or persistent obstruction of the papilla by a stone. When patients are selected based on hyperbilirubinemia and pancreatitis, gallstone recovery from the stool has been reported in 30% to 85%. [30] Thus, pancreatitis is usually accompanied by passage of a stone into the lumen of the intestinal tract. Stone passage in most patients with gallstone pancreatitis probably occurs on the day of the attack, and in many patients it may already have occurred by the time the patient reaches the emergency department. Persistence of stones in the bile duct or ampulla is associated with more severe disease. [31], [32] If gallstones predispose to acute pancreatitis, removal of the gallbladder should decrease this risk. In Minnesota, cholecystectomy in patients without a history of acute pancreatitis reduced the risk for the subsequent development of pancreatitis at least 10- to 20-fold. [23] Despite the increased risk for development of acute pancreatitis in those with gallstones and the success of cholecystectomy in decreasing the risk, the incidence of the disease is too low to warrant prophylactic cholecystectomy in the patient with asymptomatic gallstones.

Microlithiasis Studies of patients with idiopathic recurrent pancreatitis have provided compelling evidence that crystals or aggregates of crystals in bile, referred to as microlithiasis, may cause recurrent bouts of pancreatitis. [33], [34] Microlithiasis is a leading cause of otherwise unexplained acute pancreatitis. Microlithiasis is identified during ultrasonography by observing amorphous, layering, nonshadowing material (sludge) or brightly echogenic cholesterol crystals within the gallbladder (Fig. 94-3). Sonographically apparent sludge is especially common after prolonged fasting, rapid weight loss, total parenteral nutrition, gastric surgery, and adminstration of some drugs such as octreotide or ceftriaxone.

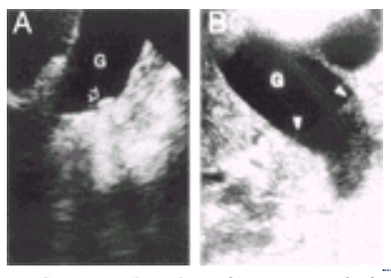

FIGURE 94-3. Ultrasound demonstrates cholelithiasis. **A**: Gallbladder (*G*) with single gallstone (*arrow*). **B**: Microlithiasis: the lower third of this gallbladder is filled with layering, nonshadowing sludge (*arrowheads*). (Courtesy of Caroline Taylor, M.D., Yale University.)

Microlithiasis can also be diagnosed in the absence of sonographically detectable sludge by examining bile for birefringent cholesterol monohydrate crystals or reddish brown, calcium bilirubinate granules. Bile can be obtained from the bile duct during ERCP or aspirated from the duodenum after slowly administering CCK octapeptide intravenously; dark gallbladder bile should be collected and examined. Endoscopic ultrasound (EUS) may be more sensitive than bile microscopy for detection of cholesterol crystals in the gallbladder. [35] Crystals, like stones, usually cause pancreatitis that begins abruptly, with an initial rise in serum levels of both pancreatic enzymes and transaminases. A minority of patients whose pancreatitis is ultimately attributed to microlithiasis have normal serum liver tests with their pancreatitis. Several forms of treatment have been used. Patients with cholesterol crystals have received ursodeoxycholic acid. Others have undergone cholecystectomy or endoscopic papillotomy alone. Each form of intervention has been reported to reduce the frequency of attacks by at least two thirds. These observations suggest that microlithiasis should be considered in patients with recurrent bouts of idiopathic pancreatitis.

