CHAPTER 131

Julián Panés and Josep M. Piqué

INTESTINAL ISCHEMIA

Intestinal ischemia is not rare, accounting for about 1 in 1000 hospital admissions. [1] The increase in the incidence of this disorder in recent years is secondary to multiple factors, such as heightened awareness for the diagnoses, the advanced mean age of the population, and the increasing number of critically ill patients. Despite better insights into the pathophysiology of intestinal ischemia, these syndromes continue to have high morbidity, as evidenced by the greater than 60% rate of mortality from acute ischemia of the small intestine. [2] *Diagnosis before the occurrence of intestinal infarction is the most important factor in improving survival for patients with intestinal ischemia*. Thus, the objectives of this chapter are to provide knowledge of the basic anatomic and pathophysiologic mechanisms underlying intestinal ischemic damage, the guidelines for identification of patients who require prompt and aggressive evaluation, and delineation of the optimal diagnostic workup and type of therapy for each patient.

ANATOMY OF THE INTESTINAL CIRCULATION

Generally, the involved segment of ischemic intestine has a linear correspondence to the location and extent of vascular occlusion. Knowledge of the vascular anatomy is therefore crucial for the understanding of the pathophysiology, clinical presentation, and therapy of intestinal ischemia.

Embryology

The mesenteric vessels arise from the primitive ventral segmental arteries. As development proceeds, there is regression of all but three primitive communications, with only the precursors to the three major mesenteric vessels remaining. The 10th segmental artery gives rise to the celiac artery that supplies the foregut, the 13th artery gives rise to the superior mesenteric artery (SMA) to supply the midgut, and the 21st or 22nd artery gives rise to the inferior mesenteric artery (IMA) to supply the hindgut. Most variations in vascular anatomy can be traced to either persistence or incomplete regression of primitive segments. [3]

Celiac Artery

The celiac artery arises from the abdominal aorta at about the level of the T-12 or L-1 vertebral body. It usually courses anteriorly and slightly inferiorly 1 to 2 cm before branching into the left gastric, common hepatic, and splenic arteries. The left gastric artery supplies the stomach and provides small branches to the esophagus that anastomose with aortic esophageal branches, and small branches that anastomose with the right gastric artery, a branch of the hepatic artery. The common hepatic artery divides into the hepatic artery, which supplies the liver; the right gastric artery, which supplies the stomach along the lesser curvature; and the gastroduodenal artery, which divides into right gastroepiploic and superior pancreaticoduodenal arteries to supply the antrum, duodenum, and pancreas. The splenic artery supplies the spleen and body and tail of the pancreas. [4]

Superior Mesenteric Artery

The SMA arises from the aorta about 1 cm below the celiac artery, usually at the level of L-1. It courses inferiorly and toward the right to terminate at the level of the cecum as the ileocolic artery (Fig. 131-1A). The inferior pancreaticoduodenal artery is one of the first branches of the SMA; it supplies the pancreatic head, uncinate process, and descending duodenum, and anastomoses with the corresponding superior branches from the celiac axis. Generally, there are more SMA branches to the distal small bowel than to the more proximal portions, thus providing greater potential for distal anastomotic communication. The middle colic artery arises from the proximal SMA to supply the transverse colon and communicates with branches of the IMA. The right colic artery may arise as a common trunk with the middle colic artery or have a separate origin from the SMA; it supplies the distal ascending colon and right colonic (hepatic) flexure. The ileocolic artery is the terminal branch of the SMA and supplies the distal ileum, cecum, and ascending colon.

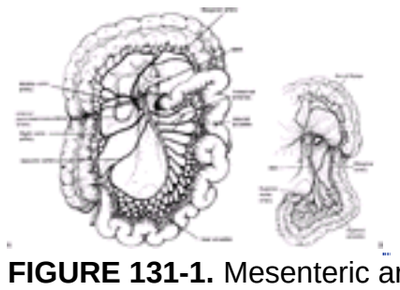

FIGURE 131-1. Mesenteric arterial circulation. **A:** The superior mesenteric artery (SMA) exits the aorta 1 cm below the celiac artery. It supplies the entire small intestine except for the superior part of the duodenum and supplies the right colon and part of the pancreas. Branches include the inferior pancreaticoduodenal artery, numerous jejunal and ileal branches, the ileocolic artery, and the middle colic artery. **B:** The inferior mesenteric artery (IMA) arises from the aorta 3 cm proximal to the aortic bifurcation. The artery branches into the left colic, several sigmoid (inferior left colic) arteries, and the superior rectal (hemorrhoidal) artery. The arcades of the SMA and IMA interconnect at the base and border of the mesentery. The connection at the base of the mesentery provides a potential collateral channel between SMA and IMA, called the *arc of Riolan*. The connection along the mesenteric border provides another potential collateral channel, called the *marginal artery of Drummond*. (From Marston A, Pegington J. Macroscopic anatomy. In: Marston A, Bulkley GB, Fiddian-Green RG, Haglund UH, eds. Splanchnic ischemia and multiple organ failure. London: Edward Arnold, 1989:13.)

Inferior Mesenteric Artery

The IMA is the smallest of the mesenteric vessels and arises from the ventral aorta about 6 to 7 cm below the SMA at the level of L-3 (see Fig. 131-1B). The artery branches into the left colic artery, which supplies the left (distal) transverse colon and splenic flexure; several sigmoid (inferior left colic) arteries, which supply the sigmoid and descending colon; and the superior rectal (hemorrhoidal) artery, which supplies a large part of the rectum. The inferior rectal (hemorrhoidal) arteries, derived from the internal pudendal arteries, and the small and inconstant middle rectal (hemorrhoidal) arteries, derived from the internal iliac arteries, also supply the rectum.

Arterial Collaterals

Extensive anastomotic and collateral circulation exists within each and among the three major intestinal vessels as well as between the mesenteric vessels and the nonmesenteric systemic circulation. Major branches of the celiac artery interconnect in the stomach and duodenum. A series of arcades interconnect neighboring branches of the SMA. [3] A similar series of arcades interconnect neighboring branches of the IMA. The primary potential pathway of collateral flow between the celiac artery and SMA is through the gastroduodenal and pancreaticoduodenal arteries (Fig. 131-2). As previously noted, there are extensive communications between the gastroduodenal artery and branches of the SMA, with the inferior pancreaticoduodenal being the most common. Additionally, omental branches of the SMA can communicate with branches of the celiac artery by the arc of Barkow. [4] An uncommon but well-described communication is the arc of Bühler, a direct communication between the celiac artery and SMA that represents a persistence of the embryonic ventral segmental arteries.

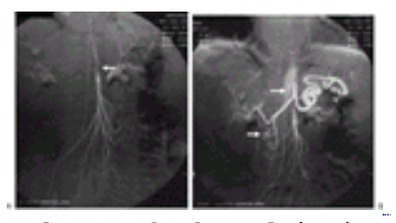

FIGURE 131-2. A: Selective digital subtraction angiography (DSA) of the superior mesenteric artery (SMA), showing a long and high-grade stenosis of the proximal artery (*arrow*). **B:** DSA injection of the celiac axis (*thick arrow*) of the same patient demonstrating collateral filling of the distal SMA through pancreaticoduodenal collaterals (*thin arrow*).

The arcades of the SMA and IMA interconnect at the base (away from the colon) and border (near the colon) of the mesentery (see Fig. 131-1B). The connection at the base of the mesentery provides a potential collateral channel between the SMA and IMA, called the *meandering mesenteric artery,* or *arc of Riolan*. [3] The connection along the mesenteric border provides another collateral channel called the *marginal artery of Drummond*.

Despite the presence of collateral channels, the vasculature has several points susceptible to poor perfusion (watershed areas). The middle part of the small intestine, in the middle of the area perfused by the SMA, is far away from collaterals from the celiac axis to the proximal SMA and from collaterals from the IMA to the distal SMA. This area is the most vulnerable to develop ischemia from SMA occlusion. Narrow terminal branches of the SMA supply the splenic flexure, and the rectosigmoid junction is supplied by terminal branches of the IMA. These two watershed areas are most vulnerable to develop ischemia during systemic hypotension if the collateral anastomoses are small or tenuous. [5]

Venous Anatomy

The venous system generally parallels the arterial distribution. The inferior mesenteric vein (IMV) drains the rectum through the superior rectal vein, the sigmoid through the sigmoid veins, and the descending colon through the left colic vein. The superior mesenteric vein (SMV) drains the small intestine, cecum, ascending colon, and transverse colon through the jejunal, ileal, ileocolic, right colic, and middle colic veins. [6] The SMV also drains the greater omentum and distal stomach with the right gastroepiploic vein and drains part of the pancreas and duodenum through the inferior pancreaticoduodenal vein. The IMV drains into the splenic vein, which then joins the SMV to form the portal vein.

MECHANISMS OF ISCHEMIC INJURY

When blood flow to the intestine decreases below a critical point, important metabolic and structural alterations appear in a variety of intestinal cells that can eventually cause cell destruction and death. Despite the fact that restitution of blood flow is necessary to limit the progression of cellular injury associated with decreased oxygen and nutrient delivery, it has become apparent that restoration of blood flow and oxygenation to the ischemic intestine can result in a paradoxical enhancement of tissue injury; a process that has been termed *reperfusion injury*. The mechanisms that are believed to participate in ischemic and reperfusion injury include the infiltration of postischemic tissues by inflammatory cells, an increased production of reactive oxygen species (ROS), alterations in vascular permeability, and inhibition of local cytoprotective mechanisms (Fig. 131-3). For a detailed description of the structure and functions of intestinal microcirculation under physiologic conditions, see Chapter 22, Gastrointestinal Blood Flow.

FIGURE 131-3. Mechanisms involved in ischemia-induced intestinal damage. Ischemia results in an increased production of oxidants, with a corresponding reduction in the synthesis of nitric oxide (NO) by endothelial NO synthase (eNOS). The enhanced generation of oxidants results in the activation of endothelial cells and leukocytes. Firm adhesion of leukocytes, which is mediated by ß2-integrins (CD11/CD18), is induced by engagement of activated leukotriene B_4 and platelet-activating factor with their receptors on rolling leukocytes. Sustained rolling and adhesion of leukocytes on endothelial cells are ensured by an oxidant-dependent synthesis of endothelial cell adhesion molecules, such as P-selectin and intercellular adhesion molecule 1. The inflammatory responses to ischemia are further amplified by oxidants derived from reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase in leukocytes and by mediators released from mast cells and macrophages that normally reside in close proximity to postcapillary venules.

Inflammatory Response

Recruitment of circulating leukocytes toward the ischemic intestine is a key event in the pathophysiology of intestinal ischemic injury. Both leukocyte and endothelial adhesion molecules participate in slowing the leukocyte as it exits the capillary and enters the postcapillary venule, which is the major site of leukocyte–endothelial cell adhesion. [7] The initial event, known as the *rolling phenomenon,* consists of a transient adhesive interaction and is mainly mediated by the selectin family of adhesion molecules: L-selectin, expressed on all leukocytes; P-selectin, detected on activated platelets and endothelial cells; and E-selectin, exclusively found in the latter. Several studies have reported an important up-regulation of P-selectin in the intestine submitted to ischemia, [8], [9] and this molecule appears to play a key role in mediating leukocyte infiltration and organ dysfunction during low-flow states or transient interruption of intestinal blood flow. [10] In addition to P-selectin, L-selectin has also been implicated in the process of tissue infiltration and organ failure resulting from ischemia. [11], [12]

Firm leukocyte adhesion and eventual emigration to the perivascular interstitium are mediated mainly by the intercellular adhesion molecule 1 (ICAM-1), a constitutively expressed immunoglobulin located on endothelial cells, and by its counter-receptors on neutrophils, the ß $_2$-integrins CD11a/CD18 and CD11b/CD18. Endothelial expression of ICAM-1 has been found to increase in tissues subjected to ischemia [13], [14] and also in distant organs, suggesting a possible role for this molecule in the pathogenesis of multiple organ failure. [15] Moreover, the administration of an antibody against ICAM-1 or against the common ß $_2$ subunit CD18 significantly prevents leukocyte accumulation and microvascular dysfunction during reperfusion. [16] Other strategies, such as administration of ICAM-1 antisense oligonucleotide [17] or the disruption of ICAM-1 or CD18 genes, [18] also prevent ischemia-induced neutrophil accumulation. Trafficking of leukocytes in venules is a determinant of the extent of ischemia-induced endothelial barrier dysfunction. The magnitude of albumin leakage in postischemic venules is highly correlated with the number of adherent and emigrated leukocytes, and adhesion molecule–directed antibodies that effectively blunt leukocyte adherence and emigration also exert an attenuating action on ischemia-induced albumin leakage. [16]

Reactive Oxidants

The increased production of ROS by both endothelial cells and leukocytes in postischemic tissues appears to be a key determinant of reperfusion injury to the microvasculature. An important source of endothelial cell–derived superoxide and hydrogen peroxide is the enzyme xanthine oxidase. Intestinal endothelial cells are enriched with the enzyme xanthine oxidase. Ischemia promotes the conversion of the nicotinamide adenine dinucleotide (NAD)-reducing dehydrogenase form of the enzyme to the oxygen-reducing oxidase form. The accumulation of hypoxanthine during ischemia allows for a burst of superoxide and hydrogen peroxide production by the enzyme when oxygen is reintroduced into the blood vessel at the time of reperfusion. [19] Although xanthine oxidase contributes to the initial oxidant stress elicited in venules after a few minutes of reperfusion, adherent leukocytes account for the substantially greater oxidant stress that occurs thereafter. [20] This contention is supported by studies that demonstrate a diminished oxidant stress in postischemic venules of animals in which postischemic leukocyte recruitment is abrogated by means of blocking monoclonal antibodies directed against endothelial or leukocyte adhesion molecules. [19], [21]

Imbalance of Proinflammatory and Protective Mechanisms

It has been suggested that ischemia induces an acute inflammatory response and microvascular dysfunction by altering the balance between nitric oxide (NO) and superoxide production. There are several lines of evidence that implicate NO bioavailability as an important determinant of the inflammatory responses observed after ischemia. These include (1) a reduction in the activity of the Ca^{2+}-dependent isoform of NO synthase in postischemic tissues; (2) the ability of NO synthase inhibitors to mimic most of the microvascular alterations normally produced by ischemia, that is, leukocyte recruitment, platelet-leukocyte aggregation, mast cell degranulation, and an increased albumin leakage; and (3) the protection against ischemia-induced leukocyte recruitment and microvascular dysfunction that is afforded by NO-releasing compounds, which replenish tissue NO levels in postischemic tissues. [22], [23]

Under normal conditions, the flux of NO greatly exceeds the rate of superoxide production. This allows for NO to scavenge the low intracellular levels of superoxide. However, within minutes after reperfusion of ischemic tissues, the balance between NO and superoxide is tipped in favor of the latter. This imbalance results from a profound increase in the production of superoxide by endothelial cells and adherent leukocytes with a corresponding decline in the synthesis of NO from endothelial NO synthase. The relatively low levels of NO are insufficient to oppose leukocyte–endothelial cell interactions and to maintain optimal tissue blood flow.

The accumulation of superoxide that occurs in the absence of NO after ischemia allows for an enhanced generation of hydrogen peroxide. The two reactive oxygen metabolites (and H_2O_2) can rapidly initiate or exacerbate the inflammatory state in venules (1) by eliciting the production of platelet-activating factor (PAF) through phospholipase activation; (2) by mobilizing the stored pool of P-selectin to the endothelial cell surface, where it mediates leukocyte rolling; and (3) by activating nuclear transcription factors, such as NF-?B and AP-1, which in turn activate genes that encode adhesion molecules such as P-selectin, E-selectin, and ICAM-1 [23] (see Fig. 131-3).

INFLUENCE OF RISK FACTORS

It is often assumed that common risk factors for ischemic disease, including hypercholesterolemia, diabetes, and hypertension, render organs such as heart, brain, or intestine more susceptible to ischemia by increasing atherosclerosis-induced flow restriction in arterial vessels. However, there is a growing body of evidence suggesting that the risk factors for ischemic disease may also exert their deleterious action by enhancing the vulnerability of the microvasculature to the injurious effects of ischemia.

Hypercholesterolemia

Elevated levels of plasma cholesterol appear to exacerbate the dysfunctional responses elicited by ischemia in all segments of the microvasculature. Endothelium-dependent relaxation of arterioles is impaired in even mild hypercholesterolemia. [24] This response is reversed by superoxide dismutase, suggesting that an accelerated production of superoxide by arteriolar endothelial cells leads to inactivation of endothelial cell–derived NO. [25] This possibility is supported by measurements of an enhanced production of superoxide by arterial endothelial cells from hypercholesterolemic animals. [24] A larger number of rolling, adherent, and emigrated leukocytes; platelet-leukocyte aggregates; and more albumin extravasation have been observed in postischemic venules of low-density lipoprotein receptor deficient ($LDLr^{-/-}$) mice and rats placed on a high cholesterol diet, compared with their normocholesterolemic controls. [26] One of the factors contributing increased leukocyte recruitment in hypercholesterolemic animals is an altered expression of adhesion molecules; in that regard, an enhanced expression of P-selectin has been demonstrated in postischemic intestinal vasculature of hypercholesterolemic rats, as compared with normal animals. [27]

Diabetes

Diabetes mellitus is another risk factor for ischemic tissue disease that appears to influence the responses of the microvasculature to ischemia. Experimentally induced diabetes is also associated with a significant enhancement in the recruitment of rolling, adherent, and emigrating leukocytes; more albumin leakage; and an accelerated formation of ROS in mesenteric venules exposed to ischemia, when compared with venules of control rats submitted to the same ischemic insult. [21], [28], [29] The enhanced recruitment of rolling leukocytes is mediated by P-selectin, whereas the exaggerated firm adhesion of leukocytes is mediated by interactions between CD11/CD18 on leukocytes and ICAM-1 on endothelial cells. Although constitutive expression of ICAM-1 is similar in diabetic and nondiabetic animals, a more profound increase in ICAM-1 after ischemia has been observed in diabetic animals than in controls. [30]

Diabetes, like hypercholesterolemia, predisposes postischemic tissues to an oxidant stress. Measurements of ROS production within and surrounding mesenteric venules of normal and diabetic animals exposed to ischemia have revealed a more intense oxidant stress in postischemic venules of diabetic animals, which is abolished by interventions (e.g., oxypurinol, anti–ICAM-1 antibody, PAF receptor antagonist) that block the exaggerated recruitment of leukocytes observed in the diabetic condition. [21] Furthermore, PAF- or leukotriene B_4 (LTB_4)-stimulated neutrophils isolated from diabetic rats produce significantly higher amounts of superoxide than their counterparts in control (nondiabetic) animals. [21] Overall, these findings suggest that leukocytes, which may be primed for activation by lipid mediators such PAF and LTB_4, are the primary source of the large fluxes of oxidants generated in postischemic venules of diabetic animals. Unlike the responses observed in hypercholesterolemic animals, wherein the exaggerated albumin extravasation from postischemic venules is tightly linked to the accompanying enhancement of leukocyte–endothelial cell adhesion, a leukocyte-independent mechanism appears to mediate the ischemia-induced endothelial barrier dysfunction in diabetes. [28]

Hypertension

Relatively little is known about the influence of hypertension on the responses of the microvasculature to ischemia. Although a number of studies suggest that hypertension is associated with altered inflammatory responses, it remains unclear whether chronic arterial hypertension enhances or attenuates the responses elicited by inflammatory stimuli, such as ischemia. [20] For example, some reports describe a greater proportion of basally activated granulocytes in the blood of spontaneously hypertensive rats (SHR) compared with normotensive (WKY) control rats, and an increased spontaneous production of xanthine oxidase–derived oxidants in the microvasculature of SHR and hypertensive Dahl salt-sensitive rats. [31] However, these observations contrast with reports describing an impaired leukocyte–endothelial cell adhesion in venules of SHR (relative to WKY) exposed to inflammatory stimuli, [32] or lack of P-selectin up-regulation in response to ischemia and reperfusion in hypertensive animals. [27] When the inflammatory and microvascular responses to ischemia were compared in mesenteric venules of SHR and WKY rats, it was noted that the number of firmly adherent and emigrated leukocytes and platelet-leukocyte aggregations in postischemic venules of SHR were quite similar to those measured in WKY. However, albumin leakage from venules was more profoundly enhanced by reperfusion in SHR than in WKY. [33]

DEFINITIONS OF CLINICAL SYNDROMES

Under the term *intestinal ischemia,* a number of clinical disorders are included in which blood supply to the intestine and mesentery is impaired, thus limiting tissue oxygenation and nutrient availability. This can be a consequence of reduced splanchnic or mesenteric blood flow in the overall territory or in a regional bed.

The spectrum of intestinal ischemia comprises number of syndromes, including *acute mesenteric ischemia* (AMI) as a result of emboli, arterial or venous thrombi, vasoconstriction secondary to low-flow states, or small bowel loop strangulation; *chronic mesenteric ischemia* (also named *intestinal angina*) due to transient, recurrent episodes of inadequate intestinal blood flow to sustain metabolic needs or to support increased metabolic demand such as that associated with digestion; and *ischemic colitis,* in which a circulatory insufficiency of the colon results in varying degrees of local tissue necrosis and systemic manifestations.

ACUTE MESENTERIC ISCHEMIA

Acute insufficiency of the blood supply to the intestine can result from emboli, arterial and venous thrombi, or vasoconstriction secondary to low-flow states.

Arterial Embolism

Embolization to the SMA constitutes about 5% of peripheral emboli and accounts for roughly 50% of all cases of AMI. The SMA is anatomically susceptible to embolism because it has a large caliber and arises from the aorta at a narrow angle. [34] In contrast, the IMA rarely suffers embolic occlusion because it has a small caliber, and the celiac axis rarely suffers embolic occlusion because it arises from the aorta at a right angle. Risk factors for mesenteric arterial embolism are listed in Table 131-1. Most mesenteric arterial emboli originate from the left side of the heart, commonly from a thrombus in the left atrium or left ventricle, or from a lesion on the mitral or aortic valves. [35] Less commonly, emboli originate from an ulcerated aortic atherosclerotic plaque or a thrombosed aortic aneurysm. The most common precipitant of thrombus dislodgment and embolization is a cardiac arrhythmia, especially atrial fibrillation. Anticoagulation markedly decreases the risk for embolization from atrial fibrillation. [36] Myocardial dyskinesia, cardioversion, and cardiac catheterization are other clinical settings for embolization. The sudden occurrence of abdominal pain in these settings should prompt evaluation for SMA embolization. A substantial fraction of patients have prior emboli, and about 20% have synchronous emboli. [35]

Embolus (55% of cases)
Cardiac arrhythmia (atrial fibrillation)
Myocardial dyskinesia
Prosthetic valve
Cardioversion
Cardiac catheterization
Recent myocardial infarction
Prior or simultaneous emboli
Thrombus (15% of cases)
Prior arterial insufficiency
Coronary
Cerebrovascular
Peripheral
Old age
Low-flow state
Diabetes
Hypercholesterolemia
Hypertension
Congestive heart failure
Hypercoagulable states
Vasculitides
Aortic or mesenteric artery aneurysm
Trauma
Nonocclusive mesenteric ischemia (30% of cases)
Cardiogenic shock
Hypovolemic shock
Congestive heart failure
Pulmonary edema
Aortic insufficiency
Major cardiac or abdominal surgery
Dialysis
Vasoconstrictive drugs

TABLE 131-1 Factors Predisposing to Intestinal Arterial Ischemia

About 15% of emboli impact at the origin of the SMA, whereas most lodge distally 3 to 10 cm in the tapered segment of the SMA, past the origin of the middle colic artery. [37] Emboli tend to obstruct mesenteric flow acutely and completely and provide insufficient time to develop protective mesenteric collaterals. Intestinal ischemia due to embolic arterial occlusion can be compounded by reactive mesenteric vasoconstriction, further reducing collateral flow and worsening the ischemic insult. [2]

Arterial Thrombosis

Thrombosis accounts for about 15% of cases of acute intestinal ischemia. Thrombosis of the SMA or celiac artery is generally associated with a preexisting stenosis, usually at the origin of the arteries. Typically, the SMA plaque slowly progresses to a critical stenosis over years, and the residual lumen suddenly thromboses during a period of low flow. Patients usually have diffuse atherosclerotic disease, with prior coronary, cerebrovascular, or peripheral arterial insufficiency (see Table 131-1). About 30% of patients have histories consistent with chronic mesenteric ischemia, including postprandial pain, malabsorption, and weight loss before the acute episode. [34]

Nonocclusive Ischemia

Nonocclusive mesenteric ischemia (NOMI) causes 20% to 30% of episodes of AMI. [38] Mesenteric ischemia without anatomic arterial or venous obstruction is due to mesenteric vasospasm that can occur during periods of relatively low mesenteric flow, especially if there is underlying atherosclerotic disease. Such low-flow states can result from cardiogenic or hypovolemic shock (see Table 131-1). The vasoconstriction is produced by sympathetic activity, possibly mediated by vasopressin and angiotensin. [39] Moreover, mesenteric vasospasm may persist and perpetuate the ischemic injury even after correction of the precipitating event. [2] Vasoconstrictive

drugs, particularly a-adrenergic agents, vasopressin, ergotamine, diuretics, and digitalis glycosides, can contribute to NOMI. Digitalis, even at nontoxic levels, can cause paradoxical and sustained contraction of both arterial and venous smooth muscle cells in the mesenteric circulation. [40]

To make the diagnosis of NOMI, physicians must have a high index of suspicion because these patients may not present with the classic symptom complex of severe abdominal pain. Predisposing factors include myocardial infarction, congestive heart failure, pulmonary edema, aortic insufficiency, dialysis, [41] and major cardiac or intra-abdominal surgery. [42] The mortality rate of this specific subset of patients is relatively high irrespective of treatment because of the underlying medical conditions and the frequent delays in diagnosis.

Venous Thrombosis

Thrombosis of the SMV causes 5% to 10% of cases of AMI. [43], [44] Symptomatic SMV thrombosis is about 20-fold more common than symptomatic IMV thrombosis because of the larger caliber and flow of the SMV. The mean reported patient age ranges from 47 to 60 years, [6] which is younger than that for superior mesenteric arteriopathy because of the association of arterial disease with atherosclerosis.

Although previously less than 50% of patients had a recognized cause, etiologic factors are currently identified in about 80% of cases. [44] Risk factors for mesenteric venous thrombosis are listed in Table 131-2; they include hypercoagulable syndromes (protein C deficiency, protein S deficiency, factor V Leiden mutation, antithrombin III deficiency, antiphospholipid syndrome), portal hypertension, abdominal infections, perforated viscus, pancreatitis, and trauma. [45] The life-threatening complications of this syndrome are induced by the resulting bowel wall edema and increased outflow resistance secondary to venous thrombosis and increased blood viscosity, which can impede arterial inflow, leading to submucosal hemorrhage, venous capillary congestion, and bowel infarction.

Hypercoagulable states
Factor V Leiden mutation
Antithrombin III deficiency
Hyperfibrinogenemia
Antiphospholipid syndrome
Protein S deficiency
Protein C deficiency
Hormones or pregnancy
Neoplasms
Hyperviscosity syndromes
Myeloproliferative disorders
Sickle cell disease
Infection or inflammation
Pancreatitis
Appendicitis
Diverticulitis
Intra-abdominal abscess
Portal hypertension
Trauma

TABLE 131-2 Causes of Mesenteric Venous Thrombosis

Clinical Presentation

Abdominal pain out of proportion to physical findings is a cardinal symptom in patients with AMI and is commonly manifest after embolic or thrombotic occlusion of the SMA. [46] The pain may initially be colicky but becomes constant with progression of ischemia. The pain may be localized or diffuse. The duration of pain is typically short. A history of chronic postprandial abdominal pain is present when acute arterial thrombosis is superimposed on chronic mesenteric ischemia. [37] Abdominal pain may not be appreciated in confused or critically ill patients, and it is absent in 20% of patients with NOMI. [45] The symptoms of acute mesenteric venous thrombosis are usually less severe than those of acute arterial ischemia. Typically, these patients have a diffuse, intermittent abdominal pain of several days' or even weeks' duration.

In the absence of pain, unexplained abdominal distention and gastrointestinal bleeding may be the earliest signs of ischemia and impending intestinal infarction. Fever, diarrhea, nausea and vomiting, and diminished bowel sounds are other common but nonspecific manifestations of AMI. Diffuse or localized abdominal tenderness, rebound, and rigidity are ominous signs and usually herald transmural bowel infarction. [47] Infarction also leads to hypotension from fluid loss and septicemia, decreased urine output from hypovolemia and renal hypoperfusion, and hyperventilation from hypoxia and acidosis. [45]

Diagnosis

Laboratory Tests Serum laboratory tests are not very helpful in making the diagnosis of AMI; no serum marker is sensitive or specific enough to establish or exclude the diagnosis. Moreover, elevations in the levels of serum markers most suggestive of intestinal ischemia usually occur only after transmural bowel infarction develops and therefore cannot be used to diagnose AMI at its early stages, when improved survival would be possible. Leukocytosis, neutrophilia, and a shift to immature leukocytes in the leukocyte differential are common, [37], [48] but these laboratory findings are nonspecific markers of inflammation and infection. About 50% of patients have metabolic acidosis, an ominous finding suggestive of intestinal infarction, and 25% have hyperamylasemia. [49] Hemoconcentration may develop from fluid loss intramurally as interstitial edema, intraperitoneally as ascites, and intralumenally from fluid transudation. [37] Intestinal necrosis is associated with elevations of serum lactate, phosphate, and alkaline phosphatase levels as well as prerenal azotemia, hypoxemia, and bacteremia. [34], [37]
Radiography Plain abdominal radiography is most useful to exclude other potential causes of abdominal pain rather than confirming the diagnosis of AMI. Completely normal plain radiographs have been reported in more than 25% of patients with mesenteric ischemia. [50] Subtle signs of AMI on plain abdominal radiographs include adynamic ileus and distended, air-filled loops of bowel, but these abnormalities are most commonly the result of other causes, such as pancreatitis, mechanical obstruction, or colonic pseudoobstruction. More specific radiographic findings occur in 25% of cases, usually with advanced disease. These findings include mural thumbprinting resulting from edema or hemorrhage (Fig. 131-4). In advanced stages of ischemia, pneumatosis of the bowel wall can be detected. Specifically, portal vein gas on abdominal radiography portends an extremely poor prognosis. [51]

FIGURE 131-4. Thumbprinting. Detail of a plain abdominal radiograph showing semiopaque projections of the wall of the left colon into the lumen (*arrows*) resulting from submucosal edema and sometimes hemorrhage. Although thumbprinting is highly suggestive of intestinal ischemia, it occurs in relatively advanced lesions.

Intralumenal barium contrast evaluations are contraindicated because residual contrast can limit visualization of the mesenteric vasculature during diagnostic angiography. On the rare occasion when barium studies are performed in a patient with abdominal pain not initially thought to have AMI, thumbprinting, stricture, or ulcerations can be found.
Duplex (Doppler) Ultrasonography Duplex ultrasonography may be of some benefit in visualizing flow in the SMA and celiac axis. With expert technical assistance,

these tests can document proximal stenoses in the SMA or celiac axis or complete occlusion of these vessels with a high specificity (92% to 100%) but relatively low sensitivity (70% to 89%). [52] Unfortunately, duplex ultrasonography is of no value in detecting emboli beyond the proximal main vessel, nor in diagnosing NOMI. Moreover, identification of significant arterial stenosis does not establish the diagnosis of intestinal ischemia because total occlusion of two or even all three splanchnic vessels can be present in asymptomatic patients.

Computed Tomography Abdominal computed tomography (CT) is only sometimes useful in diagnosing intestinal ischemia caused by arterial occlusion or NOMI but is useful in excluding mesenteric venous thrombosis and other abdominal disorders in the differential diagnosis. [51] As on plain radiography of the abdomen, most abnormalities on CT associated with AMI are nonspecific and occur late in the course of the disease. Highly suggestive findings for AMI, including portal venous gas and pneumatosis intestinalis, are seen only after infarction has developed. A comparison of plain x-ray films of the abdomen and abdominal CT in patients with proven intestinal infarction showed specific findings in 30% and 39%, respectively. [50] Both abdominal plain x-ray films and CT scans showed only nonspecific abnormalities in 35% of patients with infarcted bowel, indicating that such studies cannot be used to exclude the diagnosis of AMI even after infarction has occurred. [50] In contrast to the limited role of CT in the diagnosis of AMI caused by SMA occlusion or NOMI, CT diagnosis of mesenteric venous thrombosis has proved more valuable (Fig. 131-5). All studies report sensitivities ranging from 90% to 100%. [2], [6] In a series of 20 patients who were stable and did not have peritonitis at the time of the diagnostic workup, the most common positive finding was the demonstration of thrombus in the SMV. The CT scan can demonstrate thrombus in the portal or splenic vein as well. Abnormal bowel characteristics on CT (bowel wall thickening, pneumatosis) can strongly suggest the diagnosis of acute mesenteric venous thrombosis. CT has shown thrombosis of the SMV without associated bowel abnormalities in asymptomatic patients. Such studies have broadened our understanding of the whole spectrum of mesenteric venous thrombosis, which ranges from chronic mesenteric venous thrombosis with no symptoms to acute mesenteric venous thrombosis with bowel infarction.

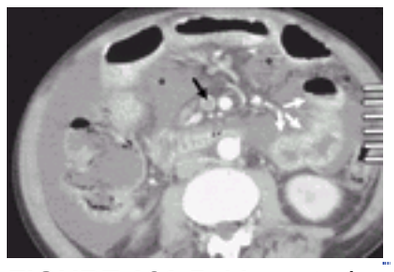

FIGURE 131-5. Mesenteric venous thrombosis in a patient with acute pancreatitis. Contrast-enhanced computed tomography scan shows small bowel wall thickening (*thick arrows*) and a hypoattenuating thrombus of the superior mesenteric vein (*thin arrow*). Ascites is also present (*asterisks*).

Although CT can be considered the primary diagnostic tool for patients suspected of having AMI from mesenteric venous thrombosis, its general use for those suspected of having any form of AMI is not supported in the literature. It has been suggested that contrast-enhanced CT scan should be the initial imaging study in patients suspected of having AMI who have risk factors for mesenteric venous thrombosis, such as a history of deep vein thrombosis or thrombophlebitis or a family history of a hypercoagulable state. [2] Spiral CT and CT angiography may be even more useful for evaluation of the splanchnic vessels, although experience with these techniques is limited. [53], [54]

Magnetic Resonance Angiography Magnetic resonance angiography (MRA) with and without gadolinium enhancement has been evaluated experimentally and clinically for the diagnosis of intestinal ischemia. High sensitivity and specificity were found for MRA in the detection of severe stenoses or occlusion of the origins of the celiac axis and SMA. [55] In patients with thrombosis of the portal or mesenteric veins the overall sensitivity, specificity, and accuracy of MRA for the detection of thrombosis have been reported to be 100%, 98%, and 99%; similar to those of digital subtraction angiography; suggesting that noninvasive contrast-enhanced MRA has the potential to replace intra-arterial digital subtraction angiography as the standard method to assess the whole intestinal venous system. [56] However, this modality is limited in its ability to identify more peripheral occlusions and NOMI.

Angiography Angiography should be performed early when acute mesenteric arterial occlusion is suspected. Because the diagnosis of AMI before bowel ischemia becomes irreversible is the most important factor in improving patient survival, and only angiography or surgery enables such early diagnosis, angiography has become a cornerstone in the evaluation of patients with abdominal pain who are at high risk for AMI. Although early angiography produces a considerable number of negative results, it is essential if diagnoses are to be made early enough to improve survival. The high sensitivity (64% to 100%) and specificity (100%) in most series [57], [58] seems to justify the reliance placed on this test. However, prompt laparotomy should be performed in patients with suspected AMI in whom expeditious angiography is not available. More controversial is the need for angiography in a patient with suspected AMI and signs of peritonitis. Because the latter indicate presence of infarcted bowel, the most compelling reason for angiography (i.e., diagnosis while the effects of intestinal ischemia are still reversible) is no longer a consideration. However, angiography may still provide valuable information in these patients because it may establish a definitive diagnosis of AMI and its cause; identify all vascular lesions, which will guide revascularization procedures; and offer the possibility to administer intra-arterial vasodilators in cases of NOMI. In cases of SMA embolization, most emboli are impacted 3 to 10 cm from the origin of the SMA, distal to the origin of the middle colic artery. The classic meniscus sign can often be visualized at the point of occlusion, which is different from the planar defect produced by a thrombus. [59] However, when angiography is performed more than 24 hours after embolization, the embolic filling defect becomes less sharp and less round because of proximal and distal clot propagation. Contrast is typically poorly visualized distal to emboli because the rapidity of embolic occlusion provides insufficient time to develop collateral flow. Other angiographic findings favoring embolus over thrombus include minimal atherosclerosis in mesenteric vessels, multiple lesions in mesenteric arterial branches, and simultaneous extramesenteric emboli. [59] Symptomatic thrombosis of the SMA is generally associated with a high-grade stenosis or occlusion of the celiac axis. The stenosis usually slowly progresses and permits reconstitution of vascular flow because of development of collaterals (see Fig. 131-2). Aortography is essential in these patients to evaluate potential inflow and outflow sites for bypass grafts as well as to clarify the extent and location of other atherosclerotic lesions in the iliac and IMAs. When the SMA distal to thrombotic occlusion fills from large collaterals, the SMA thrombus is probably chronic and not the cause of acute symptoms. In patients with NOMI, angiography usually reveals multiple areas of narrowing and irregularity in major branches. The small and medium arterial branches may be decreased or absent, producing a “pruned” arterial tree, and there is also impaired intramural vascular filling. [58] Acute mesenteric embolic or thrombotic obstruction may also produce mesenteric vasospasm, so that NOMI is diagnosed only when acute vascular obstruction is absent. The diagnosis of NOMI is strongly favored over the diagnosis of arterial thrombosis by an absence of extramesenteric atherosclerosis and by an increase in SMA caliber after transcatheter vasodilator therapy. [59] In mesenteric venous thrombosis, selective angiograms may reveal reflux of contrast material back into the aorta owing to extremely slow flow and heightened outflow resistance. A prolonged arterial phase with accumulation of contrast and thickened bowel walls is also characteristic. Extreme cases may demonstrate contrast extravasation into the bowel lumen, which may be indicative of active bleeding. The definitive diagnosis of mesenteric venous thrombosis is made during the venous phase; either a filling defect is noted within the portal vein, or, in more extensive thromboses, the entire venous phase is absent.

Treatment

General Measures Initial treatment of patients suspected of having AMI is aimed at resuscitation. Fluids are aggressively administered to replace intravascular fluid lost into the interstitium as edema, into the peritoneum as ascites, or into the lumen from fluid exudation or hemorrhage. Adequate hydration and optimization of cardiac function are particularly important in nonocclusive arteriopathy because hypovolemia and hypotension exacerbate mesenteric vasoconstriction. Medications that cause vasoconstriction, such as vasopressin or digitalis, should be discontinued. Electrolyte abnormalities and acid-base disturbances should be corrected before surgery. Broad-spectrum antibiotics are administered intravenously because intestinal ischemia promotes bacterial translocation and sepsis. Gastrointestinal decompression through a nasogastric tube is recommended because increased intralumenal pressure may decrease mucosal perfusion. Urine volume should be monitored with a bladder catheter. In critically ill patients, pulmonary pressures and cardiac output should be monitored with a Swan-Ganz catheter to optimize fluid and drug therapy. Measurements of arterial oxygen concentration will guide the need for oxygen supplementation or mechanical ventilation.

Embolism Various therapeutic approaches have been proposed for SMA emboli, including surgical revascularization, intra-arterial perfusion of thrombolytic agents or vasodilators, and systemic anticoagulation. The therapeutic option should be chosen taking into account the presence or absence of peritoneal signs, whether arterial occlusion is partial or complete, and whether location of the embolus is above the origin of the ileocolic artery or in more distal branches. There is uniform agreement that exploratory laparotomy is mandatory when signs of peritonitis are present and that embolectomy and resection of any infarcted bowel should be performed as necessary. When abdominal contamination is absent, primary anastomosis is generally performed. When extensive bowel segments are questionably viable, only unambiguously necrotic bowel is resected, and a second-look operation is performed about 24 hours later to permit demarcation between viable and nonviable bowel and to minimize the extent of bowel resection. [60] Anticoagulation with heparin is administered postoperatively to prevent recurrent embolization. [2] Several case reports and small series have reported successful nonoperative treatment of acute mesenteric arteriopathy using heparin [61] and thrombolytic agents, including urokinase, streptokinase, and recombinant tissue plasminogen activator. [62], [63] Data from that experience suggest that thrombolytic therapy is most likely to be successful when the embolus is partially occluding or is in one of the branches of the SMA or in the main SMA distal to the origin of the ileocolic artery and when the treatment is applied within 12 hours of the onset of symptoms. An important question is the long-term reocclusion rate after these therapies. Patients treated medically require close surgical observation to detect failure of medical therapy and the rapid progression to infarction. If signs of intestinal infarction develop, immediate surgery is

indicated. [2] There is some controversy about the use of vasodilators as a complementary treatment in patients with SMA embolus. There is evidence showing that vasoconstriction of both the unobstructed and obstructed branches occurs with an SMA embolus. [58] Such vasoconstriction resolves spontaneously if the embolus is removed soon after it develops. However, if the vasoconstriction has existed long enough, it can become persistent. In these cases, intra-arterial infusion of a vasodilator such as papaverine might be beneficial. [2]

Arterial Thrombosis If a diagnosis of acute thrombosis of the SMA is made, emergency surgical revascularization is recommended. Simple surgical thrombectomy is unlikely to be successful in the long term, and it has to be accompanied by revascularization performed through bypass. In a contaminated operative field, an autogenous aortovisceral graft is required, but polyester fluoroethylene prosthesis may be used when contamination is absent. [1] The proximal SMA should be opened through a longitudinal arteriotomy. If thrombectomy is successful, then a temporary intra-arterial SMA shunt can be placed while definitive revascularization is considered. The longitudinal arteriotomy in the SMA can serve as the distal anastomotic site for an antegrade bypass originating in the supraceliac aorta or for a retrograde bypass from the infrarenal aorta or iliac vessels. As for treatment of an embolus, bowel viability is assessed after revascularization to minimize bowel resection. Although thrombolytic therapy and percutaneous angioplasty have been recommended by some investigators for chronic mesenteric ischemia and SMV thrombosis, there a few reports of the use of these modalities for acute SMA thrombosis. [64], [65]

Nonocclusive Ischemia Management of NOMI is essentially pharmacological and is readily achieved by selective infusion of vasodilators into the SMA. Splanchnic vasodilators include papaverine, tolazoline, nitroglycerin, glucagon, prostaglandin E, phenoxybenzamine, and isoproterenol. [38] The greatest clinical experience is with papaverine, which is administered as a continuous infusion into the SMA at 30 to 60 mg/h. This approach has resulted in a reduction in mortality rates from 70% to 90% observed through the 1980s to 50% to 55% during the 1990s. [58], [60] Subsequent management is dictated by the patient's clinical response to vasodilator therapy. If peritoneal signs resolve, arteriography is repeated after a 30-minute saline infusion to document relief of vasospasm. Papaverine infusion should be continued for at least 24 hours thereafter. It is advisable to repeat arteriography before discontinuation of therapy unless precluded by the risk for contrast-induced nephropathy. Certain precautions specific to the use of intra-arterial papaverine are noteworthy. The patient's hemodynamic status should be carefully monitored because significant hypotension can result if the indwelling catheter migrates into the aorta and papaverine is infused into the peripheral circulation. In this event, the papaverine infusion should be substituted with saline and the position of the catheter confirmed with plain film. Immediate laparotomy is indicated during papaverine therapy if peritoneal signs do not rapidly remit with onset of infusion, if peritoneal signs develop during infusion, or if the patient deteriorates clinically as evidenced by increasing leukocytosis, sepsis, gastrointestinal bleeding, or unstable vital signs. [38] At surgery, gangrenous bowel is resected, according to the surgical principles described for an embolus. Intraoperative peritoneal lavage with warm saline and maintenance of a warm operating room temperature moistens and warms the intestine and helps reduce mesenteric vasospasm. The SMA catheter is left in place to provide vasodilator therapy during and after surgery.

Venous Thrombosis In asymptomatic individuals in whom the diagnosis has been made on a CT scan obtained for reasons other than abdominal pain, either no therapy or a 3- to 6-month course of anticoagulation is reasonable [2]; there are no studies to aid in this therapeutic decision. In symptomatic patients in whom an acute thrombosis of the SMV is diagnosed either by CT scan or angiography, treatment is determined by the presence or absence of peritoneal signs. As in all patients with AMI, signs of peritonitis mandate laparotomy and resection of infarcted intestine. In patients with SMV thrombosis, intravenous anticoagulation with heparin has been shown to prevent thrombus propagation and recurrence and to improve survival. [6], [44], [66] In the absence of peritoneal signs, heparin should be immediately initiated, with an initial bolus of 5000 units followed by continuous infusion of at 1000 units/h. Heparin dosage is then adjusted according to the prolongation of the partial thromboplastin time. Heparin is contraindicated in the presence of acute gastrointestinal bleeding from mesenteric ischemia. Heparin is administered for 7 to 10 days; then prolonged anticoagulation with warfarin for 3 to 6 months is recommended. [2] Thrombolytic therapy is rarely used for SMV thrombosis. Thrombolytic agents have been administered successfully in an antegrade fashion through the SMA, [67] retrograde through the internal jugular vein, [68] and transhepatically through the portal vein. [69] Nevertheless, these forms of therapy should be considered experimental for SMV thrombosis.

Prognosis

Until the early 1980s, the mortality rate of acute mesenteric arterial ischemia ranged from 70% to 90%. [70], [71] Early diagnosis and aggressive therapy have resulted in improved survival. In a report of 21 patients with SMA embolus, intestinal viability was achieved in 100% of patients if the duration of symptoms was less than 12 hours, in 56% if it was between 12 and 24 hours, and in only 18% if symptoms were more than 24 hours in duration before diagnosis. [72] During the 1990s, a 50% to 60% survival rate has been reported in large clinical studies. [72], [73] More than 90% survive when acute mesenteric arteriopathy is diagnosed early by angiography before peritoneal signs occur. [37] Causes of death include extensive intestinal necrosis, recurrent SMA thrombus or embolus, emboli to other sites, cardiopulmonary failure, and intestinal hemorrhage.

The mortality rate for acute SMV thrombosis, 25% to 30%, is lower than that for acute mesenteric arterial ischemia. [6], [66] Mortality is correlated with grade of venous occlusion, presence of collaterals, diagnostic delays, and comorbidity. [74] In a report of 53 patients with SMV thrombosis, 55% had major postoperative complications, such as short bowel syndrome, wound infection, sepsis, and recurrent SMV thrombosis. [44] Recurrences usually involve infarction of bowel adjacent to previously resected bowel.

CHRONIC MESENTERIC ISCHEMIA

Chronic mesenteric ischemia (intestinal angina) is a clinical syndrome characterized by recurrent abdominal pain and weight loss as a result of repeated transient episodes of insufficient intestinal blood flow, usually related to the increased metabolic demand associated with digestion.

Intestinal angina is an uncommon process that only occurs when severe atherosclerotic narrowing of a major splanchnic vessel exists in association with occlusion of one or two of the remaining vessels. This is because the very efficient collateral circulatory network in the small bowel and colon can successfully overcome the single occlusion of a major vessel. In fact, intestinal angina is very uncommon despite the finding at autopsy, performed in unselected cases, of significant stenosis of any of the three major splanchnic vessels in 29% in the overall series, and in 67% in those patients older than 80 years of age at the time of death. [75]

This ischemic syndrome is seen in middle-aged and elderly people and predominantly in women (female-to-male ratio of 3:2). Direct or indirect evidence of atherosclerosis is common in these patients, with more than one third having hypertension, coronary artery disease, peripheral arterial disease, or cerebrovascular disease. Patients with diabetes and smokers are at increased risk.

Clinical manifestations are related to limitations of the ability of the celiac artery or SMA to supply increased blood flow in response to metabolic demands after a meal, mainly because of atherosclerotic vascular lesions. Alternatively, it has been suggested that a steal phenomenon from the intestinal to the gastric circulation occurs when food reaches the stomach.

Clinical Presentation

Recurrent abdominal pain and weight loss are the two characteristic symptoms. Pain is epigastric or periumbilical, eventually radiates to the back, and appears shortly after meals, lasting for 1 to 3 hours. The intensity of the pain is related to the quantity of the meal or to the fat content, is crampy in nature, and has to be distinguished from pancreatic, biliary, or ulcer-related pain. As a consequence of the pain, patients tend to diminish food intake (sitophobia, or fear of eating), and with time, weight loss becomes obvious. Other nonspecific symptoms, such as nausea, vomiting, diarrhea, and constipation, are present in one third of patients. Isolated cases have been documented of malabsorption associated with chronic mesenteric ischemia, [76] and resolved gastroparesis has been reported after revascularization of occluded mesenteric vessels. [77]

Physical findings are not specific. Weight loss with signs of malnutrition is the most common alteration, although some patients maintain their weight despite the high frequency and intensity of the pain. Abdominal tenderness without rebound may be present during an episode of severe pain. Indirect signs of atherosclerotic vascular disease may be found, mainly diminished peripheral pulses, carotid or femoral bruits, or stigmata of past stroke.

Diagnosis

The diagnosis is mainly based on a characteristic clinical picture, presence of an occlusive lesion in the splanchnic vessels documented by angiography, and the absence of other common causes of abdominal pain. In most cases, patients undergo an extensive workup for obscure chronic abdominal pain, including routine laboratory evaluation, plain abdominal radiographs, upper and lower gastrointestinal endoscopy, small bowel barium series, and ultrasonography or abdominal CT. Laboratory abnormalities related to malnutrition, such as anemia, hypoalbuminemia, and hypocholesterolemia, may be present. When common causes of abdominal pain have been ruled out and suspicion of intestinal ischemia is well established from epigastric pain after meals and substantial weight loss, a selective angiographic

study of all three major splanchnic arteries is warranted, especially in patients with risk factors. Exceptions to this approach are patients with high risk for angiographic adverse events, such as those with renal failure or severe coagulopathy disorders. In about 90% of patients with intestinal angina, at least two major splanchnic vessels are found to be occluded or stenosed, and in up to 50% blood flow in all three vessels is severely compromised. [78] In contrast, isolated occlusion of a single vessel is uncommon in documented intestinal angina.

As is the case for AMI, other tests available for the diagnosis of chronic mesenteric ischemia include duplex ultrasonography, [79] MRI angiography, [80] MRI oximetry, [80] and tonometry. [81] In significant vascular stenosis, duplex ultrasonography shows high flow velocity and poststenotic turbulence reflected by modifications on spectral waveform and mixture of colors in the duplex image (Fig. 131-6). Retrograde hepatic artery blood flow suggests stenosis of the celiac artery. In stenosis of the SMA greater than 50% to 70%, the sensitivity of the technique is above 90%, with marginal improvement with postprandial study. [79] Sensitivity for lesions in the celiac axis are slightly lower, 85% to 87%. When performed by skilled operators, duplex ultrasonography may be a useful screening tool. However, if surgery or interventional radiology is planned, then angiography will be needed to ascertain coexisting lesions of the aorta and renal and iliac arteries.

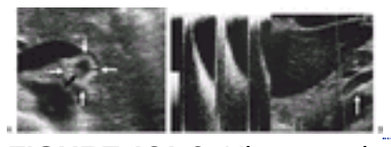

FIGURE 131-6. Ultrasound examination in a patient with celiac artery occlusion and superior mesenteric artery (SMA) stenosis. **A:** Gray-scale ultrasound showing a partial thrombus at the origin of SMA (delimited by *thick arrows*) occluding 50% of the arterial lumen (*thin arrow* shows thrombus). **B:** Pulsed Doppler study of the SMA origin of the same patient. Left half reveals a very high peak systolic velocity (3.84 m/s) resulting from the SMA stenosis (right half, *arrow*).

Tonometry seems a promising technique to evaluate the physiologic adequacy of intestinal blood flow, and the intestinal placement of the balloon has proved to be more sensitive than gastric tonometry, at least in animal studies. [81] However, its use in clinical settings has not been sufficiently evaluated yet.

Treatment and Prognosis

Surgical revascularization has been for many years the treatment of choice for chronic mesenteric ischemia. The techniques used include antegrade and retrograde bypass grafting, transaortic mesenteric endarterectomy, and aortic reimplantation of the SMA. Since the 1980s, percutaneous translumenal mesenteric angioplasty with or without stenting has been introduced.

Patients with symptomatic chronic mesenteric ischemia should be considered for surgery with the goals to relieve symptoms, improve nutrition, and prevent mesenteric infarction. Asymptomatic patients submitted to aortic reconstruction for aortoiliac occlusive disease who also have significant mesenteric occlusion should be considered for bypass grafting because these patients have an increased risk for mesenteric infarction after surgery. [82] The indication for surgery in asymptomatic patients who do not need aortic reconstruction is not clear. It has been proposed that surgery should be considered in such patients when three-vessel occlusion is documented, because of the high risk for developing ischemic symptoms or death. [83] Complete revascularization has been recommended by many surgeons, but several authors have recently proposed that bypass grafting of the SMA alone is an effective and durable procedure for treatment of intestinal ischemia. [84] Series published since the 1980s have reported a wide range of outcome figures for surgical revascularization, but results of more recent publications show mortality rates from 0% to 4%, success rates (defined as relief of symptoms) of more than 90%, and recurrence rates of less than 15%. [2] Advancing age, cardiac disease, hypertension, and additional occlusive disease influence overall mortality. Concomitant aortic replacement, renal disease, and complete revascularization are associated with high postoperative morbidity rates. [85] In patients with severe weight loss, parenteral nutrition before revascularization may reduce surgical morbidity.

The experience with percutaneous translumenal mesenteric angioplasty is not as extensive as with surgery and has been generally applied in high-risk patients. Success and mortality rates appear not to be significantly different from those of surgical revascularization, but recurrence of symptoms is slightly higher than after surgery. [86] Placement of a stent has been successfully used as an adjunctive therapy to angioplasty and, in some selected cases, as a primary method for treatment of chronic mesenteric ischemia. [87]

Based on the current information, it seems reasonable at the present time to offer surgical revascularization to low-risk patients and to perform angioplasty in those with a higher surgical risk. If it can be demonstrated that the addition of stenting to angioplasty can decrease the recurrence rate of symptoms better than angioplasty alone, then this procedure might be a valid alternative to surgery, even in low-risk patients. Surgery rather than angioplasty is indicated for suspected bowel necrosis.

In patients who survive surgical revascularization, the prognosis is excellent; 5-year survival rates approach 80%, and most patients become free from symptoms, gain weight, and resume normal eating habits. [78]

ISCHEMIC COLITIS

Ischemic colitis is the most common form of ischemic injury to the gut and occurs more frequently in elderly people. It can result from either occlusive or nonocclusive events, mainly in the territory of the IMA, in colonic branches of the SMA, and in the SMV and IMV. Thus, ischemic colitis is predominantly seen in the left colon. [88] The splenic flexure and rectosigmoid junction, where low perfusion exists (watershed areas), are commonly affected, whereas the rectum is not usually compromised because of excellent collateral perfusion. Right colon ischemic colitis is rare, [89] is mainly due to low-flow states, and is associated with poor prognosis. [90]

Large arterial vessel occlusion may be caused by thrombi or atheromatous lesions. [88] Embolization of the IMA is uncommon because most emboli are too large to enter this narrow vessel. Aortic surgery can cause ischemic colitis because of unnoticed ligation of the IMA or the occurrence of intraoperative hypoperfusion in the presence of IMA occlusion. [91] Blood flow in the small segmental arterioles may also be compromised by small vessel disease induced by diabetes, radiation, or autoimmune inflammatory arteritis. [92] Venous occlusion may occur as a consequence of hypercoagulability states (see Table 131-2), pancreatitis, or portal hypertension. [92] Vessel occlusion may be secondary to colonic obstruction from colon cancer, benign colonic strictures, adhesions, volvulus, or hernias. [93]

Nonocclusive ischemia may be present in the colon due to low-flow states or vasoconstriction induced by several drugs [94], [95] (Table 131-3). Ischemic colitis has been also reported in long-distance runners. [96]

Estrogen-progesterone	Diuretics	Alosetron
Cocaine	Pseudoephedrine	Barbiturates
Crack	Cyclosporine	Methylsergide
Ergotamine	α-Adrenergic agonists	
Vasopressin	β-Adrenergic antagonists

TABLE 131-3 Drugs Associated with Intestinal Ischemia

Clinical Manifestations

A wide spectrum of disorders can be seen as a consequence of colonic ischemia. These include acute, transient, self-limited ischemia (reversible colopathy characterized by mucosal and submucosal hemorrhage), acute fulminant ischemia (which is transmural and progresses to necrosis), and chronic ischemic colitis (partially reversible vascular disease usually manifested by late colonic stenosis).

Abdominal pain is present in more than two thirds of patients. [97] The pain is moderately severe, crampy, mostly localized in the left lower quadrant, and sometimes associated with diarrhea. Rectal bleeding manifested by either bright red blood in the stools or hematochezia is another common symptom. Bleeding is usually mild and does not require transfusion in most cases. Abdominal distention is also frequent and can be accompanied by nausea and vomiting. Physical signs during the acute episode include abdominal distention, with mild-to-moderate tenderness, fecal occult blood, tachycardia, or moderate fever. Less commonly, massive colon necrosis occurs with obvious signs of peritonitis and shock. Hypertension and history of cancer have been identified as independent prognostic factors of colonic necrosis in elderly people suffering an episode of ischemic colitis. [98] A minority of patients have subclinical acute ischemic disease and develop a colon stricture, which can be asymptomatic or manifested by constipation, diarrhea, or recurrent abdominal pain. [99]

Diagnosis

Although many patients with colon ischemia have no specific cause for such disease, all patients with any of the well-known precipitating factors who develop abdominal pain, bloody diarrhea, and abdominal distention should be investigated for ischemic colitis.

Plain abdominal radiographs usually show nonspecific, air-filled bowel dilation. The specific finding of thumbprinting (see Fig. 131-4) is seen in less than 25% of cases. [100] Colonoscopy or flexible sigmoidoscopy is the method of choice for the diagnosis of ischemic colitis because it allows direct visualization of the mucosa and tissue sampling. [97] Colonoscopy is preferable to sigmoidoscopy because 50% of the ischemic lesions are proximal to the sigmoid colon, except for ischemic injury after aortic surgery, in which lesions always involve the distal colon. The endoscopic examination has to be performed with caution and minimizing air insufflation in order to avoid perforation. The mucosa of the affected segment usually appears edematous, hemorrhagic, friable, and ulcerated. When bowel necrosis is present, colonoscopy reveals cyanotic, gray or black mucosa.

Biopsies often demonstrate nonspecific findings of vascular congestion, submucosal hemorrhage, interstitial edema, inflammatory infiltration, loss of superficial cells, and intravascular platelet thrombi (Fig. 131-7 and Color Fig. 131-7). Hyalinization of the lamina propria, full-thickness mucosal necrosis, presence of atrophic microcrypts, and hemorrhage in the lamina propria are also microscopic signs suggestive of acute ischemic injury, whereas hemosiderin deposition, along with transmural fibrosis and mucosal atrophy is a pathognomonic finding of the disease in its chronic phase. [101]

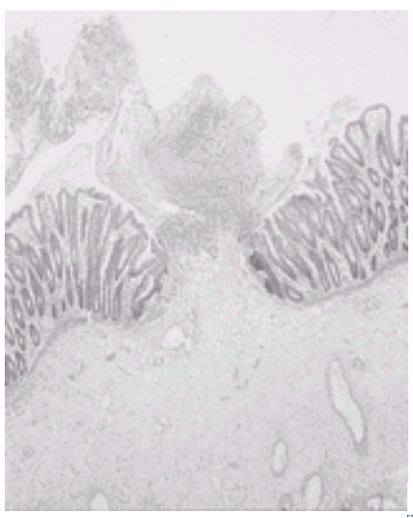

FIGURE 131-7. (See Color Fig. 131-7.) Intestinal ischemic damage. Well-delimited ulceration of the mucosa, with formation of a pseudomembrane. The remaining mucosa is normal. The submucosa has a marked edema and discrete infiltration by inflammatory cells.

Barium enema may be helpful for the diagnosis of ischemic colitis, with a sensitivity that approaches 80%. [102] Thumbprinting is the most characteristic finding, but ulcerations, mural deformity, sacculation, and transverse ridging may also be seen. CT is not usually performed for diagnosis of ischemic colitis, but it can show significant alterations of the bowel wall such as circumferential, symmetric wall thickening with fold enlargement, lumenal narrowing, and polypoid filling defects, and it may be helpful to exclude other diseases. [103]

Angiography is not usually indicated for the evaluation of ischemic colitis because by the time of clinical presentation, colon blood flow may be restored. However, in cases in which distinction between ischemic colitis and AMI is not clear, when only the right side of the colon is affected, and when a more generalized ischemic disorder is suspected, angiography must be performed. In some cases, color duplex ultrasonography is able to distinguish ischemia from inflammatory bowel disease, [104] and absence of arterial flow in the Doppler ultrasonography may be a better early predictor of outcome than clinical and laboratory findings. [105]

Differential Diagnosis

It is not uncommon that the diagnosis of ischemic colitis is established only after repeated clinical, radiographic, or endoscopic studies are performed after symptoms appear. This is because the signs and symptoms of ischemic colitis overlap with those of other colonic diseases or other mesenteric vascular diseases. Infectious colitis, inflammatory bowel disease, colon cancer, radiation colitis, diverticulitis, nonsteroidal antiinflammatory drug–induced colonic lesions, and pancreatitis should be considered.

Some pathogens, such as *Escherichia coli* O157:H7 and cytomegalovirus, may cause vascular damage in the colon, leading to hemorrhagic colitis that can be easily misdiagnosed as ischemic colitis [106], [107]; that is, ischemia may be an associated condition with these infections. [108] Pseudomembranous colitis produced by *Clostridium difficile* may also be mistaken for ischemic colitis. [109] Therefore, stool analysis for bacteria, ova, and parasites and the assay for *C difficile* toxin should be performed in some cases.

The differential diagnosis between ischemic colitis and inflammatory bowel disease can be difficult in some cases. [110] Data supporting the diagnosis of ischemic colitis are age of onset, segmental distribution of injury, abrupt transition between damaged and undamaged mucosa, rectal preservation (only useful for distinction with ulcerative colitis), and rapid resolution of lesions in subsequent colonoscopies. [111] In elderly people, the initial distinction between ischemic and ulcerative colitis may be more difficult. Because of its segmental involvement and rectal sparing, differentiation between ischemia and Crohn's colitis can also be difficult, although terminal ileum involvement and the presence of fistulae or colonic granulomata may help to diagnose Crohn's disease.

Radiation colitis can be easily suspected in patients with antecedents of such treatment, and colon cancer is differentiated mainly by pathological examination of colonic biopsy specimens. [112] Diverticulitis can mimic ischemic colitis, but CT scan is helpful to identify colon diverticula as well as mural thickening, pericolonic inflammation, and eventually fistula or abscess induced by diverticulitis. [113]

In the past decades, nonsteroidal antiinflammatory drug–induced colonic lesions have been identified more frequently than previously suspected. Abdominal pain and diarrhea with or without blood loss is the most common complaint of patients with such colonic lesions. Nonspecific inflammatory changes or erosions and diaphragma-like strictures may be seen at endoscopy, and histology may reveal findings similar to those of ischemic colitis. [114]

Treatment

Patients with reversible or transient ischemic colitis manifested by mild symptoms and signs do not need specific therapy because the event usually resolves spontaneously. In patients with more severe or persistent symptoms, bowel rest and general supportive measures, including parenteral fluids, are recommended. Precipitating factors should be corrected. This includes stopping any medication with potential vasoconstrictor effects on the mesenteric vasculature or narcotics that

may worse colonic distention. Measures should be implemented to correct low-flow states due to either hypovolemia or cardiac dysfunction. Intravenous infusion of broad-spectrum antibiotics is usually recommended, [115] although no definitive clinical evidence is available of the beneficial effects of such policy. Antibiotic use is based in the theoretical protection against bacterial translocation that occurs in severe colonic ischemia, and for early treatment of sepsis that follows massive colon gangrene. [116] In patients treated medically, endoscopy should be repeated during hospitalization to confirm diagnosis and to document recovery.

Patients showing evident signs of peritonitis require urgent surgery. In patients in whom severe symptoms, such as abdominal tenderness or fever, or laboratory findings, such as leukocytosis or metabolic acidosis, persist or deteriorate despite medical treatment, surgery is also warranted. [99] Other infrequent indications for surgery are massive bleeding, persistent ischemic lesions with protein-losing colopathy, and recurrent sepsis in a patient apparently recovered form an acute episode of ischemic colitis. In any case, segmental colectomy of the involved area should be performed, and the resected specimen should be opened in the operative room to assess the extent of mucosal injury. If surgical margins are involved, an additional segment should be resected until margins appear normal. Areas of questionable viability in the colon should also be resected. [88], [92] Recently, the use of intraoperative laser Doppler flowmetry has been proposed to ascertain the viability of colonic segments. [117]

In patients submitted to abdominal aortic graft surgery, several strategies are under investigation to improve rectocolonic microcirculation during and after surgery with the goal of preventing postoperative colonic ischemia. These include intravenous infusion of prostaglandin E_1 [118] and rectal administration of short-chain fatty acids. [119]

In cases of chronic evolution of ischemic colitis, surgery is required only when colonic stenosis becomes symptomatic. [120] Segmental resection is the procedure of choice in such cases, although transendoscopic dilation may be an alternative in selected patients at high risk for surgery.

UNUSUAL CAUSES OF MESENTERIC ISCHEMIA

Obstructing Diseases

An uncommon and controversial cause of mesenteric ischemia is the compression of the celiac artery and eventually the SMA by the median arcuate ligament, especially in thin, young patients, mostly women. It is manifested by upper abdominal pain induced by food intake and associated with weight loss. Diagnosis is made by angiography, duplex ultrasonography, contrast-enhanced CT, or MRA. Surgical division of the obstructing diaphragmatic fibers and denervation of the celiac ganglion, with or without celiac artery dilation or reconstruction, is the recommended treatment. [121]

When a segment of the large bowel is obstructed, the adjacent vasculature could be compromised, thus producing regional colonic ischemia. This phenomenon, which can manifest as an acute or chronic event, may be observed in some cases of sigmoid adenocarcinoma or small bowel carcinoid tumors, incarcerated hernia, sigmoid or cecal volvulus, intussusception, peritoneal adhesions, retroperitoneal fibrosis, neurofibromatosis, or cancer infiltrating the mesentery. [88], [122]

Vasculopathies

Several vasculitides may induce mesenteric ischemia. Polyarteritis nodosa (PAN) is characterized by necrosis of small or medium-sized muscular arteries with the eventual development of aneurysms. PAN may commonly involve the mesenteric circulation. In patients with PAN, gastrointestinal bleeding and bowel infarction with or without perforation are common events with very poor prognosis (mortality rate of about 75% to 100%). Recurrent abdominal pain and steatorrhea with weight loss are also manifestations of this syndrome. Erythrocyte sedimentation rate is usually significantly increased, and diagnosis is confirmed by characteristic angiographic findings. [123] Treatment with corticosteroids and cyclophosphamide provides the best results. [124] Bowel rest, nasogastric decompression, and parenteral nutrition are often needed. Early surgery is indicated when perforation or obstruction occurs.

Unusual cases of mesenteric ischemia have been described in systemic lupus erythematosus and in the antiphospholipid syndrome. [125] Although infrequent, intestinal ischemia may be seen also in some cases of Takayasu disease and Buerger disease, [126], [127] the latter usually presented in young men with heavy smoking. An increased risk for thrombotic events has been documented in Behçet disease and Crohn's disease, [128], [129] and primary or secondary amyloidosis may be associated with intestinal ischemia. [130]

Hematologic Disorders

Mesenteric ischemia can be associated with hypercoagulability states, mainly thrombocytosis, polycythemia, antithrombin III deficiency, antiphospholipid syndrome, proteins C or S deficiencies, 20210A prothrombin gene mutation, and factor V Leiden mutation. [131], [132], [133], [134] and [135] The diagnosis of hypercoagulability in the presence of mesenteric ischemia is crucial to prevent further episodes by means of anticoagulation.

Drugs

Several drugs may precipitate or promote mesenteric ischemia. Estrogen-progesterone combinations used as contraceptives have been described as precipitating factors for intestinal ischemia. [136] However, the frequency and the severity of the contraceptive-related ischemic events have decreased over time, probably because of more careful use of these drugs in patients at risk or because of a lower dose of estrogen included in the new generation of contraceptives. If mesenteric ischemia occurs in a young woman without any other risk factors, past or current use of oral contraceptives should be investigated.

Since the 1990s, an increased frequency of gastrointestinal events associated with cocaine has been reported, including gastric ulcerations, intestinal ischemia, perforations, and retroperitoneal fibrosis. [95] Similar complications have also been documented in crack users (the free-base form of cocaine). [137] The mechanism by which cocaine produces ischemia is uncertain, but it is known that it blocks the reuptake of norepinephrine and enhances the flux of calcium across the endothelial cell membrane, two pathways leading to vasoconstriction. [137], [138] The interval between drug ingestion and onset of symptoms varies from 1 hour to 2 days, and abdominal pain, tenderness, and bloody diarrhea are the most common presentations. Surgery is required in most cases to correct perforations or remove necrotic bowel segments.

Vasopressin used as a therapeutic agent for bleeding esophageal varices is associated with significant risk for systemic and regional ischemic events. [139] Indirect signs of transient intestinal ischemia are seen in some patients treated with vasopressin infusion as a consequence of its vasoconstrictor effect in the splanchnic vascular bed, but this drug also reduces gastrointestinal oxygen extraction. [140]

Recently, ischemic colitis has been described in association with the treatment of irritable bowel syndrome with alosetron, a selective 5-HT_3 antagonist. [141] Other drugs with possible effects promoting intestinal ischemia include ergotamine, digitalis, methysergide, pseudoephedrine, barbiturates, and amphetamines. [88]

CHAPTER 132

Steven M. Cohn and Stephen J. Bicksto

RADIATION INJURY IN THE GASTROINTESTINAL TRACT

The first reports of radiation-induced injury to the gastrointestinal tract date to the early 20th century shortly after the discovery of x-rays in 1895. [1] The use of ionizing radiation for therapy of malignancies also dates back to the early 20th century and arose out of the observations of Bergonie and Tribondeau, who suggested that "X-rays are more effective on cells which have a greater reproductive activity; the effectiveness is greater on those cells which have a larger dividing future ahead…." [2], [3] They went on to reason that radiation could be effective in destroying tumors while sparing many normal tissues. Although this concept may be somewhat simplistic in today's terms, it led to the expectation that side effects would occur in those tissues, such as the gastrointestinal epithelium, that undergo rapid cell turnover.

The use of multimodality therapies that include radiation have become commonplace in treating many malignancies; in fact, about one half of patients with cancer receive radiation therapy as a component of their treatment. Modern techniques for tomographic localization and fractionation of radiation therapy have significantly reduced short-term and long-term gastrointestinal morbidity resulting from radiation therapy. Nevertheless, most patients experience gastrointestinal symptoms associated with acute radiation therapy, such as diarrhea, abdominal pain, bloating, tenesmus, and bleeding. [4] Chest pain, dysphagia, and odynophagia may be seen when the radiation fields involve the upper gastrointestinal tract. Generally, the acute side effects of therapy can be treated with antispasmodics, antidiarrheals, and topical anesthetics. As a rule, these symptoms resolve shortly after radiation treatment ends. However, up to one fourth of patients who receive radiation therapy also develop some form of chronic injury, defined as symptoms presenting more than 3 months after completion of therapy. [4] Symptoms are usually evident within the first 2 years after initiation of therapy; however, some patients do not develop symptoms for years or even decades. [4] Thus, it is likely that gastroenterologists will continue to encounter and treat patients with acute or chronic radiation injury in their practice.

RADIATION PATHOBIOLOGY

High-energy photons from gamma irradiation, which is used for most types of radiation therapy, can interact with atoms in a number of ways. [5] The most prominent effect leading to radiation-induced injury is Compton scattering, first described by A. H. Compton in 1922. Compton scattering occurs when a gamma photon collides with an outer orbital electron, loses energy, and is deflected, and the energy lost by the photon is imparted to the electron, which is then ejected from the atom. These ejected Compton electrons subsequently cause many of the biologic sequelae of irradiation by secondary ionizations of other atoms or through generation of other highly reactive species, such as free radicals. Such radiochemical interactions can damage a variety of cellular constituents, including DNA, proteins, and lipids. Of these, induction of single- and double-stranded breaks in DNA appears to mediate most of the lethal effects of radiation on cells. Although many cellular pathways for repairing such potentially lethal genetic damage have evolved in humans, failure to repair even a single double-stranded break in DNA may result in the death of that cell.

The amount of radiation-induced damage produced in a tissue or tumor is dependent on the energy of the gamma rays or x-rays, on the absorbed dose of radiation, and on the fractionation schedule of the administered dose of irradiation. [3], [5], [6] The gray (Gy) has supplanted the rad as the accepted unit of absorbed radiation dose and is defined as 1 joule of energy deposited per kilogram of absorbing material. One Gy is an equivalent dose to 100 rad. The dose of radiation absorbed by a biologic tissue is variable and related to the biochemical properties of the tissue, including tissue oxygenation, the activity of pathways that detoxify reactive oxygen species or scavenge free radicals, and the position of cells within the cell cycle. Cells in early S phase or those undergoing mitosis appear to be most sensitive. A minority of DNA damage occurs through direct interaction with high-energy Compton electrons. However, these electrons can interact with other molecules present in the cell, including water and molecular oxygen, to generate peroxides, free radicals, and other reactive oxygen intermediates that are highly reactive with DNA and other cellular acromolecules. Unfortunately, malignant cells that are relatively hypoxic within solid tumors may be resistant to the lethal effects of photon irradiation.

Physical characteristics of the patient, previous abdominal surgeries, and concurrent medical illnesses can also influence the amount of radiation-induced damage to the alimentary tract. Predisposing factors for radiation injury have been identified: higher doses of radiation, patients whose intestines are fixed within the exposed region by adhesions from previous surgery, and those with a narrow anteroposterior diameter are at greater risk. [7] Preexisting vascular disease within the radiation field may predispose patients to increased radiation-induced vascular injury and subsequent ischemia (see subsequent section on " Pathology"). Thus, patients with diabetes, hypertension, and atherosclerotic disease are all more prone to radiation enteritis. [8] Inflammation may also modify the acute response to irradiation through growth factors, cytokines, and other inflammatory mediators produced at sites of tissue injury. For example, fibroblast growth factor-2, prostaglandin-E_2, tumor necrosis factor-a, interleukin-1 (IL-1), and IL-11 all decrease the sensitivity of tissues to radiation injury, suggesting that these mediators may have an adaptive function in cell survival. [9], [10], [11], [12] and [13] IL-12 has a mixed effect, protecting bone marrow–derived cells but sensitizing gut epithelial cells to radiation injury. [13], [14] and [15] Thus, the effects of tissue inflammation on the biologic response to therapeutic irradiation are complex and difficult to predict.

Concurrent pharmacological therapy may also alter the response of both normal and neoplastic tissue to gamma irradiation. Tissue is more susceptible to injury from radiation when it is administered together with chemotherapeutic agents or other pharmaceuticals that sensitize the gut. For instance, combination of gamma irradiation with administration of chemotherapeutic agents that alter cell cycle kinetics or lead to synchronization of the replicating cell populations may potentiate damage to normal tissues or to tumor cells because the lethal effects of radiation-induced damage vary with position in the cell cycle (see earlier discussion). Therefore, the timing of irradiation in relation to administration of these chemotherapeutic agents is an important factor in determining the relative effects on tumor versus normal tissue. Halopyrimidines such as fluorouracil, fluorodeoxyuridine, and iododeoxyuridine may sensitize tumors both by inhibiting effective DNA repair and by increasing the amount of radiation-induced DNA damage. [16], [17] Adjuvant therapy combining fluorouracil and radiation therapy for resected gastrointestinal tumors has improved survival in patients with pancreatic, rectal, and esophageal cancers. [17], [18], [19] and [20] Actinomycin D, doxorubicin, and bleomycin also sensitize cells to radiation-induced DNA damage and cell death.

Drugs with radioprotective activity are under investigation. These compounds have the potential to improve the therapeutic index for radiation therapy. For example, the prostaglandin analogs misoprostol and dimethyl–prostaglandin E_2 both decrease radiation-induced apoptosis in rapidly replicating intestinal epithelial cells and enhance epithelial stem cell survival after irradiation. [9], [12] A number of growth factors and cytokines, including fibroblast growth factor-2, keratinocyte growth factor, and IL-11, also have radioprotective activity in the intestine if administered before irradiation. [11], [21], [22] Free radical scavengers, such as amifostine (WR-2721), have been shown to be radioprotective in both experimental systems and clinical trials. [23] Whether these radioprotective agents will find a role in routine clinical practice remains to be established.

Because DNA damage is thought to be the primary mechanism mediating the lethal effects of radiation, [5], [6] a number of complex intracellular systems have evolved to repair DNA damage induced by radiation as well as damage induced by chemotherapeutic agents. Some of these proteins are specifically involved in recognition and repair of DNA damage. Other enzymes, such as DNA-dependent protein kinase, are involved in DNA replication and V(D)J recombination during immunoglobulin gene rearrangement in normal lymphocytes. These enzymes also play a central role in rejoining double-stranded DNA breaks induced by radiation injury in epithelial

cells in the gastrointestinal mucosa. [6], [24], [25]

The fate of injured cells after irradiation is a complex process. Cells that are not able to repair radiation-induced DNA damage adequately will eventually undergo "mitotic cell death" or mutation due to the genomic instability as a consequence of the unrepaired DNA stranded breaks and other DNA damage. [6] However, in rapidly replicating cell populations, DNA damage induced by relatively small doses of irradiation can also trigger apoptotic cell death, an active, genetically programmed type of cell death. In both humans and rodents, a very low frequency of physiologic apoptosis occurs continuously within the lower regions of the crypt epithelium of the normal small intestine and colon and may be an inherent part of the regulatory mechanism determining stem cell numbers in the normal adult tissue. [26], [27] After even relatively low doses (about 1 Gy) of ionizing radiation, many damaged cells within the rapidly dividing crypt epithelium of the small intestine and colon undergo apoptosis. [26], [27] and [28] Radiation-induced apoptosis occurs with the highest rates in the lower two thirds of the crypt, a region containing the epithelial stem cells and the more rapidly replicating progenitor or "transit" cell population, and reaches a maximum 6 to 12 hours after irradiation. Many of the remaining cells within the proliferative zone that do not undergo apoptosis arrest at checkpoints in G_1 or in late G_2 phases of the cell cycle. [6], [28], [29] These cell cycle checkpoints are thought to provide time for repair of DNA damage and prevent cells from entering S phase or mitosis, when the presence of even a few double-stranded DNA breaks may result in death of the cell or generation of cells with chromosomal abnormalities.

The tumor suppressor gene, *p53,* plays an important role in recognition of DNA damage and coordinating the subsequent cellular response to radiation injury, leading some investigators to describe *p53* as the "guardian of the genome." [30], [31] and [32] It is normally expressed at low levels except during DNA synthesis. Upon DNA damage, expression of *p53* is up-regulated and translocated to the nucleus, where it binds DNA and regulates the transcription of a number of genes, including *p21 cip1, waf1*, *GADD45, mdm2,* and *Bax*. [33], [34] and [35] These genes are involved in regulating apoptosis or cell cycle arrest at checkpoints at the G_1/S boundary or in G_2/M. [36], [37] and [38] Activation of *p53* occurs rapidly in the intestinal crypt epithelium following even low doses of gamma irradiation (0.5 to 1 Gy). This results in a rapid and sustained increase in the transcription of *Bax,* a proapoptotic member of the *Bcl-2* oncogene family that mediates the apoptotic response. The ultimate fate of a cell with DNA damage also depends on the expression of other counterregulatory genes that affect apoptosis. Expression of these counterregulatory genes varies along different regions of the alimentary tract and may depend on extracellular signals as well. For example, antiapoptotic members of the Bcl-2 family, including Bcl-2 and *Bcl-X* $_L$, suppress apoptosis by formation of heterodimers with *Bax*. *Bcl-2* appears to be expressed in the colonic crypts, but not in small intestinal crypt epithelial cells, thus explaining regional differences in the sensitivity of crypt epithelial cells to radiation-induced apoptosis.

Activation of *p53* in response to DNA damage causes cells to arrest at critical checkpoints, [6], [30], [31], [37] a process that is mediated by induction of *p21 cip1, waf1*, *GADD45,* and other gene products. This allows time for the cell to make a decision as to its fate (repair versus cell death) before committing itself to S phase or mitosis. Entry into S phase with damaged DNA or into mitosis in the presence of single-stranded or double-stranded DNA breaks could lead to daughter cells with unstable chromosomal structure, allowing mutations or chromosomal rearrangements to occur. Other genes, such as the gene responsible for ataxia telangiectasia (*Atm*), are thought to regulate the response to DNA damage upstream of *p53*. Thus, cells from these patients have both diminished activation of *p53,* decreased cell cycle arrest at the G_1/S cell cycle checkpoint, an increased sensitivity to ionizing radiation, and increased malignant transformations.

The clonogenic stem cell populations within the intestine and colon appear to be more resistant to radiation-induced cell loss than the more rapidly replicating transit cells. Furthermore, the survival of these clonogenic stem cells may be determined by a mechanism independent of *p53* function. [39] The increased survival and proliferation of the stem cells with radiation-induced DNA damage probably enhances the capacity for restitution of the epithelial function in the short term but also may contribute to the potential for secondary malignancies many years after therapeutic irradiation (see subsequent section on " Pathology").

PATHOLOGY

The histopathological changes in the alimentary tract follow a predictable time course and may be functionally divided into early and delayed clinical syndromes. [40] The early effects primarily involve the mucosa, which is lined by rapidly proliferating epithelial cells that are sensitive to the acute effects of radiation injury. Clinical symptoms include odynophagia, diarrhea, nausea, vomiting, or gastrointestinal bleeding, depending on the location of the radiation field, the dose of radiation, and the fractionation schedule. The delayed effects are more likely to be chronic diarrhea, fibrosis, ulcer formation, or bleeding and are secondary to damage to the vasculature of the organs involved. Although the histological hallmarks seen in tissue specimens are often characteristic of acute or delayed radiation injury, no histological feature is pathognomonic for radiation-induced damage. [40]

The histological and pathological features of acute radiation injury in the human alimentary tract are poorly defined because the acute effects of radiation therapy are generally well tolerated and tissue samples are rarely obtained. Thus, much of what is known about the acute effects of irradiation has been derived from a few studies in humans and more extensive experiments using animal models of radiation injury. [40], [41], [42], [43], [44] and [45] The earliest recognizable histological features following radiation injury to the gastrointestinal tract occur within hours and include apoptosis of lamina propria lymphocytes and epithelial cells, the cessation of epithelial cell replication, and damage to vascular endothelial cells. This results in loss of replicating cells in the squamous epithelium of the esophagus and the columnar epithelial cells in the gastric, small intestinal, and colonic epithelium. Mature, differentiated epithelial cells continue to be lost by extrusion, and in the absence of replacement by replication of the progenitor cells, there is subsequent loss of mucosal function: attenuation and damage to the squamous epithelium in the esophagus; reduced numbers of parietal and chief cells in the gastric epithelium which will decrease gastric secretion; and progressive loss of the small intestinal villous epithelium, which decreases absorptive surface area, and in some patients, leads to transient malabsorption of fats and other macromolecules, or acute diarrhea. In the colon, there are reduced numbers of mitoses and epithelial cell atypia with loss of nuclear polarity in the columnar epithelium lining the crypts. Swelling and loss of goblet cells leads to decreased mucus production. Microabscesses composed of granulocytes and eosinophils may be present. Mucosal and submucosal edema may also be observed in both the small intestine and colon.

An increase in the replicating crypt epithelial cell population in the small intestine and colon, through proliferation of stem cells located near the base of the crypts, is observed beginning about 3 days after low doses of irradiation. This increase in crypt epithelial proliferation is able to compensate for the initial loss of differentiated epithelial cells. [28] However, the survival of the stem cell population is compromised at higher single doses of gamma irradiation, limiting epithelium repair. Fractionated irradiation protocols allow higher total doses to be administered by allowing repair and recovery of replicating epithelial cells and stem cells between fractions. [6] If damage to the stem cell population is severe after high doses of radiation, then epithelial integrity and barrier function are lost, leading to translocation of lumenal bacteria and eventual death from loss of fluids and serum proteins, hemorrhage, and sepsis 7 to 10 days after irradiation. Although rarely, if ever, seen in therapeutic applications of gamma irradiation, death from this syndrome has been observed after exposure of individuals to a single whole-body dose of 10 to 20 Gy as a consequence of radiation accidents or atomic warfare. [40], [46]

Liver biopsies are rarely obtained from patients with acute hepatic injury secondary to therapeutic irradiation for solid neoplasms. However, hepatic venoocclusive disease is not uncommon in bone marrow transplant recipients after cytoreductive therapy with combined chemotherapy and irradiation (see later), [47], [48] and [49] usually occurring before posttransplantation day 30. [48] Hepatic histology shows vascular congestion that is most prominent in centrilobular areas, subendothelial edema, endothelial destruction, sinusoidal dilation, and centrizonal hepatocyte necrosis with attenuation of the hepatocellular cords. [47] Deposition of clotting factors in the walls of hepatic venules suggests that microthrombus formation may be the primary pathogenic mechanism. [50] Occlusion of central veins by thrombus is sometimes observed. As the disease progresses, deposition of collagen in hepatic sinusoids, fibrosis of hepatic venules, and sclerosis of venular walls may be seen. [47], [48] One proposed mechanism for the increased sensitivity to combined chemotherapy and irradiation in this setting involves depletion of glutathione stores in sinusoidal endothelial cells and hepatocytes. [48], [51], [52] and [53]

The delayed effects of radiation injury most commonly occur from 6 months to 5 years after radiation therapy; however, symptoms may appear as early as 3 months or as late as 30 years after radiotherapy in a small number of patients. [40], [54], [55] Vascular injury and regeneration are characteristic of chronic radiation injury and are often observed in pathological specimens. [40] However, these findings are sometimes focal and may be missed unless multiple levels through the specimen are examined. Myointimal proliferation in medium-sized muscular arteries may lead to chronic ischemic injury because of the marked decrease in the lumenal diameter of these vessels (Fig. 132-1). Ulceration of the overlying mucosa occurs in areas of localized ischemia (Fig. 132-2; see also Color Fig. 132-2). Thrombosis is sometimes seen associated with these lesions and is more frequent in vessels with fibrinoid necrosis adjacent to deep ulcerations. The presence of lipophages or foamy macrophages in the intima of small arterioles is also a characteristic finding of delayed radiation injury, although this lesion may also result from other etiologies (Fig. 132-3). Telangiectatic vessels are frequently found in the submucosa and likely account for the diffuse bleeding sometimes observed in radiation enteritis (Fig. 132-4 and Color Fig. 132-4; see later). Sclerosis or medial fibrosis indicative of healing vasculitic lesions may also be observed.

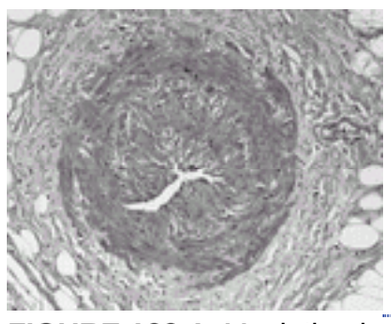

FIGURE 132-1. Myointimal proliferation nearly occludes the lumen of a moderate-sized mesenteric artery. This process usually occurs over several years after radiation injury and may lead to chronic ischemic injury to the intestine. (Original magnification × 100.) (Courtesy of Dr. Christopher Moskaluk.)

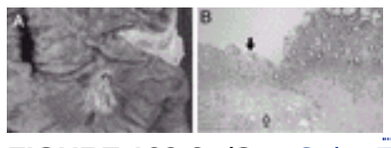

FIGURE 132-2. (See Color Fig. 132-2.) Radiation-induced ulceration in the colon. **A:** Gross appearance of a well-demarcated ulcer present in the rectum years after external radiation for an adjacent neoplasm. **B:** Histological appearance with chronic ulceration, mucosal necrosis (*solid arrow*), and dense submucosal fibrosis (*open arrow*) similar to that seen in ischemic injury. The lesion is notable for the absence of a prominent inflammatory infiltrate. (Original magnification × 20.) (Courtesy of Dr. Christopher Moskaluk.)

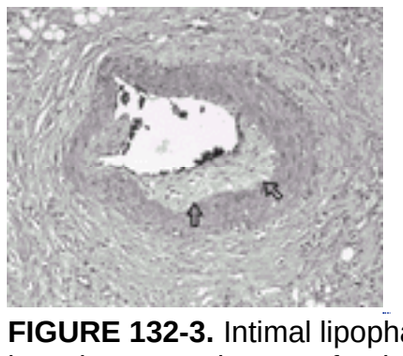

FIGURE 132-3. Intimal lipophage accumulation in intestinal arteriole after irradiation. These foam cells may be seen in the intima of small arteries and arterioles of the intestine several years after irradiation and may lead to lumenal narrowing of these vessels. (H&E, original magnification × 100.) (Courtesy of Dr. Christopher Moskaluk.)

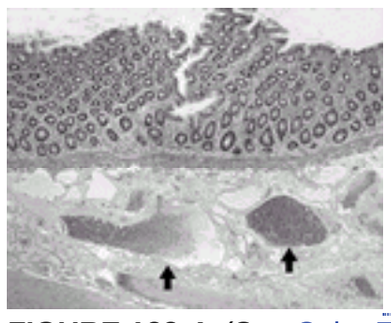

FIGURE 132-4. (See Color Fig. 132-4.) Submucosal telangiectasias (*arrow*) are seen in delayed radiation injury. Dilated venules and lymphatic channels are seen in the submucosa underlying relatively normal-appearing colonic epithelium. (H&E, original magnification × 40.) (Courtesy of Dr. Christopher Moskaluk.)

Changes in the submucosa are frequently observed in delayed radiation injury and are thought to be secondary to the chronic vascular damage described earlier. [40] Increased collagen deposition and fibrosis are often observed with minimal cellular inflammatory infiltrate. The fibrosis may be confined to the submucosa or extend through the muscularis propria and accounts for the thickening or strictures that may occur within any irradiated region of the alimentary tract. Atypical fibroblasts with bizarre nuclei are sometimes found in areas of fibrosis (Fig. 132-5, Color Fig. 132-5). The appearance of these fibrotic lesions in the small intestine may resemble that of Crohn's disease both on gross inspection and on radiologic examination, although fistulae and creeping fat are rarely observed.

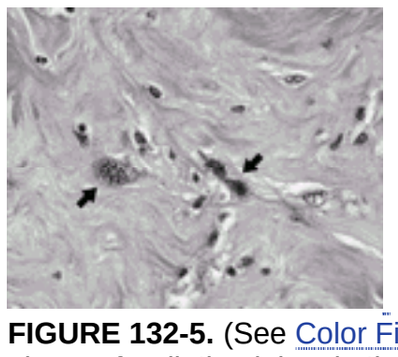

FIGURE 132-5. (See Color Fig. 132-5.) Atypical fibroblasts in radiation injury (*arrows*). Bizarre-appearing, pyknotic fibroblasts are frequently seen in the delayed phase of radiation injury in the alimentary tract. Although these atypical fibroblasts are frequently observed, their presence is not specific for radiation injury. (H&E, original magnification × 400.) (Courtesy of Dr. Christopher Moskaluk.)

Mucosal alterations in the small intestine include villous atrophy, flattening of epithelial cells, and fibrosis of the lamina propria. [40] These findings are often observed in patients with or without symptomatic radiation enteritis and may result in malabsorption when these changes are extensive. Superficial erosions and mucosal ulceration are common, sometimes penetrating deep into the submucosa and muscular propria and occasionally perforating into the peritoneal cavity. Chronic changes in the mucosa of the colon are similar to those seen in the small intestine.

Colitis cystica profunda is a rare delayed complication of radiation injury. [40] The importance of this lesion is in distinguishing it from invasive adenocarcinoma. Its symptoms are similar to colitis cystica profunda secondary to other etiologies. However, its histological appearance may differ from colitis cystic profunda of other

causes in that colonic glands extend deep into the submucosa and sometimes penetrate into the muscularis propria [40], [55] (Fig. 132-6). The presence of glands lined by normal epithelium usually makes it easy to distinguish colitis cystica profunda from adenocarcinoma in pathological specimens.

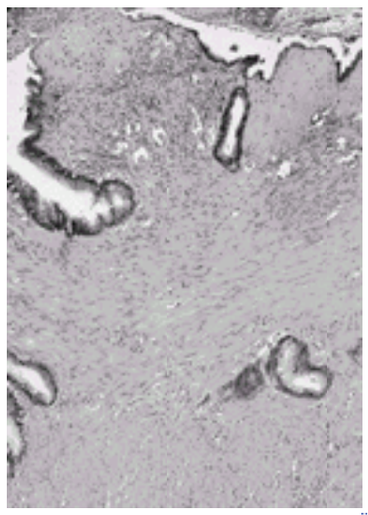

FIGURE 132-6. Colitis cystica profunda. Colonic glands are seen penetrating the muscularis mucosa into the submucosa and muscularis propria. This lesion is distinguishable from carcinoma by the normal cytologic characteristics of the epithelium lining the penetrating glands. (Original magnification × 40.) (Courtesy of Dr. Christopher Moskaluk.)

The development of secondary epithelial or stromal malignancies is also a potential complication of radiation therapy. [40], [56], [57] and [58] However, the number of documented cases is relatively small, and most of these cases generally have occurred after lower doses of gamma irradiation (less than 10 Gy). For example, the frequency of colon cancer is increased in atom bomb survivors 30 years after their exposure (relative risk of 2.4 compared with a matched control population), and an increased risk for colon cancer has been documented in a cohort of women irradiated with relatively low doses (6.25 to 10.5 Gy) for benign uterine bleeding. [40], [59], [60] and [61] Thus, whereas exposure of the colon to radiation may increase the risk for developing a secondary malignancy, the interval between therapeutic irradiation and development of secondary malignancies may be quite long. [40], [59], [60]

SPECIFIC ORGAN INVOLVEMENT

Esophagus

Radiation therapy for thoracic tumors and hematologic malignancies can result in both acute and long-term esophageal injury. The field required to treat thoracic, hematologic, and some pharyngeal malignancies frequently (25% in one series) [62] exposes the esophagus to sufficient radiation to produce pathological changes, but clinical syndromes generally require doses of 6000 cGy. [63] This threshold may be lower in patients whose tissue is sensitized by chemotherapeutic agents. Three major syndromes related to esophageal irradiation have been described: (1) acute inflammation with odynophagia or dysphagia; (2) fibrosis with stricture and dysphagia; and (3) fistula formation with aspiration into the trachea, or lethal bleeding from the aorta. During the acute phase of radiotherapy, symptoms are usually related to mucosal injury and the inflammatory response. Patients typically present with mucositis, which causes odynophagia or dysphagia beginning after the second week of treatment. Frank bleeding is unusual. [64] Acute dysphagia may also reflect a motor disturbance. A pattern of ineffective peristalsis at and distal to the radiation field may occur 4 to 8 weeks after initiation of radiation therapy.

The diagnosis of acute-phase radiation-induced esophagitis is usually evident from the patient's history and symptoms, although other conditions need to be excluded. Acute infection must be considered, particularly for those whose immune systems are impaired by the underlying disease or its treatment. Pill ulceration and reflux esophagitis are also in the differential diagnosis. Endoscopic evaluation is the test of choice, allowing characterization of the lesion and tissue sampling where appropriate. Barium swallow may offer some information in unusual circumstances when endoscopy is not clinically feasible, but these radiologic studies are normal or nondiagnostic most of the time. [65]

Prevention of acute radiation injury should be considered the first line of therapy. Limiting the total radiation exposure and careful selection of the radiation field are important preventive measures. Pharmacotherapy and dietary modifications have also been advocated. [66] If symptoms of odynophagia and dysphagia are sufficiently severe, temporary interruption of radiation therapy for several days to 1 week or enteral nutritional support may be necessary. Pharmacological therapy is often administered on an empiric basis and is directed at controlling symptoms; for example, topical lidocaine is generally given for odynophagia and may be compounded into a variety of "stomatitis cocktails" along with antacids, antihistamines (diphenhydramine), or antifungal (nystatin) ingredients. Antisecretory therapy is frequently used, but, like these cocktails, suffers from the same lack of substantiating data. [64], [67]

Patients with strictures or fistulae typically present well after radiation therapy has been completed (i.e., 6 months or later after initiation of treatment). Diagnosis and therapy of strictures and fistulae typically require a combination of radiologic and endoscopic techniques. Fluoroscopic evaluation is needed to determine the site, whereas either fluoroscopic or combined endoscopic and fluoroscopic methods can be used for subsequent dilation or stent placement. The initial approach to treatment of late esophageal stenosis is careful dilation. Balloon dilation devices may be preferable to rigid dilators because they allow isolated radial expansion of the stricture with minimal axial pressure. The complication rates for the dilation of strictures induced by adiation is not greater than dilation of strictures or other etiologies. [68] However, stent migration of conventional plastic endoprostheses was substantially higher in the radiation group (21%) than in the nonradiation group (3%) (68).