Stenosis and Spasm of the Sphincter of Oddi The sphincter of Oddi is a complex muscular structure that regulates the flow of pancreatic secretions and bile into the duodenum. The sphincter acts as a variable resistor. Abnormalities of the sphincter are best defined in patients with recurrent abdominal pain after cholecystectomy, but have been associated with recurrent acute pancreatitis as well. The biliary and pancreatic portions of the sphincter of Oddi are partly independent anatomically and functionally. Acting indirectly through inhibitory neural pathways, CCK causes both components of the sphincter to relax, facilitating the flow of bile and pancreatic juice into the duodenum after a meal. CCK may also act directly on the sphincter and cause contraction. [36] This paradoxical dysfunction of the sphincter may occur after biliary tract surgery (perhaps because the innervation of the sphincter is interrupted), vagotomy, or gastric resection, and has been demonstrated to occur in both components of the sphincter after intravenous administration of CCK octapeptide to patients during sphincter of Oddi manometry. Other secretagogues and transmitters also appear to mediate relaxation of the sphincter, including vasoactive intestinal polypeptide (VIP), glucagon, and nitric oxide. [37] Secretin has been reported to induce an initial increase in phasic contractions of the sphincter in normal subjects, followed by relaxation. [38] This may account for the transient dilation of the pancreatic duct that can be observed after secretin is administered to normal subjects. The role these substances play in the development of sphincter dysfunction is unclear. Obstruction to flow through the ampulla may be caused by dysfunction of the sphincter or by scarring and stenosis of the sphincter and the ampullary outlet. Stenosis of the sphincter is most commonly the result of previous trauma from stone passage, surgical manipulation, or endoscopic sphincterotomy, but may also be due to a primary inflammatory or fibrosing process in the ampulla of Vater. Stenosing papillitis may be caused by chronic pancreatitis, sclerosing cholangitis, or by opportunistic infections in the acquired immunodeficiency syndrome (AIDS). Criteria for clinical diagnosis of sphincter of Oddi stenosis or dysfunction are well established for biliary sphincter disease. Geenan and colleagues have described three abnormalities which suggest a diagnosis of biliary sphincter dysfunction or stenosis: dilation of the bile duct, elevation of the serum liver tests, and slow drainage of contrast from the bile duct (as seen on biliary scintigraphy or after ERCP). When all three of these criteria are present (type 1), a presumptive diagnosis of sphincter disease can be made. [39] When the obstruction is intermittent or less severe, some or none of these criteria may be evident (type 2 and type 3', respectively), and biliary manometry may be useful for making the diagnosis of sphincter dysfunction. A blinded, controlled trial showed that type 2 patients with postcholecystectomy pain who had abnormal biliary manometry were more likely to benefit from endoscopic sphincterotomy. [40] Sphincter dysfunction is also described in patients with unexplained pancreatitis. Although a dilated pancreatic duct and slow pancreatic drainage may be seen in association with pancreatic sphincter dysfunction, the use of a clinical classification incorporating these findings is unproven. Diagnosis depends on pancreatic sphincter manometry performed during ERCP. Less invasive tests for diagnosis have been proposed. The secretin-ultrasound test was developed as a noninvasive method of demonstrating pancreatic outflow obstruction, but investigators disagree on the nature of normal and abnormal responses. Some have found that dilation of the pancreatic duct after secretin administration implies obstruction of pancreatic drainage, but others report that transient ductal dilation is normal after secretin, and that failure of the duct to dilate suggests a diagnosis of chronic pancreatitis. [41] While prolonged ductal dilation after secretin administration may be abnormal, this finding has been reported in patients with previous alcoholic or biliary pancreatitis, suggesting a nonspecific response. [42] A preliminary report suggests that the rate of secretin-stimulated pancreatic secretion into the duodenum assessed by magnetic resonance (MR) can also be used to assess pancreatic ductal obstruction. Manometric abnormalities of the pancreatic sphincter have been reported in a high percentage of patients with idiopathic recurrent pancreatitis. [43] The presence of manometric abnormalities does not exclude other causes of pancreatitis that might lead to secondary sphincter disease. Uncontrolled surgical and endoscopic experience suggests that treatment of a hypertensive pancreatic sphincter prevents recurrent pancreatitis in some patients. [44] Manometry of the sphincter of Oddi is a specialized endoscopic technique. The use of a manometry catheter permitting simultaneous perfusion and aspiration and the addition of meperidine to benzodiazepines for patient sedation [45], [46] improves the safety and success of the procedure. The most accepted bnormality of the sphincter of Oddi is an elevated basal sphincter pressure of at least 40 mm Hg above duodenal baseline. Tachyoddia (frequent phasic contractions of the sphincter) or retrograde phasic contractions may also cause obstruction of flow. Because manometry is done in the fasting state and for a brief time, it may miss functional abnormalities of the sphincter induced by eating. Some patients may respond to nitrates or calcium channel blockers, and endoscopic sphincterotomy often provides symptom relief. The risks of sphincterotomy are increased in patients with suspected sphincter of Oddi dysfunction. In patients with recurrent pancreatitis and sphincter dysfunction, it is unclear if the best initial therapy is biliary sphincterotomy alone or combined biliary and pancreatic sphincterotomy. Some patients improve after biliary sphincterotomy alone because of underlying biliary microlithiasis, by disruption of a hypertensive sphincter zone located in the common channel, or because the pancreatic sphincter (which partially encircles the biliary sphincter) functions differently when the biliary sphincter is severed. Endoscopic pancreatic sphincterotomy opens the pancreatic sphincter incompletely in most patients, and those with recurrent pancreatitis or persistent symptoms after pancreatic sphincterotomy may have a persistent zone of sphincter hypertension. Recurrent pancreatitis in such patients may be due to primary sphincter hypertension or to another etiology with secondary sphincter disease. Repeated endoscopic sphincterotomy or surgical sphincteroplasty may be performed, benefiting some patients. Symptomatic stenosis of a pancreatic sphincterotomy or sphincteroplasty may occur in up to 25% of patients. Stenosis may recur after treatment and can be difficult to treat effectively. Alternatives to sphincter ablation are of unclear value in pancreatic sphincter hypertension. Medical therapy with calcium channel blockers or intra-ampullary botulinum toxin injections has been used in patients with biliary sphincter dysfunction and may be effective in pancreatic sphincter dysfunction as well. Pancreatic stenting has questionable use as a therapeutic trial, since stents can cause pain in some patients, and may induce changes of chronic pancreatitis when left in place for more than a short time. [47]