The introduction of the self-expanding metallic stent (SEMS) has made substantial changes in the therapy of esophageal cancer and radiation-induced stenosis and fistula formation. SEMS is typically a cylinder of wire mesh or coil with spring memory for a particular configuration. The first to be introduced was in 1983 [69]; coated and uncoated varieties are now available, and a variety of materials, attachments, and delivery devices are under investigation. The compromised circulation associated with radiation injury can be further worsened by the radial forces from these stents. This may account for the increased perforation rates seen in radiation strictures as compared with esophageal cancers stented before or without associated radiotherapy (36% versus 2.5%) and may contribute to the increased mortality (22% compared to 0%) seen in the same series. [70]

The coated stent is useful for patients suffering tracheoesophageal fistulae. However, enteral nutritional support may be necessary in patients with severe acute symptoms or with difficult-to-manage chronic strictures or fistulae. In patients with uncoated SEMS, later placement of a percutaneous endoscopic gastrostomy is generally feasible because the wire mesh typically embeds securely in the esophagus. Coated SEMS may not be amenable to the same wait-and-see approach.

Stomach

Gastric damage following radiation therapy is rare, but injury can occur when the stomach lies within the radiation field of an adjacent extragastric tumor. [40], [71] Gastric irradiation was used in the past as therapy for peptic ulcer disease because modest doses of radiation could significantly deplete the parietal and chief cell populations inducing gastric atrophy. [40], [72], [73] In an era before effective medical therapy was available, this approach was taken for patients with refractory ulcers. A total dose of 1600 and 1700 cGy given in 10 divided doses resulted in atrophic gastritis with associated decreases in acid and pepsin production. However, in most, acid production returned to normal basal levels within 2 years. [63], [73], [74]

Most patients receiving gastric irradiation are asymptomatic, although hemorrhage due to multiple gastric erosions has been reported as an early complication. [40] Gastric injury from higher exposures can present more dramatically with stenosis, fistulae, and perforation. [75] Strictures are more common in the antrum and cardia

than in the body or fundus. Delayed ulceration may also occur in this setting and is difficult to distinguish from peptic ulcer disease. Radiation-induced ulcers heal poorly because of obliterative arteriolitis within the ulcer bed. Ulceration and gastric strictures usually occur at doses exceeding 4500 to 5000 cGy, and about one half of patients experience clinically significant gastric injury at doses greater than 5500 cGy. [40]

The diagnosis is usually made on the basis of clinical presentation and patient history. Endoscopy may reveal an irregular thickened mucosa similar to the appearance of a gastric neoplasm or an appearance indistinguishable from peptic ulcer disease. Fluorographic upper gastrointestinal studies or computed tomography may be useful in demonstrating the presence of strictures. However, these studies may only show thickening of the gastric wall with an appearance similar to that seen in gastric malignancies. Data are lacking to guide therapy for this uncommon condition. In patients exposed to less than 2000 cGy, simple passage of time may suffice.

Small Bowel

The small intestine is particularly susceptible to radiation injury. Significant epithelial cell death may be observed as early as 4 to 6 hours after irradiation even with the relatively small 1- to 2-Gy fractions commonly used in some radiation therapy regimens. Radiation injury to the small intestine most often occurs in the clinical setting of radiotherapy for gynecologic, urologic, rectal, or retroperitoneal malignancies. The degree of injury appears proportional to radiation dosage delivered to the segment of small intestine that lies within the radiation field. [76], [77] The relatively fixed position of the duodenum, distal ileum, and cecum within the abdominal cavity make these regions particularly vulnerable to radiation-induced injury. [6], [40] At doses of more than 3000 cGy, 90% of patients have significant lesions, 40% at 1000 to 3000 cGy, and 20% at less than 1000 cGy. [78] Previous abdominal surgery that may fix loops of bowel in place is another important risk factor. [7], [79], [80]

Radiation injury to the small bowel can be divided also into acute injury and a chronic syndrome. Nausea, diarrhea, and abdominal discomfort are cardinal manifestations of acute injury. Although many of these symptoms are attributable to epithelial cell death and subsequent loss of mucosal function, symptoms such as nausea and vomiting occurring within in a few hours of irradiation may be mediated by the production of inflammatory cytokines. Fortunately, the epithelium regenerates, and function is restored within 2 weeks, with corresponding resolution of the acute symptoms. [78] This acute syndrome may foreshadow the occurrence of chronic radiation enteritis, at least in children. [81] It is not clear whether this holds for adults, of whom about 5% develop chronic enteritis after exposure. [41]

Symptoms of chronic radiation enteritis typically occur 1 to 2 years after exposure, but presentation 20 years after radiotherapy has been described. [82], [83] and [84] The central mechanism of injury is vascular damage with progressive localized ischemia (see earlier section on “ Pathology”). This leads to ulceration of the mucosa, fibrosis with stricturing, and less frequently, fistula formation or even perforation. Radiographs of the small intestine or colon may reveal evidence of single or multiple strictures or mucosal ulceration, a pattern similar to that observed in Crohn’s disease [4], [85] (Fig. 132-7). Life expectancy is poorer in patients whose enteritis is complicated by fistulae rather than bleeding. [86] Loose stools are the most common symptom and may be caused by a number of abnormalities: bile salt malabsorption in 65%, bacterial overgrowth in 45%, severe fat malabsorption in 40%, rapid intestinal transit in 35%, and lactase deficiency from villous blunting with consequent lactose intolerance in up to 20%. [8], [87]

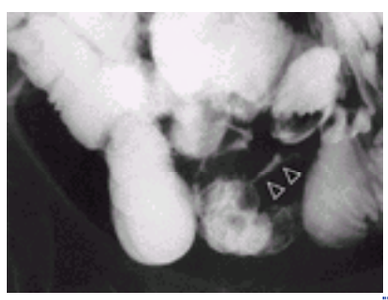

FIGURE 132-7. Barium small bowel radiograph showing an ileal stricture (*arrowheads*) in a patient with diarrhea several years after radiation therapy for cervical cancer. (Courtesy of Dr. Hubert Schaffer.)

Prostheses or mesh material may be used as a preventative measure to displace or protect the small intestine during radiation therapy. [88], [89] and [90] Acute radiation injury is treated supportively and with dose adjustment. [91] Antispasmotics and medications that decrease bowel motility must be used cautiously given that many of these patients are at risk for outright obstruction from underlying tumor or surgical adhesions. Perforation may have a bland presentation in this setting; typical signs of peritonitis, such as fever and severe abdominal pain, may be absent, and adhesions may wall off free air. [92], [93] The data are contradictory for the use of aminosalicylates as a preventative measure. In a prospective double-blind study of sulfasalazine (2 g/day) given to 87 patients undergoing radiation, diarrhea occurred in 55% of the sulfasalazine and 86% of the placebo groups, respectively. [94] However, mesalazine at 4 g/day was not beneficial in another trial. [95]

The treatment of chronic radiation enteritis requires patience and long-term pragmatism. Once symptomatic, this condition is persistent at best and worsens in many, even after surgical resection. [4] Cholestyramine is often a good choice as both a nonspecific antidiarrheal agent and when targeted at bile salt malabsorption. [87] Other antidiarrheals, such as loperamide and diphenoxylate, may also be useful. A newer peripheral opiate antagonist, loperamide- *N*-oxide, was used successfully in a series of 18 patients with radiation enteritis. [96] Treatment was associated with fewer bowel movements and improved bile salt absorption. Bacterial overgrowth can be treated with antibiotics such as amoxicillin clavulanate, ciprofloxacin, or tetracycline. The immunomodulatory effects of these agents may play a role along with their antimicrobial action, but this has not been studied in radiation enteritis.

Specialized enteral formulas, such as elemental diets, are available for treating moderate malnutrition. However, they are costly, and their superiority has not been established. [97] Total parenteral nutrition may be required for severe malnutrition or when enteral feeding is not feasible. Support with total parenteral nutrition allows correction of malnutrition, but recurrent symptoms remain a problem in up to 47% of patients. [98] Methylprednisolone may give additional benefit, but the long-term role of this relatively toxic agent is unknown. [99]

It is prudent to avoid surgery when possible in chronic radiation enteritis, given the likelihood of intraoperative and postoperative difficulties. Surgery is required in about one third of patients for management of strictures causing small bowel obstruction or for perforation. Complications are common (30%), and the mortality rate can be particularly high (more than 5%) for emergency operations. [100] Outright resection of the involved small bowel segment is considered preferable to bypass because of the high incidence of complications such as perforation, bacterial overgrowth, and fistulization. [101]

Colon and Rectum

Radiation proctosigmoiditis is among the most common complications of radiation injury. Many gynecologic and urologic tumors are treated with radiation, and the relatively fixed location of the rectum makes it more susceptible to radiation injury than the rest of the colon. [102] There is a clear dose-related incidence of injury, with acute symptoms common at doses of 3000 to 4000 cGy and with more than one third of patients suffering injury at 6,000 cGy. [103] Complication rates from patient report, rather than record abstraction, are higher still. [104], [105], [106] and [107] When a series of patients undergoing 6 weeks of radiotherapy for nongastrointestinal pelvic tumors was studied at 2-week intervals using sigmoidoscopy, biopsies, and symptom scores, histological and endoscopic abnormalities were both most pronounced after 2 weeks of therapy and improved subsequently. However, symptomatic complaints climbed consistently to the end of the 6-week observation period. [108] One third to one half of patients suffer acute injury with diarrhea and tenesmus during the first months of or after therapy. As a rule, these symptoms resolve over the following 6 months, but about 15% of patients continue to suffer chronic proctitis, manifested by rectal pain, diarrhea, and bleeding. [106] The degree of bleeding has some prognostic value: those patients who do not require transfusion have a high rate of spontaneous remission (70%), low rate of surgery (5%), and low mortality rate (25%); and patients who require blood transfusions or who suffer significant bowel disturbance have a low rate of spontaneous remission (less than 20%), often require surgery (50%), and have substantial mortality (60%). [109]

Many medical approaches have been tried for treatment of patients with acute or chronic radiation injury involving the colon and rectum. Most attention has been paid

to the unfortunate 15% of patients who suffer from chronic radiation proctitis. Unfortunately, no therapy stands out as clearly superior, and risks of each must be weighed against possible benefits. Oral aminosalicylic acid preparations by themselves do not appear effective, although they may help if combined with steroid treatment. [110] Sucralfate enemas by themselves appear effective and well tolerated. [111] Oral sucralfate was beneficial in a series of three patients, but a larger series is needed to evaluate the oral approach. [112]

Short-chain fatty acids are nutrients that promote colonocyte survival and proliferation and have been advocated to accelerate healing in radiation proctitis. In one double-blind study, placebo-treated patients ultimately reached the same level of recovery at 6 months. [113] A crossover study of 20 patients showed encouraging results, but the logistics of drug preparation and the odor of short-chain fatty acids present obstacles to this therapy. [114] Antioxidant therapy has also been investigated as a potential therapy: vitamin E (400 IU three times daily) and vitamin C (500 mg three times daily) were helpful in an open-label series of 20 patients. [115] The application of formalin has been used to treat refractory bleeding from radiation proctitis through a presumed mechanism of obliteration of the telangiectatic vessels through coagulative necrosis. In one series, 50 mL of 4% formalin solution was introduced into patients under sedation and kept in contact with the mucosa for 30 seconds and then cleared away using saline irrigation. Five to six aliquots were used in each session. However, complications were often encountered. [116] In another series of five patients (one treated with topical application of formalin-soaked gauze), severe pain occurred in one patient and acute colitis requiring hydration and antibiotics in another. In another prospective study examining 11 patients treated with four 20-mL aliquots and a total of 15 minutes contact time, all patients had decreased bleeding without reported complications. [117] Hyperbaric oxygen has been used successfully to improve the healing of ulcers in radiation proctitis. [118], [119]

Surgical and endoscopic treatments may be tried when bleeding from telangiectasia is the predominant manifestation of radiation injury (Fig. 132-8). It is critical to weigh potential benefit against risk in this setting. Patients who do not require transfusion generally do not require an interventional approach. Laser therapy can be associated with nonhealing ulcers and may aggravate bleeding or cause outright ulceration. Argon plasma coagulation is designed to create a more controlled level of treatment-induced injury and is used to obliterate natural gastrointestinal telangiectasias. Its introduction as an endoscopic treatment led to some enthusiasm about its use in radiation-related bleeding. In comparison to treatment of classic telangiectasias from other causes, argon plasma coagulation of telangiectasias associated with radiation injury appears to require more sessions to achieve hemostasis but appeared effective in several small series. [120], [121], [122] and [123]

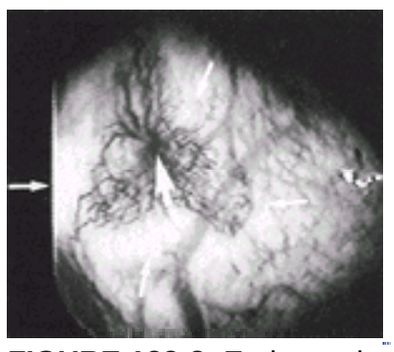

FIGURE 132-8. Endoscopic appearance of telangiectasia (*short arrows*) with prominent central arteriole (*long arrow*) and surrounding pallor in a patient with radiation proctitis.

Individual episodes of bowel obstruction may be treated conservatively with bowel rest, intravenous fluids, and nasogastric decompression, but recurrent obstruction or an unresponsive episode may require surgery. Surgical intervention for stricture generally consists of resection of the diseased segment, with primary anastomosis. Outcome is best if sufficient resection is performed to ensure that one margin is free from radiation injury. [4], [124]

Liver

Older administration techniques made liver injury common when therapeutic radiation was directed at tumors within the hepatic parenchyma. The therapeutic index using these older techniques was unfavorable, with doses of 3000 to 3500 cGy offering consistent injury and inadequate therapeutic effect. Thus, hepatic irradiation lost popularity until more modern technology, such as nonaxial planes of administration and sophisticated modeling, made it possible to deliver higher doses safely. [125]

Hepatic injury following irradiation typically manifests about 4 to 8 weeks after exposure but may occur as early as 2 weeks or as late as 7 months. In reports from the 1960s, more than one fourth of patients with radiation hepatitis had a clinical presentation consistent with Budd-Chiari syndrome or obstruction of suprahepatic veins. [126], [127] Nonspecific symptoms, such as malaise, fatigue, and weight gain, are common. Ascites is often present but may be below the threshold for bedside detection. Right upper quadrant pain is also common, but jaundice is not, in keeping with the characteristic laboratory findings in which alkaline phosphatase levels are elevated with minimal increases in bilirubin and mild elevation of transaminases. [128], [129] The acute illness is generally well tolerated and usually resolves with supportive care, but development of chronic radiation-induced hepatitis has also been described. [130] Computed tomography findings may be helpful. In one series, 23 of 31 patients (74%) showed a low-attenuation area adjacent to the hepatic tumor on tomographic scans in the targeted radiation field. A sharp, straight interface was rarely seen at the treatment margin. These findings were maximal 2 to 3 months after completion of therapy and persisted for up to 3 months. Atrophy in the treated segment or lobe and hypertrophy of the untreated liver were seen in several patients. [131] With proton-beam irradiation, abnormalities noted on computed tomography scans may persist as long as 42 months. [132] Given the setting and frequency with which combined modalities of treatment are used, the differential diagnosis for this condition must always include metastatic disease and drug toxicity.

Liver injury is a particular concern with bone marrow transplantation, in which the combination of total-body irradiation and high-dose chemotherapy for initial cytoreductive therapy is commonly used. Venoocclusive disease, presenting with weight gain (fluid retention), jaundice, and tender hepatomegaly, is common, occurring in 10% to 60% of patients within several weeks after transplantation. [48], [133], [134] Weight gain and increasing liver size with tenderness may herald the onset of venoocclusive disease and usually precede the development of hyperbilirubinemia. [48] Serum aminotransferases may also be elevated. Mortality rates from venoocclusive disease in this setting range from 0% to 67%. [48] Supportive treatment with diuretics and careful fluid and electrolyte management are usually effective in mild to moderately severe venoocclusive disease. Treatment of severe cases of venoocclusive disease has been less successful.

Chemotherapeutic regimens that potentiate hepatic injury when combined with therapeutic irradiation include mitomycin C, MOPP (nitrogen mustard, vincristine, procarbazine, and prednisone), CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), CCNU (2-chloroethyl, 3-cyclohexyl, 1-nitrosurea), and pro-MACE (prednisone, methotrexate, doxorubicin, cyclophosphamide, etoposide). [135], [136] Injury from combined therapy is clearly more severe than that seen from radiation alone and carries an overall mortality rate of 30% to 50%.

Treatment of patients with isolated radiation injury to the liver is generally supportive. Salt restriction and diuretics are often helpful. Improvement over months is the rule, with a mortality rate of less than 20%, although those patients who become jaundiced may have a worse course. [126] Treatment is similar with combined injury, but more aggressive therapy may be required.

CHAPTER 133

Philip S. Schoenfeld*

CLINICAL DECISION MAKING

WHAT IS EVIDENCE-BASED MEDICINE?

Clinical decision making is facilitated by evidence-based medicine. Evidence-based medicine (EBM) is “the conscientious and judicious use of current best evidence from clinical care research in the management of individual patients.” [1]

Conscientious use implies that physicians review articles about clinical research and apply this information to clinical decision making.
Current best evidence from clinical care research implies that physicians systematically appraise the methods and results of clinical research articles. **This is the focus of this chapter.**
Judicious use implies that clinical experience facilitates a thoughtful assessment of an individual patient’s unique situation. [2] The risks and benefits of different tests or treatments must be balanced against an individual patient’s preferences and risks from a specific disease.

The medical literature is expanding at an exponential rate, [2] and the time available for reading may be hurried and fragmented. Thus, many physicians may feel that a systematic review of clinical research is impractical. In recognition of this dilemma, EBM provides frameworks (Table 133-1 and Table 133-2) for the rapid and systematic appraisal of clinical research studies. Studies using improper methodology produce biased results. Use of EBM frameworks (see Table 133-1 and Table 133-2) allows rapid review of abstracts of published research, identifies studies likely to produce biased results, and “tosses out” those studies.

1. When are diagnostic tests necessary?
   a. Is the pretest probability of disease so high or so low that further diagnostic tests are not needed?
   b. How is pretest probability estimated?
2. Assessing study design
   a. Was there a blinded comparison of the diagnostic test to a gold standard test?
   b. Were negative study tests verified by performing the gold standard test?
   c. Was the diagnostic study tested in patients similar to the population in whom the test will be used?
3. Getting from pretest probability to posttest probability
   a. Interpret and apply data about sensitivity and specificity.
   b. Use likelihood ratios to maximize the data from a diagnostic test.
4. Applying the results of clinical research to your patient
   a. Are the results applicable to your patient?
   b. Is the test available with reproducible accuracy?

From ref. 3.

TABLE 133-1 Critical Approach to an Article About a Diagnostic Test

1. Assessing study design
   a. Did the study use concealed random allocation?
   b. Were patients and physicians blinded about allocation to treatment or placebo groups?
   c. Did groups receive equal treatment (co-interventions) except for the experimental study treatment?
   d. Did the study use an intention-to-treat analysis?
   e. Was follow-up of study patients complete?
2. Clinically significant results and statistically significant results
   a. Estimating treatment-effect size: relative risk reduction, absolute risk reduction, and number needed to treat
   b. Evaluating the sample size in a non-statistically significant study: were enough patients entered into the study?
   c. What is the precision of the treatment effect: how large are the 95% confidence intervals?
3. Applying the results of clinical research to your patient
   a. Are the results applicable to your patient?
   b. Are the potential treatment benefits worth the potential side effects, cost, and inconvenience to your patient?

From ref. 19.

TABLE 133-2 Critical Approach to an Article About a Therapy

This chapter outlines systematic frameworks for the critical appraisal of studies about diagnostic tests and therapies; reviews different presentations of study results; and discusses the application of study results to patient care and clinical decision making. Clinical scenarios are used to illustrate the practical application of EBM concepts.

CRITICAL APPRAISAL OF AN ARTICLE ABOUT A DIAGNOSTIC TEST

Case Scenario A—Part I

A 65-year-old woman presents for colon cancer screening after watching a report about this topic on a morning news show. The patient has never been screened for colon cancer. You describe the potential benefits and risks of colonoscopy. However, the patient is hesitant to undergo colonoscopy because she heard that colon perforations can occur during colonoscopy. She has heard that a new “x-ray” test can look for polyps in the colon, and she asks if that would be an appropriate test for

her. Specifically, you consider the following questions:

1. What is the probability of colon polyps in this woman?
2. How accurate is “virtual” or CT colonoscopy for the diagnosis of colon polyps?

You decide to apply EBM frameworks [3] to appraise a recent study [4] that examines the accuracy of CT colonoscopy and answers these questions.

When Are Diagnostic Tests Necessary?

Is the Pretest Probability of Disease So High or So Low that Further Diagnostic Tests Are Not Needed? The pretest probability defines the likelihood that a patient has a specific disorder before any diagnostic test result is available. Diagnostic tests should be ordered when the pretest probability is intermediate. Thus, if the pretest probability of a specific disorder is 50%, then accurate diagnostic tests may rule out the disorder or definitively confirm the presence of the disorder. Conversely, if the pretest probability is very high or very low, then ordering additional diagnostic tests may be unnecessary. Several examples illustrate the concept of pretest probability. What diagnostic tests would you order for a hospitalized patient who suddenly develops diarrhea? Stool tests for ova and parasites are routinely ordered to evaluate diarrhea, but the pretest probability of a parasitic infection in a hospitalized patient with new-onset diarrhea approaches zero. [5] In this situation, the pretest probability is so low that stool tests for ova and parasites should not be obtained. Conversely, patients with peptic ulcers are rarely tested for *Helicobacter pylori* in some countries (e.g., Armenia) because the prevalence of *H pylori* approaches 100%. Thus, these peptic ulcer patients are automatically treated for *H pylori* without performing diagnostic tests to rule in this diagnosis. What constitutes an intermediate pretest probability that suggests the need for diagnostic tests? Clinical judgment governs this decision, based partly on the cost, accuracy, and side effects of the diagnostic test and the consequences of a “missed” diagnosis (i.e., if a missed diagnosis may have fatal consequences, then clinicians will have a lower threshold to order diagnostic tests).

How Is Pretest Probability Estimated? When physicians evaluate a patient’s complaint, they intuitively use their experience and clues from the history and physical exam to estimate pretest probabilities for different medical disorders. However, these estimates are frequently inaccurate. [6] The prevalence of a disorder (the proportion of patients with a specific disorder at a distinct point in time) may provide a more accurate estimate of pretest probability. Valid studies about the prevalence of a particular diagnosis should meet several methodologic criteria. [7] First, the technique for confirming the diagnosis should be explicit and credible. For example, colonoscopy would be an explicit and credible test to estimate the prevalence of colon polyps. However, flexible sigmoidoscopy, which does not examine the right side of the colon, might not be a credible test. Second, the technique for confirming the diagnosis should be applied to consecutive patients who present with a specific complex of symptoms, physical exam signs, or laboratory results. For example, the study about prevalence of colon polyps might require that all study patients are older than 50 years of age and asymptomatic (e.g., no hematochezia or abdominal pain). Finally, clinicians should determine whether the characteristics of their patients are similar to those of the patients examined in the study. For example, if your patient has a family history of colon cancer in a first-degree relative, then this patient’s risk for colon cancer and colon polyps would be higher than among patients without a family history of colon cancer.

Case Scenario A–Part II

A recent abstract estimates the pretest probability for colon polyps in the case scenario patient. [8] In this study, asymptomatic women referred for colon cancer screening underwent colonoscopy. Colonoscopy is a credible diagnostic test to define the prevalence of colon polyps. Consecutive women referred for colon cancer screening were offered colonoscopy. Patients were asymptomatic (e.g., denied history of hematochezia, change in bowel habits, or abdominal pain) and were screened with complete blood cell counts and fecal occult blood tests to rule out anemia or occult gastrointestinal (GI) bleeding. In this trial, the prevalence of colon polyps among asymptomatic women was 21%, and the prevalence of advanced colon polyps (i.e., polyps larger than 10 mm, villous adenomas, adenomas with high-grade dysplasia, or colorectal carcinoma) was only 3%. Although the prevalence of advanced colon polyps is not very high, you recognize that a missed diagnosis of advanced colon polyps could lead to a fatal colon cancer. Therefore, you decide that diagnostic testing for colon polyps is warranted, and you proceed to review the study about the diagnostic accuracy of virtual colonoscopy. [4]

Assessing Study Design

Was There a Blinded Comparison of a Diagnostic Test to a Gold Standard Test? A *gold standard* or reference standard refers to a diagnostic test that definitively establishes the presence or absence of disease. For example, a study examining the diagnostic accuracy of magnetic resonance cholangiography (MRC) for the diagnosis of choledocholithiasis used endoscopic retrograde cholangiopancreatography (ERCP) as the reference test. [9] Reference standards are usually costlier, riskier, or more inconvenient than new diagnostic tests being studied. Otherwise, performing the reference standard would be more sensible. Biopsies, autopsies, surgical pathology, or even prolonged patient follow-up may also be reference standards that determine the presence or absence of disease. The results from the reference standard and the diagnostic test should be examined by investigators who do not know the patient’s history or the results of other tests. This “blinded” comparison is especially important when the interpretation of test results are subjective. For example, in the study assessing the diagnostic accuracy of MRC, [9] the radiologist’s interpretation of the MRC would be biased if he or she knew that the ERCP demonstrated choledocholithiasis. Establishing a reference standard test may be an elusive goal. New technologies may be more accurate than the established reference standard test. If a potentially poor diagnostic test is being used as the reference standard, then the diagnostic accuracy of the new test may appear worse than it truly is. For example, one study evaluated the accuracy of ultrasonography to diagnose cholelithiasis but used oral cholecystograms as the gold standard test. [10] In this study, only patients with abnormal cholecystograms were referred for surgery. Five patients in this study had positive ultrasounds for cholelithiasis, but normal cholecystograms. Based on this study’s analysis, these positive ultrasounds were false-positive test results (i.e., patients did not truly have disease). Ultimately, several of these patients underwent cholecystectomy because of recurrent symptoms, confirming the presence of cholelithiasis and demonstrating that oral cholecystograms may not be an adequate gold standard test.

Were Negative Study Results Verified by Performing the Gold Standard Test? Study results will be distorted if investigators use results of the new diagnostic test to decide whether or not to perform the gold standard test. This *verification bias* may produce biased study results in more than 50% of diagnostic test studies. [11] For example, in the study about the accuracy of MRC for choledocholithiasis, [9] a few patients with normal MRCs actually had choledocholithiasis on ERCP. If ERCPs were withheld from these patients (because investigators assumed choledocholithiasis was absent based on the normal MRCs), then MRC would appear more accurate than it truly is.

Was the Diagnostic Study Tested in Patients Similar to the Population in Whom the Test Will Be Used? Patients with end-stage disease may have grossly abnormal diagnostic test results, making it easy to differentiate healthy people from ill patients. For example, virtual colonoscopy might easily differentiate patients with normal colons from patients with end-stage, near-obstructing colon cancer. The real value of a diagnostic test is its ability to identify patients with early manifestations of disease (e.g., colon polyps) that could be easily confused with a normal finding (e.g., stool). To assess the accuracy of a diagnostic test properly, the test should be studied in a broad range of patients, similar to the patients seen in clinical practice. [12] The best example of this *spectrum bias* may be carcinoembryonic antigen (CEA). CEA was evaluated as a diagnostic test for colorectal cancer. Initially, the test was studied in patients with advanced colorectal cancer and in normal controls. [13] The results demonstrated that almost all (98%) of the advanced colorectal cancer patients had elevated CEA levels, whereas almost all normal controls had low levels of CEA. These initial results raised hope that CEA might be a useful screening tool for colorectal cancer. When this test was studied in a broad population of patients with early-stage colorectal cancer and patients with other GI disorders, the test was inaccurate and unable to differentiate patients with early cancer from patients with other disorders. [14]

Case Scenario A—Part III

The study assessing the diagnostic accuracy of “virtual” or computed tomographic (CT) colonoscopy used conventional colonoscopy as a gold standard, which is appropriate. Conventional colonoscopy was performed in all patients who underwent CT colonoscopy, which eliminates verification bias. However, the accuracy of CT colonoscopy was assessed in patients with an increased risk for colon polyps (i.e., patients with a personal history of colon polyps, family history of colon cancer, or positive flexible sigmoidoscopy or positive fecal occult blood test). Thus, the prevalence of colon polyps in this population may be higher than in the asymptomatic, average-risk woman in the case scenario. However, there is no evidence that colon polyps are larger or more easily identifiable in this population than in asymptomatic patients. Overall, you determine that the article has adequate methodology and you proceed to review the results.

Getting from Pretest Probability to Posttest Probability

Interpreting and Applying Data About Sensitivity and Specificity Sensitivity and specificity can be calculated from the classic 2 × 2 table (Fig. 133-1). The 2 × 2 table is completed by filling in the true-positive test results (positive test result when disease is present), false-positive test results (positive test result when disease is absent), true-negative test results (negative test result when disease is absent), and false-negative test results (negative test result when disease is present). For example, a recent study assessed the accuracy of ferritin for the diagnosis of iron deficiency anemia, using bone marrow aspirates as a gold standard for diagnosis of iron deficiency. [15] This trial found that 150 patients had high ferritin levels (more than 45 µg/L) and 85 patients had low ferritin levels (45 µg/L or less). Of the 85

patients with low ferritin levels, 70 had iron deficiency anemia (true-positive test results) and 15 did not (false-positive test results). Of the 150 patients with high ferritin levels, 135 patients did not have iron deficiency anemia (true-negative test results), and 15 did (false-negative test results).

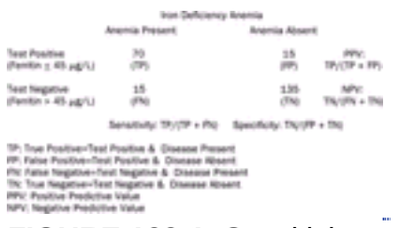

FIGURE 133-1. Sensitivity and specificity of ferritin for the diagnosis of iron deficiency anemia (36% prevalence of iron deficiency anemia) in an elderly population. (From ref. [15].)

In the 2 × 2 table (see Fig. 133-1), the formulas for sensitivity (the percentage of patients with the disease in whom the test results are positive) and specificity (the percentage of patients without the disease in whom the test results are negative) are defined. Using these formulas, the sensitivity of ferritin (with a cutoff point of 45 µg/L of ferritin) for iron deficiency anemia is 82%, and the specificity is 90%. Unfortunately, sensitivity and specificity "work backward" from clinical practice, evaluating patients with known disease and providing data about the presence or absence of certain diagnostic test results. However, patients present with symptoms and diagnostic test results, and we "work forward" with these results to determine the likelihood of disease. The positive predictive value (PPV) and negative predictive value (NPV) from the 2 × 2 table (see Fig. 133-1) provide these data. The formulas for PPV (the percentage of patients with positive test results who have the disease) and NPV (the proportion of patients with negative test results who do not have the disease) are also provided in the 2 × 2 table. Using these formulas, the PPV for low ferritin level (45 µg/L or less) in the diagnosis of iron deficiency anemia is 82%. Hence, 82% of patients with ferritin levels of 45 µg/L or less had iron deficiency anemia. The NPV for high ferritin level is 90%, or 90% of patients with ferritin levels of more than 45 µg/L did not have iron deficiency anemia. Before clinicians apply PPV and NPV to their individual patients, the limitations of these statistics must be recognized. Sensitivity and specificity usually remain relatively constant, although they may vary slightly depending on the severity of disease in a specific patient population. However, PPV and NPV vary widely depending on the prevalence of the disease. For example, consider if all internal medicine admissions to a hospital were screened with ferritin for iron deficiency anemia. In this diverse population, the prevalence of iron deficiency anemia might only be 5%, although the prevalence of iron deficiency anemia was 36% among the elderly anemic patients in the ferritin–iron deficiency anemia study. [15] Assuming that the sensitivity and specificity remain constant, a new 2 × 2 table (Fig. 133-2) can be constructed, producing a significantly lower PPV of 32% and a significantly higher NPV of 99%. Hence, when prevalence of a disease decreases, the PPV decreases, and the NPV increases.

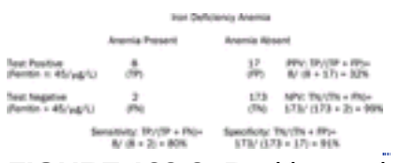

FIGURE 133-2. Positive and negative predictive value of ferritin in the diagnosis of iron deficiency anemia in a hypothetical population of 200 hospitalized patients (5% prevalence of iron deficiency anemia).

Use Likelihood Ratios to Maximize the Data from a Diagnostic Test Likelihood ratios express the likelihood that a particular range of values for a diagnostic test will be found in a patient with a specific disease. They overcome two weaknesses of sensitivity/specificity and PPV/NPV. First, likelihood ratios predict the presence of disease based on a diagnostic test result (similar to PPV/NPV), but likelihood ratios do not change with different disease prevalence (unlike PPV/NPV). Second, studies reporting sensitivity and specificity usually provide data about the accuracy of a diagnostic test around only one value. For example, the ferritin–iron deficiency anemia study [15] calculated sensitivity and specificity of ferritin around a cutoff point of 45 µg/L (i.e., ferritin level less than or equal to 45 µg/L is consistent with iron deficiency anemia and ferritin level greater than 45 µg/L is not consistent with iron deficiency anemia). Intuitively, a patient with a ferritin level of 5 µg/L is more likely to have iron deficiency anemia than a patient with a ferritin level of 40 µg/L, but the sensitivity and specificity cannot differentiate between these two patients. However, likelihood ratios are usually calculated for multiple ranges of diagnostic test results, thereby maximizing the information from a diagnostic test. Thus, likelihood ratios may facilitate the application of diagnostic test results to patient care. Mathematically, the likelihood ratio for a positive test result is as follows:

$$\frac{\text{sensitivity}}{1 - \text{specificity}} \quad \text{or} \quad \frac{\text{true positive rate}}{\text{false positive rate}}$$

The likelihood ratio for a negative test result is as follows:

$$\frac{1 - \text{sensitivity}}{\text{specificity}} \quad \text{or} \quad \frac{\text{false negative rate}}{\text{true negative rate}}$$

In the ferritin–iron deficiency anemia study, [15] likelihood ratios were calculated for four ranges of ferritin: less than or equal to 18 µg/L, 19 to 45 µg/L, 46 to 100 µg/L, and more than 100 µg/L (Fig. 133-3).

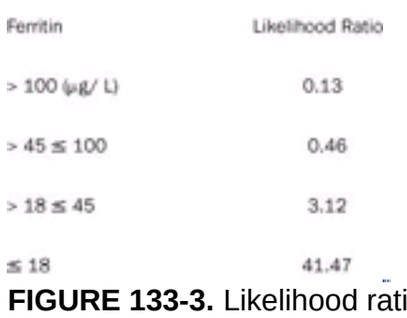

FIGURE 133-3. Likelihood ratios for ferritin in the diagnosis of iron deficiency anemia.

By using a nomogram, [16] likelihood ratios easily convert pretest probabilities to posttest probabilities (Fig. 133-4). Simply place the base of a ruler at the pretest probability and angle the ruler through the likelihood ratio in order to see the posttest probability. For example, clinicians might assume that a 70-year-old patient with a history of myocardial infarction, daily use of aspirin, an MCV of 78, and a hemoglobin level of 11 g/dL has a 50% pretest probability of iron deficiency anemia (moderately higher than the prevalence of iron deficiency anemia among a general population of elderly anemic patients). If this patient has a ferritin level of 5 µg/L, then the pretest probability of 50% and the likelihood ratio of 41 produces a 98% posttest probability that iron deficiency anemia is present. Conversely, if this patient has a ferritin level of 110 µg/L, then the posttest probability is 10%.

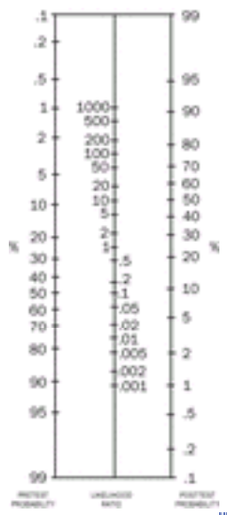

FIGURE 133-4. Nomogram for interpreting diagnostic test results. (Adapted from ref. [16].)

Case Scenario A—Part IV

CT colonoscopy found all three colon cancers in study patients. For patients with large polyps (at least 10 mm), CT colonoscopy produced sensitivity of 96% and specificity of 96% with likelihood ratio for a positive test of 24 and likelihood ratio for a negative test of 0.04. For patients with polyps of any size, CT colonoscopy produced sensitivity of 82% and specificity of 84% with likelihood ratio for a positive test of 5 and likelihood ratio for a negative test of 0.2. The prevalence of large (more than 10 mm) polyps is about 3%, and the prevalence of any colon polyps is about 21%. Therefore, using likelihood ratios, a positive CT colonoscopy for large polyps predicts a 42% posttest probability of large polyps. A positive CT colonoscopy for colon polyps (any size) predicts a 60% posttest probability of colon polyps (any size).

Applying the Results of Clinical Research to Your Patient

Are the Results Applicable to Your Patient? A study may have valid methodology, and the results may indicate that the diagnostic test is accurate. However, if the study patient population is much different than your patients (e.g., geriatric versus pediatric patients, symptomatic versus asymptomatic patients), then the diagnostic test may perform much differently in your patients. If your own patient meets all of the inclusion criteria of a study and the prevalence of disease is similar in your setting, the results are probably applicable to your patient. Physicians need to use their own judgment when there are no definitive research data about the accuracy of the diagnostic test in specific patients. For example, no research is available about the accuracy of CT colonoscopy among asymptomatic individuals referred for colon cancer screening. These average-risk patients may have a lower prevalence of polyps than high-risk patients (e.g., patients with a personal history of colon polyps), but it is unlikely that average-risk patients form different types of polyps than high-risk patients. Thus, results from the CT colonoscopy study [4] should be applicable to the case scenario patient.
Is the Test Available with Reproducible Accuracy? Even when a diagnostic test is adequately described to permit replication in your clinical setting, the test may not be available. Some diagnostic tests require special equipment or skilled examiners, which may not be widely available. For example, CT colonoscopy is not widely available outside academic medical centers in 2003. Many diagnostic tests, including CT colonoscopy, require a subjective interpretation. A well-designed study of a diagnostic test will have the diagnostic test results reviewed by examiners with different levels of expertise. If experienced and inexperienced practitioners produce similar interpretations of diagnostic test results, then you may be assured that study results may be reproduced in your own clinical setting. For example, previous studies [17] have demonstrated that both experienced and inexperienced radiologists can accurately diagnose choledocholithiasis on MRC.

Case Scenario A—Part V

CT colonoscopy is available in your hospital, so you can provide this diagnostic test for your patient. She is an asymptomatic, average-risk patient, and the study examined the accuracy of CT colonoscopy in high-risk patients. However, you doubt that high-risk patients will develop different polyps, so you decide that the results are applicable to your patient. The CT colonoscopy study [4] did not have multiple radiologists review CT colonoscopy results, so you are uncertain whether your hospital's radiologists can produce similarly accurate results with CT colonoscopy. Overall, you decide that CT colonoscopy will not be your routine test of choice for colon cancer screening at this time. Nevertheless, based on your interpretation of your patient's wishes as well as the very high accuracy of CT colonoscopy for large polyps, you decide to proceed with CT colonoscopy for this individual patient.

CRITICAL APPRAISAL OF AN ARTICLE ABOUT A THERAPY

Case Scenario B—Part I

You are seeing a 75-year-old man with osteoarthritis of the hip and a past history of a nonsteroidal antiinflammatory drug (NSAID)– associated bleeding ulcer. His primary care physician has referred this patient because treatment of osteoarthritis with acetaminophen and physical therapy has been ineffective. The primary care physician wants to start the patient on a cyclooxygenase-2 (COX-2)–selective NSAID (coxib), but she is still concerned about the risk for recurrent NSAID-associated bleeding ulcers. Specifically, she asks these questions:

1. Among NSAID-using patients, do coxibs cause fewer serious GI complications (i.e., bleeding, perforation, or obstruction) than conventional NSAIDs?
2. If coxibs do cause fewer serious GI complications, how large is the reduction?

You recently saw an article [18] that addresses this issue. The VIGOR trial randomized more than 8000 rheumatoid arthritis patients to receive rofecoxib or naproxen and examined the frequency of serious NSAID-associated GI complications. You apply EBM frameworks (see Table 133-2) to appraise the study, [19] determining whether the study has appropriate methodology that is likely to produce accurate results.

Assessing Study Design

Did the Study Use Concealed Random Allocation? A patient's response to treatment may be influenced by many factors other than treatment. Age, severity of illness, and comorbid medical problems will affect a patient's prognosis and limit the effect of treatment. Therefore, these factors should be distributed equally between the treatment and placebo group (or between a "new" treatment group and a control group) in order to identify a "true" or accurate estimate about the effectiveness of the treatment. In a randomized trial, every patient has an equal chance of receiving treatment or placebo when they enter the trial, so that these factors are usually distributed equally between the treatment and placebo group. In a nonrandomized trial, physicians determine which patients enter the treatment group and which patients enter the placebo group. For unclear reasons, patients with a good prognosis are disproportionately entered into the treatment group in a nonrandomized trial. Patients with good prognosis are more likely to have a favorable outcome, regardless of the effectiveness of treatment. [20] Nonrandomized trials illustrate that these studies demonstrate larger treatment effects than randomized trials and are more likely to demonstrate a false-positive result. [20] Concealment of allocation maintains the integrity of randomization. In concealed random allocation, researchers who obtain informed consent and enroll patients into a trial do not know whether the next study patient will receive treatment or placebo. If concealment of allocation was used, then the methods section of a study should indicate this (e.g., sealed, opaque, sequentially numbered envelopes were opened after patients gave informed consent; a central coordinating center was called for treatment assignment after a patient gave informed consent). Researchers may subconsciously wish to show that the therapy being studied is superior to the control therapy. Therefore, without concealed allocation, researchers may subconsciously assess a patient's prognosis and guide patients with good prognosis into the treatment or new therapy group and guide patients with a bad prognosis into the placebo or control therapy group.
Were Patients and Physicians Blinded About Allocation to Treatment or Placebo Groups? Blinding simply means that the patients and physicians do not know if the patient received placebo or treatment. This is particularly important when the outcome is subjective. For example, the VIGOR trial [18] assessed the frequency of dyspepsia among study patients. However, the assessment of dyspepsia is quite subjective and variable. Both the patient and the study physicians may assume that coxibs, like rofecoxib, are less likely to cause dyspepsia than conventional NSAIDs, like naproxen, possibly introducing bias into their subjective assessment of dyspepsia. Blinding both the patients and health care personnel (double blinding) is the best method to avoid this bias. Double blinding has been demonstrated to prevent inflated estimates of treatment benefit in randomized trials. [21] *Randomization, concealed allocation, and double blinding are the only techniques that have*

been shown to reduce inflated estimates of treatment benefit in epidemiologic studies. [20], [21] The importance of blinding is self-evident, but it may be difficult to ensure. For example, a recent double-blind, randomized controlled trial compared tegaserod with placebo among patients with constipation-predominant irritable bowel syndrome (IBS). [22] In this trial, the study endpoint was global assessment of improvement in IBS symptoms, which is clearly a subjective outcome. However, tegaserod, a 5-HT $_3$ partial agonist, stimulates colonic motility and rapidly increases the frequency of bowel movements in constipated patients. Thus, patients using tegaserod may have noted the rapid increase in frequency of bowel movements and assumed that they were using tegaserod. This knowledge may have "unmasked" the blinding process and biased the subjective assessment of improvement in IBS symptoms. One possible resolution: ask patients to guess whether they had received tegaserod or placebo at the end of the trial. If 50% of patients receiving tegaserod guess correctly and 50% of patients using tegaserod guess incorrectly, then the blinding process still worked. Even when the study outcome is objective, it is still helpful to maintain double blinding. For example, one study of primary prevention of bleeding esophageal varices with beta-blockers examined overall mortality as a study outcome. [23] This is certainly an objective outcome, but double blinding was still maintained in this study because of the risk for co-interventions. Co-interventions are treatments other than the study treatment that may affect the outcome, especially when the co-interventions are unequally distributed between the treatment and placebo groups. For example, isosorbide-5-mononitrate has been shown to reduce variceal bleeding. [24] Without double blinding, the physician or the patient might be tempted to start isosorbide-5-mononitrate in one group more than the other group. Double blinding limits the unequal use of cointerventions.

Did the Groups Receive Equal Treatment (Co-Interventions) Except for the Experimental Study Treatment? Additional treatments or co-interventions are most problematic when they are very effective, such as the additional use of isosorbide-5-mononitrate in a study about the effectiveness of beta-blockers to prevent variceal bleeding. Although the methodology of a study may be strengthened if all co-interventions are withheld, it may be unethical to withhold effective treatment to patients enrolled in a study. Research does not occur in a vacuum, and patients receive additional treatments or co-interventions to optimize their health while participating in a study. To balance this conflict, the indications to use co-interventions should be clearly described in the Methods section, their use should be limited, and their use should be recorded for later analysis. The VIGOR trial [18] clearly described the use of co-interventions in the Methods section. Patients were allowed to take other treatments for rheumatoid arthritis, including acetaminophen, methotrexate, and corticosteroids, even though concurrent use of corticosteroids with NSAIDs increases the risk for serious NSAID-associated GI complications. [25] The frequency of serious NSAID-associated GI complications among corticosteroid-using patients in patients using rofecoxib and patients using naproxen was recorded for subgroup analysis. Concurrent use of other NSAIDs was forbidden because use of multiple NSAIDs increases the risk for NSAID-associated GI complications. [25] Patients on NSAIDs develop dyspepsia, and over-the-counter preparations to treat dyspepsia are readily available. So, recognizing that trials do not occur "in a vacuum," researchers allowed patients to use antacids or *limited* doses of H $_2$-receptor antagonists. In *limited* doses, these medications are unlikely to affect the occurrence of serious NSAID-associated GI complications, but allowing use of these medications will treat dyspepsia.

Did the Trial Use an Intention-to-Treat Analysis? In almost every study, some patients stop taking the study medication (treatment or placebo). They are noncompliant, or they believe that study medication is causing side effects. An intention-to-treat analysis includes all randomized patients in the final data analysis, regardless of whether the patients completed the study or were compliant. An adherence-to-protocol analysis excludes patients who did not complete the study owing to noncompliance or side effects. An intention-to-treat analysis preserves the value of randomization because some poor-prognosis patients may not be able to complete the study, but these patients should be included in order to understand fully the true effectiveness of a treatment. An example best illustrates the concept of intention-to-treat analysis. In a randomized trial comparing surgical esophageal transection versus standard therapy with sclerotherapy, [26] some patients randomized to surgery never had the operation because they became too ill or refused surgery. These ill and noncompliant patients have a poor prognosis, regardless of whether or not they undergo surgery. If researchers excluded these poor-prognosis patients from the surgery group analysis (or switched these patients to the sclerotherapy group in the middle of the study), then even a useless surgical procedure might appear effective compared with sclerotherapy. Systematic exclusion of patients with a poor prognosis from one treatment group, rather than random loss of patients from both groups, leads to a bias in favor of one therapy. An adherence-to-protocol analysis only includes patients who complete therapy, estimating the likelihood of a good outcome for patients who complete therapy. However, an adherence-to-protocol analysis may lose the value of randomization because patients unlikely to have a good outcome are eliminated from analysis. For example, if a hypothetical therapy cured 50% of patients and caused life-threatening side effects in the other 50% of patients, the adherence-to-protocol analysis would indicate benefit with therapy, but the intention-to-treat analysis would indicate that the hypothetical therapy was much less effective or potentially even dangerous. Because an intention-to-treat analysis includes both compliant and noncompliant patients, it estimates the likelihood of achieving a desired outcome when a patient first starts a treatment, consistent with "real-world" medical practice. Robust studies will present both an intention-to-treat analysis and an adherence-to-protocol analysis, allowing the reader to assess fully the results and to make up their own mind about the benefits of treatment.

Was Follow-Up of Study Patients Complete? When patients drop out of studies, several explanations are possible. The patients may have disappeared because they experienced a side effect or even died from the study treatment, or they may stop follow-up because their symptoms resolved. How can you determine whether the loss to follow-up biased study results? In a treatment study with a positive result, the study results could be recalculated, assuming that all treatment group patients lost to follow-up had a poor outcome and assuming that all control group patients lost to follow-up had a good outcome. If the recalculated results still demonstrate a treatment benefit, then the loss to follow-up did not cause a falsely positive study result. To avoid recalculations, one short cut is available [19]: only rare studies will still demonstrate a positive treatment effect upon recalculation of study results if more than 15% to 20% of patients are lost to follow-up.

Case Scenario B—Part II

The VIGOR trial randomized more than 8000 rheumatoid arthritis patients to receive rofecoxib or naproxen and examined the frequency of serious NSAID-associated GI complications. The study met all criteria for a well-designed study: randomization, concealed allocation, equal and minimal use of co-interventions, use of double blinding, use of an intention-to-treat analysis, and minimal patients lost to follow-up. Based on this analysis, you decide that the study is likely to produce accurate and unbiased results, and you proceed to review the statistical representations of the results.

Clinically Significant Results and Statistically Significant Results

Estimating Treatment-Effect Size: Relative Risk Reduction, Absolute Risk Reduction, and Number Needed to Treat The relative risk reduction (RRR) expresses the decreased risk for an adverse outcome in the treatment group compared with the risk for an adverse outcome in the placebo or control group. For example, in a randomized, double-blind, intention-to-treat trial, patients with endoscopically treated bleeding ulcers received either intravenous proton pump inhibitor (PPI) or placebo. The study endpoint was recurrent peptic ulcer bleeding: 22.5% of patients receiving placebo had recurrent bleeding, whereas 7% of patients receiving intravenous PPI had recurrent bleeding. [27] The RRR may be calculated as follows:

$$\frac{\text{\% placebo patients with bleeding} - \text{\% treatment patients with bleeding}}{\text{\% placebo patients with bleeding}} = \frac{22.5\% - 7\%}{22.5\%}$$

This RRR is 69%. Hence, a patient with an endoscopically treated bleeding ulcer is 69% less likely to develop recurrent bleeding from the ulcer when receiving an intravenous PPI compared with a similar patient not receiving an intravenous PPI. Absolute risk reduction (ARR) is the reduction in adverse outcomes between the placebo group and the treatment group. Although the RRR compares the risk for adverse outcomes between treated and placebo patients, the ARR identifies the actual reduction in adverse outcomes for treated patients. In the study of patients with endoscopically treated bleeding ulcer treated with intravenous PPI, the ARR may be calculated as follows:

$$\text{\% placebo patients with recurrent ulcer bleeding} - \text{\% IV PPI patients with recurrent ulcer bleeding} = 22.5\% - 7\% = 15.5\%$$

Therefore, a patient with an endoscopically treated bleeding ulcer who receives intravenous PPI may decrease their individual risk for recurrent ulcer bleeding by 15.5%. The RRR can be misleadingly large if adverse outcomes are infrequent in patients receiving placebo or no treatment. This concept is best illustrated by comparing the number needed to treat (NNT) and ARR with the RRR. Consider the results from the VIGOR trial. [18] The results from this trial were reported as frequency of serious NSAID-associated GI complications (severe upper GI bleeding, perforation, or obstruction) per 100 patient-years of NSAID use. There were 0.6 complications per 100 patient-years among patients using rofecoxib and 1.4 complications per 100 patient-years among patients using naproxen. Based on these data, the RRR is as follows:

$$\frac{\text{\% naproxen patients with complications} - \text{\% rofecoxib patients with complications}}{\text{\% naproxen patients with complications}} = \frac{1.4\% - 0.6\%}{1.4\%} = 60\%$$

In other words, a patient who uses rofecoxib is 60% less likely to have a serious NSAID-associated GI complication compared with a similar patient who uses naproxen. This sounds impressive until you consider the ARR. The ARR is as follows:

$$\begin{aligned}&\%\ \text{naproxen patients with complications} -\\&\%\ \text{rofecoxib patients with complications} =\\&1.4\% - 0.6\% = 0.8\%\end{aligned}$$

In other words, an average NSAID-using patient who uses rofecoxib reduces his or her individual risk for a serious NSAID-associated GI complication by only about 0.8%. The NNT allows interpretation of study results in terms of patient care, especially when the RRR is large and the incidence of adverse outcomes is small. Specifically, the NNT is the inverse of the ARR or 1/ARR, estimating the number of patients who need to be treated in order to prevent one additional adverse outcome. In the VIGOR trial, the NNT is as follows:

$$\frac{1}{\text{ARR}} = \frac{1}{0.8\%} = \frac{1}{0.008} = 125$$

In other words, for every 125 average patients treated with rofecoxib instead of naproxen for 1 year, one additional serious GI complication will be prevented. Patients and physicians may be less likely to choose a potentially better, but more expensive, treatment if the study results are presented as the ARR or NNT instead of the RRR. [28] Considering all three statistics (ARR, RRR, NNT) helps patients and physicians assess the potential benefits of therapy. Although the ARR and NNT may appear to be more useful than the RRR, the RRR is valuable because of its versatility. It provides the best estimate of treatment benefit among patients with varying risks of adverse outcomes. [29] NSAID-using patients receiving naproxen in the VIGOR trial only had a 1.4% risk for serious NSAID-associated complications per 100 patient-years of use. However, how beneficial would rofecoxib be in a 78-year-old man with a past history of upper GI bleeding? Based on previously published data, [25] this patient would have a significantly higher baseline risk for serious NSAID-associated GI complications, approaching 10 per 100 patient-years of use (i.e., 10% risk per year). Given this baseline risk, applying the RRR decreases the risk for serious NSAID-associated GI complications from 10% to 4%. This produces an ARR of about 6% (10% - 4% = 6%) and an NNT of about 17 (1/6% = 1/0.06 = 17). For this high-risk patient, the added expense of a coxib is outweighed by the significantly improved safety profile. The value of the RRR is that it can be applied to patient populations with different inherent risks for adverse outcomes. [29]

Evaluating the Sample Size in a Non–Statistically Significant Study: Were Enough Patients Entered into the Study? Studies that do not demonstrate statistical significance may be interpreted as negative studies (i.e., the treatment is no more likely than placebo to reduce adverse outcomes). However, an adequate number of patients have to enter a trial in order to demonstrate a statistically significant RRR, regardless of the effectiveness of the treatment. Many trials that do not yield statistically significant results have not entered enough patients into the trial to demonstrate reliably an RRR of 25% or even 50%. [30] When assessing study results, it should be clear if a non–statistically significant result represents a truly ineffective treatment or an inadequate enrollment of patients into a study. When investigators plan a study, multiple outcomes may be analyzed, but the sample size is calculated based on only one outcome. For example, in a study comparing ligation plus octreotide versus ligation alone in the prevention of recurrent bleeding from esophageal varices, [31] the investigators estimated that ligation plus octreotide would reduce recurrent bleeding from varices by 70% compared with ligation alone. The study entered enough patients to demonstrate a statistically significant RRR of 70% for recurrent bleeding, and a statistically significant RRR of 76% was measured in the study. Investigators also evaluated 30-day mortality and found that combined treatment reduced 30-day mortality by 52% compared with ligation alone, but this RRR was not statistically significant ($p = 0.09$). However, only enough patients to demonstrate a statistically significant RRR of 70% for recurrent bleeding were enrolled in this study. Because the study demonstrated a strong trend for reduced 30-day mortality with combined treatment, this therapy may truly be efficacious in reducing 30-day mortality, and this non–statistically significant result is likely due to an inadequate sample size.

What Is the Precision of the Treatment Effect: How Large Are 95% Confidence Intervals? Traditionally, a p value of 0.05 or less indicates statistical significance. Studies with p values of 0.05 or less indicate that there is a 5% or less likelihood that the difference between treatment and placebo occurred due to chance. However, p values do not provide data about the accuracy or precision of study results. Confidence intervals do provide information about the precision of study results. The 95% confidence interval (95% CI) estimates the range within which the true RRR or ARR resides 95% of the time (i.e., if you repeated the same trial 100 times, then the RRR would fall within the 95% CI in 95 of 100 trials). When the lower limit of the confidence interval for RRR is greater than zero, then the treatment is significantly better than placebo. If the upper limit of the confidence interval around the RRR is less than zero, then the treatment is actually harmful or worse than placebo. For example, the RRR in the VIGOR trial for fewer serious NSAID-associated GI complications with rofecoxib is 60% with 95% CI of 20% to 80%. [18] Thus, the RRR for serious GI complications with rofecoxib has a 95% likelihood of being between 20% and 80% with the best estimate being 60%. The magnitude of confidence intervals is determined by the sample size. [32] Studies with large sample sizes have narrower 95% CIs and a more precise estimate of the true RRR. When the upper limit of a CI around an RRR is greater than zero, but the lower limit of the CI is less than zero, it is possible that the treatment could be better, worse, or no different than placebo. If the magnitude of benefit is moderate and the CI is wide and barely crosses zero, then the treatment probably is beneficial and the trial simply did not enter enough patients. For example, one study [33] examined patients with bleeding esophageal varices and compared band ligation to sclerotherapy for reducing rebleeding. The RRR for recurrent variceal bleeding with ligation was 48%, with 95% CI of -15% to 68%; however, only 77 patients were entered into this study, which was not adequate to demonstrate a statistically significant RRR of 48%. A metaanalysis [34] pooled the results from several studies, allowing the analysis of 547 patients. With this larger sample size, the RRR for recurrent variceal bleeding with ligation was 42% (almost the same RRR as the original randomized trial), but with a statistically significant 95% CI of 16% to 60%.

Case Scenario B—Part III

Given these results, you conclude that rofecoxib, a coxib, is less likely than naproxen, a conventional NSAID, to cause upper GI bleeding, perforations, or obstruction. Because your patient is older than 70 years of age and has a past history of NSAID-associated bleeding peptic ulcer, you estimate that his annual risk for a serious

NSAID-associated GI complication is about 10% per year. Given this baseline risk, you estimate that use of rofecoxib instead of naproxen will reduce the baseline risk by 60% (i.e., the RRR = 60%). Therefore, this patient's annual risk will be reduced from 10% to 4%, producing an ARR = 6% (10% - 4% = 6%) and an NNT = 17 (1/6% = 17), which seems very beneficial. However, you realize that you must balance issues of treatment benefit with issues of safety and cost when deciding about treatment.

Applying the Results of Clinical Research to Your Patient

Are the Results Applicable to Your Patient? If your patient meets the inclusion and exclusion criteria of a study, then the results should be applicable to that patient. Even if your patient is a year too old to be included in the study or has a history of a comorbid disease not allowed in the trial, these issues may not prevent the application of study results to your patient. Ultimately, physicians must use their clinical judgment to decide whether a patient differs significantly from study patients, preventing application of study results to that patient. A study may not identify a statistically significant difference between placebo and treatment for all patients entered in a study, but it may find a significant difference for a subgroup of patients. Often, this subgroup of patients has more severe disease with a higher frequency of adverse outcomes. However, physicians should be cautious before applying subgroup analyses to their patients, even if their patients fit into the subgroups. If investigators evaluate multiple outcomes in many subgroups, eventually one subgroup analysis will be statistically significant simply owing to chance. The results of subgroup analyses are more likely to be valid if (1) the treatment effect is large; (2) only a few subgroup analyses were performed; (3) the subgroup analyses were hypothesized a priori (i.e., before performance of the study); (4) it is consistent with current understanding of pathophysiology; and (5) other, independent studies have produced similar findings. For example, the VIGOR trial demonstrated that rofecoxib decreased clinical upper GI events (i.e., symptomatic ulcers, significant upper GI bleeding, perforation, or obstruction) in the subgroup of patients with a past history of clinical upper GI events. This subgroup analysis was one of only a few subgroup analyses; it was hypothesized a priori. Pathophysiology suggests that selective inhibition of COX-2 isoenzymes reduces the inflammatory response without inhibiting COX-1 isoenzymes in GI mucosal cells and platelets, which should prevent clinical upper GI events.

Are the Potential Treatment Benefits Worth the Potential Side Effects, Costs, and Inconvenience to Your Patient? When deciding whether to start a new treatment, both the patient and physician should consider the inconvenience, side effects, and costs associated with the treatment. When balancing the potential benefit of a treatment versus the potential consequences, the NNT is a helpful tool. If the treatment is cheap and convenient and the consequences of the adverse event are potentially severe, then a large NNT may be acceptable. For example, hundreds of health care providers are vaccinated with hepatitis B vaccination in order to prevent one case of hepatitis B. If the treatment is expensive and inconvenient and has potentially significant side effects, then the treatment may still be acceptable if the NNT is small and the consequences of an adverse outcome are life-threatening.

Case Scenario B—Part IV

The VIGOR trial was a multicenter, international study of rheumatoid arthritis patients. Although your patient has osteoarthritis, it is unlikely that this will produce any difference in the frequency of NSAID-associated GI complications among consistent NSAID users. You are concerned about the cost of rofecoxib (average wholesale price of about $2.50/day) compared with the much lower cost of generic naproxen. Also, you note that patients using rofecoxib had a slight, but statistically significant, increase in myocardial infarctions compared with patients using naproxen (0.4% versus 0.1%, respectively). This change may be partly attributed to antiplatelet effect from naproxen. Although you are concerned about these issues, you believe that the risk for serious NSAID-associated GI complications is so high in your patient that

this outweighs concerns about myocardial infarction.

CONCLUSION

Ultimately, decisions about the use of diagnostic tests and treatments are balanced by possible benefits, harms, costs, patient preferences, and availability of these interventions. In this chapter, principles for the systematic appraisal and application of clinical research have been reviewed. This information will provide a basis to interpret the diagnostic and therapeutic applications of GI technology, which will be discussed in ensuing chapters.

CHAPTER 134

Dawn Provenzale

ECONOMIC ANALYSIS IN THE DIAGNOSIS AND TREATMENT OF GASTROINTESTINAL DISEASES

In the face of rising national health care expenditures, gastroenterologists have met increased demand to justify their practices and procedures and to demonstrate the value of their services to both private and public consumers. In order to evaluate economic analyses and determine their value for clinical practice, the reader must have an understanding of certain concepts that provide the basis for economic analysis in the medical literature. In addition, the criteria for performing an economic analysis must be clearly understood so that the reader can critically evaluate these economic analyses and determine which can be applied to their practice. [1]

This chapter is divided into three parts: (1) definitions of the terms costs and charges, (2) a discussion of the different types of economic analyses, and (3) an outline of the criteria for performing an economic analysis and the application of these criteria to screening of patients with gastroesophageal reflux disease (GERD) and surveillance of patients with Barrett esophagus.

COSTS AND CHARGES

In the economic sense, the cost of a service is designated by foregone opportunities. An item used for one purpose cannot be used for another purpose. Thus, the cost of a service can be defined as the resources, or items needed to provide the service, the "opportunity costs." Charges, on the other hand, may be regulated or set by the marketplace and may not reflect the true cost of providing a service, [2] but rather profit or loss to the institution, and may be falsely inflated or deflated. [2]

Most economic analyses include direct medical costs. These include the cost of hospital care, medications, laboratory tests, radiologic procedures, and office visits. Indirect medical costs reflect the cost of loss of life, livelihood, absenteeism from work, or decreased earning ability. Because they are difficult to measure, incorporating indirect costs into economic evaluations remains controversial. Intangible costs reflect the costs of pain, suffering, and other nonfinancial outcomes of disease. They, too are difficult to measure and are not typically included in economic analyses, although quality-of-life measures often attempt to capture these effects.

An example will help distinguish between costs and charges and provide information on how charges (prices) are set in the marketplace. We will use as an example two automobile manufacturers, JM and Kryler, as outlined by Finkler. [2] The companies each produce an identical automobile. The cost to each manufacturer to produce this car is $4200. That is, the resources required to build these cars amounts to $4,200. The government imposes a pollution control program, and each company must include a pollution control device in their cars. JM and Kryler each spend $1 billion to solve the pollution control problem, but the impact of this expenditure is different for each manufacturer. JM sells 10 million cars. The increase in cost to produce the JM car is $100 ($1 billion / 10 million cars = $100). Kryler, on the other hand, sells 1 million cars. The increased cost to produce the Kryler cars amounts to $1000 per car ($1 billion / 1 million cars = $1000). Both companies sell their cars for $5000. JM cars now cost $4,300 to produce, so JM makes a $700 profit on each car. Kryler cars now cost $5,200 to produce, and sold at $5000 per car, the company incurs a $200 loss per car. If Kryler had sold the car for the $5,200 production price, the buyers would have gone to the less expensive but comparable manufacturer, JM. Thus, prices, or charges, may be set through a "consensus" to maintain comparability among different companies.

We can now apply this concept to the field of medicine: "There are two hospitals that perform an identical type of open-heart surgery. One hospital, the high-volume hospital, performs 500 operations per year, whereas the second, low-volume hospital, performs 50 operations per year. The cost to perform the surgery at the high-volume hospital is $4300 per patient, whereas the cost to perform the surgery at the low-volume hospital is $5200 per patient. The surgery is more expensive at the low-volume hospital because there are fewer patients to share a variety of equipment and other costs related to open-heart surgery. Both hospitals charge $4500 for this operation. As in the case of the automobile manufacturers, the large-volume hospital makes a profit of $200 per patient or $10,000 per year ($200 × 500 patients), whereas the low-volume hospital incurs a total loss of $35,000 per year ($700 × 50 patients). Both hospitals charge the same amount to perform the surgery. (This consensus approach to setting hospital rates may reflect competition for health maintenance organization contracts or the hospital's desire not to appear as an outlier.) To offset the loss, the low-volume hospital can increase the charge in some area in which the hospital is particularly efficient or can spread the loss over a very-large-volume service where it will have minimal effect. For example, the hospital may charge an extra 7 cents for a particular laboratory test, which, over the hospital's 500,000 volume of laboratory tests, will have a minimal effect. A charge of $30.07 as compared to $30.00 for a laboratory test will cause much less discussion than $5,200 versus $4,500 for open heart surgery." [2]

TYPES OF ECONOMIC ANALYSES

There are several types of economic analyses to which these basic concepts apply. A cost-identification, or cost-minimization, analysis is the simplest. In this type of analysis, the outcomes of the different treatment alternatives for a particular health problem are assumed to be equivalent. For example, if the analyst wished to examine the economic impact of alternative therapies for achalasia (e.g., pneumatic dilation versus surgery), the outcomes of these alternative management strategies (e.g., symptom relief) would be assumed equal. This type of analysis calculates the costs incurred due to the disease and the medical resources used to treat it, providing the opportunity to determine the cost of alternative management strategies for a certain disorder. In a cost-identification analysis, the costs for each management strategy are summed.

The results are expressed in terms of cost per service provided (e.g., cost per cancer detected), or in the case of achalasia, cost per dysphagia-free day, month, or year. The strategy that is least expensive is the preferred strategy. The goal of the cost-identification analysis is to find the least expensive way of treating the disorder in question.

A cost-effectiveness analysis expands on cost-identification to measure the net cost of providing a service and also to measure the outcomes obtained. Typically, in a cost-effectiveness analysis, the outcomes for the alternative management strategies are not equal. One strategy typically has a better outcome than another (e.g., provides a longer life expectancy or more dysphagia-free days). The cost per specified health effect of a technology or program (e.g., costs per life-year gained or cost per case identified) is calculated to determine the net benefits for the net expenditure of costs for a particular practice or program, and an incremental cost-effectiveness ratio (i.e., the additional costs for the additional benefit obtained) is calculated. The incremental cost-effectiveness ratio is compared with ratios

from other interventions. The lower the ratio, the more cost-effective the intervention.

A cost-utility analysis takes the construct of measuring net costs and net benefits one step further by assigning values to different outcomes in order to reflect the relative importance of the various outcomes. For example, liver transplantation for cirrhotic patients may have a substantial effect on quality of life that will not be identified by using only life expectancy or years of life gained from transplantation as the measure of outcome. A cost-utility analysis considers the net expenditure for the net benefit obtained, as in the cost-effectiveness analysis. The net benefits, however, are adjusted to reflect both the quantity and the quality of the outcome; for example, life years gained are adjusted to reflect quality of life. The results are expressed in a ratio such as cost per quality-adjusted life year (QALY) gained, and incremental cost-utility ratios comparing alternative strategies are calculated. A cost-utility ratio is similar to a cost-effectiveness ratio, except that a cost-utility ratio combines the quality and quantity of the outcomes to produce a more robust and meaningful outcome measure. Expressing results in a cost-utility ratio permits comparison to other health care interventions.

A cost-benefit analysis provides an explicit decision about whether the cost of the practice is worth the benefit obtained from it. This is accomplished by expressing cost and benefit in the same units—typically, in monetary terms. This requires that the health effects of a particular practice or strategy (e.g., life years saved, cases of cancer prevented) also be expressed in monetary terms. In cost-benefit analysis, the practice or program is evaluated by subtracting the cost of that program from the benefit to derive the net benefit. If it is positive, the program passes the cost-benefit test. If two or more *mutually exclusive* programs have positive net benefits, one chooses that program with the greatest net benefit. [1]

CRITERIA FOR PERFORMING AND EVALUATING ECONOMIC ANALYSES

In addition to being familiar with the different types of economic analysis, it is important to understand how they are performed and how the results can be applied to clinical practice. The following steps are useful for determining the validity of an economic analysis [3] (Table 134-1). The criteria will be reviewed and discussed. [1]

1. Was a well-defined question posed in answerable form?
2. Was a comprehensive description of the competing alternatives given?
3. Was there evidence that the program's effectiveness had been established?
4. Were all the important and relevant costs and consequences for each alternative identified?
5. Were costs and consequences measured accurately in appropriate physical units?
6. Were costs and consequences valued credibly?
7. Were costs and consequences adjusted for differential timing?
8. Was an incremental analysis of costs and consequences of alternatives performed?
9. Was a sensitivity analysis performed?
10. Did the presentation and discussion of study results include all issues of concern to users?

From ref. 3.

TABLE 134-1 Criteria for Evaluating an Economic Analysis

1. Was a Well-Defined Question Posed in Answerable Form?

The first step in the assessment of an economic analysis is to decide whether a well-defined question has been posed in an answerable form. [3] Alternative strategies for comparison should be stated and the perspective of the analysis (e.g., that of the patient, a health maintenance organization, or society) defined. As an example, the investigator who wishes to examine the cost-effectiveness of screening individuals with GERD for Barrett esophagus might pose the following question: Taking the perspective of an HMO, is screening for Barrett esophagus in patients with longstanding GERD cost-effective compared with common medical practices such as breast and cervical cancer screening?

2. Was a Comprehensive Description of the Competing Alternatives Given?

In the second step of a critical appraisal, the reader should assess the report for a complete description of the competing alternatives (the alternative practices, strategies, interventions). In the case of screening GERD patients, the analysis should explicitly state the results that will trigger further analysis (e.g., columnar epithelium with goblet cells on biopsy) and what additional analysis will be performed (e.g., endoscopic surveillance). The reader should also seek some definition of the events that will result in evaluation of patients in the no-screening strategy (e.g., worsening of GERD symptoms, dysphagia). Enough information should be provided to the reader to judge the generalizability of the program to his or her own practice and to determine whether the relevant costs or consequences have been included.

3. Was There Evidence that the Program's Effectiveness Had Been Established?

The third step in an assessment of an economic analysis is to determine that the effectiveness of the program under study has been established, that is, that a causative link of the program to the outcome exists. In the case of screening for GERD, the reader should be provided with some evidence that screening reduces mortality from esophageal cancer. We are interested in economic evaluations of cost-effective approaches to effective practices. Therefore, if the effectiveness of the practice under study has not been established, the reader should not waste his or her time on the remainder of the report. With respect to screening for GERD, there is no direct evidence (i.e., results of randomized trials) that this practice actually reduces mortality from esophageal cancer, but indirect evidence (i.e., case series) related to early diagnosis and surveillance of patients with Barrett esophagus suggests that screening individuals with GERD may be beneficial. [4], [5], [6], [7] and [8]

4. Were All the Important and Relevant Costs and Consequences for Each Alternative Identified?

The next step in the evaluation requires that all the important and relevant costs and consequences, or benefits, of the alternative strategies be identified. A comprehensive description of the different types of costs and of the distinctions between them is beyond the scope of this chapter, but some definitions are noteworthy. Most economic analyses consider only the direct medical costs of providing a particular service. This would include the costs of equipment and supplies, facility costs, salaries for physicians and support personnel, and other operating and organizational costs. Direct nonmedical costs incurred by patients and their families, such as any out-of-pocket expenses not covered by insurance, may also be included in some analyses, although this is uncommon because direct nonmedical costs are highly individualized and difficult to measure. Indirect costs created by time lost from work or the psychosocial costs reflected in pain or distress suffered by the patient are typically not included in economic analyses because of the difficulty in measuring them.

The costs of screening for GERD would include costs of endoscopy plus biopsies if taken; salaries of technical staff and physicians, endoscopists, pathologists; and any out-of-pocket expenses to the patient. In addition to cost, a summary of the health consequences (risks and benefits) of the program should be listed. These consequences may include changes in the physical, psychological, or emotional functioning of the patient and may be measured in terms of life years gained, disability prevented, or QALYs gained. Thus, a list of relevant consequences of a screening program for GERD patients would incorporate any increase in life expectancy from cancer prevention and some measure of disability or work loss days prevented by this program. With regard to costs, direct medical cost consequences that should be considered include changes in physician visits and hospitalizations and the ordering of follow-up tests such as endoscopy.

5. Were Costs and Consequences Measured Accurately in Appropriate Physical Units?

In the next component of the critical appraisal, the reader must determine whether the costs and consequences were measured accurately and in the appropriate physical units. In this step, the reader should seek a list of the elements of the analysis described under question 4 and the units for their measurement. For example, in a screening program for GERD, endoscopy might be performed for $600 per test. [9] Other screening tests should be similarly listed, and physician visits and fees should be included. The consequences and the units for their measurement should be explicitly stated. In the screening example, the reader should search for evidence that benefits, such as years of life gained from early diagnosis, disability days avoided, or cancers prevented, are valued and are measured in the appropriate units (e.g., days, years, visits).

6. Were Costs and Consequences Valued Credibly?

In the sixth step of a critical evaluation of an economic analysis, the reader must determine whether the costs and consequences included in the analysis are comprehensive and are plausible. The most appropriate concept of the cost of a service or procedure is the economic opportunity cost, which is the value of the components of the service or the items used to produce the service. Costs may be estimated in a variety of ways, and a clear explanation of the data and the methods used to calculate them should be presented.

The newer information systems that measure resource consumption [10] have promoted the accurate assessment of costs for economic analysis. Hospital accounting departments may also provide information about costs. If estimates of costs (of resources consumed) are not available, charges that have been adjusted to reflect costs may be used as proxy for them. One approach to adjusting charges for acute inpatient care is to calculate cost-to-charge ratios (computable from the cost reports submitted by most hospitals to Medicare). These ratios can be used to convert billed charges to resource cost estimates. Third-party reimbursement levels (e.g., the Medicare Diagnosis Related Group [11] payment) have also been used as a proxy for the opportunity cost. Thus, there are diverse methods for obtaining costs. The reader should seek an explanation of the method that was used to determine costs for each analysis. [1]

An explanation of how benefits are calculated should also be provided. In a cost-effectiveness analysis, for example, health consequences are measured in terms of life years saved. Therefore, assigning a value to benefits is straightforward—each life year gained or lost (at a point in time) counts the same. Indirect costs, such as the cost of time lost from work or school, and benefits, as required for one form of cost-benefit analysis, may be more difficult to ascribe. For example, the indirect cost of lost work time may be difficult to calculate for certain groups such as housewives, elderly people, children, and unemployed people. Because indirect benefits are even more difficult to measure, their incorporation into economic evaluations remains controversial. [1]

In cost-utility analysis, a variant of cost-effectiveness analysis, benefits may be measured in terms of QALYs. The analysis examines both the number of years of life gained from a practice and the quality of those years. In other words, a cost-utility analysis considers that certain practices may be associated with discomfort and disability. Outcomes are adjusted to account for these quality-of-life effects. The studies that incorporate quality-of-life measures, also known as *patient preferences* or *utilities,* attempt to quantify how much better the quality of life is in one health state compared with another (e.g., without cancer versus with cancer). The results are reported in quality-adjusted life units (e.g., days, months, or years) gained from a particular strategy. For a GERD screening program, the quality of life of those in the screened and the unscreened strategies would be measured and compared. The quality-of-life measurements should evaluate the short-term inconvenience or disability associated with screening and the long-term disability associated with potential outcomes, including the diagnosis of Barrett esophagus, the risk for adenocarcinoma, and the inconvenience associated with surveillance endoscopy. The results of a cost-utility analysis are reported as an incremental cost-utility ratio.

7. Were Costs and Consequences Adjusted for Differential Timing?

The costs and health consequences for some interventions occur relatively close to the initiation of the program; for example, vaccination for influenza. For other interventions, particularly those involving screening, the timing of the expenditures and the timing of the health benefits of the program may differ significantly. In a cancer screening program, the costs typically arise early on, whereas the benefits of screening (including increased life expectancy) will occur in the future. To adjust for these differences in the timing of outcomes, it is appropriate to apply standard discounting formulas from economics to calculate the present value of both costs and health consequences, that is, to determine their value as viewed by the decision maker today. [12] Discounting considers that a dollar today is worth more than a dollar in the future, and, because life years are valued relative to dollars in economic analyses, they are also discounted. Most economic analyses use discount rates ranging from 3% to 6%, with 3% as the current recommended standard. [13]

8. Was an Incremental Analysis of Costs and Consequences of Alternatives Performed?

To set priorities for resource allocation, it is necessary to consider the additional costs that one program incurs over another, compared with the additional benefits that are produced. The average costs (the total cost for the procedure or program) and average benefits obtained from the program are easily calculated but do not provide the crucial information needed to determine health policy. It is the additional, or incremental, costs and benefits compared to an alternative practice or program that permit the policy maker to maximize health benefits with a limited health care budget. [1] Costs and health consequences (benefits) should be listed, and a cost-effectiveness ratio, the metric for evaluating tradeoffs across treatment alternatives, should be calculated for each strategy being compared. As an example, Table 134-2 lists both the average and incremental cost-utility ratios for alternative strategies for surveillance of patients with Barrett esophagus. Cost-utility ratios are similar to cost-effectiveness ratios except that the outcomes reflect not only the quantity (e.g., life years gained) but also the quality of those years and consider disability and discomfort associated with the health condition under analysis (QALYs). Costs, here, refer to the direct medical costs of the surveillance tests themselves as well any “induced costs” due to complications of surveillance procedures, the treatment costs for cancers that might be detected through surveillance, and the costs for the evaluation and treatment of cancers detected in those who are not undergoing surveillance but who develop symptoms that lead to evaluation for cancer.

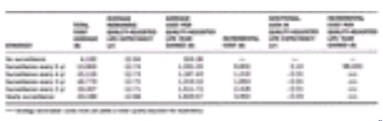

TABLE 134-2 Average Costs and Incremental Costs for Surveillance of Patients with Barrett Esophagus

First, we focus on the average cost-utility ratio. The average cost-utility ratio, or cost per QALY gained, is calculated by dividing the total costs of a particular strategy by the gain in life expectancy for that strategy. For the no-surveillance strategy, which serves as the basis for comparison, the costs amount to $4100 (column 2) and the remaining quality-adjusted life expectancy is 12.64 years (column 3). The average cost-utility ratio is $4100 / 12.64, or $324.36 per QALY gained, as shown in column 4. Moving to the next strategy, surveillance every 5 years, column 2 shows that the cost is $13,900, and column 3 shows that the quality-adjusted life expectancy is 12.74 years. In column 4, the average cost per QALY gained is $13,900 / 12.74, or $1091.05.

Next, we will focus on the calculation of the incremental cost-utility ratio. Column 5 shows that the additional cost for adding surveillance every 5 years compared to no surveillance is $13,900 - 4100 = $9800. The average remaining quality-adjusted life expectancy for the individual who does not undergo surveillance is 12.64 years, whereas the quality-adjusted life expectancy for those undergoing surveillance every 5 years is on average 12.74 years. The years of life gained when surveillance every 5 years is initiated is 12.74 - 12.64 = 0.10 years (37 days) (column 6). The additional 0.10 years is the incremental benefit obtained by performing surveillance every 5 years. The incremental cost per QALY gained, or the incremental cost-utility ratio as shown in column 7, is the incremental cost divided by the additional QALYs gained: $9800 / 0.10 = $98,000, as shown in column 7.

The incremental cost-utility ratios for the more aggressive surveillance strategies (every 1 to 4 years) are not calculated because these strategies are dominated by surveillance every 5 years. In other words, they cost more than surveillance every 5 years and they yield a lower quality-adjusted life expectancy than surveillance every 5 years, as shown in Table 134-2 (columns 2 and 3). It is only with these incremental cost-utility or cost-effectiveness ratios that the policy maker can determine whether the additional benefit is worth the additional cost of adding surveillance compared with a previous policy of no surveillance.

Using these ratios, policy makers who have a fixed budget can allocate funding based on incremental gains and losses. These cost-utility or cost-effectiveness ratios alone, however, cannot identify cost-effective practices. They must be placed in a decision context that is expressed in one of two forms. In the first form, an explicit threshold or maximum amount that the policy maker is willing to spend is stated. For example, the policy maker may be willing to spend $100,000/QALY gained on surveillance of patients with Barrett esophagus. Given our current estimates of cancer risk, surveillance every 5 years would increase quality-adjusted life expectancy and would not exceed the threshold of $100,000/QALY gained. In the second form of decision context, a list of medical practices and their associated cost-utility ratios, also known as a *league table,* is used as a basis for comparison with surveillance of patients with Barrett esophagus. Table 134-3 lists incremental cost-utility ratios for other accepted practices. Surveillance of patients with Barrett esophagus every 5 years has an incremental cost-utility ratio of $98,000/QALY gained, similar to the incremental cost-utility ratio for screening for carotid disease ($130,000/QALY gained) [14] (see Table 134-3). The incremental cost-utility ratio for surveillance

every 5 years of $98,000/QALY gained is lower than the incremental cost-utility ratio for empiric omeprazole therapy in patients with dyspepsia ($780,000/QALY gained), [15] and surveillance of patients with Barrett esophagus would be considered cost-effective compared with this treatment strategy.

	$/QALY GAINED
Prophylaxis for NSAID-associated ulcers with low-dose misoprostol (100 μg 4 times daily) for elderly (>60 yr old) versus no prophylaxis for patients with rheumatoid arthritis taking NSAIDs.	11,000[16]
Dual air bags versus driver's-side only air bags in driving population (and passengers)	69,000[17]
Screening for carotid disease, with carotid endarterectomy if positive versus no screening for carotid disease in 65-year-old men with no symptoms of carotid disease	130,000[14]
Give omeprazole alone empirically versus check serum *Helicobacter pylori* antibody and treat *H pylori* in adults presenting to primary care physicians with diagnosis of dyspepsia	780,000[15]

QALY, quality-adjusted life year.

TABLE 134-3 Incremental Cost-Utility Ratios

Calculating incremental cost-effectiveness or cost-utility ratios for the alternative strategies is essential but does not provide us with a decision rule upon which to base health policy. Critical parameters for decision making include the cost of one strategy compared with another and the resources available to provide surveillance. Those who make health policy must also consider the number of patients affected by Barrett esophagus, the number who might benefit from surveillance, and the number who would benefit from other comparison practices. In addition, the incidence of cancer is paramount in the decision-making process for Barrett esophagus patients. Thus, the policy maker must consider several factors simultaneously when making decisions about funding. These include the budget, or willingness-to-pay threshold, the number of patients who would benefit from surveillance and the benefits to be gained, and the comparison between the cost of surveillance and the cost of other accepted medical practices.

From the patient's perspective, the quality of life associated with surveillance, the short-term discomfort and time lost from daily activities associated with procedures, and the long-term disability associated with esophagectomy are also important factors.

9. Was a Sensitivity Analysis Performed?

As a result of variations in the literature estimates (each of which is affected by sampling and other types of errors) and differences in the opinions of experts in the field, there will be uncertainty surrounding one or more parameters in any economic analysis. To examine the effects of such variation on the results of the analysis, a sensitivity analysis should be performed. In sensitivity analysis, the value of each parameter of interest is varied over a broad range to determine the sensitivity of the results to variations in the parameter. The sensitivity of the preferred strategy to change in the underlying assumptions of the model is a measure of the strength or robustness of the conclusions. If the preferred strategy is altered by sensitivity analysis, then the analysis is said to be sensitive to the value of that parameter. The reader of an economic analysis should seek some evidence that a sensitivity analysis has been performed. In an evaluation of surveillance of patients with Barrett esophagus, a critical sensitivity analysis would be to vary the expected incidence of cancer over a broad range to determine the impact of an increase or decrease in the expected number of cases on the preferred strategy.

10. Did the Presentation and Discussion of Study Results Include All Issues of Concern to Users?

Assumptions and methodologic judgments are an integral part of an economic analysis. The reader should be provided with a list of the assumptions and value judgments that were made to perform the analysis, in order to determine the validity of the study and the applicability of the results to his or her practice. For example, in surveillance of patients with Barrett esophagus, esophageal adenocarcinoma is assumed to occur as a progression from no dysplasia to low-grade dysplasia to high-grade dysplasia and finally to cancer. In ddition, it is assumed that endoscopy is not a perfect test. There may be false-positive or false-negative results for dysplasia or cancer because of sampling error by the endoscopist and misinterpretation by the pathologist. The reader must decide whether these assumptions are credible and the results applicable to his or her practice. In sensitivity analyses, the authors should consider a broad range of parameter assumptions to increase the generalizability of their analysis to populations that differ from their own.

These 10 criteria for economic appraisal provide a framework for reading and evaluating economic analyses in the medical literature. A more detailed discussion of these criteria for economic appraisal can be found in reference 3, which provides a comprehensive review of the principles of health program evaluation.

CHAPTER 135

Richard A. Rippe, Kevin Behrns, and David A. Brenner

MOLECULAR BIOLOGIC APPROACHES TO THE DIAGNOSIS AND TREATMENT OF GASTROINTESTINAL DISEASES

The development and application of the science and techniques of molecular biology has had a profound impact on the diagnosis and therapy of gastrointestinal disease. Furthermore, molecular biology has revolutionized the way in which these diseases are approached conceptually. Key concepts that are required to understand the regulation of gene expression include deoxyribonucleic acid (DNA) transcription, ribonucleic acid (RNA) translation, posttranslational control, and the effects of DNA mutations on gene expression.

DNA

The genetic material of all known organisms and many viruses is DNA, which consists of chemically linked subunits. Each subunit, called a *nucleotide,* contains a nitrogenous base (a purine [adenosine and guanine] or pyrimidine [cytosine or thymine]), a pentose sugar, and a phosphate group (Fig. 135-1). Nucleotides are linked by phosphodiester bonds forming single-stranded nucleic acids.

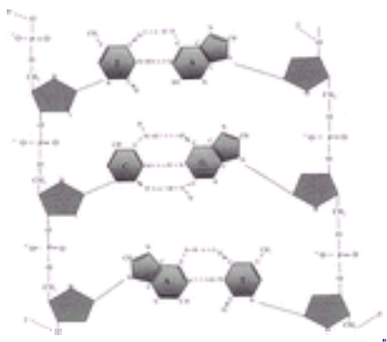

FIGURE 135-1. DNA double helix. A nucleotide consists of the deoxyribose sugar (R) and phosphate backbone with nitrogenous base (A, C, G, or T). Adenonine (A) always pairs with thymidine (T), and guanine (G) always pairs with cytosine (C). The two nucleotide chains run in antiparallel directions, one strand runs in the 5' to 3' direction, and the other strand runs in the 3' to 5' direction. (Reprinted with permission from Rippe RA, Behrns K, Brenner DA. Molecular biology for the GI clinician. Gastroenterol Updates 1998;3.)

The DNA double helix consists of two chains that are complementary and antiparallel. They are complementary because adjacent nucleotides always pair in a specific way: adenine to thymine and guanine to cytosine, so that the base sequence of one strand determines that of the other (see Fig. 135-1). They are antiparallel because the 3' to 5' orientation of the sugar-phosphate backbone of one chain is opposite the 5' to 3' orientation of the other chain.

Transcription

Transcription is the synthesis of RNA from its DNA template and is catalyzed by DNA-dependent RNA polymerases. A gene includes all DNA sequences required for the synthesis of the RNA, including transcribed and regulatory sequences. Promoters are the regulatory sequence immediately 5' to the transcription unit and are required for proper transcription initiation. Enhancers are orientation- and position-independent regulatory sequences that increase the transcription rate of a given transcription unit.

Translation

Translation is the synthesis of proteins from the information encoded in its messenger RNA (mRNA). The genetic code consists of groups of three nucleotides called *codons* that specify the amino acid sequence or define sites for the initiation or termination of translation.

TECHNIQUES IN MOLECULAR BIOLOGY

The foundation of recombinant DNA technology involves cutting (restriction digestion) DNA into pieces of interest and then joining them together to generate new recombinant DNA molecules, which can then be mass-produced in bacteria. This process is often referred to as *molecular cloning*. Typically, recombinant constructs consist of vector DNA (DNA molecules that are able to replicate in a given host bacteria) joined to the segment of DNA of interest. Plasmids, the most widely used vector DNA, are extrachromosomal circular DNA molecules that are found primarily in bacteria. They typically contain a gene that confers antibiotic resistance that is used for selection purposes. DNA sequences of interest are inserted into the plasmids and are then grown to high numbers in bacteria, thus generating sufficient quantities for further studies.

Enzymes Used in Molecular Biology Techniques

Most of the methodology used in molecular biology involves the application of specific enzymes. These enzymes can be classified into four groups, including restriction endonucleases, polymerases, ligases, and modifying enzymes. Many current enzymes have been cloned and mutated to enhance performance and reduce cost.

The restriction endonucleases comprise a large group of enzymes that recognize specific nucleotide sequences and cleave double-stranded DNA at precisely these locations. Restriction endonucleases are found naturally in bacteria and are important for degrading foreign DNA. The cleavage sites recognized by the restriction endonucleases are typically four to eight nucleotides in length. Digestion products may have either 5'- or 3'-overhanging nucleotides, also called *cohesive termini* or *sticky ends,* or the digestion may result in blunt-ended molecules. Joining ends of DNA is accomplished with DNA ligases. DNA ligases catalyze the formation of a phosphodiester bond between 5'-phosphate and 3'-hydroxyl ends in duplex DNA. Generating recombinant DNA molecules can be achieved efficiently by digesting double-stranded DNA with appropriate restriction endonucleases, isolating the pieces of interest, and ligating the pieces together to create recombinant molecules (Fig. 135-2).

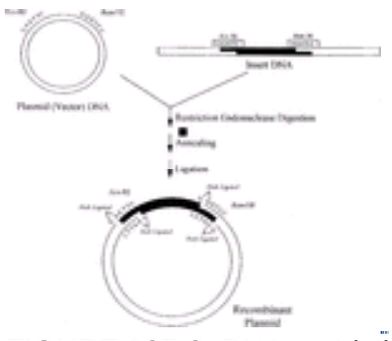

FIGURE 135-2. DNA restriction endonuclease digestion, annealing, and ligation creating a new recombinant molecule. Plasmid DNA and the insert DNA are digested with the same restriction endonucleases (*Eco* RI and *Bam* HI) to create complementary single-stranded nucleotides (“sticky ends”), which anneal together, and the DNA backbone is restored by ligation. (From Rippe RA, Behrns K, Brenner DA. Molecular biology for the GI clinician. Gastroenterol Updates 1998;3.)

Another major group of enzymes includes the polymerases, which catalyze the synthesis of nucleic acids from nucleic acid templates. These enzymes are classified by the type of nucleic acid that is synthesized and the type of nucleic acid template replicated. All polymerases synthesize DNA in a 5' to 3' direction and complementary to the template strand. The DNA-dependent DNA polymerases synthesize DNA from DNA templates. In addition to synthesis activity, many of the polymerases possess exonuclease activity, an enzymatic property that removes nucleotides one at a time from the ends of the polynucleotide chain, thereby functioning as a biologic “proofreader.” The exonuclease activity has been used extensively in the laboratory to label double-stranded DNA uniformly.

Klenow fragment is a modified DNA polymerase that also possesses bidirectional exonuclease activities. Because the Klenow fragment possesses both exonuclease activity and polymerase activity, it is useful in DNA cloning protocols. For instance, random priming radiolabeling techniques are used often in Southern and Northern blotting procedures and the creation of these probes utilizes the Klenow fragment. This technique involves first denaturing double-stranded DNA into single strands by heating. Short oligonucleotides then bind in complementary fashion to the denatured DNA, and the fragment is subsequently extended using Klenow enzyme in the presence of deoxynucleotide triphosphates (dNTPs), one of which is radiolabeled (i.e., a ^{32}P-dCTP).

Another group of DNA-dependent DNA polymerases that are used extensively in the polymerase chain reaction (PCR) include the heat-stable DNA polymerases, such as *Taq I*. Originally isolated from *Thermus aquaticus, Taq I* has now been cloned and engineered genetically to improve performance. This enzyme is active over a broad temperature range and is stable with repeated temperature cycling.

The RNA-dependent DNA polymerases synthesize a complementary DNA (cDNA) copy of an RNA template. These enzymes are called *reverse transcriptases* and typically are derived from either retroviruses or the Moloney murine leukemia virus. Reverse transcriptase creates cDNA copies of a population of mRNA molecules. Single-stranded cDNA molecules are converted into double-stranded DNA and cloned into appropriate vectors to generate cDNA libraries. These cDNA libraries are used to isolate genes of interest.

Blotting Techniques

Nucleic acids and proteins are readily detected by fixing these molecules to a nitrocellulose membrane and identifying them by hybridization with specific probes. The detection of specific DNA sequences was described originally by E. M. Southern in 1975 in a technique termed *Southern blotting*.[1] The technique was modified for the detection of RNA sequences and named Northern blotting. Specific proteins are detected by Western blotting.

Southern Blotting Southern blotting involves digesting high-molecular-weight DNA (e.g., genomic DNA) with restriction endonucleases and separating the generated DNA fragments according to size by agarose gel electrophoresis. The DNA fragments are denatured in the gel into single-stranded DNA and subsequently transferred (blotted) from the gel to a solid support, typically a nitrocellulose based membrane. The transferred DNA and a radiolabeled DNA or RNA bind to each other in complementary base-pair fashion to form a hybrid, a process called *hybridization*. The radiolabeled signals are detected by autoradiography, through exposure to x-rays (Fig. 135-3).

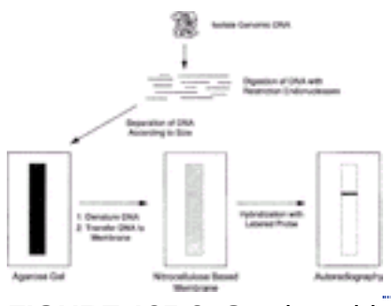

FIGURE 135-3. Southern blotting. Detection of specific DNA sequence in a complex mixture of DNAs (such as genomic DNA) by hybridization with a labeled probe. The hybridization depends on the normal base-pairing of the probe nucleic acid with the complementary genomic DNA sequence. (From Rippe RA, Behrns K, Brenner DA. Molecular biology for the GI clinician. Gastroenterol Updates 1998;3.)

Northern Blotting Northern blotting is an adaptation of the Southern blotting method for detection of RNA. RNA is isolated, separated by electrophoresis in formaldehyde-agarose gels, transferred to nitrocellulose-based membranes, and hybridized to specific RNA or DNA probes. Standards of known size allow estimation of the size of RNA of interest. This technique measures the steady-state levels of a particular mRNA under set experimental conditions. Steady-state mRNA levels do not, however, indicate the stage at which gene expression may be regulated. Some conditions might affect the rate at which the gene is transcribed, whereas other conditions may affect the turnover rate, or stability of the mRNA molecule.

Western Blotting Western blotting (immunoblotting) is a method used to detect and quantitate specific proteins using antibodies. The procedure involves extracting proteins from a given source, separating the proteins based on their size by electrophoresis in a polyacrylamide gel and transferring them from the gel to a nitrocellulose-based membrane. Once transferred, the proteins are spotted for binding to a specific antibody. A primary antibody binds to the protein of interest and is subsequently detected using a secondary antibody complexed to an enzymatic detection system. A substrate that undergoes color change when cleaved by the enzymatic detection system allows visualization of the antigen-antibody complexes (Fig. 135-4). The radioimmunoassay and enzyme-linked immunosorbent assay techniques were derived in principle from the Western blot.

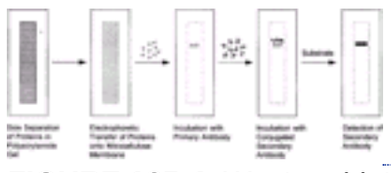

FIGURE 135-4. Western blotting. Detection and quantification of specific proteins using antibodies. Proteins are separated by size on a polyacrylamide gel and transferred electrophoretically to a nitrocellulose membrane. The primary antibody binds to the protein of interest, and the secondary antibody binds to the primary antibody. The secondary antibody contains a detection system that allows identification of the proteins. (From Rippe RA, Behrns K, Brenner DA. Molecular biology for the GI clinician. Gastroenterol Updates 1998;3.)