Pancreas Divisum During fetal development, the dorsal and ventral buds of the pancreas each form ducts that enter the duodenum. When the pancreatic buds fuse, the ducts ordinarily join as well. The ventral duct drains the pancreas through the major papilla (duct of Wirsung) and the remnant opening of the dorsal duct forms the

minor papilla (duct of Santorini). When fusion between the two ducts is partial or absent, the dorsal duct drains most of the pancreas through the minor papilla. This anatomic variant is known as pancreas divisum, and may cause pancreatitis. The relationship of pancreas divisum to pancreatitis has been debated. Pancreas divisum is a common abnormality; autopsy series report an incidence of about 7%. The incidence assessed by ERCP ranges from 0.3% to 8%. This variability is likely the result of differences in the patient populations and definition of the anomaly. For example, some studies include only patients with a complete separation between the dorsal and ventral ducts. Although earlier studies estimated that pancreas divisum can be found in about 25% of patients with unexplained recurrent pancreatitis, many subsequent studies have not confirmed this association. [48] Proponents of the pathological association have suggested that resistance to the flow of secretions through the duct of Santorini causes ductal hypertension and pancreatitis. Studies of experimental pancreatitis have shown that obstruction of the pancreatic duct alone may result in pancreatitis. [29] It is likely that a small number of people with pancreas divisum experience recurrent pancreatitis related to obstruction at the duct of Santorini. These may be individuals with a particularly diminutive orifice of the minor papilla. Treatment studies provide the best evidence that obstruction to flow through the minor papilla can cause pancreatitis. A small, blinded, randomized trial showed that endoscopic treatment of the minor papilla prevented recurrent pancreatitis when compared to sham therapy in patients with pancreas divisum. [49] A larger body of uncontrolled surgical and endoscopic experience supports this conclusion and suggests that improved dorsal duct drainage is most likely to help patients with otherwise unexplained recurrent acute pancreatitis. About 70% of such patients will improve substantially after minor papilla sphincterotomy. Patients with chronic pancreatitis are less likely to respond, and those with chronic abdominal pain but no history of pancreatitis will have symptomatic improvement only about 30% of the time. [50] Endoscopic treatment of pancreas divisum is possible because the narrowest part of the minor papilla orifice is usually at the level of the duodenal mucosa. An experienced therapeutic endoscopist best accomplishes deep cannulation of the dorsal duct and minor papilla sphincterotomy. Most experts leave a stent or nasopancreatic drain after minor papilla sphincterotomy to prevent edema from temporarily obstructing the pancreatic duct orifice. Botulinum toxin injections into the minor papilla have been reported to predict response to endoscopic sphincterotomy in patients with divisum and recurrent pancreatitis. [51]