In Situ Hybridization and Immunohistochemical Detection

The study of gene expression often requires the detection of proteins or mRNA within single cells or tissues (in situ analysis). In situ hybridization examines the expression of mRNA, whereas immunohistochemical detection indicates the presence of specific proteins. In situ hybridization provides a sensitive method to locate specific cells that express a gene of interest. The technique involves fixing tissue sections to slides, treating the sections with reagents to increase cellular permeability, and then hybridizing the tissue with either labeled RNA or DNA probes. Probes labeled with enzymes or fluorescent tags (fluorescent in situ hybridization) have excellent resolution, rapid detection, and avoidance of the safety problems associated with radioactive isotopes. In situ hybridization has been used successfully to localize genes on chromosomes, to identify tissues and specific cells in which viruses are replicating, and to locate cells expressing low abundance messages.

Immunohistochemical analysis allows for the localization of proteins to individual cells within tissue samples or to subcellular compartments. Similar to other protein detection methodologies, immunohistochemical analysis uses specific antibodies to bind to the protein of interest, followed by antigen-antibody detection using secondary antibodies directed against the primary antibody.

DNA Sequencing Techniques

Many applications of molecular biology require determination of the DNA sequence, such as a gene or cDNA. Two methods are used to sequence a DNA fragment: chemical sequencing and dideoxy sequencing. Sequencing using chemical degradation was originally described by Maxam and Gilbert. [2]

The second and more popular method of sequencing DNA is called *dideoxy sequencing* or *chain termination sequencing,* as originally developed by Sanger. [3] This method is based on the ability of DNA polymerase to synthesize a complementary strand of DNA from a template (Fig. 135-5). Specific complementary primers are hybridized to the DNA template, and then DNA polymerase is added to allow elongation of the synthesized strand. Four reactions, each containing four dNTPs, one of which is radiolabeled and one of which is a ddNTP, are performed. When the polymerase incorporates the ddNTP in the newly synthesized DNA strand, chain elongation terminates. When one of the four possible ddNTPs (ddATP, ddCTP, ddGTP, ddTTP) is included in each of four reactions, and the reaction products are separated in electrophoretic sequencing gels, a typical sequencing ladder is obtained from which the nucleotide sequence can be read easily. Dideoxy sequencing is now automated. The success of the human genome project depended on high-throughput automated DNA sequencing.

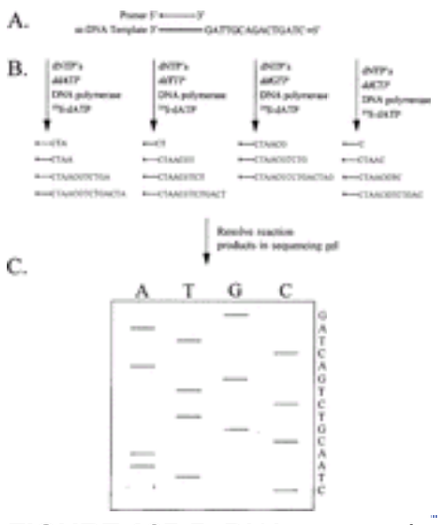

FIGURE 135-5. DNA sequencing by the dideoxy method. Primers specific to the DNA are hybridized to the template (**A**), and then DNA polymerase, dNTPs (dATP, dCTP, dGTP, and dTTP), and a ddNTP are added (**B**). Incorporation of the ddNTP halts chain elongation (**B**). Reaction products are resolved on a sequencing gel (**C**). (From Rippe RA, Behrns K, Brenner DA. Molecular biology for the GI clinician. Gastroenterol Updates 1998;3.)

Polymerase Chain Reaction

PCR allows for the rapid amplification of small amounts of nucleic acids. [4] The numerous clinical applications include diagnostic detection of infectious agents, tissue typing, prenatal diagnosis of genetic diseases, and analysis of allelic sequence variations. In the laboratory, PCR methodology is used for DNA sequencing, cloning, gene isolation, and analysis of gene expression.

The basis of PCR is simple but elegant (Fig. 135-6). Two primers are designed that are complementary to the flanking regions of the sequence to be amplified. The primers are added to the template DNA along with a DNA-dependent DNA polymerase that allows new chain synthesis. The reaction mixture is heated to denature (separate the strands) the template DNA, followed by cooling to allow for hybridization of the primers to the template. The DNA polymerase is then allowed to synthesize complementary strands from each primer. Adding the primers in vast excess and repeating the cycles of denaturation, annealing (binding of the primer to the template), and synthesis results in an exponential rate of amplification of the target sequence. The efficiency of PCR has been improved with the discovery of heat-stable DNA polymerases, like *Taq* polymerase, and newer genetically altered enzymes. These heat-stable polymerases retain their enzymatic functions despite thermal cycling. PCR technology has been used extensively for detection of genetic mutations in patients.

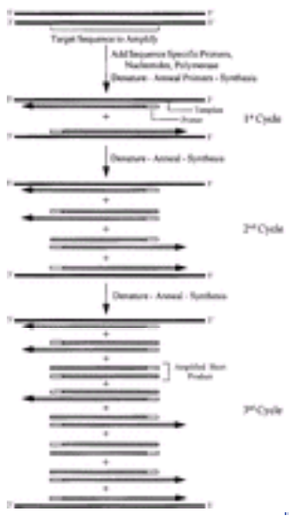

FIGURE 135-6. Amplification of DNA by the polymerase chain reaction (PCR). The template DNA contains the target sequence of interest. Specific DNA primers hybridize to the 5' ends of the target sequence. The reaction also requires a heat-stable DNA-dependent DNA polymerase (such as *Taq I*) and four deoxynucleotides. Repeated cycles of denaturation (usually at 94°C), annealing of primers to template DNA, and DNA synthesis (usually at 72°C) results in the exponential amplification of the target DNA. (From Rippe RA, Behrns K, Brenner DA. Molecular biology for the GI clinician. Gastroenterol Updates 1998;3.)

APPLICATIONS OF MOLECULAR BIOLOGY TO THE CLINICAL LABORATORY

Clinical laboratories are rapidly developing approaches to detect a variety of mutations. The different technical approaches available may be categorized as either targeted or screening mutation detection strategies.

Targeted mutation detection entails straightforward and largely routine procedures by which DNA samples may be analyzed for previously identified mutations using an assay designed for maximum specificity. This approach targets known mutations in potentially large cohorts of clinically indicated patients as well as in disorders marked by one or a few common alleles, and may confirm or establish clinical diagnoses. Furthermore, in families at risk for a particular genetic disease, targeted mutation detection allows for rapid screening of an entire family for the mutation identified in the proband, thereby permitting accurate carrier determinations. Rapid testing of large numbers of patients also permits an assessment of the mutation's frequency among disease-causing alleles, thereby determining which mutations are most prevalent in different patient populations and guiding the creation of effective clinical mutation testing panels.

By contrast, mutation screening analyzes genes for all sequence variants present. By definition, these strategies are not predicated on specificity for specific alleles but rather are designed for highly sensitive detection of all possible variants. In principle, all sequence variants present will be detected without regard to advance knowledge of their pathogenic consequences. Once evidence for a sequence variant is found, the sample must be sequenced to identify it fully. Only when combined with appropriate genetic data and in vitro functional studies can investigators distinguish between disease-causing mutations and polymorphisms without clinical consequence. From a basic research perspective, mutation screening is a critical and obligatory final step toward identifying genes that underlie genetic disease. Screening may also be applied toward the detection of mutations in diseases marked by many different mutations (allelic heterogeneity) and may also aid in the establishment of correlations between genotype and phenotype.

Use of Restriction Endonucleases to Detect Mutations

Mutations represent a fundamental change in the local DNA sequence and may involve single-nucleotide substitutions, small deletions or insertions, or more complex rearrangements. Beyond their potential for clinical consequences, gene mutations may also, by virtue of their changes in nucleotide sequence, create novel recognition sites for restriction endonucleases or destroy preexisting ones. For example, a DNA fragment harboring a mutation might *not* be cleaved with a particular restriction enzyme that normally cleaves wild-type DNA. Conversely, a different mutation might create a novel restriction site not present in the wild-type DNA. In either case, mutated DNA would produce a restriction digestion pattern distinct from that seen with nonmutated DNA when the digestion products are compared after electrophoresis on either agarose or polyacrylamide gels. An example of this commonplace approach applied to mutation detection in cystic fibrosis [5] is shown in Figure 135-7. Other examples include mutation detection in Wilson disease, [6] intrahepatic cholestasis of pregnancy, [7] progressive familial intrahepatic cholestasis, [8] and a $_1$-antichymotrypsin deficiency. [9]

FIGURE 135-7. Restriction endonuclease–mediated detection of the CF causing mutation, W1282X. A restriction recognition site (CCTC/GAGG, *in blue*) present for the endonuclease, *Mnl*1, in the normal *CFTR* exon 20 is ablated by the W1282X mutation (*in blue*). *Arrows* indicate polymerase chain reaction primers. Gel at right shows W1282X-negative (-), W1282X heterozygote (+/-), and W1282X homozygote (+/+) patterns.

Using restriction enzymes to distinguish between alleles is a commonplace technique. This method also has advantages over approaches associated with radioisotope usage and their collateral costs and concerns. The large variety of restriction endonucleases that are commercially available represents a substantial resource to molecular laboratories, and the wide variety of recognition sequences associated with these enzymes affords the investigator many choices for designing straightforward mutation detection strategies.

Despite this large supply of different restriction endonucleases, less than half of known DNA sequence variants independently alter restriction digestion patterns for a commercially available enzyme. Additionally, some enzymes are either unreliable or prohibitively expensive for use in routine, high-throughput analyses.

Single Nucleotide Polymorphisms

Single-nucleotide polymorphisms (SNPs) are the most common variant in the human genome, with a density of at least one common SNP per kilobase pair of DNA. There is now available for research purposes a dense SNP map to study genetic factors important in human diseases, including complex genetic traits. The underlying concept is that genetic markers in close proximity to the responsible mutant genes are in linkage disequilibrium. The technology to perform SNP analysis is rapidly evolving. For example, a microarray chip has been produced that contains more than 1000 SNPs and provides extensive genotype analysis on a patient in one experiment. [10]

Polymerase Chain Reaction–Mediated, Site-Directed Mutagenesis

When confounding factors impede the design of facile restriction-based assays, laboratories may employ a modification of this approach. PCR-mediated, site-directed mutagenesis is a technique by which a novel restriction digestion pattern can be purposefully generated in association with virtually any mutation. This strategy is known by a variety of other names, [11], [12] including *restriction site-generating PCR* [13] and *amplification-created restriction site*. [14] These techniques, identical in approach, involve the design of one PCR primer that abuts the mutation locus and includes typically one or two nucleotides mismatched relative to the template DNA.

If properly designed, this mutagenic primer will bind specifically to its target DNA and support multiple rounds of PCR amplification. All PCR products generated not only will include the mutation locus under study but will also incorporate the base change inherent to the mutagenic primer. The combination of the mutation and the novel base change of this primer creates a novel restriction pattern specific to the different alleles at this locus where none was present previously. This methodology has become commonplace in the literature, including applications for mutations in the *Ras* oncogene, [15] *BRCA1,* [16] ß-thalassemia, [17] medium chain acyl-coenzyme A dehydrogenase deficiency, [18] hereditary hemochromatosis, [19] and a $_1$-antitrypsin deficiency. [20]

Amplification-Refractory Mutation System

In the amplification-refractory mutation system protocol, also known as *allele-specific PCR,* primers are designed that will amplify only one of the alleles present at the locus of interest. [21] This is accomplished with primers that are substantially mismatched relative to one allele, but have sufficient complementarity to anneal to, and amplify, the other allele. Typically, the amplification-refractory mutation system is designed to amplify one allele, whereas a separate reaction will be specific for the other allele at that locus. This technique has also been applied to cystic fibrosis, [22] primary biliary cirrhosis, [23] and the drug-metabolizing liver enzyme, cytochrome P450 CYP2D6 (debrisoquine 4-hydroxylase). [24]

In the absence of any advance knowledge of the likelihood of mutations being present in a DNA fragment, screening strategies are applied. Various technologies are available for the detection of any and all sequence variants that may occur. Many of these approaches will require subsequent DNA sequencing to elucidate the nature of the mutations detected. These approaches, nonetheless, complement targeted mutation detection strategies because all sequence variants will be detected, not just those that have been previously reported and have highly specific assays available.

Single-Stranded Conformational Polymorphism Analysis

Single- and double-stranded DNA fragments may assume distinct secondary structures after they are denatured. These structures are highly dependent on their nucleotide sequences, so that a DNA fragment with a mutation will have an altered structure relative to the normal fragment. The single-stranded conformational polymorphism (SSCP) analysis screening strategy takes advantage of the different rates at which these fragments will migrate through polyacrylamide gels. [25] After amplification of a genomic fragment, the PCR product is typically digested into smaller fragments. It is then partially denatured to single strands and transferred immediately to ice. The sample is then electrophoresed on a nondenaturing polyacrylamide gel. Both double-stranded and single-stranded fragments will be apparent on the gel as distinctly migrating bands. The presence of a mutation or polymorphism within the PCR product will be apparent through band mobility shifts in either the double- or single-stranded fragments or both, when compared with DNA fragments without sequence variants (Fig. 135-8). SSCP is used widely and has been employed for mutation screening in Wilson disease, [26] Alagille syndrome, [27] progressive familial intrahepatic cholestasis, [28] and cystic fibrosis. [29] Other permutations of SSCP, such as conformation sensitive gel electrophoresis, have also been reported. [30]

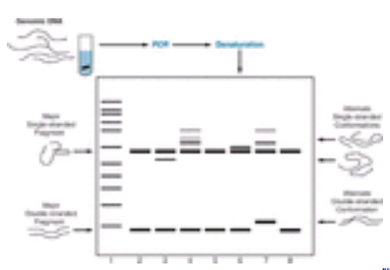

FIGURE 135-8. Single-stranded conformational polymorphism analysis. The polymerase chain reaction product is denatured, placed on ice, and electrophoresed on nondenaturing polyacrylamide gels. Lane 1: size marker. Lanes 2, 5, and 8: no bands of altered mobility are seen in samples with the wild-type sequence. Lanes 3, 4, 6, and 7: bands of altered mobility establish presence of sequence variants. Different variants may yield different electrophoretic patterns. Multiple bands reflect distinct fragment conformations.

Many mutation screening strategies are predicated on heteroduplex formation. Two single-stranded fragments of DNA, such as recently synthesized PCR products, will form fully matched, stable homoduplex structures at appropriate chemical and temperature conditions if they have 100% sequence complementarity. DNA fragments that differ at a small number of nucleotides will also form duplexes, but these fragments will fail to base-pair where the nucleotides are not matched. These heteroduplexes may have subtly altered conformational properties and become substrates for specific chemical as well as enzymatic reactions. When amplifying a DNA fragment from an individual heterozygous for a nucleotide substitution, the final PCR product will include both homoduplex structures for each allele and heteroduplexes derived from the imperfect annealing of dissimilar fragments. Whenever heterozygosity is established, either through gel electrophoresis or through chemical analysis, direct sequence analysis is used to identify the underlying mutation or polymorphism. A heteroduplex detected in a large gene allows DNA sequencing efforts to be targeted toward the fragment that gave rise to the heteroduplex, thus making mutation detection more efficient.

Chemical and Enzymatic Cleavage

Heteroduplex DNA may be cleaved in a sequence-specific manner using either chemical or enzymatic agents. Chemical cleavage of DNA mismatches (CCM) involves agents that modify specific bases when present in the single-stranded form. In imperfectly annealed, heteroduplex fragments, the nucleotide mismatch manifests as a very localized single-stranded region with bases vulnerable to chemical modification. Hydroxylamine modifies unpaired cytosines, whereas osmium tetroxide modifies unpaired thymines. Piperidine is then added to cleave the mismatched products, which are then electrophoresed to resolve the digested fragments. [31] Thus, every possible single-base mismatch, as well as small insertions and deletions, is subject to chemical cleavage. Phenylketonuria, [32] acute intermittent porphyria, [33] and hemophilia A [34] are among the disorders for which CCM has been used. Not only can the presence of a mutation be established, but its approximate location within the fragment also becomes apparent from the size of the digestion products.

An enzymatic protocol for mismatch-directed cleavage using T4 endonuclease VII avoids the chemical toxicity of the CCM reagents. [35], [36] In vivo, T4 endonuclease VII resolves the complicated structures of genetic recombination by recognizing kinks and loops produced in recombining DNA. These transient structures are similar in nature to the mismatch-bearing fragments that typify heteroduplexes. Enzyme mismatch cleavage thus cleaves heteroduplex fragments, allowing the digestion products to be characterized by electrophoresis (Fig. 135-9). Mutation detection using enzyme mismatched cleavage has been described for hereditary nonpolyposis colorectal cancer [37] and for hereditary pancreatitis. [38] As with CCM, some positional information is also generated.

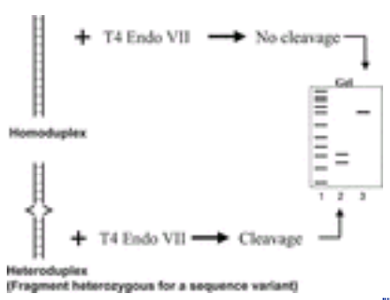

FIGURE 135-9. T4 endonuclease VII–mediated cleavage. Homoduplex polymerase chain reaction (PCR) fragments have no localized single-stranded domains and will not be cleaved by Endo VII and produce a single uncut band after electrophoresis (lane 3). Heteroduplex PCR fragments will be cleaved by Endo VII, giving cleaved fragments (lane 2). Lane 1: size marker.

Heteroduplex Analysis

The conformational changes associated with heteroduplex structures often lead to fragments with altered electrophoretic mobility. Heteroduplex fragments may be separable from homoduplex forms, thereby establishing heterozygosity for a sequence variant in that sample. A method that exploits the differential migration of homoduplexes from heteroduplexes uses mutation detection enhancement (MDE) gels (BioWhittaker Molecular Applications, Rockland, ME). This proprietary gel matrix is formulated to enhance the electrophoretic separation between homoduplex and heteroduplex fragments in a straightforward manner. [39] After PCR, DNA products are renatured slowly to enhance heteroduplex formation and are subsequently electrophoresed on MDE gels. Heteroduplex and homoduplex fragments migrate on a gel with different mobilities, an effect that is directly related to the subtle structural differences between them. This technique has been used for mutation detection in Wilson disease, [40] acute intermittent porphyria, [41] Duchenne muscular dystrophy, [42] and hereditary breast cancer (*BRCA1*). [43]

Denaturing Gradient Gel Electrophoresis

The differential conformational properties of heteroduplex fragments may be exploited by other methodologies. As a result of their mismatched bases, heteroduplexes denature into single strands more readily than their homoduplex counterparts. Denaturing gradient gel electrophoresis (DGGE) uses a chemical gradient within the electrophoretic gel to take advantage of this difference. [44], [45] The chemicals involved, typically urea or formamide, denature PCR fragments from double- to single-stranded forms. PCR of heterozygous samples yields heteroduplex fragments with altered denaturation properties. Once denaturation of a fragment occurs, its migration through the gel effectively ceases. The appearance of these slowly migrating bands on DGGE gels is indicative of heterozygosity for a DNA sequence variant in the underlying sample. This “melting process” is sensitive not only to the nature of the mismatch and the underlying mutation but also to the sequence of the fragment as a whole. DGGE is another widely used technique, having found utility for detecting mutations in cystic fibrosis, [46] erythropoietic protoporphyria, [47] *p53* mutations in hepatocellular carcinoma, [48] tuberous sclerosis, [49] and hereditary breast cancer. [50]

Protein Truncation Test

Cell-free expression systems can be used as a bridge between genomics and proteomics by converting nucleic acid sequence (usually in the form of RNA) into protein sequence. One in vitro expression system is referred to as the *protein truncation test* and can be used to perform mutation analysis, particularly for those mutations that alter the reading frame of the expressed protein, so-called truncating mutations, which lead to a shortened protein product. This method is particularly useful in detecting mutations in large genes that are frequently altered by nonsense and frameshift mutations (the result of small insertions or deletions) in addition to large deletions. Examples of the underlying disorders include familial adenomatous polyposis, [51] cystic fibrosis, [52] Duchenne and Becker muscular dystrophy, [53] neurofibromatosis type 1, [54] and hereditary breast and ovarian cancer defined by tumor suppressor genes such as *BRCA1* and *BRCA2*. [55], [56]

The current method involves reverse transcription PCR, in which total RNA is used to produce single-stranded cDNA. PCR amplification, using a forward primer that includes the gene’s regulatory sequences necessary for transcription and translation (Fig. 135-10), results in a functional protein coding segment. Protein synthesis is completed by adding this segment to an in vitro translation and transcription system that includes radiolabeled amino acids and results in a labeled protein. A novel, lower-molecular-weight band indicates the presence of a truncated polypeptide, representing a truncating mutation in that sample. The position of the band indicates the relative size of the product, from which the position of the genomic alteration can be extrapolated (see Fig. 135-10). Confirmation of the mutation is achieved by genomic sequencing.

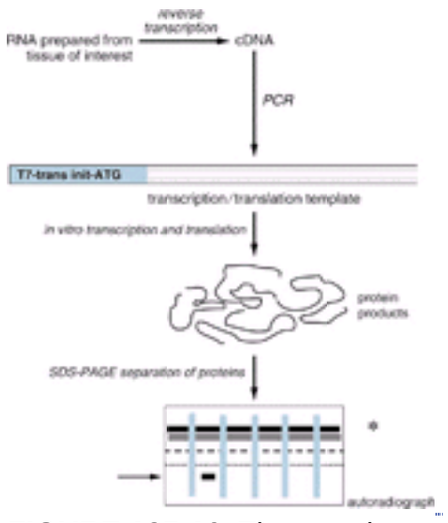

FIGURE 135-10. The protein truncation test. RNA is usually isolated from peripheral blood lymphocytes from whole blood collected in the presence of ACD or EDTA anticoagulants. (The quality of RNA isolated from tissue is dependent on rapid freezing of tissue to -70°C or below.) Coupled in vitro transcription/translation kits, using a rabbit reticulocyte extract, are commercially available. A labeled amino acid, usually ^{35}S-lysine, is added to the in vitro assay to label the synthesized proteins for autoradiography. The *arrow* adjacent to the autoradiograph indicates the presence of a band of lower-than-expected molecular weight, representing a truncated protein. The *asterisk* identifies the full-length, nontruncated protein.

Missense mutations do not usually result in size alterations of proteins; therefore, other procedures must be used for missense detection, so that maximum analytic sensitivity is often combined with scanning techniques for nontruncating mutations. Using this approach, the sensitivity for *BRCA1* and *BRCA2* mutation detection can approach 90%.

Real-Time Polymerase Chain Reaction

Allele-specific mutation detection is also amenable to automation. The Perkin-Elmer 7700 TaqMan allelic discrimination protocol enables high-throughput genotyping using real-time PCR. This strategy entails the use of a short DNA probe with a fluorescent dye attached to one end and a quenching agent linked to the other end. This probe is designed to match perfectly one allele at a particular locus but to be mismatched relative to other alleles. As the synthesis of the PCR product advances, the DNA polymerase 5'-exonuclease activity digests any probe in its path, releasing the fluorescent dye from the quencher and generating a fluorescent signal. If the probe is mismatched relative to the template, its affinity for the template will be greatly reduced under appropriately stringent conditions. Probe not bound to the template will neither be digested nor generate signal. A similar probe may be designed to detect the other alleles, and these assays may be pooled as long as each probe carries a different, separately detectable, fluorescent dye. Real-time PCR approaches to mutation detection have been reported for a $_1$-antitrypsin deficiency, [57] hemochromatosis, [58] Tay-Sachs disease, [59] and the study of mephenytoin metabolism by CYP2C19 (mephenytoin 4'-hydroxylase) variants. [60]

Microarrays

Functional genomics is the study of all genes expressed by a specific tissue and the changes in their expression pattern during a stimulus such as a disease state. Microarrays bring the analysis of gene expression to a genomic scale by permitting the simultaneous measurement of changes in expression of thousands of genes in a single study. Previously, analysis of gene expression was conducted one gene at a time, such as with the Northern blotting technique discussed earlier. Microarrays (also known as *DNA hybridization arrays* and *high-density oligonucleotide arrays*) measure the relative levels of mRNA for thousands of genes. The microarrays have four components: probes, targets, hybridization, and detection. Using the genetic databases available from the Human Genome Project, specific probes are constructed for each human gene to be placed on the array. These probes may be cDNAs that are amplified from plasmids or oligonucleotides synthesized onto the array matrix. The target consists of a labeled cDNA from the tissue or cell of interest. In most cases, an experimental condition (such as a diseased tissue) is compared with a control condition (such as a normal tissue). The cDNAs are labeled either with radioactivity or a fluorescent label. If different fluorescent labels are used for the experimental and control RNA, then both targets may be incubated on the same microarray. The labeled targets are then hybridized to the probes, which

enable the complementary target and probe sequences to bind specifically. The array is then washed to remove nonhybridized probes, reduce nonspecific hybridization, and minimize background. The specific hybridization is then detected by quantitating the amount of label that has annealed to the probe (i.e., either radioisotopic or fluorescence detection) (Fig. 135-11). Massive amounts of data are generated by the detection of hybridization on these arrays. The data must be normalized and then analyzed. New modes of analysis are being developed to analyze effectively this vast volume of information.

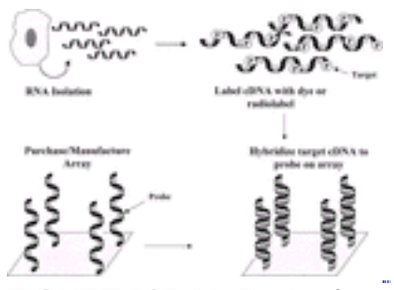

FIGURE 135-11. DNA microarrays for studying gene expression. RNA from a tissue of interest is converted into a labeled cDNA probe and hybridized to thousands of genes. The relative expression of genes representing the entire human genome can be detected on a single chip.

CHAPTER 136

Gregory Zuccaro, Jr.

REPROCESSING OF GASTROINTESTINAL ENDOSCOPES AND ACCESSORIES

The risks associated with gastrointestinal endoscopy are generally discussed in terms of those directly related to the procedure (e.g., oversedation, bleeding after polypectomy, perforation of the gastrointestinal wall). However, another theoretical risk of endoscopy involves the introduction of pathogens from the endoscope or accessories into patients undergoing a procedure. Because the endoscope and accessories often come into contact with potentially infectious fluids (e.g., blood) from one patient, and then are reused in subsequent patients, pathogens could be passed from patient to patient if not completely removed after each use. Nonpathogenic organisms could theoretically be transmitted to immunocompromised hosts by the same mechanism. Another potential mechanism whereby infection could be introduced through endoscopy is colonization of the endoscope or accessories by organisms in the environment after proper reprocessing, with introduction of these organisms into a subsequent patient. Although apparently rare, clinically significant infections have been documented in the literature by each of these scenarios. In most cases, a breakdown in accepted practices of endoscope and accessory reprocessing can be identified.

Endoscope and accessory reprocessing involves a series of steps that result in the generation of a patient-ready system: a system free of any organisms that might pose a risk for infection to the subsequent patient undergoing endoscopy. In keeping with the concept of universal precautions, each patient is assumed to be potentially infected with a pathogen.

TRANSMISSION OF INFECTION THROUGH ENDOSCOPY

The risk for transmission of infection from patient to patient through endoscopes and accessories appears to be quite small. An American Society for Gastrointestinal Endoscopy (ASGE) review identified 28 cases of transmission of infection through endoscopy since the implementation of standard guidelines for endoscope reprocessing. In each case, the reviewers felt that some breach in endoscope reprocessing techniques occurred (although this may not be true because some cases apparently occurred in the face of accepted reprocessing techniques). They estimated that the risk for infection from endoscopy was about 1 in 1.8 million. [1] This estimate may be understated, in view of the many reports of infection cited in the following paragraphs.

Hepatitis Virus

Transmission of hepatitis C virus from a carrier undergoing colonoscopy to two subsequent patients has been documented. [2] Hepatitis C virus genotyping and nucleotide sequencing established that all three patients were infected with the same isolate. Accepted reprocessing techniques were not performed between each procedure. Transmission of hepatitis B from patient to patient has been reported. [3] Acute hepatitis B infection developed 96 days after endoscopy and therapy for a bleeding ulcer. The endoscope was used immediately before to treat bleeding esophageal varices in a patient with hepatitis B. In this case, however, the endoscope and accessories had been reprocessed carefully following accepted protocols. Serotyping of the hepatitis B virus showed the same subtype in both patients. The patient with the bleeding ulcer did receive blood transfusions; nevertheless, the investigators (and subsequent reviewers [4], [5] and [6]) feel that this case most likely represents transmission of hepatitis B. Several clinical series indicate that the likelihood of hepatitis B virus transmission from patient to patient is extremely low. [7], [8], [9], [10], [11], [12], [13], [14], [15], [16] and [17] In many of these series, the endoscope and accessories were not reprocessed following currently accepted protocols, yet no infection in subsequent patients was evident. Transmission of hepatitis virus from patient to patient through endoscopy, although possible, is exceedingly rare.

Human Immunodeficiency Virus

Transmission of human immunodeficiency virus (HIV) as a result of gastrointestinal endoscopy or bronchoscopy has not been reported, but the virus can be recovered from these instruments after procedures in infected patients. Sampling of the suction and the air and water channels immediately after use in patients with HIV infection revealed HIV-specific DNA by polymerase chain reaction in 7 of 20 endoscopes. [18] In a similar study, all 7 bronchoscopes tested were positive for HIV-specific DNA. [19] HIV was readily eradicated from all contaminated endoscopes and bronchoscopes using standard reprocessing techniques.

Salmonella species

Numerous reports implicate endoscopy in transmission of *Salmonella* infections. [20], [21], [22], [23], [24], [25], [26] and [27] A group of patients developed *Salmonella newport* infection after undergoing colonoscopy subsequent to this procedure being done in a patient with acute *S newport* infection. [20] *S newport* identical to that recovered from the index case was identified in 8 of 48 patients who had procedures before the transmission was recognized. The apparent source of infection was not a colonoscope but the spring from a pair of biopsy forceps. In all of these series, the technique of endoscope reprocessing was less rigorous than currently recommended.

Pseudomonas aeruginosa

Pseudomonas aeruginosa is a ubiquitous organism. It can be found in tap water and can quickly colonize any damp area, including the channel of a reprocessed endoscope, water bottle, or endoscopic automated reprocessor. *Pseudomonas* species have even been identified as contaminants within hospital disinfectants, including chlorhexidine. [28] Therefore, although the prior discussion involved transmission of organisms from patient to patient through a contaminated endoscope, pseudomonal infections involve the introduction of this organism from the environment into a patient.

In one clinical series, 7 patients had *P aeruginosa* bacteremia after endoscopic retrograde cholangiopancreatography (ERCP) in a 1-year period, with 1 death related

to the infection. [29] In each case, the infected patient was the first case of the day in which that duodenoscope was used. In 6 of the 7 cases, the endoscope had been reprocessed more than 48 hours before the endoscopy. Cultures from these endoscopes after prolonged storage were positive for *P aeruginosa, Escherichia coli,* and *Serratia marcescens.* Similar culture results were obtained from other devices in the endoscopy suite, including wash basins, water irrigation bottles, and irrigation syringes. Infection control measures, including alcohol flushing of endoscope channels after reprocessing before compressed air drying to eliminate moisture that would serve as the medium for bacterial growth, resulted in elimination of further cases. The endoscope has been identified as the source of infection in several other series as well. [30], [31], [32], [33], [34], [35], [36], [37], [38], [39] and [40] Patients may become infected even when the pancreatobiliary tree is normal at the time of ERCP. [35]

There may be sources of *P aeruginosa* infection other than the operating channel of an endoscope. Struelens and colleagues [41] noted an increase in post-ERCP bacteremia after the implementation of automated reprocessors in the endoscopy suite. *Citrobacter* and *Pseudomonas* species were among the organisms identified in patients and cultured from duodenoscopes, and the reprocessor also showed evidence of bacterial contamination. Additional steps, including alcohol and air flush of the duodenoscope channels after reprocessing, and disinfection of the automated reprocessor, remedied the situation. Although the literature on transmission of *P aeruginosa* involves primarily duodenoscopes, other endoscopes may be similarly colonized. Alvarado and associates [42] noted a significant increase in the colonization rate of upper gastrointestinal endoscopes with *P aeruginosa* after reprocessing in a recently purchased endoscopic automated reprocessor. When endoscopes that had been manually reprocessed were tested, none were found to be contaminated with *P aeruginosa.* Certain areas of the endoscopic automated reprocessors, including the water inlet hose and air vents, were not accessible to the disinfectant solution and served as a reservoir for the organism. This design flaw in the original endoscope automated reprocessor has been corrected. The problem was corrected in the endoscopy suite by implementation of additional steps to the disinfection process, including rinsing of endoscope surfaces and channels with 70% isopropyl alcohol after machine disinfection, then drying with forced air for 10 to 20 minutes. [43]

Serratia marcescens

Serratia marcescens has been reported as an infectious complication of ERCP, sclerotherapy, and bronchoscopy. Two consecutive patients developed complications of ERCP related to the organism: acute hemorrhagic pancreatitis (patient died) and acute cholecystitis. [44] Cultures from the duodenoscope biopsy channel and intraoperative cultures for both patients grew *S marcescens*. A case of *S marcescens* mediastinitis and empyema after variceal sclerotherapy was reported, although the organism was not recovered from the endoscope or endoscopy suite. [45] Transmission was also reported through bronchoscopy to six patients after the instrument had been used on a patient with *S marcescens* pulmonary infection. [46] The organism was recovered from the bronchoscope on subsequent testing. Before this episode, the disinfection process involved only mechanical cleaning, suctioning water and alcohol through the operating channel, wiping the scope with alcohol, and drying the operating channel by aspirating ambient air. After the consecutive infections were identified, povidone-iodine (Betadine) was added to the operating channel cleaning regimen, and gas sterilization was performed. These additional steps eliminated the organism.

Helicobacter pylori

There are multiple clinical series documenting the patient-to-patient transmission of *Helicobacter pylori*. In 1979, a group of volunteers undergoing studies of gastric acid secretion developed rapid hypochlorhydria. [47] Endoscopic biopsy revealed histological gastritis. Although no organism was recovered, the investigators suspected an infectious etiology. A similar report noted gastritis and hypochlorhydria in 4 of 6 volunteers undergoing gastric acid analysis for a clinical study. [48] Contaminated pH probes rather than endoscopes were the source of infection in these series, emphasizing that proper disinfection must be performed for all gastrointestinal devices (e.g., manometry catheters, pH probes). Gastritis with *H pylori* developed in an individual with normal baseline histology who underwent serial gastric analysis and endoscopy as part of a research protocol. [49] Presumably, the endoscopic procedure was the source of the infection, although no information was offered as to whether the source was the endoscope, the biopsy forceps, or other unidentified agent.

A retrospective review of patient-to-patient endoscopic transmission of *H pylori* with restriction enzyme analysis of bacterial DNA suggested the rate of transmission due to endoscopy and biopsy was 1.1% over 3 years. [50] The method of endoscope disinfection involved mechanical cleaning, a 30-minute wash with 2% glutaraldehyde, sterile water rinse, and hot air dry. Biopsy forceps were not always sterilized between uses but sometimes “cleaned and disinfected.” All of the patients infected with *H pylori* in their series underwent mucosal biopsy, raising the possibility that the forceps was the source of infection. In a study of nine patients with recurrent infection after *H pylori* eradication, two had recurrent infection introduced through endoscopy. [51] The investigators reported that “improved” reprocessing techniques eliminated further transmission. The source of transmission (endoscopy, forceps) was not specified.

Mycobacterium species

The contamination of a flexible endoscope with *Mycobacterium* organisms has been regarded primarily as a problem for bronchoscopists and not gastrointestinal endoscopists. However, with the possibility of transmission of atypical mycobacteria to immunocompromised hosts, a review of this literature is relevant to gastrointestinal endoscopists.

Early reports describe patient-to-patient transmission of *Mycobacterium tuberculosis* through bronchoscopy when disinfection was performed using an iodophor, a chemical disinfectant currently felt to be inadequate for endoscope reprocessing. [52], [53] However, use of a bronchoscope colonized with *M tuberculosis* does not necessarily lead to cross-infection. In one series, 19 patients had bronchoscopy using a bronchoscope colonized with *M tuberculosis*. None of the patients developed symptoms or signs of tuberculosis or positive skin tests.

Continual colonization of bronchoscopes with *Mycobacterium chelonae* led to clinically significant respiratory infection in two immunocompromised patients. [54] Glutaraldehyde disinfection of the bronchoscopes did not remedy the problem, nor did ethylene oxide sterilization. When the bronchoscopes were sent for structural analysis, punctures of the operating channels were found, with gross contamination of proteinaceous material within. The bronchoscopes still were functional despite these internal defects. Clinical experience such as this is the basis for current recommendations regarding leak testing of flexible endoscopes with each use.

M tuberculosis and *Mycobacterium avium* were transmitted through contaminated bronchoscopes, despite use of a rigorous reprocessing protocol involving mechanical cleaning and 2% glutaraldehyde. [55] The endoscope channels were not the source of infection, but persistent mycobacterial infection was present on the suction valve. This infection could not be eradicated with glutaraldehyde, but was eradicated with steam autoclaving. Persistent colonization of endoscopes and bronchoscopes with *Mycobacterium chelonae* has also been linked to persistent colonization within an automated reprocessor. [56] Attempts to disinfect the reprocessor were not successful because of the formation of biofilm within a portion of the reprocessor. Addition of 70% alcohol rinsing to the endoscopes after reprocessing eliminated the problem. A similar case of *Mycobacterium abscessus* transmission was traced to persistent colonization of an automated reprocessor. [57]

Other Organisms

Other microorganisms that have been reported to be transmitted through endoscopy or bronchoscopy include *Listeria, Strongyloides, Rhodotorula, Trichosporon, Enterobacter,* and *Citrobacter* species. [5], [38], [58], [59], [60] and [61]

STERILIZATION AND LEVELS OF DISINFECTION

The Association for Professionals in Infection Control and Epidemiology (APIC) has put forth definitions helpful in a discussion of endoscope reprocessing [62] (Table 136-1). Varying levels of disinfection and sterilization may be achieved when reprocessing an endoscope and accessories. In fact, the same agent may achieve sterilization or high-level disinfection of an endoscope, depending on factors such as the amount of exposure time and the degree to which debris and organic material were removed before exposure to the agent. It is reasonable, therefore, to ask whether an endoscope and accessories should be sterilized between each use, or if a lower standard, such as high-level disinfection, is acceptable.

TERM	DEFINITION
Sterilization	Complete elimination of all forms of microbial life
Disinfection	Elimination of most or all pathogenic organisms
High level	Elimination of all microorganisms except high levels of bacterial spores
Intermediate level	Elimination of most microorganisms; some viruses, fungi, and bacterial spores may not be eliminated
Low level	Elimination of most bacteria, but not more resistant organisms such as mycobacteria and spores
Cleaning	Removal of foreign material (e.g., blood, tissue) from the endoscope and accessories; includes wiping, brushing channels, enzymatic detergents, ultrasonic cleaners

TABLE 136-1 Definitions in Endoscope Reprocessing

In 1968, Spaulding [63] proposed a classification scheme that has been accepted and retained (with minor modifications) by experts in infection control, including the APIC. A device that enters sterile tissue or the vascular system is called a *critical device* and must be sterilized before use. *Noncritical devices* involve contact with intact skin, and intermediate or low-level disinfection is acceptable. A device that comes into contact with mucous membranes, but not sterile tissue or the vascular system, is called a *semicritical device,* and high-level disinfection is deemed sufficient for these items. However, this produces somewhat of a double standard for endoscopy. In many cases, endoscopes simply contact mucosal surfaces, fitting the Spaulding classification scheme nicely. However, a biopsy forceps, sclerotherapy needle, or papillotome may come in contact with the vascular system. Because these devices are passed through the operating channel of the endoscope, should the endoscope be considered a critical device? Although there is no simple answer to this question, most experts in infection control, including the APIC, have recommended high-level disinfection for the endoscope, but sterilization of accessories that come into direct contact with the vascular system. [6]

Problems Specific to the Endoscope and the Endoscopy Unit

The endoscope is a complex structure, with multiple channels and interior surfaces in its internal composition. Areas that cannot be accessed with a cleaning device or disinfectant or sterilant cannot be reprocessed reliably. The operating channel of the endoscope is accessible to a cleaning brush, and manual cleaning of this channel is essential in endoscope reprocessing. The operating channel may become damaged, forming a nidus of persistent colonization. This damage may not be recognizable to the operator because the endoscope may perform normally until the damage is advanced and fluid invasion of the system causes overt malfunction. The air-water channel of the endoscope is smaller and, in many endoscopes, cannot be brushed manually; forcing air through the channel after the procedure, and liquid or gas disinfectants or sterilants that can insinuate themselves into these small areas are used to disinfect this area of the endoscope. The newer, totally immersible endoscopes lend themselves to this aspect of reprocessing. Some newer endoscopes do allow for mechanical cleaning of the air-water channel.

Another aspect of disinfection is the time allotted for the process. Most endoscopy suites have a limited number of endoscopes available and therefore require reasonable turnaround times. A highly effective technique for sterilizing or providing high-level disinfection that requires several hours is not practical and cannot be implemented in most endoscopy suites.

Organisms and Their Resistance to Chemical Disinfectants and Sterilants

Organisms are not equal in their resistance to destruction by chemical disinfectants or sterilants. Among the most susceptible are viruses such as hepatitis B and HIV. These viruses are readily inactivated (i.e., rendered unable to cause infection if injected into a susceptible host) by a number of chemical disinfectants and sterilants. [62] Among the agents effective in hepatitis B inactivation are glutaraldehyde at 1% and 0.1% concentrations (5-minute exposure), 80% ethyl alcohol (2-minute exposure), and 98°C heat for 2 minutes. [64] Hanson and colleagues [65] reported that 2% glutaraldehyde was effective in inactivating HIV in serum within 2 minutes, but 1% glutaraldehyde was ineffective after 15 minutes of exposure, and 70% ethanol did not inactivate the virus after a 10-minute exposure. Resnick and colleagues [66] reported that HIV was rendered noninfective with exposure to solutions of 0.5% sodium hypochlorite (1 minute), 70% alcohol (1 minute), and 0.08% quaternary ammonium chloride (10 minutes). Van Bueren and associates [67] also found inactivation of cell-free and cell-associated HIV with 10-minute exposure to 70% alcohol.

In general, the bacteria that may lead to cholangitis or other infections from endoscopy, including *P aeruginosa, S marcescens,* and *Salmonella* species, are also destroyed by common disinfectants and sterilants. [62] There is a recent report of isolation of a strain of *P aeruginosa* resistant to disinfection by glutaraldehyde. [68] Small viruses, including polio virus and hepatitis A, may be more difficult to inactivate. Chemical disinfectants, including 70% ethanol, 3% and 6% hydrogen peroxide, and dilute aldehydes, are only variably effective against poliovirus. [69] Solutions of 2% glutaraldehyde and high-concentration hypochlorite are necessary to inactivate the virus reliably. Only 0.5% sodium hypochlorite, 0.3% organochlorine, 2% glutaraldehyde, and modified quaternary ammonium compounds effectively inactivated coxsackievirus, adenovirus, parainfluenza virus, and coronavirus. [70] Only 2% glutaraldehyde, quaternary ammonium compounds with high concentrations of HCl, and sodium hypochlorite were effective in hepatitis A inactivation. [71] Among the less efficacious compounds were iodines, alcohols, acetic acids and peracetic acids, and hydrogen peroxide. Peracetic acid and 2% glutaraldehyde are among the chemical sterilants able to inactivate human rotovirus. [72] Among the less efficacious agents were 70% ethyl alcohol and sodium hypochlorite. Protozoan species are also relatively more resistant to destruction. Campbell and colleagues [73] found that *Cryptosporidium* oocysts were resistant to many common disinfectants but were inactivated by some agents, including formol saline and ammonia compounds. The commonly used agents in reprocessing endoscopes were not tested in this series.

Among the most resistant microorganisms are mycobacteria and bacterial spores. Several agents, including quaternary ammonium compounds, dilute sodium hypochlorite, 70% ethanol, povidone iodine, iodophors, and chlorhexidine, are ineffective against *M tuberculosis;* more concentrated sodium hypochlorite and 2% glutaraldehyde are effective. [74] Contact times are important; 2% glutaraldehyde did not destroy the organism in 1 minute but did in 10 to 30 minutes. A study with spores of *Bacillus subtilis* and *Clostridium sporogenes* found that 6% hydrogen peroxide solution was extremely effective against the spores, whereas 2% glutaraldehyde solutions reduced the number of viable spores but did not completely eradicate all spores, even with prolonged exposure times. [75] Glutaraldehyde, peracetic acid, and 10% hydrogen peroxide were the most effective agents in a study of *B subtilis* spores, but none totally eradicated all spores. [76] Some mycobacterial species have been reported to be resistant to even prolonged exposure to glutaraldehyde solutions. [77]

Common Chemical Disinfectants and Sterilants

A large number of chemical disinfectants and sterilants may be used in hospitals or endoscopy suites (Table 136-2 and Table 136-3). Several factors determine the suitability of a given agent for endoscope reprocessing: (1) The agent must be effective against a broad range of viruses, fungi, and bacteria, including mycobacteria. (2) The time of exposure necessary for this activity must not be prohibitively long. (3) The agent must not damage the endoscope or accessories. (4) The agent should not be toxic to staff or patients. (5) The cost must not be prohibitively high.

AGENT	ATTRIBUTES	DISADVANTAGES
Ethylene oxide (gas sterilant)	Highly effective (including action against spores)	Takes hours Potential toxicity to staff
Glutaraldehyde	Exposure times reasonable Relatively inexpensive Large experience with product	Potential toxicity to staff Not sterilant with 20-min exposure May cause colitis in patients
Peracetic acid	Highly effective (including action against spores) Not toxic to staff Effective against organic matter	More costly than glutaraldehyde
Hydrogen peroxide	Highly effective (including action against spores)	May cause colitis in patients

TABLE 136-2 Commonly Used Disinfectants and Sterilants for Endoscope Reprocessing

AGENT	REPORTED DISADVANTAGES
Iodophor solutions	May not reliably eradicate *Mycobacterium tuberculosis*[80] May be difficult to rinse from endoscopes
Hypochlorite solutions	May be less active against organic matter May corrode endoscope components
Quaternary ammonium compounds	Not sufficiently active against some microorganisms, including mycobacteria, some viruses
Alcohols	Flammable; may be a hazard if not properly handled Not effective against spores May not penetrate some proteinaceous material
Phenols	Residual material may remain even after rinsing, posing risk of irritation of mucous membranes

TABLE 136-3 Chemicals Not Typically Used as Sole Disinfectants in Endoscope Reprocessing

Gas sterilization of endoscopes has long been established as an effective method. Ujeyl and coauthors [78] found that as little as a 20-minute exposure time rendered endoscopes free of microorganisms with no apparent damage. Alfa and associates [79] raised concerns about the ability of sterilizers to eradicate completely organisms from the narrow lumens of endoscope channels. Multiple bacteria, including *P aeruginosa,* mycobacteria, and bacterial spores, were inoculated into plastic tubing 3.2 mm in diameter and sterilized with several agents, including ethylene oxide. None of the tested methods completely sterilized the narrow lumen when serum and salt were also present. [79] This result emphasizes the need for mechanical cleaning before disinfection and sterilization with any gas or chemical.

One commonly used chemical sterilant is glutaraldehyde. In the exposure time typical for endoscopy suites, it is an effective high-level disinfectant. If allowed sufficiently long contact times, sterilization is possible. Effective killing of bacteria, tubercle bacilli, and viruses occurs within 10 minutes, and vegetative spores in less than 3 hours. [80] Kovacs and colleagues [81] found that 2% glutaraldehyde achieved high-level disinfection from *M chelonae* in endoscopes with only a 10-minute exposure, but only if mechanical cleaning and alcohol rinse were also performed. However, not all clinical series support effective killing of mycobacteria within 10 minutes. The length of exposure with 2% alkaline glutaraldehyde time to achieve 99% eradication of all mycobacterial species ranged from 10 to 40 minutes (10 minutes for *M tuberculosis*) in another study. [82] These data have led to differing recommendations for the exposure time necessary for 2% glutaraldehyde to achieve high-level disinfection. The U.S. Food and Drug Administration (FDA) had required labeling of Cidex (2% glutaraldehyde, Johnson & Johnson) as effective as a high-level disinfectant only after a 45-minute exposure at 25°C. [83] However, Rutala and Weber [83] and prior APIC guidelines [6] argued that this amount of exposure time was only necessary if no mechanical cleaning of the endoscope had occurred before glutaraldehyde treatment and that exposure times of at least 20 minutes were sufficient to achieve high-level disinfection if mechanical cleaning was performed. Guidelines of several professional societies support a 20-minute exposure time for high-level disinfection, [84], [85] as do the most recent APIC guidelines for infection prevention and control in flexible endoscopy. [86] Testing of endoscopes contaminated with *Enterococcus* species or *H pylori* confirms these recommendations. [87] and [88] Recently, new glutaraldehyde preparations of varying concentrations, intended for use at varying temperatures and exposure times, have been introduced; it is essential that manufacturers' recommendations be reviewed and followed.

Rhinitis, dermatitis, nausea, headache, and respiratory difficulties are among the reported adverse effects on staff of glutaraldehyde exposure. [89], [90], [91], [92] and [93] Epidemiologic studies have suggested that spontaneous abortions are higher among staff performing sterilization with ethylene oxide, but not glutaraldehyde. [94] Adequate ventilation is necessary in areas where this agent is handled; staff should wear appropriate protective equipment, and the atmosphere should be periodically tested to be sure that concentrations are within appropriate parameters.

Glutaraldehyde has been linked to episodes of colitis in patients undergoing endoscopy. In one series, [95] 6 patients experienced low-grade fever, tenesmus, and bloody diarrhea, with symptoms lasting about 5 days. It was felt that the colitis was due to a gradual buildup of glutaraldehyde in the post-reprocessing rinse water and failure of the staff to use forced air to dry the channels after reprocessing. In a similar outbreak, most of the cases were in patients whose sigmoidoscope was reprocessed by a new staff member who did not flush residual glutaraldehyde from the endoscope channels after reprocessing. [96]

Peracetic acid is an effective chemical sterilant, active against all organisms, including bacterial spores. [97], [98] Bradley and colleagues [97] evaluated the Steris System 1 Processor (Stersis Corp., Mentor, OH) (0.2% peracetic acid) in the reprocessing of endoscopes contaminated with vegetative bacteria and spores. All bacteria were killed within 1 minute, and spores within 5 minutes. The investigators noted that the cost per cycle was higher than for reprocessing with glutaraldehyde. Whitbourne and Preston [99] confirmed the efficacy of the Steris processor on 10 medical devices contaminated with high titers of bacterial spores (about 107 colony-forming units/mL). [99] The process involves exposure of the medical device to the peracetic acid for 12 minutes, followed by several automatic rinses with water sterilized by passage through a membrane filter, for a total cycle time of about 25 minutes. Fuselier and Mason [100] reprocessed cytoscopes for 1 year using the Steris System 1 processor, and then used high level disinfection with Voluntary Hospital Association Plus 2% glutaraldehyde solution the next year. They reported no clinical differences between the two systems, but no microbiologic data were presented. Yearly operating costs for the Steris processor totaled $6037, compared with $445 for the HLD system. [100]

Hydrogen peroxide is another agent active against a wide range of microorganisms. Vesley and coauthors [101] tested the efficacy of 2% glutaraldehyde, 6% hydrogen peroxide, and ethylene oxide in endoscopes contaminated with *Pseudomonas* or *Bacillus* species. Ethylene oxide was the most effective agent overall. Hydrogen peroxide was more effective than 2% glutaraldehyde against the *Bacillus* organisms. The exposure times for these liquid chemicals was only 10 minutes, however, not the minimum 20 minutes recommended by the APIC for glutaraldehyde. As with glutaraldehyde, hydrogen peroxide may cause iatrogenic colitis. [102]

ESSENTIAL CONCEPTS IN REPROCESSING OF ENDOSCOPES AND ACCESSORIES

The overriding principle in endoscope reprocessing is that each patient must be assumed to possess potentially an infectious agent that could be passed through the endoscope to a subsequent patient. It is inappropriate for an endoscopy unit to reserve an endoscope or set of endoscopes for patients identified with some known pathogen. Rather, processes must be in place where all endoscopes are reprocessed in such a way that all potential pathogens would be eliminated.

Several professional societies, including the APIC, the Society of Gastroenterology Nurses and Associates (SGNA), and the ASGE have published guidelines for proper reprocessing of endoscopes and accessories. [84], [85] and [86] Essential aspects of these guidelines are presented below and summarized in Table 136-4. These are not intended to be a substitute for the step-by-step detail presented in the guidelines.

1. Inspection for damage should be performed after each case. Leakage testing may identify internal damage not apparent from endoscope performance.
2. Mechanical cleaning before exposure to the disinfectant or sterilant is essential.
3. High-level disinfection is the current standard for endoscope reprocessing.
4. Endoscopic accessories that may contact the vascular system must be sterilized if reused; mechanical cleaning alone or high-level disinfection is inadequate.
5. Channels must be adequately dried after high-level disinfection to prevent colonization with microorganisms.
6. If glutaraldehyde is used for high-level disinfection, the effective concentration must be continually monitored.
7. Continuous quality improvement is essential for each endoscopy unit.

TABLE 136-4 Some Essential Concepts in the Reprocessing of Endoscopes and Accessories

Inspection for Damage

Leaks, tears, and other disruptions to the external or internal integrity of the endoscope may be a nidus of continual colonization by microorganisms. [54] Internal damage to the endoscope may not be apparent to the endoscopist until it is far advanced because the endoscope may perform well. The endoscope must be carefully

inspected before reprocessing. Leak testing may detect internal structural damage at an early stage.

Mechanical Cleaning

Removal of organic material before exposure to chemical disinfectants or sterilants is the most important step in endoscope reprocessing. Scrupulous cleaning of external surfaces, use of enzymatic detergents on external surfaces and internal channels, passing a brush through the operating channel, brushing or forcing air through the more narrow air-water channel, and manual or ultrasonic cleaning of detachable parts of the endoscope are all part of this process. Special attention must be given to difficult-to-access portions of the endoscope, such as elevators and elevator channels of the duodenoscope. The elevator should be mechanically cleaned and the channel flushed.

Removal of organic and foreign material is necessary to achieve high-level disinfection. Alfa and associates [103] studied the suction channels of 10 bronchoscopes, duodenoscopes, and colonoscopes immediately after the procedure. They identified multiple compounds and organisms, including protein, hemoglobin, carbohydrate, endotoxins, and bacteria. Mechanical cleaning eliminated a good deal of this material, but protein and some bacteria remained. Lewis and Arens [104] noted persistence of HIV and vegetative bacteria after high-level disinfection of dental devices when the organism was entrapped in commonly used lubricants. The necessary exposure time of the liquid chemical sterilants to achieve high-level disinfection is decreased by prior mechanical cleaning.

Mechanical cleaning of the endoscope, without exposure to chemical sterilant, eliminated microorganisms in one study from 66 of 68 sites tested. [18] Other studies document the efficacy of mechanical cleaning in the inactivation of hepatitis B virus, [105] hepatitis C virus, [106] *H pylori,* [107], [108], [109] and [110] gram-negative bacteria, [111] and *Clostridium difficile.* [112] Thorough mechanical disinfection plus use of an approved chemical disinfectant or sterilant is highly effective in eliminating bacteria and viruses from endoscopes but is not effective when mechanical cleaning is ineffective. [113]

Use of a Recommended Disinfectant or Sterilant for High-Level Disinfection

Manual high-level disinfection may still be performed, but, with the advent of totally submersible endoscopes, automated reprocessors have become more common. These machines lessen the amount of time staff members must devote to the overall process and lessen exposure to glutaraldehyde, if this is the agent of choice. Vesley and colleagues [101] showed that automated reprocessors were more effective than manual high-level disinfection in killing *B subtilis*. However, Fraser and associates [114] found no difference in overall endoscope contamination rates when endoscopes disinfected manually were compared with those disinfected in automated reprocessors. Automated reprocessors do have potential drawbacks. Persistent infection of the endoscope reprocessor with resultant contamination of the endoscope has been documented. [42] The endoscope must be properly positioned within the machine, with all adapters and covers correctly placed. Furthermore, with endoscopic automated reprocessors using glutaraldehyde, the effective concentration of the disinfectant will decrease with repeated use. [115] Dilute glutaraldehyde is less effective in its action against microorganisms. [116], [117] A test strip or other device must be used at least daily to monitor the concentration of the liquid disinfectant, possibly more frequently depending on procedure volume. Solutions must be changed in accordance with the manufacturer's recommendations. Dilution must also be monitored with the use of hydrogen peroxide. A definite advantage of the Steris processor is that the chemical sterilant is not recycled; therefore, this monitoring process is not necessary. Orthophthalaldehyde is a high-level disinfectant that appears to be stable for up to 14 days of use. [118] Orthophthalaldehyde is approved by the FDA for use in endoscope reprocessing. It is used in some parts of the world, primarily outside the United States. [86]

Rinsing and Drying

The chemical sterilant must be rinsed from the internal and external surfaces of the endoscope. If tap water (which may be colonized with microorganisms) is used, a rinse with 70% alcohol should be performed. Drying with compressed air (or drying cycles on some automated washers) will also decrease the likelihood of residual moisture, which can be a source of colonization. Drying of endoscopes before prolonged storage significantly decreases the rate of bacterial colonization, [119] and forced air drying adds effectiveness to the disinfection process. [120] Alcohol rinse before prolonged storage also may decrease the likelihood of colonization. Endoscopes should be stored with the insertion tubes uncoiled and in a well-ventilated cabinet to facilitate continued air drying.

Reprocessing of Endoscopic Accessories

Because biopsy forceps and other accessories may come into contact with the vascular system, these items should be sterile before each use. Both disposable (single-use) and reusable forceps are commercially available. Improperly reprocessed biopsy forceps may be the source of transmission of infection. Single-use, disposable forceps do not expose patients to this risk. Two recent trials support the use of disposable over reusable forceps in terms of cost and function. [121], [122]

Most accessories for therapeutic ERCP, including papillotomes, guide wires, and extraction balloons, are labeled as single-use items. These items incur a significant cost for the endoscopy suite and are not entirely compensated by technical room reimbursements. [123] Reusable papillotomes are available. These devices function well after multiple uses and sterilizations but cost more than single-use papillotomes. [124], [125] The cost associated with endoscopic accessories has led some centers to reprocess items labeled as single use. Kozarek and colleagues [126] found that most single-use papillotomes performed well with multiple uses and sterilizations. No organisms were recovered from the devices after manual cleaning followed by ethylene oxide sterilization. In a follow-up study, this group found that the single-use papillotomes could be used an average of 3.4 times, and such reuse saved about $66,000 in 1 year for their practice. No infectious complications were attributed to the reuse. [127] These authors have also studied the reuse of other single-use items, such as argon plasma coagulation probes, and assert that sterilization could be achieved and up to 10 uses from a single probe obtained. [128] In a 1995 survey of hospitals in Australia, 58% were reusing at least some medical devices labeled as single use, [129] and a more recent survey documented that reuse is common in the Asia-Pacific region. [130] There are no data to indicate how common this practice is in the United States. The most recent APIC guidelines state only that this practice is "controversial" and that implementation of such a program "requires a major institutional commitment, including a monitoring committee with clearly defined protocols." [86]

Continuous Quality Improvement

Proper reprocessing of endoscopes and accessories requires an organized plan, motivated and educated staff, and a continuous quality improvement process that monitors each step of the process. Breakdowns in reprocessing techniques can lead to clinically significant infections and even death. The process can fail because of technical or human error. Staff and processes must be assessed and improved continually. Each unit should develop its own plan and should generate data on factors including competence of staff and results of random cultures from endoscopes, reprocessors, and accessory equipment.

COMPLIANCE WITH RECOMMENDATIONS FOR ENDOSCOPE REPROCESSING

One concern about endoscope reprocessing is the complexity of the process and the potential that some steps might be omitted or performed inadequately in a busy endoscopic practice. Several investigators have examined the actual practice of endoscope reprocessing, either with surveys or site visits. A 1988 survey of 74 endoscopy suites in Western Europe revealed that if a procedure was just completed in a patient with no known infectious disease, high-level disinfection was not performed after upper endoscopy in any center, in only 13% of centers after colonoscopy, and in only 30% of centers after ERCP. [131] In a 1989 survey, only 45% of Australian hospitals responding followed a process for high-level disinfection after each case. [132] Two years later, a repeat survey indicated that high-level disinfection was satisfactorily performed by 75% of respondents. [133] A 1991 survey in 107 endoscopy units in North Carolina found that glutaraldehyde was the chemical disinfectant used in 91% of units. Only 51% exposed the endoscope to the glutaraldehyde for at least 20 minutes (a 10-minute cycle was used in most other centers), and 54% rinsed with only tap water (not sterile water or alcohol after tap water) after disinfection. [134] A U.S. survey of SGNA members and nonmembers with an interest in endoscope reprocessing found that 93% performed chemical disinfection after each case; glutaraldehyde was the disinfectant used in 88% of respondents' practices. [135]

A more sobering report came from Kaczmarek and coauthors, [136] who directly studied the endoscopic reprocessing practices in 26 endoscopy suites: 24% of endoscopes cultured after high-level disinfection were positive for bacterial growth. A lack of sterilization of all biopsy forceps was observed in 78% of units. Several other basic errors in the disinfection process were observed. Variability was also observed in 18 endoscopy areas in eight Massachusetts hospitals; however, high-level disinfection was practiced in 17 of 18 endoscopy areas. Glutaraldehyde soak times varied from 10 to 45 minutes, and not all areas performed sterilization of biopsy forceps. [137] In a more recent survey, a significant minority of U.S. centers did not completely conform to established society guidelines for reprocessing. [138] In a

1996 survey of 20 Japanese endoscopy suites, endoscopes in all centers were used in consecutive patients with mechanical cleaning but no high-level disinfection. [139]

FUTURE TRENDS

Proper reprocessing of endoscopes demands time and careful attention, is not foolproof, and is associated with significant cost. Therefore, the concept of a sheathed or disposable endoscopic system is very attractive. A new endoscopic system in which the working surfaces are covered with a disposable sheath has been assessed in clinical trials. [140], [141] In a prospective trial, the length of time required to perform endoscopy was slightly longer than with the conventional endoscope, whereas the set-up and reprocessing times were far shorter. [142] Recent reports indicate promise for new techniques of endoscope reprocessing using superoxidized or acidic electrolytic water. [143], [144] and [145]

SUMMARY

Introduction of infection into patients undergoing endoscopy is rare, but it may occur. Infection may be due to patient-to-patient transmission or introduction of microorganisms from the environment into patients. Potential sources of infection include the endoscope, accessories, and automated reprocessors. High-level disinfection is recommended for reprocessing endoscopes, but sterilization is indicated for accessories that may come into contact with the vascular system. The process of high-level disinfection requires close attention to multiple steps. Several clinical series have demonstrated breakdowns in this process, with resultant morbidity and mortality. A continuous quality improvement system is essential for each endoscopy center.

CHAPTER 137

Martin L. Freeman

SEDATION AND MONITORING FOR GASTROINTESTINAL ENDOSCOPY

Delivery of safe but effective sedation and analgesia can be a challenge for the endoscopist. Cardiopulmonary complications are still one of the leading causes of morbidity and mortality due to endoscopic procedures. To administer sedation properly, it is necessary for endoscopists to understand the definitions and hazards of conscious versus deep sedation, the role of electronic monitoring devices such as pulse oximetry, and the pharmacology of the agonist and reversal agents used. They must develop a systematic approach to sedation and analgesia, in conjunction with well-trained gastrointestinal assistants, and know the limitations of their abilities.

CONSCIOUS VERSUS DEEP SEDATION: DEFINITIONS AND JCAHO REGULATIONS

The term *conscious sedation* has traditionally been used to describe the pharmacological state of restfulness induced for such procedures as endoscopy (Table 137-1). A recent Task Force of the American Society of Anesthesiologists has suggested that *sedation and analgesia* most accurately describes the state that allows patients to tolerate unpleasant procedures while maintaining adequate cardiorespiratory function, and the ability to respond purposefully to verbal or tactile stimulation. [1] They suggest that *conscious sedation* is an imprecise term and should be replaced. *Monitored anesthesia care* (MAC) is another term currently used to differentiate sedation and analgesia without endotracheal intubation from general anesthesia.

1. *Minimal sedation (anxiolysis).* A drug-induced state during which patients respond normally to verbal commands. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.
2. *Moderate sedation or analgesia ("conscious sedation").* A drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.
3. *Deep sedation or analgesia.* A drug-induced depression of consciousness during which patients cannot be easily aroused, but respond purposefully following repeated or painful stimulation. The ability to maintain ventilatory function independently may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.
4. *Anesthesia.* Consists of general anesthesia and spinal or major regional anesthesia. It does not include local anesthesia. General anesthesia is a drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to maintain ventilatory function independently is often impaired. Patients often require assistance in maintaining a patent airway, and positive-pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

From ref. 7.

TABLE 137-1 Defining Levels of Sedation and Anesthesia

Sedation is defined as a reduction in the level of consciousness induced by the medications used to facilitate acceptance of endoscopic procedures. Sedation may range from minimal or no visible change in patient status to loss of consciousness and protective reflexes. For some patients, no sedation may be required, and topical anesthesia may suffice for upper endoscopic procedures. Analgesia is defined as the reduction in pain or perception of nociceptive stimuli induced by the use of medication, primarily opioids. Analgesics are commonly used in low or moderate doses to reduce discomfort without impairment in consciousness, but higher doses can depress respiration and induce sedation. Patients who are given analgesics in higher doses may experience suppression of ventilatory drive, depression of consciousness, and impairment of protective reflexes.

The usual intended goal for sedation and analgesia may be defined as a medically controlled state of depressed consciousness that (1) allows protective reflexes to be maintained, (2) retains the patient's ability to maintain a patent airway independently and continuously, and (3) permits appropriate response by the patient to physical stimulation or verbal commands such as "open your eyes" [2], [3] (see Table 137-1). Conscious sedation, as summarized by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), is most appropriate for a patient who will accept it willingly and is able to cooperate. On the other hand, it is not suitable for a patient who is uncooperative, mentally impaired, or extremely anxious, and such patients may be best approached with general anesthesia, particularly if a prolonged therapeutic procedure, such as endoscopic retrograde cholangiopancreatography (ERCP), is to be undertaken.

A degree of safety is implied when a state of conscious sedation is achieved compared with deep sedation or general anesthesia. Although one might assume that the degree of care provided to patients under conscious sedation could be less intense or thorough, moving from a state of consciousness to deep sedation is a dose-related continuum that also depends on patient response. The state originally intended might not be the one ultimately achieved. There is a large variability in the pharmacokinetics and pharmacodynamics of sedative drugs in patients; thus, a "standard" dose of sedatives may produce undersedation in some patients and substantial oversedation resulting in anesthesia in others. [4], [5] and [6] Therefore, those who administer sedatives should have the knowledge and equipment, including

monitoring devices and airway management skills, to deal with an oversedated patient.

The JCAHO had previously issued a strict set of standards for anesthesia care that apply when patients, in any setting, receive, for any purpose or by any route, either general anesthesia or sedation (with or without analgesia) that, in the manner used, may reasonably be expected to result in the loss of protective reflexes. [3] Since that time, the JCAHO has developed new definitions of levels of sedation and analgesia. The impetus for this change was in part the recognition that loss of protective reflexes is often a late indicator that a patient receiving conscious sedation is in trouble and in part anecdotal evidence from the field that negative outcomes and even death were occurring as a result of conscious sedation. [7] Following the lead of the American Society of Anesthesiologists, the JCAHO has issued a new set of definitions (see Table 137-1). They emphasize the continuum that exists between the level of sedation intended and that which is achieved. Importantly, for moderate and deep sedation, the JCAHO emphasizes the need for qualified personnel, specifically with respect to competency to manage a compromised airway, to provide adequate oxygenation and ventilation, and to manage an unstable cardiovascular system. The JCAHO guidelines reflect the narrowing gap between practices in the anesthesia and endoscopy communities. The American Society of Anesthesiologists published a set of guidelines for nonanesthesiologists who administer sedation and analgesia. [1] The American Society for Gastrointestinal Endoscopy (ASGE) issued a set of standards of practice specific to monitoring and sedation for gastrointestinal endoscopy. [8] These two documents set forth relatively similar guidelines pertaining to personnel; training; equipment; appropriate preoperative, intraoperative, and postoperative assessment and monitoring; and use of sedative and analgesic agents (Table 137-2).

Preprocedure assessment of the patient, including assessment of eligibility for sedation and analgesia, previous adverse experiences with sedation and analgesia, coexisting medical conditions, allergies, current medications, cardiopulmonary status, and ascertainment of preprocedure fasting
A well-trained gastrointestinal assistant present whose primary role is patient sedation and monitoring
Preprocedure documentation of blood pressure, pulse, respiratory rate, and oxygen saturation
Equipment set up:
Nasal oxygen cannula
Oral suction catheter
Airway resuscitation equipment
Reversal agents immediately available
Establishment of intravenous access
Intraprocedural monitoring of heart rate, blood pressure (frequent, automated monitoring mandatory for high-risk patients), respiratory rate, pulse oximetry, electrocardiogram (mandatory for high-risk patients)
Use of supplemental oxygen as appropriate
Education of personnel regarding pharmacology of agents administered
Titration of sedative or analgesic agents to effect
Documentation of medications delivered, vital signs, respiratory parameters, and level of consciousness throughout procedure
Postprocedural monitoring of level of consciousness, pulse oximetry, and vital signs
Special regimens or consultation with appropriate medical specialty or anesthesiology for patients with special problems such as severe cardiopulmonary disease, uncooperative mental state

TABLE 137-2 Practice Guidelines for Sedation and Analgesia by Nonanesthesiologists

CARDIOPULMONARY COMPLICATIONS OF ENDOSCOPY

Cardiopulmonary complications are said to cause 50% of the morbidity and 60% of the mortality associated with endoscopy. [9], [10], [11], [12], [13], [14], [15] and [16] The true incidence of complications is not known and is likely underestimated because most data are derived from retrospective surveys rather than prospective studies specifically designed to study cardiopulmonary complications. One major recall-based U.S. survey suggested that only 0.5% of ASGE members responding experienced any cardiopulmonary complication annually. [17] Assuming 500 procedures per year per endoscopist (roughly the median for the respondents), this represents a complication rate of 0.01 per 1000 procedures. In contrast, a retrospective study using data entered at the time of endoscopy into an ASGE computer-based management system suggested that a serious cardiopulmonary complication occurred in 5.4 per 1000 procedures, [18] a 500-fold higher incidence; mortality alone was 0.3 per 1000. Another ASGE database study described one respiratory or cardiopulmonary arrest occurring per 1000 procedures. [19] One of the few truly prospective studies [16] found a 30-day procedure-related cardiopulmonary mortality rate of 0.4 per 1000 diagnostic upper endoscopies in the United Kingdom. It has been suggested that this cardiopulmonary complication rate has not decreased since the 1980s, in stark contrast to anesthesia-related deaths, which have decreased to 1 per 26,000 (0.04 per 1000), presumably as a result of better training standards and the widespread adoption of monitoring equipment. [10]

Two large studies have shown that procedures involving administration of opioids such as meperidine (usually given in combination with benzodiazepines) were most likely to be associated with adverse events. [18], [20] ERCP is associated with the highest rate of hypoxemia, although cardiopulmonary outcomes for this procedure in clinical practice outside randomized controlled trials have not been specifically studied. [12], [21], [22] and [23] Therapeutic procedures generally have a higher rate of complications than diagnostic ones, [24], [25] and acute upper gastrointestinal bleeding is associated with a high incidence of aspiration and other complications. [26], [27]

Types of Cardiopulmonary Complications

At least six major types of cardiopulmonary complications may occur as a result of endoscopy. These include respiratory depression, pulmonary aspiration, cardiac arrhythmias, myocardial ischemia, hemodynamic disturbances, and allergic reactions. In addition, indirect morbidity may occur because of inability to complete a therapeutic procedure owing to sedation-related problems. [21]

Respiratory Depression

Respiratory depression can manifest as hypoxemia or CO_2 retention, usually but not always occurring in parallel. [21], [22] A wealth of data show that arterial oxygen desaturation occurs frequently during both upper and lower gastrointestinal endoscopy. [10], [21], [22] and [23], [28], [29], [30], [31], [32], [33], [34], [35], [36], [37], [38], [39], [40], [41] and [42] Defining significant arterial oxygen desaturation as oxygen saturation (SpO_2) less than 90%, these studies show that at some point, up to 40% of patients undergoing upper endoscopy, 50% of patients undergoing colonoscopy, and perhaps 60% or more of patients undergoing ERCP experience significant desaturation. The mechanisms of hypoxemia are varied: opioids and benzodiazepines depress respiration both centrally by blunting ventilatory response to CO_2 and peripherally by blunting hypoxic ventilatory drive. [43], [44], [45], [46], [47], [48] and [49] The physical presence of the endoscope appears to cause minor degrees of hypoxemia, [50], [51] and [52] presumably as a result of coughing or aspiration, or by a reflex mechanism; significant airway obstruction is unlikely because even large-diameter endoscopes do not appear to cause sustained CO_2 retention. [22] Greater degrees of hypoxemia occur with larger-diameter endoscopes [36], [40], [41] and in examinations performed by inexperienced endoscopists. [53] Splinting or looping during colonoscopy may cause transient desaturation. [32] Endoscope-induced desaturation is generally transient or minor; severe and prolonged desaturation, particularly if culminating in respiratory arrest, is almost invariably the result of drug-induced respiratory depression, sometimes occurring after the endoscope has been removed. [21], [19], [22]

The significance of oxygen desaturation during endoscopy has been questioned by some investigators. [54], [55] However, these small series lacking prospective determination of patient outcome do not allow the conclusion that hypoxemia is safe, particularly because adverse events are relatively rare. It is likely that most hypoxic episodes are well tolerated. However, sustained desaturation to less than 90%, the point at which the oxyhemoglobin dissociation curve becomes very steep, may be of concern in elderly patients and in those with ischemic heart disease. [56], [57] Substantial data suggest that hypoxemia during endoscopy may result in tachycardia, [33] ST-segment elevation or depression indicative of ischemia, [33], [36], [37], [58], [59] and [60] and both atrial and ventricular arrhythmias. [36], [61] Hypoxemia is thought to cause most cardiac arrhythmias occurring during endoscopy. [10], [36]

A few studies suggest that patient variables such as increased age, obesity, or pulmonary disease increase the likelihood of desaturation. [23], [39], [62] Most studies, however, have shown that it is impossible to predict by medical illness or age which patients will become hypoxemic. [21], [22], [29], [32], [38], [55]

Use of Supplemental Oxygen

Numerous studies show that routine use of low-flow nasal oxygen during endoscopy prevents or diminishes hypoxemia. Bell and colleagues [31] showed that

administration of 2 L per minute nasal oxygen prevented hypoxemia in patients undergoing upper endoscopy with midazolam. Gross and Long [34] showed that 3 L per minute nasal oxygen reduced by more than half the incidence of hypoxemia in patients undergoing colonoscopy with midazolam and meperidine. Other studies have shown that oxygen reduces but does not abolish hypoxemia during endoscopy, [33], [35] suggesting that the use of oxygen does not eliminate the need to monitor oxygen saturation.

Does oxygen administration prevent deleterious events? During ERCP, patients with saturations below 90% had significantly higher pulse rates than patients who were not hypoxic, suggesting that correction of oxygen may alleviate tachycardia and hence myocardial stress. [33] Another intriguing study showed that administration of oxygen, compared with room air, prevented ST-segment changes indicative of ischemia in patients undergoing upper endoscopy. [63] Based on these findings, and in keeping with standard practice in anesthesia, Bell and others [9], [10] advocate routine preadministration of oxygen for most patients having sedation or endoscopy. Advantages to this approach include low cost (about $3 per patient) and proven prevention of hypoxemia in most cases. Preoxygenation does remove the ability of the oximeter to reflect hypoventilation or apnea, however, as discussed in the next section.

A logical approach would be that recommended by the British Society of Gastroenterology [50]—to preadminister nasal oxygen to those patients who can least tolerate hypoxemia (elderly patients and those with coronary artery disease). With those exceptions, I recommend reserving oxygen through nasal cannula, which should be set up at the bedside before each case, to patients who have sustained desaturation not responsive to verbal encouragement to breathe. Oxygenating mouth guards have been shown to be as effective as nasal cannulas, [64] but they have the distinct disadvantage of being removed immediately after the procedure, a time at which maximal desaturation may occur. [19], [20], [21] and [22] Generally, 2 to 3 L per minute through nasal cannula is adequate. Even higher flow rates occasionally may not correct hypoxemia, especially if both opioids and benzodiazepines are given. [10], [27] Furthermore, higher flow rates of oxygen probably should be avoided because they can mask severe CO_2 retention. [21], [22]

Carbon Dioxide Retention

Pulse oximetry measures arterial oxygen saturation, and not alveolar hypoventilation, which is directly reflected by increases in arterial CO_2 tension. Severe CO_2 retention may occur during endoscopy. [21], [22] The degree of hypoventilation has been shown to be in part related to sedative drug doses, which is logical because the commonly used sedatives or analgesics cause CO_2 retention by centrally depressing ventilatory responsiveness to CO_2. [44], [47], [49] CO_2 retention does not correlate well with the clinically assessed level of sedation or with the presence of underlying medical illnesses such as cardiac or obstructive lung disease. [21], [22] Although oxygen supplementation readily corrects hypoxemia, it does not correct underlying hypoventilation; once oxygen is applied, severe hypoventilation may occur without reliable detection by either pulse oximetry or clinical observation. Transient desaturation in patients already on oxygen generally indicates severe CO_2 retention.

Aspiration

Pulmonary aspiration of gastric contents or blood potentially may result in pneumonia and adult respiratory distress syndrome as well as cardiopulmonary arrest. Inhalation of gastric contents carries a high risk for mortality: 5 deaths were reported among 16 cases of inhalation of gastric contents in a survey of endoscopy in the United Kingdom. [65] Pneumonias occurred in 11 of 1300 patients after upper digestive endoscopy, with 8 deaths [16]; a correlation was seen between use of topical anesthetic sprays and the development of pneumonia. Aspiration is particularly likely when protective reflexes are blunted by excessive sedation or encephalopathy, when significant amounts of fluid or food are still in the stomach, as in patients with diabetic gastroparesis, and in the setting of acute upper gastrointestinal bleeding. In a prospective study, 20% of patients undergoing endoscopy for acute upper gastrointestinal bleeding developed clinically apparent aspiration pneumonia. [27] Aspiration did not occur in patients with endotracheal intubation.

The following precautions should be taken to avoid aspiration during upper endoscopy:

A vigilant gastrointestinal assistant should be prepared to suction the oropharynx with a catheter.
When large quantities of food or fluid are encountered, excessive insufflation should be avoided and the procedure should be terminated unless essential.
Sedation and topical anesthetic sprays should be minimized.

Endotracheal intubation or use of esophageal overtubes is recommended to protect the airway for patients with active upper gastrointestinal bleeding who have ongoing active hematemesis, are unstable, are mentally obtunded, or are uncooperative. [66]

Cardiac and Hemodynamic Complications

Myocardial ischemia and infarction may occur during endoscopic procedures, particularly in those patients with cardiac disease. [25], [58], [59] and [60] There are few prospective data regarding the incidence of clinically significant arrhythmias during gastrointestinal endoscopy. Tachyarrhythmias or bradyarrhythmias may occur as a result of hypoxemia, or from stress due to noxious stimuli. [61] Arrhythmias are more common in patients with a history of cardiopulmonary disease. [36] Although the importance of hypoxemia in producing cardiac arrhythmias and ischemia has been stressed, [9], [10], [61] other factors may be important. In one study of patients undergoing ERCP, Holter monitoring showed that myocardial ischemia correlated better with periods of tachycardia than with periods of hypoxemia. [58] Tachycardia is frequent [33] and may be extreme, with heart rates reported up to 200 beats per minute during stressful, prolonged upper procedures such as ERCP. [67] Tachycardia occurs mostly during upper rather than lower gastrointestinal endoscopic procedures [22] and most commonly occurs in elderly patients and those with cardiac disease. [23] Significant increases and decreases in blood pressure occur during gastrointestinal endoscopy. [32], [37], [68] In a detailed study of 395 patients undergoing ERCP, 7% of patients experienced a peak heart rate and blood pressure double product of greater than 25,000, equivalent to a maximal level cardiac treadmill test. [21] This is an enormous myocardial workload, particularly for the frail and elderly patients often undergoing these procedures.

Hemodynamic disturbances during endoscopy consist primarily of vasovagal reactions and of fluctuations in blood pressure and pulse. Vasovagal reactions usually manifest as perspiration and bradycardia and typically occur as a result of painful stimuli during colonoscopy. Although atropine is widely used to treat vasovagal reactions, few data support its routine use to prevent such events. Hypotension may result from vasodepressor effects of opioids, benzodiazepines, and other medications given during endoscopy.

To avoid the cardiac stress of tachycardia and hypertension during endoscopic procedures, two suggestions come to mind: first, atropine should not be given in upper gastrointestinal procedures unless bradycardia occurs; second, the often-stated axiom that the least sedation possible is the safest [10], [50], [69] may not be true. In a study of patients undergoing endoscopy without premedication, tachycardia occurred in 97% of subjects, ST-segment depression in 14%, supraventricular tachycardia in 6%, and ventricular ectopic complexes in 1.6%. [70] All of these changes were more frequent in cardiac than noncardiac patients. On the other hand, two studies have shown that opioid premedication attenuates endoscopy-induced increases in pulse and blood pressure, [71], [72] suggesting that optimal safety to the patient is a balance between preventing hypoxemia (which can be corrected with nasal oxygen) and preventing endoscopy-induced tachycardia and hypertension.

Procedure Termination as a Complication of Sedation

Procedure termination due to inadequate or excessive sedation has to be considered a sedation-related complication, resulting in morbidity due to delayed therapy, extended hospitalization, repeat or alternative procedures such as surgery, and increased cost. There are few published data on the prevalence of this problem, but it is not uncommon; Diab and others [73] found a 7% incidence of premature procedure termination during upper endoscopy using midazolam alone for sedation, without meperidine. In a prospective multicenter study, 4.1% of all ERCPs (mostly therapeutic) had to be terminated prematurely because of difficulty with sedation. [21] If difficulty is anticipated in sedating a patient for a therapeutic procedure, general anesthesia may be a safer and more cost-effective alternative.

MONITORING

Guidelines issued by the JCAHO, [3] the ASGE, [8] the British Society of Endoscopy, [50] and the American Society of Anesthesiologists [1] state that the most important aspect of monitoring a patient during sedation is a well-trained gastrointestinal assistant closely observing the patient. All of the above organizations now recommend the universal use of electronic monitoring as adjunctive devices, particularly pulse oximetry. The recent availability of compact, portable, all-in-one multichannel

oximeter–electrocardiograph–automated blood pressure units have greatly facilitated electronic monitoring and documentation during endoscopy.

Pulse Oximetry

A pulse oximeter is a spectrophotometric device that detects and calculates the differential absorption of light by oxygenated and reduced hemoglobin to produce a measurement called SpO_2, an estimate of oxygen saturation. [74] The rationale for using pulse oximetry is that it diagnoses hypoxemia before the signs and symptoms become apparent. [75], [76] One study showed that trained anesthesiologists in a well-lit operating room, blinded to oximetry, failed to recognize most major hypoxic events (sustained desaturation to less than 85%), including a number of patients with saturations below 72%. [75] Changes in respiratory rate and heart rate were seen in less than 15% of severe desaturations. A number of investigators have found that changes in respiratory rate or depth, as well as level of sedation, are poor indicators of hypoxemia or CO_2 retention during endoscopy, [21], [28], [77] so that even apparently awake and normally breathing patients may have severe respiratory depression. Pulse oximetry provides an early warning of impending respiratory failure (long before clinical observation) and thus allows the endoscopist to withhold sedation, stimulate the patient physically or verbally, and, if necessary, administer antagonists to reverse hypoventilation or manage the airway before clinically dangerous hypoxemia occurs.

Some endoscopists have resisted the notion that oximetry may be beneficial in endoscopy. [54], [55], [78] A retrospective survey from Switzerland, where pulse oximetry was rarely used (2.5% of procedures), claimed a minuscule cardiopulmonary complication rate (0.1%, with no deaths, in 115,200 endoscopies) and questioned the need for oximetry; the validity of complication data from such surveys, however, is questionable. Despite use of pulse oximetry, Iber and colleagues [79] reported a 7% incidence of major cardiopulmonary complications of sedation during endoscopy. In contrast, the prospective audit of endoscopy in the United Kingdom found a correlation between lack of monitoring and complications. [16] The controversy regarding use of electronic monitoring is fueled by a lack of studies assessing whether oximetry affects outcome in gastrointestinal endoscopy. Such a study is unlikely to be done in the setting of gastrointestinal endoscopy, owing to the relative rarity of adverse events and thus the huge numbers of patients necessary to detect a difference. A prospective, randomized evaluation of pulse oximetry in 20,802 patients undergoing primarily general anesthesia in the operating room was recently reported; using pulse oximetry resulted in a 19-fold increase in detection of hypoxemic events but did not significantly reduce rates of cardiovascular and respiratory complications. [80] However, in anesthesia, unlike endoscopy, airway and ventilation are actively controlled, in conjunction with oxygen supplementation, by trained practitioners not directly involved in the procedure. Pulse oximetry would be more likely to affect patient outcome in endoscopy, in which the patient is required to ventilate spontaneously while being given respiratory depressant drugs by less trained practitioners in a darkened room.

Finger pulse oximetry has a number of practical limitations: motion may cause false alarms when the probe becomes dislodged, and a displayed pulse waveform, or plethysmogram, is essential so that true desaturations can be distinguished from motion artifact (i.e., an arterial waveform correlates with the pulse). Pulse oximeters may be inaccurate with extreme hemodynamic disturbances such as shock or vasoconstriction. [74] As discussed, pulse oximetry may not reflect even severe hypoventilation (CO_2 retention) in a patient receiving supplemental oxygen. [21], [22]

Carbon Dioxide Monitors

Technical limitations presently make noninvasive CO_2 monitoring impractical. Although end-tidal CO_2 is a relatively accurate indicator of arterial $PaCO_2$ in endotracheally intubated patients undergoing mechanical ventilation, monitoring of end-tidal CO_2 through nasal cannula in a spontaneously breathing patient is grossly inaccurate and should not be used in gastrointestinal endoscopy or other settings to estimate arterial PCO_2. [74], [81] Its main utility during sedation and analgesia is to give a graphic display of respiratory rate, so that apnea can be detected in patients receiving supplemental oxygen. Although quite accurate [21], [22], [82], [83] and interesting from a research standpoint, transcutaneous CO_2 monitors are impractical for routine use because they require daily calibration and a 10- to 15-minute equilibration period on each patient. In a randomized controlled trial of CO_2 monitoring during ERCP, CO_2 monitoring effectively prevented the most drastic degrees of CO_2 retention. [21] There was little apparent difference in outcome of the patients as long as oxygen saturation was aggressively maintained with nasal oxygen. As with all studies of cardiopulmonary complications, enormous numbers of patients would be necessary to show a significant difference in clinical outcome.

Blood Pressure Monitoring

Assessment of blood pressure before, during, and after endoscopic procedures is generally considered to be a minimum requirement. [1], [3], [8], [84] Automated blood pressure monitors are being used more often during endoscopy, although their efficacy has not been documented. A prospective randomized study of 618 patients undergoing routine endoscopy found that blood pressure monitoring did not result in a difference in outcome. [68] In that study, patients with coronary artery disease were more prone to hemodynamic disturbances. Again, negative conclusions about the effect of monitoring on outcome are limited in a study of this sample size because adverse outcomes are rare.

During routine endoscopic procedures, blood pressure should be monitored about every 10 minutes. Under special circumstances, more frequent, automated blood pressure monitoring is advisable: blood pressure should be monitored every 3 to 5 minutes in patients with acute gastrointestinal bleeding; every 5 to 10 minutes in patients undergoing prolonged procedures, where hemodynamic disturbances are anticipated owing to higher than usual doses of sedatives; and every 5 to 10 minutes in patients with underlying cardiopulmonary disease who are less likely to tolerate severe fluctuations in blood pressure. Hypotension can be treated by withholding further benzodiazepines or narcotics, by giving intravenous fluids, or by giving reversal agents. Hypertension can be treated by giving more sedatives or analgesics if the patient is undersedated, by decreasing noxious stimuli such as looping of the endoscope, or by switching to a different agent such as droperidol if a prolonged procedure is anticipated.

Electrocardiographic Monitoring

Few specific guidelines have been established for use of electrocardiographic (ECG) monitoring during endoscopic procedures. Numerous studies have documented the occurrence of cardiac arrhythmias during endoscopy, particularly during periods of hypoxemia or tachycardia. Some hospitals require ECG monitoring for all patients undergoing sedation. Although not mandated, ECG monitoring during endoscopy is recommended in the following situations: known cardiopulmonary disease, older age, acute gastrointestinal bleeding, and prolonged procedures such as therapeutic ERCP. [1]

DRUGS FOR ENDOSCOPY

Although major therapeutic endoscopic procedures such as ERCP require sedation and analgesia, routine endoscopy and colonoscopy may be performed safely without sedation. [57], [84], [85], [86], [87], [88], [89], [90], [91], [92] and [93] Practice regarding sedation varies widely in different countries, perhaps related to cultural assumptions, socioeconomic conditions, and other factors. In the United States and the United Kingdom, sedation is widely used for colonoscopy and endoscopy [17], [20], [91]; in France, about 80% of colonoscopies are performed under general anesthesia [86]; whereas in Germany, [92] Finland, [87], [88] and Switzerland, [93] most examinations are carried out without sedation. Physicians' and nurses' assessments of patient satisfaction with sedation for endoscopic procedures correlate poorly with the patients' own assessments. [94], [95] A recent prospective study showed that both topical sprays and intravenous sedation independently improve patients' tolerance of and satisfaction with upper endoscopy. [93] Endoscopy is better tolerated by older than by younger patients, [84], [91] by men than by women, [84], [90], [91], [94] by patients without abdominal pain, [91] by patients with low anxiety scores, [90] and by patients who have had a previous endoscopy. [84] Clues to patient dissatisfaction with sedation for colonoscopy include higher education and longer procedures. [95] Particularly in those groups of patients shown least likely to tolerate upper or lower endoscopic procedures, sedation should be offered to reduce the psychological and cardiovascular stress, enhance tolerance, and improve compliance with subsequent endoscopies. [57] Patients with cardiovascular disease may require adequate sedation to prevent excessive cardiovascular stress; premedication reduces myocardial oxygen demand by attenuating the endoscopy-induced increase in blood pressure and pulse rate, resulting in a decreased rate-pressure product and decreased serum cortisol concentration. [70], [71] and [72]

Endoscopists must carefully appraise their end points for sedation. Patient requirements may be different for different procedures. For example, in upper endoscopy, the goal is usually sedation to alleviate anxiety, gagging, and cardiovascular stress; for colonoscopy, on the other hand, the primary requirement is analgesia to allow some tolerance for distention and endoscope looping. Choice of drugs should be tailored accordingly. Brief procedures such as outpatient endoscopy and most

colonoscopies can be achieved with minimal amounts of either sedation or analgesia, whereas therapeutic procedures such as complex therapeutic ERCP may require deep sedation so that the patient can remain comfortable and cooperative for a prolonged period of time. Another approach to sedation is to allow patients to administer their own sedation: several studies have shown that patient-controlled analgesia is a reasonable alternative to physician-controlled medication. [94], [96]

Topical Agents

Topical agents such as benzocaine (Cetacaine) and lidocaine are frequently sprayed in the pharynx for upper endoscopy. There is controversy regarding whether they improve patient tolerance, but two randomized, double-blind, placebo-controlled studies have shown significant decreases in patient discomfort during intubation and endoscopic examination and improved assessment of patients' tolerance by endoscopists. [93], [97] In one study, most patients indicated that they preferred to have their next endoscopy performed with topical anesthesia. [97] In contrast, another study suggested that topical anesthesia makes little difference in tolerance of the procedure. [98] It is likely that topical anesthesia will provide the most additional benefit in lightly sedated patients. In addition, gag response after topical anesthetic can be a significant predictor of patient tolerance. [99] To be effective, topical anesthesia must be delivered to the posterior pharynx and not merely to the tongue and mouth, sometimes requiring depression of the tongue with a tongue blade or finger. Systemic absorption of topically administered lidocaine has been documented, occasionally resulting in arrhythmias, seizures, and methemoglobinemia. [100] These complications are extremely rare, and in my opinion, carefully administered topical spray is a useful adjunct that may result in decreased necessity for systemic sedation.

Anticholinergics and Antispasmodics

Anticholinergics such as atropine are sometimes used to decrease oral secretions or prevent vasovagal reactions, but they are of uncertain value and have significant potential side effects. A randomized, controlled trial of atropine before colonoscopy showed no statistically significant difference with respect to number or severity of vagal episodes, and neither the endoscopist nor the patients noted any difference in ease or tolerance of the procedure. [101] Atropine may exacerbate the tachycardia that often accompanies upper endoscopy, [102] thus contributing to cardiovascular stress. A randomized, controlled study in pediatric patients found that addition of atropine during upper endoscopy provided no increase in safety or benefits but did decrease oxygen saturation. [103] It is thus recommended that atropine be used only to counteract vasovagal episodes when they occur.

Antispasmodics such as hysoscyamine butylbromide [104] and hysoscyamine sulfate [105] have been shown to be useful in premedication for colonoscopy, with better patient tolerance and easier colonoscope insertion. In contrast, antispasmodics were shown to be of no benefit for flexible sigmoidoscopy. [106] Tachycardia is a potential side effect of these medications.

Benzodiazepines

Benzodiazepines are the most widely used sedatives for gastrointestinal procedures. They are a relatively safe group of drugs with a high therapeutic index. The two drugs used most commonly in the United States and the United Kingdom are midazolam (Versed) and diazepam (Valium). The pharmacology of benzodiazepines is summarized in Table 137-3. These drugs are best titrated using intermittent intravenous injection to achieve a degree of sedation that is considered clinically adequate. Midazolam is about fourfold to fivefold more potent than diazepam on an intravenous dose basis. Numerous studies have demonstrated the equivalency of these two drugs with respect to safety. [11], [18], [20], [48] Despite a significantly longer plasma half-life, recovery time after diazepam is not significantly longer than after midazolam. [11] Potential advantages of midazolam over diazepam include increased amnestic effect and a reduction in local pain and phlebitis on injection. [107] However, other randomized trials have not consistently demonstrated superiority of midazolam over diazepam. [108], [109] and [110] With both drugs, the dosage requirement decreases markedly with increasing age, an effect that may be more pronounced with midazolam than with diazepam. [6], [111]

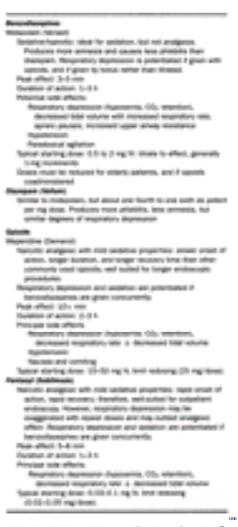

TABLE 137-3 Pharmacology of Commonly Used Sedatives and Analgesics

A starting dose of 0.5 to 2 mg of midazolam should not be exceeded. In older, sicker patients after a single intravenous dose of either drug, maximal central nervous system and respiratory depression are seen within 3 to 5 minutes; further increments, usually of 1 mg (or 0.5 mg in elderly or sensitive patients) can be titrated to effect. Risk for overdose increases significantly if an inadequate period of time (less than 2 to 3 minutes) is allowed between multiple intravenous dose administrations.

The major side effect of benzodiazepines, respiratory depression, results from blunting of central ventilatory response to CO_2 and peripheral response to hypoxemia. [44], [45], [48] Respiratory depression is usually mild when benzodiazepines are titrated carefully as sole agents [112] but is greatly potentiated by coadministration of opioids [113]; thus, doses must be reduced when narcotics are also used. Other side effects include hypotension and occasional paradoxical reactions with agitation and disorientation.

Opioids

Opioids such as meperidine and fentanyl are primarily analgesics with a mild sedative effect and are frequently combined with benzodiazepines to improve patient comfort and decrease the intensity of painful stimuli. The pharmacology of opioids is summarized in Table 137-3. The major side effect is respiratory depression, which is due to central depression of ventilatory response to CO_2 and results in CO_2 retention and hypoxemia due to decreased respiratory rate with or without decreased tidal volume. [47] Used alone, opioids improve tolerance in patients undergoing endoscopy. [71], [72] When used in combination with benzodiazepines, they may result in enhanced tolerance and even amnesia [114], [115] but greatly potentiate respiratory depression. [113] Meperidine (Demerol) is the opioid most widely used by endoscopists in the United States; fentanyl (Sublimaze) is widely used by anesthesiologists and small but increasing numbers of endoscopists. [17] There are significant differences between meperidine and the newer agents, such as fentanyl. Meperidine has a slower onset of opioid effect (5 to 10 minutes versus 2 to 5 minutes), and recovery time for meperidine may be significantly longer than with fentanyl, [115] requiring longer observation and recovery times. Meperidine might provide a slight margin of safety owing to more gradual onset of effects, including respiratory depression. [116] A disadvantage of fentanyl is cumulative respiratory depression with successive doses, despite rapid elimination from the plasma, which might result in dissociation between analgesia and respiratory depression. [47], [117] One study purported to show that meperidine was better than other opioid agents with respect to patient comfort and amnesia during colonoscopy, [115] but the doses of other opioids may not have been equivalent. Overall, fentanyl may be preferable to meperidine for outpatient endoscopy because of rapid onset and recovery. Meperidine is well suited to prolonged procedures such as extended colonoscopy or ERCP, in which gradual onset and sustained analgesia is desired.