Toxic

Alcohol Alcoholic pancreatitis may present as an acute bout of pancreatitis. Although experience has suggested that these episodes are invariably associated with established, chronic, underlying pancreatic damage, this may not always be the case. In one series of patients who died of acute alcoholic pancreatitis, almost 40% demonstrated little histological evidence of chronic pancreatitis. [52] The incidence of pancreatitis is surprisingly low in alcoholic patients. Dreiling and Koller [53] reported that for 100 alcoholic patients, clinical pancreatitis develops in only 5%, cirrhosis in 15%, both in 1%, and neither in 80%. While these data may underestimate the true prevalence of disease, they indicate that in addition to the amount of alcohol ingested, unknown factors affect a person's susceptibility to disease. Several major physiological mechanisms may contribute to the development of alcoholic pancreatitis, including abnormal sphincter of Oddi spasm or relaxation, obstruction of small ductules by proteinaceous plugs, and direct toxic and metabolic effects. [54] Chronic ethanol feeding may also sensitize the pancreas to other insults. Stimulation of proinflammatory cytokines by ethanol may have a central role in this sensitization. Alcohol has been reported to have variable effects on the pressure at the sphincter of Oddi. Alcohol has also been found to stimulate pancreatic secretion through cholinergic pathways. Some have proposed that the combination of alcohol-induced sphincter of Oddi spasm and stimulated secretion is responsible for pancreatitis. The pharmacological doses of ethanol used in many of these studies, however, leave the importance of these effects in question. Ethanol may change the concentration and composition of proteins secreted by the pancreas, resulting in the formation of protein plugs within small pancreatic ductules. These plugs are indistinguishable from those found early in the course of cystic fibrosis, which raises the possibility that these two diseases somehow may be linked. The protein plugs may obstruct small pancreatic ducts and promote pancreatitis. Increased viscosity and elevated protein concentrations found in pancreatic secretions from alcoholic patients are likely to contribute to plug formation. By forming a rigid, insoluble protein structure, specific secretory proteins such as lithostathine and glycoprotein-2 may contribute to the formation of these protein plugs and to stone formation. [55] Of note, glycoprotein-2 is closely related to the principal constituent of renal tubular casts, Tamm-Horsfall protein. The failure to alkalinize the acinar lumen in alcoholics may also contribute to plug and stone formation. Ethanol also may change the amounts of potentially damaging proteases in pancreatic secretion. For example, increased amounts of lysosomal enzymes and an increased trypsinogen:pancreatic trypsin inhibitor ratio has been reported in pancreatic juice from alcoholic patients. Alcohol's metabolic by-products may generate some its toxic effects. The pancreatic acinar cell has the ability to metabolize ethanol through oxidative and nonoxidative pathways. The oxidative metabolites include acetaldehyde and acetate. The nonoxidative metabolites of alcohol are nonesterified fatty acids. Both types of products have been identified in the pancreas and may contribute to toxicity. Alcohol may affect systemic and pancreatic lipid metabolism. One of the first pancreatic effects of ethanol in animals is the accumulation of lipid droplets within the acinar cell. Acute ethanol ingestion has been found to enhance de novo pancreatic triglyceride synthesis and alter membrane fluidity and integrity. [56] Fragile pancreatic lysosomes develop in ethanol-fed rats. [57] Pancreatic stimulation by supraphysiological doses of CCK can cause pancreatitis. Further, by augmenting pancreatic injury, CCK may play a role in many forms of pancreatitis. [58] Ethanol dramatically sensitizes the acinar cell to CCK-stimulated intracellular zymogen proteolysis. [59] Ethanol also may stimulate CCK release from the small intestine. [60] Thus, a combination of moderately elevated CCK levels and ethanol may result in pancreatic "hyperstimulation," zymogen activation, and autodigestion. In addition, ethanol may have systemic effects that promote the development of pancreatitis. Ethanol can exacerbate hyperlipidemia, for example. Diets, especially those rich in fat, may contribute to the deleterious effects of alcohol. Chronic alcoholics have diminished reticuloendothelial function and delayed clearance of protease-inhibitor complexes. Finally, inherited factors, such as deficiencies in protease inhibitors, may predispose one to alcoholic pancreatitis.

Drugs A variety of drugs have been associated with pancreatitis. [61] With few exceptions, the mechanisms of drug-induced disease are unknown and most are idiosyncratic reactions. Drug-induced pancreatitis may be classified by the certainty of its relationship to disease. Rechallenge is taken as the gold standard of proof, but such information is often unavailable. A partial listing of medications grouped according to probability that they cause pancreatitis is presented in Table 94-1.