Combination of Benzodiazepines and Opioids

Combinations of opioids and benzodiazepines are widely used in the United States [17], [18] and less often in the United Kingdom. [20] The combination of benzodiazepines and opioids results in additive or even synergistic effects. This results in improvements in the induction of anesthesia, [114] in the ability of patients to tolerate upper endoscopy from the physician's standpoint, and in the ability to complete the examination, but in little difference on the patients' reported tolerance of the procedure. [73] As already emphasized, the combination of benzodiazepines and opioids has been shown to cause significantly more hypoxemia and apnea than either class of drug used alone. [113] This phenomenon may explain the observation in two large surveys that additional use of opioids or combinations of agents has been associated with adverse cardiopulmonary outcomes of endoscopy. [12], [20] Therefore, continual vigilance in monitoring is essential when these drugs are coadministered. The doses of each class of drug need to be significantly reduced when used concurrently. It is generally advised to give the opioid first and to allow several minutes for the opioid to take effect before administering the benzodiazepine. [2], [118] The benzodiazepine should then be carefully titrated in smaller doses than when the drug is used alone.

Droperidol

Droperidol is a neuroleptic agent with antiemetic and anxiolytic properties that produces mild sedation and a sensation of indifference or detachment. Droperidol has been reported to be useful in sedating patients who are inadequately sedated with standard combinations or have paradoxical agitation. [119], [120] and [121] Droperidol does not appear to exacerbate opioid-induced respiratory depression [122] but may result in hypotension, so that automated blood pressure monitoring is advised. Droperidol is typically given in a dose of 1 to 2.5 mg, up to 5 mg. Many centers have found this agent to be useful in prolonged endoscopic procedures such as endoscopic ultrasound [120] and ERCP, [123] and in difficult-to-sedate patients, [121] particularly when the patient becomes restless or develops respiratory depression with standard doses of other medications. Randomized, controlled trials have shown that addition of droperidol to standard combinations of benzodiazepines and opioids during complex endoscopic procedures significantly improves patient- and physician-perceived tolerance of the procedure. [120], [121], [122] and [123] However, recent reports of rare serious arrhythmias have resulted in widespread restriction of its use.

Propofol

Propofol is a phenol-derivative short-acting anesthetic with a rapid onset of action. It is used widely in the anesthesia community both for the induction and maintenance of general anesthesia and for less deep stages of monitored anesthesia care. Propofol can be administered either by bolus injection or by continuous infusion. [124] There have been a number of recent reports of the use of propofol for gastrointestinal endoscopy. [125], [126], [127], [128], [129] and [130] Most of these studies have shown that compared with standard sedation with benzodiazepines and opioids, propofol results in improved tolerance of the procedure from both the physician's and the patient's point of view and in faster recovery times. However, the administration of propofol by nonanesthetists, as advocated by some endoscopists, is controversial. [8], [85], [86], [130] This agent has a very rapid onset of action, may result in unconsciousness within 30 seconds of administration, produces significant respiratory depression, [131] and acts synergistically with benzodiazepines [132] and opioids. [133] In one study, propofol administration for ERCP resulted in one case of prolonged apnea requiring mask ventilation. [133] It is notable that in virtually all of the published studies of propofol for gastrointestinal endoscopy, the drug was administered by nurse anesthetists or M.D. anesthesiologists, who, unlike gastrointestinal endoscopy unit personnel, have extensive training and experience with anesthetic administration and airway management, including emergency endotracheal intubation. Even anesthesia personnel find induction and maintenance of deep sedation with propofol without endotracheal intubation to be challenging at times. Although it is possible that gastrointestinal endoscopy unit personnel might be able to administer propofol safely in sufficiently small doses to achieve the light sedation necessary for colonoscopy or endoscopy, it is my opinion, as well as the opinion of a number of others in gastroenterology [85] and anesthesia, [130] that in general, the administration of propofol is best left to anesthetists.

Antagonists

Antagonists to both benzodiazepines and opioids (Table 137-4) are an essential part of the pharmacotherapy of sedation and should be available for immediate administration in all areas where sedation is used. They do not, however, substitute for careful administration of agonist agents and are likely to attenuate, rather than prevent, major complications.

***Flumazenil* (Romazicon)**
Reverses benzodiazepine-induced sedation smoothly, without autonomic stimulation. Effective in reversing benzodiazepine-induced component of respiratory depression.
Peak effect: 3–5 min
Duration of action: 1–2 h
Potential side effects
Resedation (more likely after high-dose benzodiazepine or combination sedation)
Seizures (only in benzodiazepine-habituated patients)
Typical dose: 0.2–0.5 mg IV for reversal of sedation; titrate to effect up to 1-mg total; 1–3 mg IV for benzodiazepine overdose
Naloxone (Narcan)
Reverses opioid-induced analgesia, CNS effects, and respiratory depression. Should not be used routinely because of high potential for untoward side effects. If given nonemergently, lowest possible doses should be used.
Peak effect: 1–2 min
Duration of action: 1–3 h (less than that of meperidine or fentanyl)
Potential side effects
Pain, agitation, nausea and vomiting
Tachycardia, arrythmias, sudden death (primarily in cardiac patients due to catecholamine release)
Pulmonary edema
Withdrawal syndrome in opioid-habituated patients
Typical dose: 0.04 mg (1/10 amp) IV for reversal of analgesia/sedation, titrate to effect 0.4 (1 amp) for narcotic overdose and respiratory arrest

TABLE 137-4 Reversal Agents

Flumazenil (Romazicon) is a benzodiazepine receptor antagonist (see Table 137-4). When given in adequate doses (0.2 to 1 mg), flumazenil reverses benzodiazepine-induced sedation within a few minutes, with minimal side effects. Earlier patient discharges are frequently possible after administration of this drug. [134], [135], [136] and [137] Flumazenil may also be useful to reverse paradoxical reactions to benzodiazepines. [138] There is a potential for resedation because its duration of action is significantly shorter than that of either midazolam or diazepam. In clinical practice, this is rarely a problem unless large doses of benzodiazepine or additional agents have been used. [44], [135] If respiratory depression or deep sedation occurred before administration of flumazenil, the patient should be monitored for extended periods of time (up to 2 hours). Reversal of ventilatory depression due to benzodiazepines is variable and may be delayed, [45], [135] especially if there has been coadministration of an opioid. [139] In patients given combinations of benzodiazepines and opioids, flumazenil effectively reverses the benzodiazepine component of ventilatory depression. [140] Flumazenil may provoke withdrawal or occasionally seizures in patients habituated to benzodiazepines.

Naloxone (Narcan) is the most widely used, and perhaps abused, opioid antagonist. In one large data base study, it was used in 8% to 14% of all endoscopies. [18] Although naloxone can effectively reverse respiratory and central nervous system effects of opioids, the degree and extent of reversal is dose dependent. [47] Naloxone has rapid elimination kinetics such that its duration of effect can be substantially less than that of the opioid, resulting in renarcotization. The major adverse effect of narcotic antagonists is that patients can experience severe pain and catecholamine release, resulting in increased risk for tachyarrhythmias and cardiovascular adverse events, particularly in patients with underlying ischemic heart disease. Unexpected sudden deaths have been reported in healthy patients receiving routine reversal of opioid anesthesia with naloxone. [47] Patients habituated to narcotics may experience severe withdrawal reactions. Therefore, routine reversal of opioid analgesia should be avoided. In a semi-elective situation, small doses (i.e., 0.04 mg, or 1/10 ampule) should be administered and repeat doses titrated to effect; a full ampule, or 0.4 mg, of naloxone should be reserved for emergencies such as respiratory arrest.

Overall Approach to Sedation and Monitoring

It is important to establish a rapport with the patient and explain the process of conscious sedation (see Table 137-2). This may help determine whether the patient

will be likely to cooperate and determine the level of sedation required. The type of procedure should influence the type and depth level of sedation; in general, diagnostic endoscopy usually requires mild sedation; colonoscopy relatively more analgesia; and therapeutic ERCP the most prolonged and deepest sedation to ensure cooperation. The patient's underlying illness and risk factors, particularly cardiopulmonary disease, should be assessed. Before administering medication, baseline vital signs, respiratory rate, and SpO_2 should be noted. Medication should be given in small increments. Clinical observation of the patients' response is a key in determining the subsequent titration of medication. If a combination of a benzodiazepine and an opioid is to be used, it is recommended to begin with an opioid. Before giving the next dose of medication, the patient should be observed for at least 2 minutes (and much longer between meperidine doses) to determine its effect. Whether or not an opioid is given, benzodiazepines should be titrated in small doses.

Prophylactic oxygen should be administered to those patients at higher risk, such as patients with known coronary artery disease or very elderly patients. Before administering further medication, it is useful to observe not only the patient but also the pulse oximeter; even alert and responsive patients may have significant respiratory depression, and on room air, the oximeter can be used as an early warning device. If oxygen saturation begins to decrease, regardless of the patient's appearance, further medication should be delayed. The patient can be stimulated verbally or if necessary physically to encourage breathing. If an SpO_2 below 90% persists more than transiently, nasal oxygen should generally be administered. After administering nasal oxygen, SpO_2 usually returns to baseline or above; further administration can be titrated carefully as needed, with the realization that this patient has declared a sensitivity with respect to respiratory depression from the medications administered. If after 30 to 60 seconds, nasal oxygen does not reverse hypoxemia or hypoxemia worsens, verbal or physical stimulation should be performed, followed by airway assessment, and assisted ventilation or administration of a reversal agent should be considered. If significant desaturation occurs while the patient is already on oxygen supplementation, then special caution must be taken. Even transient desaturation in patients on oxygen supplementation may indicate severe CO_2 retention, and further sedation should be limited or withheld. [21], [22] Such transient desaturation may be the only warning of an impending respiratory arrest.

In all cases after a procedure, patients should be carefully monitored, both clinically and with pulse oximetry and blood pressure monitoring, until they are responsive, oxygen saturation is persistently greater than 90% while breathing room air, and vital signs are stable. It is particularly important to continue monitoring of the patient into the recovery area because maximum hypoventilation and hypoxemia may occur after the procedure is completed.

CHAPTER 138

Guido N. J. Tytgat

UPPER GASTROINTESTINAL ENDOSCOPY

This chapter reviews the current status of upper endoscopy employed for diagnosis and treatment, and it discusses the use of flexible endoscopes with fiberoptic or video systems. Diagnostic considerations include when to use endoscopy, in which situations it is useful to the patient, how to use biopsy and cytology, and some new approaches to diagnosis. [1], [2] and [3]

In a section that introduces the technical aspects of endoscopy, followed by an analysis of indications, limitations, and pitfalls of upper intestinal endoscopy, some areas of interest are highlighted: dysphagia, gastroesophageal reflux disease, dyspepsia, peptic ulcer disease, upper gastrointestinal bleeding, and upper gastrointestinal neoplasia. This chapter also addresses the risks and contraindications of endoscopy to help the reader understand the cost-benefit analysis of a procedure compared with alternative diagnostic or therapeutic approaches. The final section considers speculations about endoscopy trends in the future and improvements in diagnostic and therapeutic modalities.

TECHNICAL CONSIDERATIONS

A variety of factors are necessary for safe and effective endoscopy. These include properly trained endoscopists; well-trained and clinically experienced assistants; high-quality, well-maintained endoscopic equipment; and a well-designed endoscopy suite containing all the necessary facilities and accessories for endoscopy and for emergency procedures that may occur during endoscopy.

It is mandatory to have equipment that goes to the bedside for endoscopy, especially for acutely ill patients in the intensive care unit. Adequate storage is essential for the many endoscopic accessories. There must be an area for endoscope disinfection and preparation of accessories for sterilization. It is critical to have an area in which to watch patients after endoscopy, especially if they have received sedation or have serious medical illnesses.

Performance of electrocautery requires state-of-the-art electrocautery units. All electric devices should be checked periodically for electrical safety by the hospital electrical safety team. Equipment to document the visual appearance of lesions is also strongly advised.

Fiberoptic Endoscopes

The critical part of a flexible fiberoptic endoscope is the fiber bundle that transmits a coherent image. The imaging bundle consists of several thousand thin glass fibers, 6 to 12 μm in diameter, that transmit light. Each fiber consists of an inner core of glass surrounded by an outer glass layer made of a second type of glass with a lower refractive index. Light entering the fiber reflects off the junction between these two types of glass and propagates down the fiber. A total of 10,000 to 40,000 fibers are grouped together to form the imaging bundle and generate a coherent image. The resolution of the imaging bundle depends on the diameter of the fibers. Fibers may break with excessive bending and torquing or during withdrawal of an accessory, particularly if the tip of the endoscope is flexed. A broken fiber appears as a black dot in the visual image.

The small image at the proximal or viewer's end of the coherent fiber bundle is enlarged with a 15× to 30× magnifying lens in the endoscope ocular. The image cannot be overly magnified because this would make individual fibers visible, interfering with image interpretation. Standard flexible fiberoptic endoscopes have a depth of focus that allows examination of objects 3 to 100 mm away from the tip. The field of view of the imaging system is up to 110 or 120 degrees. Special

high-magnification endoscopes are available.

Endoscope design includes the objective lens system, which focuses the target onto the fiberoptic image bundle; the light source, which illuminates the target; a nozzle for air insufflation; a nozzle for a water jet to clean the viewing objective lens; and a suction channel, which is used to remove gas and fluids and also to pass a variety of accessories by way of the endoscope into the intestinal lumen. Side-viewing endoscopes contain these same features but have a different design that allows the examiner to look sideways; the suction or accessory channel has an elevator, which can change the position of an accessory.

The endoscope control handle contains valves for air and water as well as suction and control knobs. These knobs are attached to wires that go down the length of the flexible insertion tube to the distal bending tip. By maneuvering these wires in an up-and-down or right-and-left direction, it is possible to turn the tip of the endoscope and inspect the entire lumen of the organ being evaluated. In most endoscopes, it is possible to turn the tip of the bending section more than 100 degrees (retroflex) to allow the inspection of surfaces such as the cardia of the stomach, which are difficult to see with the instrument in a straight position.

Endoscopes for the upper intestinal tract are designed to be torque stable. Clockwise or counterclockwise rotation of the control handle results in the same rotation of the tip. The flexibility of the insertion tube varies; often, it is more flexible distally and less flexible proximally.

Videoendoscopes

Videoendoscopy, introduced in the mid-1980s, has changed the field of endoscopy. Videoendoscopy is now used almost universally. The image is generated electronically using a charge-coupled device (CCD) located in the tip of the endoscope. These devices are about 3 mm in diameter.

The first videoendoscopes used a color wheel. Green, red, or blue light was sequentially sent down the illumination bundle of the endoscope and activated the CCD at the tip. It was possible to reconstruct a color image using the three sets of images generated by the colored lights. The videoprocessor displayed a full-color image of the gastrointestinal tract lining. Later videoendoscopes use a color chip that actually obtains the image in color on the tip of the endoscope. These devices use 30,000 to 850,000 pixels of resolution. [4] By incorporating high-pixel-density CCDs, high-resolution endoscopes provide greater mucosal detail. High-resolution endoscopes are capable of discriminating objects 10 to 70 µm in diameter, compared with the naked eye, which is capable of discriminating objects 125 to 165 µm in diameter. Other than the method of delivering the image, the videoendoscope is similar to a fiberoptic endoscope, with the same controls for air, water, and suction; knobs for up-and-down and right-and-left bending of the tip; and a suction channel to remove gas and fluid and to pass a variety of accessories to the tip of the endoscope. A therapeutic gastroscope with a 6-mm accessory channel has been designed for the removal of blood clots and debris. [5] There are also buttons on the videoendoscope control handle to activate videotaping, freeze the image, and obtain a photograph.

There are several advantages inherent in videoendoscopy: the control unit is located away from the endoscopist's face, reducing the chance of contamination by way of splatter from the suction port; everyone present in the room can watch the monitor; the image can be sent outside the room, and multiple television sets can be used for simultaneous observation throughout the hospital, elsewhere in the city, or even by way of satellite to another country; for complicated procedures, the assistants can better assist the primary endoscopist because they can watch the procedure on the monitor simultaneously; and images can be easily documented and stored for teaching or clinical follow-up. Digital images can now be recorded on magneto-optical disks. These images can be recalled from a central image storage system and sent to any location in the endoscopy service. The disks can be used for image processing and for management and reliable storage of endoscopic images and information. [6], [7] The video system is not sensitive to irradiation and is less sensitive to damage caused by bending and torquing than are fiberoptic imaging systems.

Passing the Endoscope

There are two methods of passing an endoscope perorally: the blind method and the direct vision method. The blind method involves passing the tip of the endoscope into the patient's mouth, through a bite guard if necessary, and advancing the tip of the endoscope to about 18 to 20 cm from the incisor teeth. The patient is asked to swallow, which opens the cricopharyngeal sphincter, and the tip of the endoscope is gently advanced into the proximal esophagus. This may be performed by simply bending the tip of the endoscope without placing one or two fingers in the patient's mouth to guide the tip. In some circumstances, one or two fingers may be used to keep the tip of the endoscope midline and guide the endoscope as it is advanced. Care should be taken to avoid a finger bite. The direct vision technique involves passing the endoscope through a bite guard and watching endoscopically to observe the anatomy of the hypopharynx as the tip of the instrument is advanced in the midline into the direction of the closed cricopharyngeal sphincter. The patient is asked to swallow, and under direct vision, the tip of the instrument is passed away from the epiglottis and larynx into the proximal esophagus. This technique is in general more advisable but is especially important in patients with distortion of the hypopharyngeal anatomy (e.g., tumor, prior surgery) or with a suspected proximal diverticulum, in whom blind passage might cause inadvertent injury to the proximal esophagus or perforation of the diverticulum. The direct vision technique also allows an inspection of the hypopharyngeal anatomy. Detailed knowledge of the hypopharyngeal anatomy is mandatory to identify both pyriform sinuses lining the entry to the esophagus. Small-diameter endoscopes (5.3-mm fiberoptic or 6-mm videoendoscopic outer diameter) can also be passed transnasally for unsedated esophagogastroduodenoscopy. [8] Such instruments have a 2-mm accessory channel and are occasionally used for screening office endoscopy.

Most experienced endoscopists prefer to hold the endoscopic controls (e.g., air, water, and suction valves; tip direction wheels) in the left hand. The right hand is used to advance the instrument and intermittently to come back to the endoscope control to turn the control wheels. Torquing the endoscope is accomplished by rotating the instrument control handle, which results in rotation of the entire shaft and tip of the endoscope.

Endoscopic Examination

The endoscopic examination is carried out under direct vision. The esophagus is studied from 20 to 40 cm. At 40 cm lies the ora serrata, which is the junction between the pearly stratified squamous mucosa and the redder gastric columnar epithelium. It is also possible to identify the level of the diaphragm by having the patient sniff. This is important for identification of a hiatal hernia. The esophageal folds can be seen to change with air distention. It is possible to recognize extrinsic pressure on the esophagus from adjacent structures such as the aorta and the left main-stem bronchus.

With slight angulation to the left and anteriorly, the endoscope is passed into the stomach. Air is insufflated to facilitate gastroscopy. The fluid in the gastric pool is aspirated to improve endoscopic inspection and to reduce the likelihood of regurgitation and aspiration during the procedure. It is important to notice the presence of food, bile, or blood in the gastric fluid pool. The gastric mucosa is inspected, and observations are made about the amount of mucus, mucosal appearance, erythema, defects, fold thickness and pliability, and the appearance of blood vessels. Normally, it is not possible to see blood vessels except when the stomach is overdistended with air. The gastric folds begin in the upper portion of the stomach and extend down to the entrance into the antrum. With gentle distention of the stomach, these folds often flatten.

Endoscopy of the stomach is not complete without a careful retroflexion examination in which the tip of the endoscope is bent more than 180 degrees. This retroflexion, together with endoscopic rotation, allows inspection of the lesser curvature, cardia, and fundus. A lesion such as a tumor, Mallory-Weiss tear, or ulcer is often not seen in these areas unless the endoscope is retroflexed. Retroflexion also permits inspection of a hiatal hernia. After retroflexion, the instrument can be rotated clockwise and counterclockwise and gently moved in and out to inspect the entire area of the cardia, lesser curvature, and fundus.

The incisura angularis is a fold that marks the entrance to the antrum. The fold is located on the lesser curvature of the stomach. The mucosa in the antrum does not have rugal folds. Peristalsis begins in the midbody and progresses downward; the frequency is about three contractions per minute. These contractions progress to the pylorus and stop. The pylorus is usually open at rest, but it closes as the contraction wave reaches it. It is useful to watch several contraction waves as they progress toward the pylorus to determine whether there is an area of wall that is less pliable, suggesting an inflammatory or neoplastic infiltration. Peristalsis may be weak or absent in a heavily sedated patient.

After thorough gastric inspection, the tip of the endoscope is placed through the pylorus into the duodenal bulb. It is sometimes necessary to create a loop along the greater curvature before the tip of the endoscope can progress to and through the pylorus. With most end-viewing endoscopes, the entire surface of the duodenal bulb can be inspected. With a small-caliber endoscope, it is possible to inspect the fornices. The endoscope is passed beyond the apex of the duodenal bulb into the second descending portion of the duodenum. Passage from the tip of the bulb into the descending duodenum is often possible under direct vision but occasionally requires looking to the right and down and advancing the instrument gently, even though it is not possible to see the lumen until the tip of the instrument enters the descending duodenum. The duodenal bulb is usually free of folds; duodenal Kerckring folds begin in the descending portion of the duodenum. The endoscope is withdrawn, inspecting the mucosa of the duodenum, stomach, and esophagus. With a cooperative patient, it is often possible to inspect the larynx and hypopharynx

as the instrument is withdrawn.

In transnasal esophagogastroduodenoscopy, a small-caliber endoscope is passed through the most patent side of the nasal cavity after local application of lidocaine gel and a nasal decongestant. After inspection of the pharynx, the scope is introduced into the esophagus after traversing the upper esophageal sphincter under direct vision. Following evaluation of the esophagus, the stomach and duodenum are entered and evaluated. [9]

ACCESSORIES AND METHODS FOR SPECIAL APPLICATIONS

During endoscopy, to increase diagnostic information beyond the visual appearance, a variety of endoscopic accessories can be passed down the biopsy channel. These include measuring devices, biopsy forceps, cytology brushes, needles for cytologic puncture or injection therapy, Doppler probes, probes to obtain an ultrasound image, and probes capable of measuring electrical activity or the pH of fluid at the tip of the endoscope.

Biopsy Forceps

Although all biopsy forceps are similar, they vary in diameter, in whether a central spike is present to impale the tissue and thereby improve the sample size, and in whether the cups are closed or fenestrated [10] (Fig. 138-1). Gentle manipulation is required because excessive force on the control handle can break the forceps. As with other endoscopic accessories, it is important to ensure that the forceps are functioning properly before use. Forceps are available for single or multiple biopsies. Forceps are reusable or disposable.

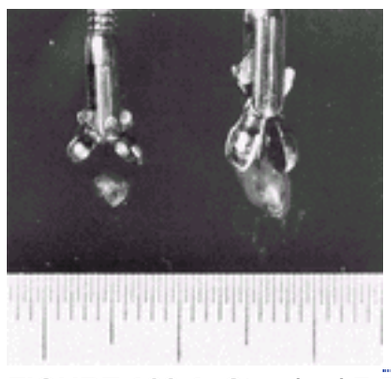

FIGURE 138-1. Standard 7-French (2.3-mm) and large-caliber biopsy forceps.

After obtaining the biopsy specimen, the tissue is removed from the cup, often using the tip of a toothpick. It is possible to orient this material on a mesh to improve the diagnostic quality of the specimen. The larger biopsy forceps are useful to obtain a larger surface area and volume specimen, which may be helpful for diagnosis in gastric lymphoma or linitis plastica.

Most endoscopic forceps obtain mucosa and, occasionally, a small amount of submucosa. To sample more deeply into a lesion such as a submucosal tumor, needle cytology may be applied, or repetitive sampling with a large biopsy forceps should be made in the same area. Another technique for obtaining larger samples involves turning the endoscope toward the mucosa and suctioning the mucosa into the open biopsy forceps to impale the tissue. This turn and suction or aspiration biopsy technique provides a more adequate size of tissue sample. [11]

Alternatively, a large-particle biopsy may be obtained using a polypectomy snare. The snare is placed over the fold or polypoid area, tightened, and gently pulled away from the wall. Prior injection of saline or diluted adrenaline in the submucosa may lift the mucosa to facilitate snaring and to prevent deep mural damage. As the snare is pulled through the lesion, the electrosurgical current causes coagulation and prevents bleeding (Fig. 138-2).

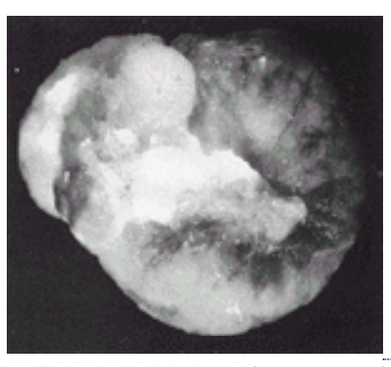

FIGURE 138-2. A large-particle biopsy specimen of a large gastric erosion was taken with an electrosurgical snare.

The lift-and-cut biopsy technique uses an endoscope with two channels to pass a forceps and a snare. The snare is opened, and the forceps is directed through the snare. The tissue is grasped by the forceps and pulled up into the snare. The snare can be tightened, and the tissue can be excised with electrocautery. This technique may result in unexpectedly large, deep biopsy specimens and is not recommended for the inexperienced endoscopist.

Tissue may also become available for histopathological examination through endoscopic mucosal resection (EMR). [12], [13] Most EMR techniques incorporate a submucosal injection to separate the lesion from the muscularis propria. Saline with or without epinephrine is commonly employed. EMR may be carried out using an endoscope fitted with a straight or oblique rimmed transparent cap. A polypectomy snare is passed down the accessory channel and opened inside the rimmed cap. The lesion is suctioned into the cap and the snare tightened around the lesion. The snare is then advanced out of the cap so that the extent of the captured mucosa can be confirmed before transection.

Cytology Brushes

Cytology brushes are used to obtain cell samples from the surface of a lesion for cytologic study or for examination of an exudate to detect, for example, the presence of *Candida*. These brushes are often protected by a plastic overtube or sheath, which allows the examiner to advance the brush out of and pull it back into the sheath. The sheath prevents loss of material and oropharyngeal contamination of the specimen because it covers the brush as it is removed. After removal of the cytology brush from the endoscope biopsy channel, the mucus and fluid are placed on a glass slide and into Carnoy solution or another appropriate fixative solution. [14] These brushes are disposable or can be sterilized. Cytology brushing is especially important in areas that are inaccessible for biopsy, such as narrow strictures in the esophagus.

Material can be aspirated for cytologic examination using an endoscopic needle technique. A 4-mm long, 23-gauge sclerotherapy needle can be placed into the target, such as a submucosal tumor or an ulcerating malignancy, to obtain cellular material from below the mucosa or below the surface exudate, adding to the diagnostic yield of biopsy and brush cytology. [15]

Measuring Devices

Occasionally, it may be important to know the actual size of a target. Endoscopic estimation is often inaccurate. The closer the tip of the endoscope is to the target, the larger the target appears. Measuring methods include using open biopsy forceps with a known distance between the tips of the biopsy cups, using a spring-type measuring probe with gradations of known length, and using a projected grid obtained by employing an argon laser that allows the examiner to see the contour of the target. When image processing is used to correct for distortion, a significant decrease in error can be obtained in vivo. [16]

Measuring Mucosal Blood Flow

Several devices can be passed down the accessory channel to study blood flow and distribution. Doppler ultrasound probes (Fig. 138-3) can detect the flow in blood vessels below the mucosa, such as varices, or in an artery in the base of an ulcer. Doppler devices can be used before and after endoscopic hemostatic therapy, such as injection or thermal therapy for an artery in the base of an ulcer. The Doppler probes have a circumferential radiating pattern (i.e., Doppler signal) and have a controllable depth of acoustic interrogation. [17], [18], [19] and [20] It is also possible to use a laser Doppler device to measure mucosal red blood cell velocity, a parameter thought to correlate with mucosal blood flow. The acoustic and laser techniques require the probe to touch the target mucosa. [21], [22]

FIGURE 138-3. A Doppler ultrasound probe is passed through the instrumentation channel of a side-viewing endoscope.

Reflectance spectrophotoscopy can also be achieved by passing a probe to touch the mucosa gently and measure mucosal oxygen saturation and hemoglobin concentration. [23] Videoendoscopes can be used to calculate the red-to-green signal ratio and estimate mucosal blood hemoglobin. [24] This method assumes that hemoglobin is the predominant light-absorbing pigment in the mucosa and that the degree of absorption of light is proportional to the amount of hemoglobin present.

Endoscopic Ultrasonography

Endoscopists are limited to inspection of the mucosal surface. By combining endoscopy with ultrasound, it is possible to look below the surface at lesions of the intestinal wall and at lesions involving adjacent structures. There are two approaches to this combination of technologies. In the first approach, the endoscope has an ultrasound device built into the tip of the endoscope. In the second approach, an endoscopic catheter is passed down the biopsy channel of the endoscope (see Fig 138-3). Puncture of tissue using ultrasound guidance allows histological and cytologic samples to be obtained from wall abnormalities or possible metastases to adjacent lymph nodes and various therapeutic interventions. [25], [26], [27] and [28] Endoscopic ultrasonography is discussed in Chapter 154.

Chromoscopy

Dye scattering (i.e., chromoendoscopy) is an in vivo technique in which dye is scattered on the mucosa to study and outline the fine detail of the target structure or to enhance the ability to detect a particular lesion (contrast or relief staining endoscopes) or in which the dye is absorbed by certain cell types (vital staining). [29], [30] and [31] The dye solution can be swallowed by the patient before endoscopy, or the dye can be sprayed against the mucosa using a catheter passed down the biopsy channel of the endoscope. The dyes most often reported to be useful are 1% to 3% Lugol solution, 1% to 2% methylene blue, 0.2% to 0.3% indigo-carmine, 1% to 2% toluidine blue, and 0.3% Congo red. Before using any of these dyes, it is necessary to reduce mucus. This is often accomplished using a solution of dimethyl polysiloxane, sodium bicarbonate, and pronase. A 10% solution of *N*-acetylcysteine can also be used before spraying the dye. [32]

Contrast Chromoendoscopy Dyes can be used to accentuate minute alterations in mucosal architecture by accumulating in normal or abnormal mucosal structures, indentations, crevices, or irregularities and accentuating small lesions. This is best achieved using indigo-carmine or methylene blue (Fig. 138-4; see also Color Fig. 138-4).

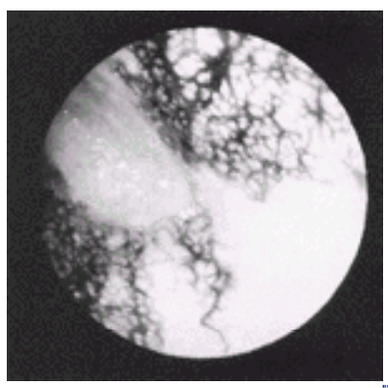

FIGURE 138-4. (See Color Fig. 138-4.) Gluten enteropathy with total villous atrophy. Mosaic appearance of the mucosal lining, accentuated by methylene blue entering deep mucosal crevices.

Vital Staining The dye is absorbed by epithelial cells but may also penetrate necrotic tissue. One or 2 minutes after spraying, the mucosa is washed with water, and the surface can be observed. Lugol solution stains intracellular glycogen in nonkeratinized squamous epithelium. Metaplastic columnar epithelium in the esophagus or injured squamous mucosa does not stain. Esophageal cancer and high-grade dysplasia do not stain with Lugol solution. Methylene blue dye when used for vital staining detects intestinal metaplasia, but not squamous epithelium, in the esophagus or intestinal metaplasia in the stomach. Congo red stains the acid-producing parietal cell mucosa; after the dye is acidified, it turns from red to dark blue. Because toluidine blue stains nuclear DNA more strongly than cytoplasmic RNA, dysplastic or neoplastic cells stain blue. Lugol staining is useful in looking for plaques overlying varices, studying the esophageal mucosa in patients with cancer of the head and neck and in those who are alcoholics and smokers, delineating neoplasms of the esophagus, and excluding a synchronous lesion or an area of dysplasia. Vital staining in the stomach may be useful in a nonhealing ulcer if early gastric cancer is suspected or to study an area of mucosal abnormality such as scarring or discoloration of the mucosal surface. Vital staining may help to detect or exclude areas of dysplasia or malignancy.

Removal of Foreign Bodies

In removing a foreign body, the endoscopist should ensure that the airway is not obstructed and should be certain that the foreign body does not injure the lining of the gastrointestinal tract. During removal of a foreign body, an overtube provides a degree of protection of the airway by preventing dropping of the foreign body during removal, but the only way to ensure complete airway patency is to use a cuffed endotracheal tube.

The mucosa can be protected, especially in the removal of sharp objects, by using an overtube to protect the intestinal lining during removal of a sharp foreign body. It is possible to remove foreign bodies with rigid and flexible endoscopes. Foreign bodies in the area of the hypopharynx and very proximal esophagus are often best removed with an open laryngoscope and grasping forceps. For other foreign bodies, flexible endoscopes are used, preferably with a large instrumentation channel (2.8 to 3.5 mm). The larger channel allows a variety of instruments to be used to grasp and hold the foreign body. These include baskets of the Dormia type, forceps for grasping the foreign body, and polypectomy snares. Alligator forceps with teeth are useful for grasping coins and other types of smooth objects. If an object is

irregular or soft, other devices, such as baskets, snares, and graspers with three prongs, can be used. [33] Experienced clinicians know that flexible endoscopes cannot remove all foreign bodies safely. An irregular, sharp object, an object with a ragged surface, or an object that is impacted in the wall (e.g., dental plate) may require a rigid laryngoscope or esophagoscope to be passed under general anesthesia for removal of the foreign body.

If the foreign body is sharp, a plastic overtube can be used on the endoscope [34] (Fig. 138-5). The endoscope can be withdrawn into the overtube while grasping the foreign body, which protects the mucosa from injury by the sharp foreign body as it is being removed. This also eliminates the possibility of dropping the foreign body in the hypopharynx, causing pulmonary aspiration of the object. The overtube is useful if the endoscope must be passed several times for removal of a foreign body, such as a piece of meat. An alternative to a plastic overtube is a simple latex protector hood fastened to the tip of the endoscope. [35]

FIGURE 138-5. A plastic overtube around the endoscope allows safe retrieval of sharp or pointed foreign bodies.

Most experienced endoscopists practice before attempting foreign body removal. A foreign body similar to that swallowed by the patient is manipulated with the type of instrument available to grasp the foreign body during endoscopy. This time spent in forethought and planning makes the foreign body removal safer and easier. [36]

Endoscopic Control of Upper Gastrointestinal Bleeding

Upper gastrointestinal bleeding is a commonly encountered problem in clinical medicine. For about 85% to 95% of these patients, a precise diagnosis of the cause of the bleeding can be obtained. For a few patients with massive hemorrhage, emergency surgery may be required. In most patients with bleeding, endoscopy can be performed as soon as the patient is stabilized hemodynamically. Endoscopic treatment of nonvariceal and variceal bleeding is discussed in Chapter 147 and Chapter 148.

Polypectomy

Polypectomy is accomplished using a wire snare placed over the polyp (Fig. 138-6) and tightened at the base of the polyp. Snares of a variety of sizes and shapes are available, including a symmetric ellipse, a hexagon, and a slightly hooked configuration. After the handle is closed, the tip of the snare should retract at least 1 cm into the plastic overtube. As the snare is tightened on the lesion, an electrocoagulative current is applied, alone or in combination with a cutting current, during the transection of the polyp.

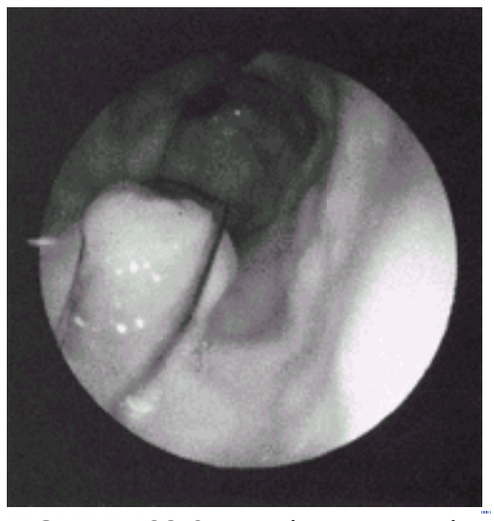

FIGURE 138-6. In polypectomy, the snare loop is positioned around the sessile, adenomatous, gastric polyp.

After the loop has been passed over the polyp, it may be helpful to advance the plastic tube around the wire snare to the spot on the polyp at which the snare will be closed. Thereby, it is possible to control where the transection occurs as the loop is closed. As polypectomy is accomplished, the endoscopist can see a whitish discoloration on both sides of the loop, which indicates that coagulation is taking place.

The complications with gastric polypectomy include hemorrhage and perforation. Because of the thickness of the gastric wall, perforation is unusual, but hemorrhage may be a significant problem. [37] The risk for bleeding is probably greater in large polyps with thick stalks. Injection of the stalk with epinephrine is recommended but may not always prevent bleeding. Mechanical hemostatic devices such as endoloops [38] or clips [39] can prevent bleeding after polypectomy.

Mucosal Resection

Removal of a focus of high-grade dysplasia or early malignancy in the upper intestinal tract through mucosal resection is increasingly performed. The technique is schematically illustrated in Figure 138-7. Usually, the lesion is first examined with endosonography to prove its superficial nature. In principle, the lesion should be limited to the mucosal layer. After proper localization with chromoscopy or fluorescence endoscopy, the lesion is lifted after submucosal injection of saline or diluted epinephrine. Thereafter, the lesion is aspirated, usually into a cap-fitted endoscope or a specially designed overtube, allowing positioning of a polypectomy snare around the aspirated tissue fragment. Transection follows with electrocoagulation, allowing the specimen to be retrieved for histopathological examination. [2], [40], [41], [42], [43] and [44]

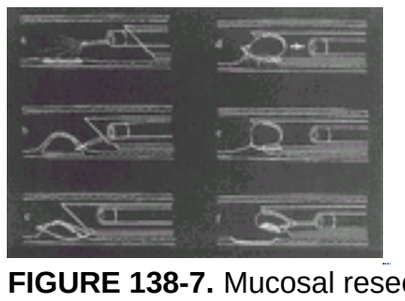

FIGURE 138-7. Mucosal resection of superficial malignancy. **A:** Dye spraying to delineate the lesion. **B:** Lifting the lesion by submucosal injection. **C:** Positioning of the snare. **D:** Aspiration of the polyp-like lesion in overtube. **E:** Transection of the lesion. **F:** Grasping of the transected lesion. (From ref. [40].)

Dilation

Flexible endoscopy is playing an increasingly important role in dilating strictures. Endoscopically passed guidewires are used to guide the tip of the dilating device, especially in treating diverticula, eccentric strictures, tight or tortuous strictures (Fig. 138-8; see also Color Fig. 138-8), and angulated strictures, such as those formed after surgical anastomosis. [45]

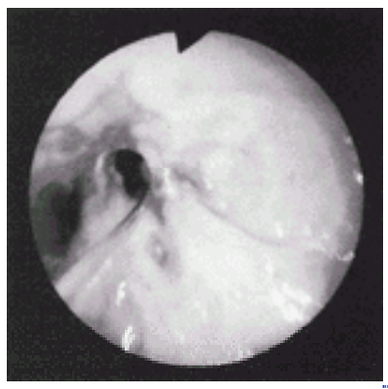

FIGURE 138-8. (See Color Fig. 138-8.) A guidewire has been passed through this eccentric, reflux-induced stricture.

The guidewire with a spring tip is passed by way of the endoscope. If the small-caliber endoscope can be passed through the stricture, the wire can be positioned under direct vision below the narrowed area. If it is not possible to pass the endoscope through the stricture, the wire can be passed under direct endoscopic vision in the stricture if necessary with further fluoroscopic monitoring to ensure that the wire is correctly placed. The guidewire and the spring tip should remain below the area to be dilated throughout the procedure. Several different types of dilators are available. It is also possible to pass catheters with balloon tips through the biopsy channel of an endoscope to dilate strictures. [46] These balloons vary from 4 to 20 mm in diameter when fully inflated. Some balloon catheters have a central channel that can be passed over a guidewire.

Pyloric stenosis is often dilated with through-the-scope balloons that are 3 cm long and have diameters from 9.9 to 17.8 mm (30 to 54 French). These balloons are best passed through a large-caliber instrumentation channel. It is mandatory to monitor passage of the balloon and its inflation with fluoroscopy to be certain that the waist of the balloon, representing the stricture, has been obliterated. [47]

Stents

In some patients with cancer of the esophagus, nonsurgical palliation with stents may be the preferred method of treatment (Fig. 138-9). Endoscopy is critically important to diagnose the malignancy, evaluate the degree of narrowing, measure the length of the tumor narrowing, and determine the distance from the top of the tumor to the incisor teeth, an important factor in placing the prosthesis.

FIGURE 138-9. Esophageal carcinoma before (**A**) and after (**B**) stenting with a Tygon endoprosthesis.

An endoscope usually cannot be passed through the lumen of a patient presenting with an obstructing tumor. In this circumstance, a guidewire is passed through the instrumentation channel under endoscopic guidance. Fluoroscopy is used to follow the tip of the guidewire until it enters the stomach and is positioned along the greater curvature. The endoscope is removed, and the guidewire can be used to dilate the malignant narrowing with metal olives, balloons, or bougies. After the length of the stricture is determined, the prosthesis length should be long enough to include 2.5 to 3 cm proximal to the narrowing and the same distance distal to the narrowing to prevent early restenosis by tumor.

Stents that can be placed in the esophagus include nonexpandable and expandable devices. Nonexpandable stents are inserted using an introducing device, which can be a balloon, a bougie, a Key-Med introducer, or a small-diameter endoscope. [2], [48] Expandable stents are increasingly the therapy of choice, and several covered and noncovered self-expanding metal stents (e.g., Wall, Gianturco, Ultraflex, Song) are commercially available. [49], [50] These devices are passed over a guidewire through the malignant narrowing, within a sheath covering the compressed stent. After the constraining sheath is released, the stent is left in place and expands. The expanding stents have the advantage of producing a wide lumen through the stenosing tumor mass without having to dilate the tumor before placement. However, these stents are difficult to remove or not removable. Stents covered by a silicone membrane may prevent tumor ingrowth.

Laser Tumor Ablation

An endoscope can be used to guide an Nd:YAG laser to open a lumen obstructed by tumor. It is preferable to start coagulating at the distal portion of the tumor so that this tissue can slough and pass down the gastrointestinal tract. This may require dilating the tumor before laser therapy. [51], [52] If it is not possible to dilate the tumor, it may be necessary to begin laser coagulation at the proximal margin. This is more difficult because it may not be clear where the lumen is, and tumorous tissue edema may impair passage of the endoscope to the more distal portions of the tumor. In general, the laser is applied in a circumferential pattern for a tumor that extends around the circumference of the esophagus. To avoid cavitation, the laser beam should not be focused on one spot for a long time. Treated areas appear necrotic and yellow-white. If the tumor does not slough spontaneously, this tissue is gently removed before further treatment with the laser.

An alternative method of applying laser photocoagulation is with contact laser probes, which use lower power. These probes have a tip made of ceramic or sapphire attached to the tip of the quartz fiber delivery system. For small tumors of the esophagus and stomach, photodynamic therapy may be used. A photosensitizing agent, such as a hematoporphyrin derivative, is injected intravenously and is taken up in high concentration in the area of the tumor. A light is used to activate the agent by

selecting an appropriate wavelength for the particular drug. This produces cytotoxic singlet oxygen, resulting in necrosis of the tumor. [53], [54]

Local Irradiation Tumor Therapy

Cesium or iridium can be used to treat a tumor using intracavitary radiotherapy. [55] This therapy requires precise positioning of the applicator into the area of the tumor. Endoscopy is used to place a guidewire, over which the applicator is passed. Fluoroscopy documents the exact locations of guidewire, applicator, and tumor. The applicator probe is fixed in position by attachment to a facemask. The patient is transferred to the treatment area, and the position of the applicator is confirmed by fluoroscopy before passage of the radioactive compound for therapy.

Thermal Tumor Therapy

Direct heat also can be used to treat tumors for palliation. One device for this application is a bipolar device located on a conventional olive dilator. [56] The bipolar electrodes are arranged as stripes around the entire circumference of the olive or a portion of the circumference. Diameters of the probes vary from 6 to 15 mm. A guidewire is passed endoscopically through the narrowed lumen, the endoscope is removed, and the tumor probe is passed over the guidewire. [57], [58] The distal tumor margin is treated by bringing the probe up into the tumor at distances appropriate to cause overlapping coagulation through the narrow tumor segment. Alternative therapies include the use of the argon plasma coagulation device.

PATIENT PREPARATION

Before endoscopy is performed, patients should be asked about relevant medical illnesses, previous endoscopic or radiologic procedures, previous gastrointestinal surgery, and medications, especially those that may be related to gastrointestinal tract inflammation or irritation or interfere with coagulation. It is essential to know whether the patient has a history of dysphagia because this may give an indication that the person has a Zenker diverticulum, another type of diverticulum, or a history of aspiration. Aspiration suggests a fistula in a patient with a cervical or thoracic malignancy or inflammatory disease.

The physician should know about bleeding tendencies in the patient or the patient's family and about any history of drug allergies. If there is a history of bleeding abnormalities, a clotting screen with a prothrombin time, partial thromboplastin time, platelet count, and bleeding time is indicated. If there is evidence of chronic liver disease or other hematologic disorder, it is important to check coagulation.

Diagnostic endoscopy with biopsy is usually safe in patients who are taking oral anticoagulants or aspirin. However, for a patient who is to be treated with electrocoagulation for polypectomy or hemostasis, anticoagulants should be discontinued before the endoscopic procedure and for as long as 2 weeks after the procedure to prevent delayed bleeding. Aspirin-containing compounds and other antiplatelet agents such as nonsteroidal antiinflammatory drugs (NSAIDs) and ticlopidine should be avoided for an appropriate interval (i.e., aspirin for 7 to 10 days; NSAIDs for 2 to 3 days) before an endoscopic procedure that may involve removal of tissue. [59]

Most patients begin fasting after midnight the evening before the endoscopy. The patient should have no liquids for 4 hours before endoscopy and no solids for at least 6 to 8 hours beforehand. Patients with gastric outlet obstruction may be kept on a clear liquid diet for 24 to 48 hours, and lavage of the stomach with a large-bore tube may be necessary to remove retained stomach contents.

The patient must provide written or verbal informed consent before the procedure. Medications may be given before upper endoscopic procedures to anesthetize the posterior pharynx, reduce anxiety, [60] reduce discomfort, and diminish motility and secretions. Which medications are used depends on the clinical situation, including the patient's age, the existence of debilitating diseases, the anxiety level of the patient, the medication, and the patient's history of alcohol use. Upper gastrointestinal endoscopy is almost never performed with general anesthesia, with certain exceptions, such as removal of foreign bodies in small children.

For endoscopic procedures that are expected to be brief and in which small-caliber or pernasal endoscopes are used, no intravenous sedation may be necessary unless the patient is anxious. For therapeutic procedures that involve larger-diameter instruments and longer periods, the patient is usually given intravenous sedation. [61]

Bacteremia may be associated with endoscopic procedures. In a patient with a preexisting heart condition, there may be risk for infectious endocarditis, although this risk is small. The efficacy of antibiotic prophylaxis for endocarditis is unproven, although prophylaxis appears to be effective in patients with prosthetic valves, surgically constructed systemic-pulmonary shunts, and hypertrophic cardiomyopathy. [62], [63] and [64] Prophylactic antibiotics are advised for patients with known endocarditis or prosthetic cardiac valves. For gastrointestinal endoscopic procedures, the standard regimen is 2 g of ampicillin, administered intravenously or intramuscularly, plus gentamicin (1.5 mg/kg, not to exceed 80 mg), administered intravenously or intramuscularly 30 minutes before the procedure, followed by 1.5 g of amoxicillin taken orally 6 hours after the initial medication. Alternatively, the parenteral regimen may be repeated once at 8 hours after the initial dose.