PROVEN	PROBABLE	POSSIBLE/ QUESTIONABLE
L-Asparaginase	Protease inhibitors	Carbamazepine
Azathioprine	Acetominophen	Corticosteroids
Didanosine	5-Aminosalycilic acid	Cimetidine
Estrogens	Ergotamine	Furadantin
ACE inhibitors	Furosemide	Metronidazole
6-Mecaptopurine	Isoniazid	Minocycline
Pentamidine	Procainamide	Piroxicam
Sulfasalazine	Rifampicin	Ranitidine
Valproate	Thiazides	Tetracycline

ACE, angiotensin-converting enzyme.

TABLE 94-1 Examples of Drug-Induced Pancreatitis

Immunosuppressants are one family of drugs that can cause pancreatitis. Within this group, azathioprine and its major metabolite, 6-mercaptopurine are the major offenders; in one series of 396 patients taking these medications, pancreatitis was induced in 3.3%. [62] Symptoms developed in all patients within the first month of therapy. Rechallenge with either azathioprine or 6-mercaptopurine was invariably associated with a rapid recurrence of pancreatitis. Furthermore, attempts to desensitize with slowly increasing doses of 6-mercaptopurine were not successful. Both cyclosporine and tacrolimus have been rarely associated with acute pancreatitis. The rare (approximately 2%) but severe (approximately 50% mortality) pancreatitis associated with renal or liver transplantation may be linked to drug therapy or to infection. Some drugs used to treat AIDS can cause severe pancreatitis. Trimethoprim-sulfamethoxazole can precipitate pancreatitis, albeit uncommonly. Intravenous or aerosolized pentamidine cause pancreatitis depending on the cumulative dose of the drug. Another cause of pancreatitis in patients with AIDS is the antiviral agent, 2',3'-dideoxyinosine (DDI). The onset of DDI-associated pancreatitis is typically delayed for several months after the initiation of therapy. Although the mechanism of DDI-induced pancreatitis is unknown, patients with a previous history of pancreatitis and those with advanced infection seem to be at the highest risk for this complication. Decreasing the dose of DDI reduces the incidence of this serious complication. Human immunodeficiency virus (HIV) protease inhibitors may cause pancreatitis indirectly by elevating serum triglyceride levels. Antiinflammatory agents cause pancreatitis. Sulfasalazine and, in a small number of patients, oral 5-aminosalicylic acid have both been reported as causes of pancreatitis. [63] Early reports of corticosteroids and corticotropin causing pancreatitis are difficult to interpret because most patients had other possible causes of disease. Corticosteroids may directly precipitate pancreatitis as demonstrated by rechallenge, but this appears to be a rare event. [64] Tetracycline has been linked to pancreatitis in patients with fatty degeneration of the liver, particularly during pregnancy. Although symptoms usually develop within weeks, they have been reported after 2 years of medication. Rarely, tetracycline may precipitate pancreatitis in the absence of underlying liver disease. [65] Antihypertensives and diuretics are widely used and though the incidence of pancreatitis is low with these drugs, they constitute an important family of disease-producing agents. Included on the list are furosemide, thiazide diuretics, and angiotensin-converting enzyme (ACE) inhibitors. A few agents induce metabolic abnormalities that predispose to pancreatitis. For example, therapy with estrogens or the retinoid derivative, isotretinoin, is associated with a dose-dependent increase in triglycerides and pancreatitis. [66] Agents that overstimulate neural pathways may cause acute pancreatitis. In animal models, neural stimulation can initiate pancreatitis or augment that caused by other agents. Parathion, an alkylphosphate cholinesterase inhibitor, is a widely applied agricultural insecticide. Ingestion or absorption of parathion through the skin may induce injury. Almost 50% of patients with toxic exposure to this agent will exhibit biochemical evidence of pancreatitis. Although parathion-induced pancreatitis is usually mild, fatal hemorrhagic pancreatitis has been reported. [67] Acting through neural pathways, ergotamine poisoning decreases blood flow to cause ischemic pancreatitis and hepatitis. [68]

Scorpion Venom The venom of the scorpions *Tityus trinitatis* and *Tityus serrulatus,* found in Trinidad and Brazil, respectively, may induce a form of hyperstimulation pancreatitis. The toxic polypeptides in tityustoxin have been characterized; acting through cholinergic pathways, they are potent stimulants of pancreatic secretion in vitro and induce pancreatitis in animals. [69] In addition to causing pathological enzyme activation, tityustoxin may stimulate pancreatic secretion, induce sphincter of

Oddi spasm, and change blood flow.

Metabolic