INDICATIONS FOR UPPER ENDOSCOPY

Endoscopy is a highly accurate method of evaluating the mucosal surface of the esophagus, stomach, and duodenum. In addition to the various indications discussed in this section and summarized in Table 138-1, endoscopy is used to evaluate the patient with upper gastrointestinal symptoms before barium radiography is performed. This approach is referred to as *primary panendoscopy*. [65], [66], [67], [68], [69], [70], [71], [72], [73], [74] and [75] In many centers, the cost of this primary endoscopy is reduced because it can often be performed quickly and without any sedation.

Persistent or recurrent dyspepsia or heartburn	
Persistent nausea or vomiting	
Dysphagia or odynophagia	
Hematemesis or melena	
Early satiety or anorexia with weight loss	
Chest pain with negative results on cardiac evaluation	
Iron deficiency anemia with negative results on colon evaluation	
Caustic ingestion	
Suspected malabsorption (for small bowel biopsy)	
Failure to lose weight or recent weight gain after surgery for obesity	
Abnormal or equivocal barium meal radiographic studies	
Mass lesion	
Abnormal fold pattern	
Ulcer crater in esophagus or stomach	
Esophageal or gastric outlet stricture or obstruction	
Deformity or scar in a symptomatic patient	
Survey for Malignancy	
Barrett esophagus	
Familial polyposis or Gardner syndrome	
Follow-up of adenomatous gastric polyp	
Inadequately treated achalasia	
Therapeutic Endoscopy	
Control of bleeding	
Ligation or sclerosis of varices	
Dilation of stricture or narrow stoma	
Percutaneous gastrostomy	
Polypectomy	
Stenting an esophageal tumor	
Laser or tumor probe cauterization of a tumor	
Removal of foreign body	
Placement of feeding tube in the duodenum	
Follow-up Endoscopy	
Gastric or esophageal ulcer, healing or biopsy	
Ligation or sclerosis of varices	
Laser or tumor-probe cauterization of a tumor	
Removal of internal gastrostomy bolster

TABLE 138-1 Indications for Upper Gastrointestinal Endoscopy

Dysphagia

Dysphagia is an important symptom in gastroenterology that mandates a full evaluation, and endoscopy is critical in the evaluation of these symptoms. [76] Some endoscopists think a barium esophagogram should be performed before endoscopy, but endoscopy is increasingly used as the first diagnostic test in a patient with dysphagia. In a patient whose symptoms suggest dysphagia caused by Zenker diverticulum, it is essential to have a barium esophagogram study before endoscopy to avoid injury to the diverticulum during passage of the endoscope. Endoscopy in patients with a Zenker diverticulum may be difficult and dangerous because the esophageal lumenal opening becomes almost invisible. To avoid perforation of the diverticular sack, it may be wise first to insert a soft nasogastric tube through the

nose and to use the latter as a guide to locate the laterally displaced esophageal lumen. Endoscopic incision of the septum between esophagus and diverticulum proves to be an efficient and safe method for treating symptomatic disease, especially in high-surgical-risk patients. [77], [78]

If a patient has symptoms referable to the pharynx or neck, enlarged cervical lymph nodes, or neck pain, evaluation should be done first with direct inspection of the larynx, pharynx, and nasal passages. Flexible endoscopy is of limited value in examining the pharynx and hypopharynx. It is possible to view lesions that cause dysphagia endoscopically, including reflux-induced strictures (see Fig. 138-8), caustic injury strictures, strictures resulting from radiation, achalasia, and benign (Fig. 138-10; see also Color Fig. 138-10) and malignant tumors.

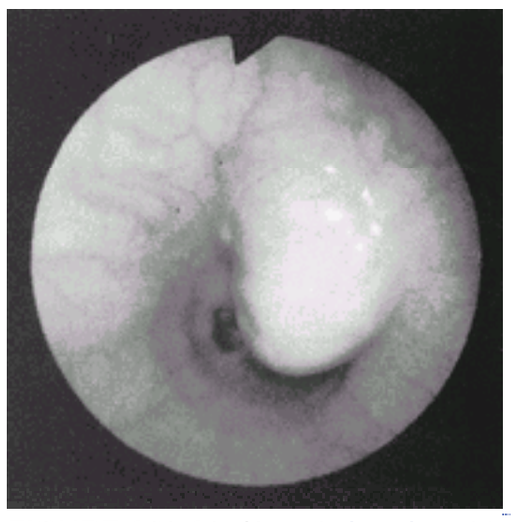

FIGURE 138-10. (See Color Fig. 138-10.) Esophageal leiomyoma.

Esophageal Cancer

A patient often presents with esophageal cancer after the malignancy is far advanced. Advanced cancers have three morphologic appearances. A tumor that is nodular and friable with a hemorrhagic surface with ulcers or erosions is referred to as *exophytic* and has a wide base (Fig. 138-11; see also Color Fig. 138-11). The second type of tumor, in which the lesion is an ulcer with heaped-up surrounding edges, is referred to as *ulcerative*. The third morphologic presentation is a thickened, rigid length of esophageal wall caused by infiltrating cancer, referred to as *infiltrating,* in which the mucosa is often nodular and appears fixed.

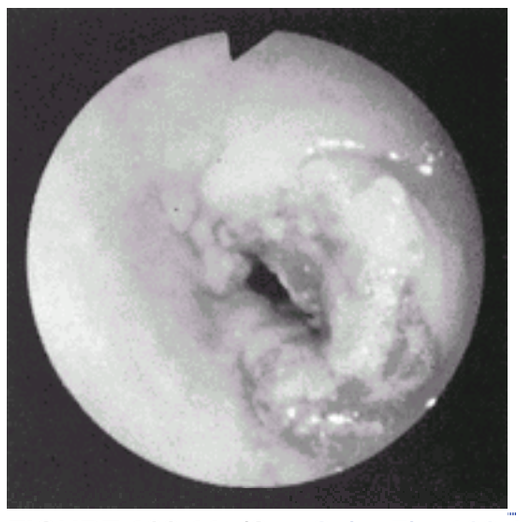

FIGURE 138-11. (See Color Fig. 138-11.) Esophageal carcinoma obstructs the esophagus.

The diagnosis of esophageal cancer requires multiple endoscopic biopsies. Obtaining tissue for a good histological examination is occasionally difficult because of overlying inflammatory exudate, but in most polypoid tumors, biopsies are positive because the proximal tumor edge is visible and can be directly targeted. If the approach to the lesion is tangential, it may help to use biopsy forceps with a central spike. An alternative is to use needle cytology. If nodular lesions are proximal to the main lesion, a biopsy should be performed because such lesions may represent intramural metastasis from the primary tumor.

If the lesion appears as a narrowing or stenosis, it may be difficult to obtain positive biopsy specimens. In this instance, multiple biopsies and brush cytologies may be necessary to make a precise diagnosis. There are two approaches to obtaining tissue from the narrowed area. The first is to use a small-diameter endoscope, which can be passed through the stenotic segment and can obtain biopsy specimens from the entire length of the stenosis. If the stenosis is too tight to permit even a small-caliber endoscope, it may be possible to obtain brush cytology samples from the narrowing and perform a biopsy at the proximal edge. The second approach is to perform dilation of the narrowed segment before performing biopsy and cytology procedures. By dilating up to a diameter of 10 mm, it is possible to pass a small-caliber endoscope through the length of the lesion and obtain biopsy specimens from the proximal and distal edges and along the length of the stenosis.

Overall, a correct diagnosis of esophageal cancer is made in more than 90% of patients if six or more biopsies are performed and if cytologic samples are examined. Multiple biopsies are especially important if there is a large amount of necrotic tumor and exudate. [1]

Gastroesophageal Reflux Disease

Not all patients with esophageal reflux symptoms require endoscopy. If a patient has a chronic or intermittent symptom complex, if the symptoms are not controlled using standard antireflux measures, or if the symptoms occur at night and cause difficulty with coughing, hoarseness, and aspiration, endoscopy may be indicated. Of the patients who present with reflux symptoms, about one half have endoscopic evidence of mucosal injury in the distal esophagus (Fig. 138-12; see also Color Fig. 138-12). The purpose of endoscoping the patient is to detect this injury, to grade the severity of acid-pepsin or bile-induced injury, and to detect esophageal columnar metaplasia in the distal esophagus.

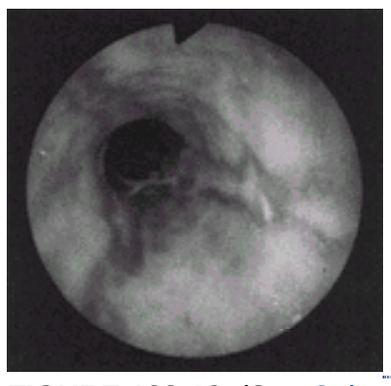

FIGURE 138-12. (See Color Fig. 138-12.) Reflux esophagitis with confluent but noncircumferential breaks or erosions.

It is possible during endoscopy to diagnose a hiatal hernia. The level of the diaphragmatic impression must also be located, if necessary by having the patient sniff during assessment. If, during quiet observation without excessive distention of the esophagus with air, the gastroesophageal junction is more than 2 to 3 cm above the diaphragm, this condition is thought to represent an axial hiatal hernia. The hernia appears endoscopically to be a pouch or widening lined with gastric folds just below the mucosal junction and just above the diaphragm. After the instrument is passed into the stomach and is retroflexed, it is possible to examine the cardia from below and diagnose a hiatal hernia.

Grading of reflux mucosal injury may be accomplished by several schemes, but the modified Savary and the Los Angeles systems [79], [80] and [81] are now often used. One difference between the various systems is whether minor or equivocal changes are included. These changes include erythema, friability, and blurring of the ora serrata.

The sentinel fold or polyp is an abnormality found in some patients with a hiatal hernia. It is a fold with a polypoid proximal margin that is located just distal to the squamocolumnar junction. There is often a small erosion or ulcer on the proximal tip of the fold, which may be seen in a patient with a hiatal hernia and reflux.

Esophageal Columnar Metaplasia

Esophageal columnar metaplasia, also called Barrett metaplasia, is a change in the normal appearance of the esophagus; the mucosa that is normally stratified squamous is replaced by a columnar mucosa. The normal ora serrata or squamocolumnar junction is located more proximally in the esophagus. The only way to determine the anatomic junction of the esophagus and the stomach is that this junction occurs just proximal to the gastric folds. [82], [83] and [84] The distance from the proximal margin of the gastric folds to the squamocolumnar mucosal transition does not vary and should be consistent from one endoscopy to the next.

If the distance from the squamocolumnar junction to the proximal gastric folds in a hiatal hernia is longer than 2 to 3 cm, it usually means that there is a segment of columnar metaplastic mucosa (Fig. 138-13; see also Color Fig. 138-13). A short segment is diagnosed when less than 2 to 3 cm of specialized or intestinal-type columnar metaplastic epithelium is found.

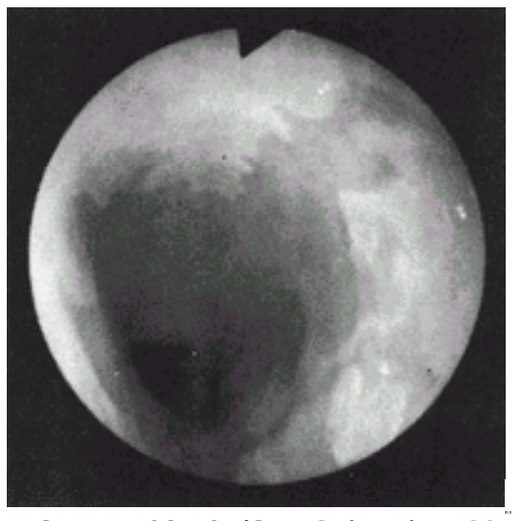

FIGURE 138-13. (See Color Fig. 138-13.) A columnar mucosa–lined esophagus, also known as Barrett esophagus.

Biopsy is not routinely performed in patients with esophageal reflux symptoms unless columnar metaplasia is suspected. In a patient with reflux esophagitis, periodic endoscopy is not required. Exceptions are patients who have not responded to therapy, especially if they have severe esophagitis, and patients who are to undergo any surgery for reflux, in whom presurgical endoscopy is indicated.

Dyspepsia

The symptom complex known as dyspepsia includes pain, burning in the epigastrium, nausea, epigastric fullness, and bloating or distention. Only about one of five patients who present with these symptoms actually has a peptic ulcer. It is now accepted that upper endoscopy is the first-line investigation for patients presenting with significant dyspeptic symptoms. It may be difficult for the clinician to decide whether endoscopy is appropriate. Gastric malignancy and peptic ulcer disease are rare in the dyspeptic patient younger than 45 years of age unless infected with *Helicobacter pylori* or taking NSAIDs. Diagnostic endoscopy might be limited to the latter patients. Now that effective anti– *H pylori* treatments are available, it might be argued that young *H pylori*–positive dyspeptic patients would be better managed by empiric treatment of the infection rather than by referral for endoscopy first. [85], [86]

In some patients with dyspepsia, endoscopy may show patchy erythema, subepithelial hemorrhage, or erosions without distinct ulceration (Fig. 138-14 and Fig. 138-15). Erosions typically have a white base surrounded by a rim of erythema. In evaluating a patient with chronic dyspepsia, not uncommonly resistant to empiric therapy, mucosal biopsies may be taken from the gastric antrum and the corpus. [87], [88] Whether all chronic dyspeptic patients or only those with erosive abnormalities should undergo biopsy remains a controversial issue. *H pylori*–associated inflammation is the dominant factor in the pathogenesis of peptic ulcer disease that is not associated with NSAIDs. [89] The role of *H pylori* infection in functional dyspepsia is still not clarified. [90], [91]

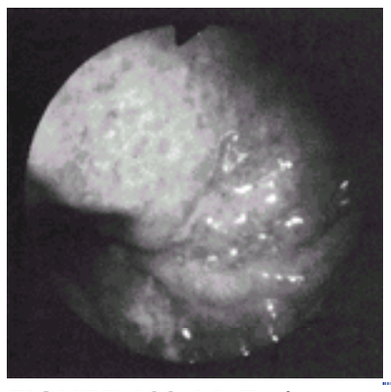

FIGURE 138-14. Endoscopy reveals punctate erythema and swelling.

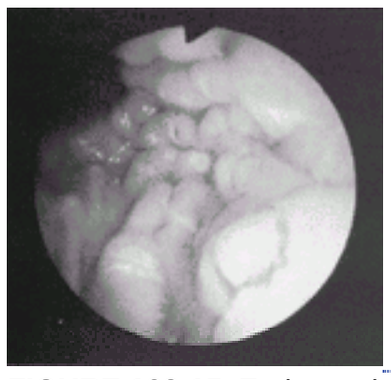

FIGURE 138-15. Endoscopic view of erosive gastropathy.

Gastric Ulcers

Most often, benign gastric ulcers are found close to the incisura or in the distal corpus of the stomach along the lesser curvature. The antrum just proximal to the pylorus is another common area of ulceration, especially of drug-induced ulceration. Ulcers occur in the upper portions of the stomach more commonly in elderly people. If multiple ulcers are present, a drug-induced etiology should be suspected. [92] Most gastric ulcers have diameters less than 3 cm. Typically, an ulcer has a white base with erythematous mucosal margins. These margins are smooth and slightly raised in a benign gastric ulcer. The folds surrounding a benign gastric ulcer usually radiate in an unbroken fashion from the ulcer margin without intervening nodularity; nodularity raises the suspicion of a malignant ulcer.

It is often impossible to be certain from the endoscopic appearance that no malignancy is present in a gastric ulcer. Of those ulcers that appear benign radiographically, 5% to 10% are found to be malignant in some studies. Endoscopy and biopsy are therefore mandatory if a gastric ulcer appears to be indeterminate or suspicious (Fig. 138-16; see also Color Fig. 138-16). Endoscopists should realize that there is an appalling lack of agreement on descriptive terminology and interpretation of ulcer features. [93]

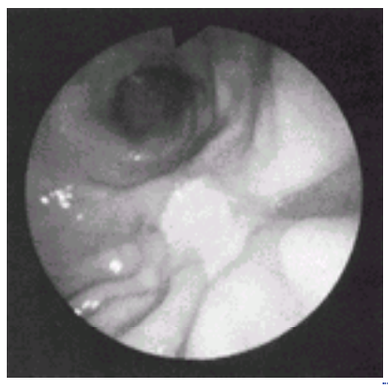

FIGURE 138-16. (See Color Fig. 138-16.) Atypical gastric ulceration along the greater curvature was presumably induced by nonsteroidal antiinflammatory drugs.

Under endoscopic guidance, the physician should obtain multiple biopsy specimens from the margin and the base of a gastric ulcer. [94], [95] At least six biopsy specimens should be taken. It is important to take the biopsy specimens of the ulcer margin as close to the ulcer base as possible to increase the yield if a tumor is present. If the ulcer base is abnormal or appears to have nodules, a biopsy should be performed there. It may be important to follow gastric ulcers until full healing with a repeat endoscopy and multiple biopsies in certain circumstances. It is possible for a malignant ulcer to heal with therapy.

If the patient presented initially with an upper gastrointestinal bleed, biopsies are often deferred. If the endoscopic appearance of the lesion was atypical, it may be important to repeat endoscopy and biopsy after several weeks of therapy.

Duodenal Ulcers

Endoscopy is considered to be the most accurate imaging modality in the evaluation of the duodenal bulb to detect a duodenal ulcer. About 50% of duodenal ulcers are located on the anterior surface of the duodenal bulb. As with gastric ulcers, the mucosa surrounding the ulcer is often red. Adjacent to the ulcer, there may be a second duodenal ulcer, duodenal erosions, or duodenal scarring from previous ulceration. If there is profound scarring from previous ulceration, outpouchings of the bulb may develop, resembling diverticula (Fig. 138-17; see also Color Fig. 138-17). Duodenal ulcers heal at a rate of several millimeters per week. In a patient with a duodenal ulcer, an antral biopsy should be obtained to document the presence of *H pylori* infection. If appropriate, antimicrobial sensitivities can also be obtained. It is not recommended that biopsies be taken directly from a duodenal ulcer unless it is in some way atypical, suggesting the presence of Crohn's disease, malignancy, or infectious or parasitic disease.

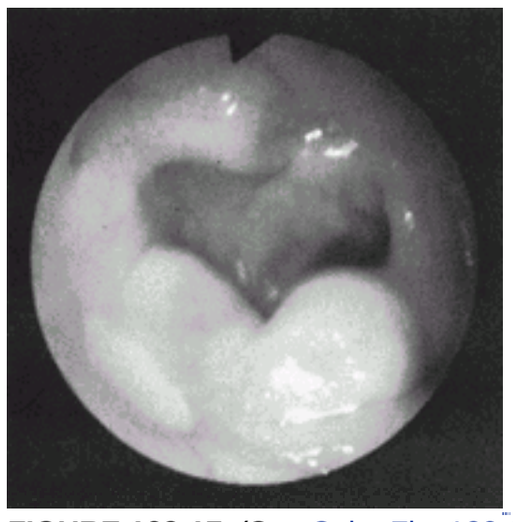

FIGURE 138-17. (See Color Fig. 138-17.) This deformed bulb was caused by scarring after prior ulceration and recurrent duodenal ulcer.

Upper Gastrointestinal Tract Bleeding

In a patient who presents with upper gastrointestinal bleeding, endoscopy is the first diagnostic procedure undertaken. It is usually possible to perform endoscopy on all patients with upper gastrointestinal bleeding unless they have torrential hemorrhage. Most endoscopists stabilize hemodynamically a patient presenting with upper gastrointestinal bleeding and then perform endoscopy. Endoscopy provides valuable information for the diagnosis and planned therapy of the patient, and the advent of therapeutic endoscopy has given the endoscopist the chance to change the natural history in the bleeding patient. Urgent early endoscopy is indicated if the patient presents with hemodynamic stability, if the patient has liver disease, if the patient is rebleeding, or if there is a history of previous aortic-prosthetic surgery because of the possibility of aortoenteric fistula.

The esophagus is examined to determine whether obvious lesions are present that can account for the bleeding, such as esophageal varices or a mucosal Mallory-Weiss tear. In a patient with bleeding varices, both the esophagus and stomach are examined for varices and for portal hypertensive or congestive gastropathy. Varices are assessed by size (e.g., small, medium, large) and the presence of red color signs on the surface of the varix (e.g., red wale markings, hematocystic spots, cherry-red spots). Portal hypertensive or congestive gastropathy may appear as multiple erythematous areas outlined by a white reticular network (mosaic-like pattern), a fine pink speckling (scarlatina-like pattern), or cherry-red spots on a finely granular mucosa with or without spontaneous bleeding in areas of confluence (red-spot pattern). The three patterns are likely to represent particular aspects of a continuous spectrum of congestive mucosal changes. The gastric examination is performed with the instrument straight and retroflexed. Before endoscopy, it is often advisable to lavage the stomach to remove clots; if a clot is still present in the stomach, most endoscopists advance the tip of the endoscope over the clot and into the antrum. If there is brisk duodenal bleeding, blood can be seen refluxing back through the pylorus into the antrum. The endoscope is passed through the pylorus into the duodenal bulb and down into the descending duodenum. If an ulcer is encountered, its size, appearance, associated visible vessel or adherent clot, and bleeding activity are assessed. The instrument is withdrawn into the stomach and retroflexed to examine the lesser curvature, cardia, and fundus. If blood and clots are present, the patient's position may have to be changed to allow the entire gastric mucosa to be inspected. In some instances, it is possible to follow a trail of blood up the mucosa and find the actively bleeding lesion.

In the esophagus, the most important lesions are esophageal varices and Mallory-Weiss tears. Other lesions include cancers, Barrett ulcers, and severe reflux esophagitis. The most common causes of bleeding in the stomach are gastric ulcer, gastric varices (Fig. 138-18; see also Color Fig. 138-18), vascular abnormalities such as telangiectasias (Fig. 138-19; see also Color Fig. 138-19), gastric erosions or hemorrhagic gastropathy (e.g., due to stress, NSAIDs), or a Dieulafoy vascular lesion. In the duodenal bulb, the most common cause of bleeding is duodenal ulcer (Fig. 138-20). Other lesions include erosive duodenitis, often thought to be drug induced. The duodenum may also bleed from vascular abnormalities and from tumors, especially pancreatic tumors infiltrating into the duodenum.

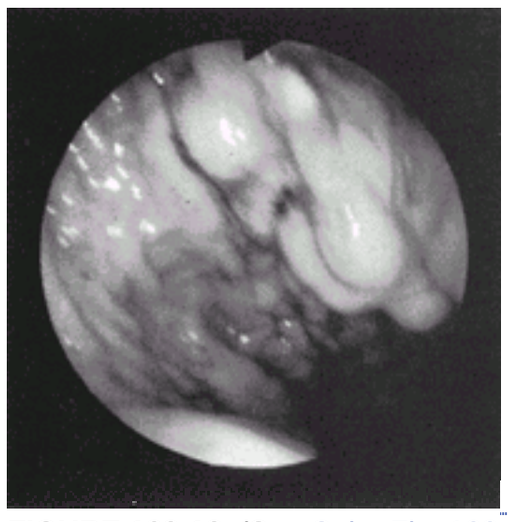

FIGURE 138-18. (See Color Fig. 138-18.) Gastric fundus varices.

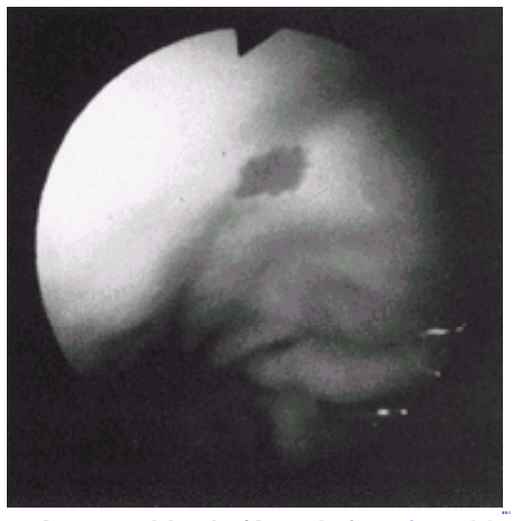

FIGURE 138-19. (See Color Fig. 138-19.) Gastric mucosal vascular ectasia.

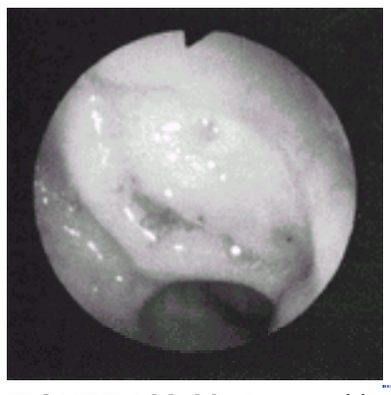

FIGURE 138-20. A vessel is visible in the base of this duodenal ulcer.

Infection of the Esophagus

Candida species infection of the esophagus has several characteristic endoscopic appearances, including a typical white exudate, pseudomembranes, friable mucosa, and rarely, ulcers. The most accurate method of diagnosing fungal infection of the esophagus is endoscopic brushing and biopsy. [97] Brush specimens of the esophageal exudate show mycelia. Some endoscopists obtain a biopsy specimen because the sample may show evidence of deeper tissue involvement with fungus. It is not useful to culture the exudate or the biopsy specimen, because *Candida* species may be demonstrated by culture without significant mucosal infection.

In the differential diagnosis of esophageal infection in the immunocompromised host, several viral infections must be considered, including herpes simplex virus (HSV), varicella-zoster virus (VZV), and cytomegalovirus (CMV). Each of these viruses may be associated with ulcers in the esophagus, usually in patients who are immunocompromised. CMV is thought to affect the deeper, submucosal tissue, and HSV and VZV affect more superficial epithelium.

In HSV infection, vesicles are often seen as the initial lesion. As the lesion progresses, the center of the vesicle sloughs, leaving a small ulcer, the edges of which are usually raised. If these ulcers coalesce, extensive areas may be involved. The diagnosis is made by histological examination and viral culture of brushings or biopsy specimens taken from the edge or center of the ulcers. A necrotizing esophagitis can also occur from VZV infection, especially in immunocompromised patients. As with HSV, lesions may vary from vesicles to larger lesions, and biopsy specimens and brushings are obtained for histological analysis.

The lesions of CMV esophagitis involve the submucosa. The typical endoscopic appearance is that of a geographic pattern ulcer, which may be large, especially in the distal esophagus. [1] Endoscopic brushing of the exudate is less useful for culturing CMV. Biopsy specimens from the center of the ulcer are often required for the diagnosis of CMV. [97] In the immunocompromised host, CMV infection may involve the mucosa and submucosa of the stomach and duodenum in addition to the esophagus.

Removal of Foreign Bodies

Foreign body ingestion occurs in all types of patients, but there is an increased incidence in children, in patients who wear dental plates, and in psychiatrically ill patients or prisoners. Most commonly, adults present with dysphagia or esophageal obstruction caused by a piece of meat or a bone, but children and psychiatrically disturbed patients ingest a variety of objects. [36] The foreign body tends to lodge in the esophagus in areas of physiologic narrowing, such as near the left main-stem bronchus, aortic arch, and just above the diaphragm. [98] Not all ingested foreign bodies require removal, but some foreign bodies that are impacted or have sharp edges should be removed. Of immediate clinical concern is impaction of a foreign body in the esophagus or hypopharynx. Profuse salivation in a patient is considered a clinical sign of esophageal obstruction that must be addressed immediately.

Any foreign object that impacts in the esophagus needs attention, including coins or batteries, which contain corrosive elements. If a radiopaque foreign body passes spontaneously into the stomach, serial abdominal flat films can be used to watch its progress through the gastrointestinal tract. A sharp object, such as an open safety pin or razor blade that remains stuck for more than 2 or 3 days, should be removed endoscopically or surgically.

A coin often lodges in the proximal esophagus just distal to the cricopharyngeal muscle. Posteroanterior and lateral radiographic views of the neck are necessary to identify the exact location of the foreign body and to determine whether the foreign body is in the esophagus or the trachea. A rigid laryngoscope and forceps can be used to remove the coin; alternatively, forceps or a snare is passed by way of a flexible endoscope. The patient can be placed in Trendelenburg position to prevent aspiration of the coin into the trachea if an endotracheal tube is not used. Special care is required if a coin or button battery is pulled through the upper esophageal sphincter because these foreign bodies may become dislodged from a snare or toothed forceps as they are being removed.

A foreign body such as meat is commonly encountered in adults and may totally obstruct the distal esophagus. A polypectomy snare can often be used to grasp and remove the meat. Experience has shown that after a meat bolus has been snared or placed in a basket, it is best to pull the bolus up against the tip of the endoscope as the endoscope is being withdrawn to minimize the likelihood of the bolus becoming dislodged from the snare or basket as it is being removed. If the meat fragments into smaller pieces, an overtube is necessary to reduce patient discomfort. As the endoscope is passed in and out to remove small pieces of the foreign body, the overtube protects the airway and prevents a piece of the foreign body from being dropped in the hypopharynx.

In some instances, a small-diameter endoscope can be passed next to the obstructing bolus to determine whether a stricture is present below the meat. If a stricture is found, it can be dilated with a balloon. The instrument can be withdrawn to above the bolus of meat and can be used to push the bolus of meat gently down into the patient's stomach. However, pushing a foreign body distally without knowing the cause of the obstruction should be avoided because this can cause a perforation.

The greatest difficulty in protecting the airway occurs with sharp objects such as pins and razor blades. If a single-edged razor blade is lodged in the esophagus, an overtube should be used. The razor blade should be pulled into the overtube as it is gently removed, protecting the esophageal mucosa. An overtube is also helpful for removing a pin. If a safety pin is open in the esophagus with the sharp end of the pin pointing proximally, the best management approach is to push the pin into the stomach, rotate it, and pull it out by the hinge with the pointed portion of the pin trailing and pointing away from the endoscope. Other commonly encountered foreign bodies are small batteries. The batteries should be removed to prevent possible serious and even fatal complications if they are stuck in the esophagus. If small batteries rapidly move into the stomach, they usually pass without problems.

After a foreign body has passed the pylorus and is in the small bowel, it usually passes spontaneously. In some instances, a foreign body must be removed surgically from the stomach or from the intestinal tract beyond the stomach if endoscopic removal is not successful. A radiograph should be taken immediately before attempted removal because, in many instances, the foreign body has spontaneously passed out of the stomach, and endoscopy is no longer indicated.

Caustic Injury

Caustic injury may vary from a minimal and superficial burn to severe necrosis involving the entire upper gastrointestinal tract into the duodenum. Ingestion of alkali is often more problematic than ingestion of strong acids. [99] Endoscopy allows the physician to assess the organs injured and, to some degree, determine the extent of the injury. In most instances, endoscopy should be performed early in the patient's evaluation if the patient is stable. If there is evidence of a full-thickness injury to the intestinal tract with possible perforation, shock, or severe injury to the hypopharynx or epiglottis, endoscopy should not be performed. The examination is usually performed with a small-caliber endoscope. The recommended technique of passage is under direct vision with minimal air insufflation. If an area of severe necrosis is visualized, the endoscopy should not proceed beyond this area.

It is possible to divide the extent of the injury caused by caustics into three degrees of injury. [100] The mildest or first-degree injury is characterized by mild friability, erythema, and edema but no evidence of necrosis or ulceration. These superficial injuries often heal completely without long-term sequelae. Second-degree injuries extend into the wall and occasionally to the muscularis propria. Endoscopically, a more severe injury is seen with necrosis, ulcers, exudates, and areas of hemorrhage. These deeper injuries characteristically result in strictures of the severely injured organ, the esophagus or stomach. The most severe injury is a third-degree burn involving the full thickness of the wall. The injury is seen endoscopically as a dark exudate, with sloughing of the mucosa in addition to hemorrhage and ulceration. The organ may appear aperistaltic and dilated. This injury often leads to the late sequelae of esophageal stricture or strictures in the stomach.

Third-degree burns may also be associated with injury to adjacent organs and may present with mediastinitis or peritonitis.

The purpose of early endoscopy is to determine the extent and severity of the burn. A black necrotic area with ulceration suggests an injury through the full thickness of the wall and an increased risk for perforation. In these patients, early surgical intervention must be considered before perforation occurs. If, at the initial endoscopy, an area of full-thickness injury is suspected, it is usually recommended that the endoscopy be discontinued at that point and repeated after 48 hours to determine whether these areas appear to be healing. The patient must be watched for clinical signs of perforation requiring operative intervention.

Drug-Induced Injury

Some medications, such as tetracycline, ascorbic acid, and iron preparations, have an acid pH and directly injure the mucosa. Some medications, such as potassium preparations, are designed for slow release, and if they remain for a prolonged time in the esophagus, they can cause injury. Also, bisphosphonates may damage the esophagus. This problem is made worse if the patient swallows the medication with a small amount of water before going to bed. In elderly patients, a reduced amount of saliva also may contribute to the problem. [101], [102] Endoscopically, these patients have ulcerations of the esophagus characteristically located above areas of physiologic narrowing, where these medications tend to lodge. The injury may vary from friability and erythema to multiple clear-cut ulcerations, often seen as "kissing" ulcers in direct opposition to one another on the esophageal mucosa. These iatrogenic drug-induced injuries may promote esophageal stricture, especially if the medication is taken over a long period.

Mass Lesions

Endoscopy is often used to evaluate masses seen on barium radiographs in the upper gastrointestinal tract, especially in the stomach. Endoscopic ultrasound may prove to be important in the evaluation of these mass lesions. Gastric adenocarcinomas are categorized by the Borrmann classification into four types of tumors. Type 1 is an exophytic mass protruding into the gastric lumen. Type 2 is a protruding mass with associated ulceration. Type 3 is a diffusely infiltrating tumor, often associated with ulceration. Type 4 is an infiltrating mass without associated ulcer. Type 3 lesions can be confused with a benign gastric ulcer. To make this distinction, at least six to eight biopsy specimens from all quadrants of the ulcer are necessary to detect carcinoma. Brush cytology may also be useful. Type 4 adenocarcinoma is often referred to as *linitis plastica* and has diffuse involvement of the gastric wall. This tumor may be mainly submucosal, and biopsy of the mucosal surface over the tumor may reveal relatively normal tissue. It is important to retrieve specimens from any abnormal areas of mucosa associated with these lesions because these are most likely to be the areas in which the tumor has broken through to the surface and to be positive for tumor. Most endoscopists prefer using biopsy forceps of large caliber for these biopsies or needle cytology.

The classification of early gastric cancer was defined by the Japanese Endoscopic Society. Type 1 is a small polypoid lesion. Type 2 can be elevated (2a), flat (2b), or depressed (2c). Type 3 is a lesion that presents as a gastric ulcer with an adenocarcinoma at the margin, often producing a discolored and slightly depressed area. The most common types of early gastric cancer are types 2c and 3. Endoscopic gastric mucosal resection is increasingly employed in early gastric cancer, to remove the tumor with the surrounding mucosa and part of the submucosa after submucosal saline injection to raise the lesion, appropriately stained with indigo-carmine dye scattering to define the extent of the lesion. This technique is especially suitable for cancer confined to the mucosa (with low probability of lymph node metastasis) and with a diameter of 20 mm or less. [103], [104], [105] and [106]

The appearance of gastric lymphoma varies from nodular or polypoid to that of ulcerations surrounded by a nodular and infiltrated mucosa. A deep, volcano-like ulcer is reported, which has elevated surrounding margins. The ulcers are characteristically irregular in their margins and are associated with nodules. Exudate in the base may appear gray. Multiple biopsies often are necessary to diagnose a gastric lymphoma correctly.

ENDOSCOPIC SURVEILLANCE FOR PREMALIGNANT LESIONS

The incidence of neoplasia is increased in several conditions and in some postoperative circumstances in the upper gastrointestinal tract. However, well-designed controlled studies are lacking to define precisely the risk in these conditions of developing malignancy, and it is difficult to determine exactly which conditions require periodic surveillance. [107]

Achalasia

Esophageal cancer develops in 2% to 8% of patients with untreated achalasia after more than 15 years of disease. If the patient is adequately treated with balloon dilation or a surgical myotomy, there may be a smaller increase in the risk for malignancy. [108] There does not appear to be a role for endoscopic surveillance in achalasia. However, any patient with achalasia who experiences a change in signs or symptoms should undergo endoscopy to determine whether a malignancy is present.

Esophageal Columnar Metaplasia

There is an increased risk for adenocarcinoma, in the range of 8% to 10%, in patients with Barrett metaplasia. The premalignant risk does not appear to be reduced by antireflux surgery, despite the fact that this surgery may be associated with a reduction in inflammation. Most endoscopists agree that patients with columnar metaplasia should be screened endoscopically with multiple biopsies, although the exact frequency of surveillance has not been determined. [109], [110], [111], [112] and [113]

Gastric Polyps

Adenomatous gastric polyps are thought to be associated with an increased risk for containing malignancy within the polyp. [114], [115] Hyperplastic polyps are not associated with cancer in the polyp, but adenomatous and hyperplastic polyps may be associated with gastric atrophy, which has been associated with gastric cancer in areas other than the polyp.

Larger adenomatous polyps appear to pose a greater risk for malignancy. It is necessary to remove the entire polyp for adequate histological assessment because random biopsies may miss a focal cancer. Polypectomy may also treat symptoms caused by a polyp, such as bleeding or obstruction. If a polyp is encountered, it should be removed by endoscopy or surgery. The size of the polyp, the number of polyps, and the patient's general medical condition are important factors in determining whether surgery or endoscopy should be used for treatment. If the polyp is hyperplastic, no further surveillance endoscopy is indicated. If the patient has a limited number of small adenomatous polyps (less than 2 cm), endoscopic removal of the polyp is recommended. These patients are followed with surveillance endoscopy to detect recurrent polyps or the development of a carcinoma. If the polyp is adenomatous but is large and sessile, there is an increased risk for complications from endoscopic removal, and surgical therapy is often recommended.

Atrophic Gastritis

Chronic gastritis with severe atrophy is associated with gastric adenocarcinoma (Fig. 138-21; see also Color Fig. 138-21). Only rarely can extensive intestinal metaplasia be identified endoscopically. Mucolysis followed by methylene blue staining may facilitate the recognition of intestinal metaplasia endoscopically and allow targeted biopsy of the lesion. There is no consensus whether regular surveillance should be carried out in such patients.

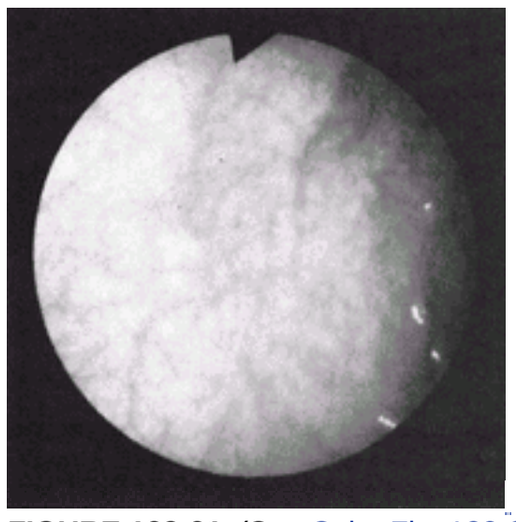

FIGURE 138-21. (See Color Fig. 138-21.) Atrophic gastritis.

Autoimmune Gastritis and Pernicious Anemia

Several population-based studies indicate that the risk for gastric adenocarcinoma and carcinoid tumor is increased in patients with pernicious anemia, but only slightly over that of the general population. Periodic surveillance endoscopy in patients with pernicious anemia is not recommended, except in patients who have known dysplastic changes of the mucosa. [116], [117] and [118] The importance of small carcinoids and endocrine cell hyperplasia in the corpus requires further investigation.

Adenocarcinoma in the Gastric Remnant After Partial Gastrectomy

Several studies have demonstrated that patients undergoing gastric resection for benign gastric or duodenal ulcers are at increased risk for later developing dysplasia and adenocarcinoma. The reported increase in the risk for cancer ranges from 2% to 8.7%. [119] However, other reported series have failed to demonstrate an increased risk for carcinoma in these postoperative patients. The risk for malignancy is not thought to be high enough to warrant routine endoscopic screening of patients who have had gastric resections. In countries in which the risk for postgastrectomy cancer is several times the normal incidence, however, the patients should be screened endoscopically, especially patients who underwent surgery before 50 years of age and those in whom resection was performed at least 15 years ago. If endoscopy is being performed for a different indication on a patient who had gastric resection many years earlier, some endoscopists recommend taking multiple biopsy specimens from the margin of the stoma to look for evidence of dysplasia or early cancer.

RISKS AND CONTRAINDICATIONS

Endoscopic examination of the upper gastrointestinal tract by an experienced endoscopist is a safe procedure even during pregnancy [120] or after esophagogastroduodenal surgery. [121] Cardiopulmonary complications, infection, bleeding, and perforation occur only rarely. Each of these complications is thought to occur in fewer than 0.1% of patients undergoing endoscopy. Overall, the incidence of serious complications with diagnostic upper gastrointestinal endoscopy is estimated to be about 1 in 1000 procedures, with an estimated mortality between 1 and 6 per 20,000 examinations. The smaller-caliber endoscopes are even safer. Several studies have suggested that the complication rate of endoscopy in patients who were experiencing acute gastrointestinal bleeding is higher than in patients who were electively examined. There is, however, no evidence that endoscopy exacerbates bleeding. Cardiopulmonary complications account for more than one half of endoscopy-associated deaths. [122]

Contraindications to endoscopy include suspected perforation, an uncooperative patient, severe shock or respiratory distress, and severe injury to the hypopharynx. Patients with coagulopathies should be examined endoscopically only in life-threatening situations and if the result of the endoscopy is thought to be critical to the patient's care.

ASSESSMENT OF RESULTS

Physicians have for years debated the relative merits of endoscopy and barium contrast radiography in evaluating the esophagus, stomach, and duodenum. [123], [124] and [125] Studies comparing these diagnostic modalities have always suffered from the problem of which technique is to be used as the standard. Radiologists contend that they are able to detect important lesions of the upper gastrointestinal tract in a manner comparable to that achieved with endoscopy. [125] There are distinct advantages to endoscopy. First, endoscopy allows detection of superficial mucosal lesions, such as reflux esophagitis, gastritis, and duodenitis, better than radiography. Endoscopy is thought to be more sensitive and specific for peptic ulcer. Endoscopy permits cytology and biopsy, making endoscopy superior to radiology for diagnosing infectious conditions such as esophagitis with *Candida* species infection or CMV, or for diagnosing gastritis with *H pylori*. However, each type of diagnostic study fails to detect certain lesions, and there are clinical circumstances in which one or the other of these modalities is best or in which a combination of modalities is required.

In upper gastrointestinal bleeding, endoscopy is the diagnostic procedure of choice. Barium radiography has a low rate of detection of the bleeding source, and the barium can interfere with subsequent endoscopy or angiography. Endoscopy offers the possibility of hemostatic therapy. The rapid increase in use of endoscopy is easily understandable because endoscopy is thought to be more accurate, allows the endoscopist to take targeted biopsy specimens, permits brush cytology, and permits the delivery of various types of therapy.

FUTURE TRENDS

The role of endoscopy in clinical medicine will continue to evolve now that new imaging modalities are being developed, [126] such as high-resolution endoscopy, [127] fluorescence endoscopy, [128] optical coherence tomography, [129] and confocal laser scanning microscopy. [130] Ultrasound endoscopy will be used increasingly for diagnosis and for guiding therapy. Wireless capsule endoscopy is on the horizon. Time will tell how useful this technology will ultimately become. [131], [132]

The training of new endoscopists is important, and as part of this education, a standardization of terminology is vital, especially in the use of videoendoscopy to examine areas of inflammation. Issues such as interobserver and intraobserver variability must be considered as we examine the sensitivity and specificity of endoscopy.

CHAPTER 139

Paul Swain

ENTEROSCOPY

Enteroscopy is the endoscopic evaluation of the distal duodenum, jejunum, and ileum. [1], [2] and [3] Upper endoscopy with conventional forward or side-viewing instruments of a meter in length can reach the junction of the second and third portions of the duodenum, and colonoscopy can intubate and inspect the terminal ileum for a few centimeters. These methods will not be considered in this chapter. There are four methods available for enteroscopy: push enteroscopy, sonde enteroscopy, intraoperative enteroscopy, and wireless capsule enteroscopy. Specialized instruments have been developed for sonde and push enteroscopy (Fig. 139-1).

FIGURE 139-1. A sonde-type enteroscope (Olympus SIF-SW) with the balloon at its tip inflated and a push-type enteroscope (Olympus SIF-10).

PUSH ENTEROSCOPY

Push enteroscopy involves advancing a long endoscope into the small bowel during upper intestinal endoscopy; it has become the most common form of enteroscopy. During push enteroscopy, an endoscope can be pushed beyond the ligament of Treitz into the proximal jejunum. Instruments have been specially designed for this application which have increased tip flexibility, relatively small diameter, improved transmission of force to the endoscope tip, and a conventional biopsy channel. [1], [2] and [3] Initial experience in push enteroscopy was gained using an adult or pediatric colonoscope passed through the mouth. [4], [5], [6], [7], [8] and [9] A colonoscope can be advanced a fair distance into the small bowel, although probably not as far as a push-type enteroscope. A pediatric colonoscope may be superior to an adult colonoscope for enteroscopy because of its smaller outer diameter, but both have been used.

Minor improvements in the design of dedicated push-type enteroscopes, including increased angulation, [1], [2] and [3] better push transmission, [1], [10], [11], [12] and [13] and increased length, [12] combined with greater clinical experience, have led to deeper intubation of the jejunum. As a result, push-type enteroscopy has become much more widely practiced.

Technique

The sedation needed to perform enteroscopy may be slightly greater than that required for gastroscopy because the procedure takes longer and is more uncomfortable. In selected patients, enteroscopy can be performed without sedation. Because the bending section is longer, to allow increased angulation in all directions, and because the instrument is heavier, due to its increased length in comparison to a gastroscope, the instrument is slightly more difficult to handle during esophageal intubation and passage across the pylorus, but the push characteristics and increased flexibility allow for better handling in the jejunum.

A complete examination of the esophagus and stomach should be performed with the instrument before entering the duodenum since looping of the instrument in the stomach may produce red marks, usually on the greater curve, which are difficult to distinguish from vascular ectasias on pull-back. Reducing air nsufflation and consequent distention of the stomach by sucking out the air in the stomach before entering the duodenum may lead to deeper insertion of the instrument. The patient may feel discomfort as the instrument is advanced, distending the greater curvature of the stomach. Paradoxical or arrested tip motion occurs if the instrument loops within the fundus. By exerting pressure and clockwise torque, the endoscopist can generally push through the loop. Abdominal pressure on the left side of the upper abdomen can sometimes help reduce the loop forming in the stomach. As with endoscopic retrograde cholangiopancreatography (ERCP), pulling back once the endoscope has entered the second part of the duodenum will produce “paradoxical” advancement. The ligament of Treitz is usually encountered 85 to 110 cm from the incisors and usually requires full tip deflection to find the lumen. Once around the ligament, the first jejunal loop can be identified by a straight configuration, which points in a caudal direction if seen on x-ray. Buscopan or glucagon can be used to reduce peristaltic activity and may be useful during therapeutic intervention, but it is probably best to avoid administering either until the endoscope has reached as far as possible since peristalsis may help to advance the scope.

Overtube

A variety of methods have been used to try to reduce the tendency of the enteroscope to loop in the stomach. These include the use of abdominal pressure, internal stiffening devices, [1] and overtubes. Overtubes designed for enteroscopy have varied from 60 to 100 cm in length. Some have two ring-shaped metal tip markers to facilitate placement under screening and to prevent the overtube tip from being compressed. Others have a more pliable Gortex tip of 10 cm in length, which may limit mucosal trauma when advancing the overtube over the endoscope. The overtube is initially backloaded onto the shaft of the endoscope. Once the endoscope tip is within the jejunum, the overtube is advanced down the esophagus until its distal tip rests within the second portion of the duodenum for the 60-cm overtubes and to or beyond the ligament of Treitz for the 100-cm overtubes. Fluoroscopy is probably necessary if an overtube is being used since prepyloric placement does little to aid deep intubation. The softer Gortex-tipped overtube may buckle in the stomach and fail to provide sufficient rigidity. The endoscope should be lubricated and the overtube dipped in water before use. As the overtube is advanced, the endoscope shaft needs to be straightened by twisting the endoscope shaft clockwise while pulling it backward. (This is much the same maneuver as positioning a side-viewing duodenoscope within the duodenum during ERCP.) Overtube use is possibly responsible for a majority of the complications reported with enteroscopy. Several experienced enteroscopists have abandoned the use of the overtube, but it may sometimes be helpful in advancing the enteroscope further into the small bowel. Some commercially available enteroscopes are too floppy to be used without an

overtube.

Therapeutic Applications

Push enteroscopes include a standard 2.8-mm biopsy channel that has been used for several therapeutic functions within the proximal small intestine as well as for directed biopsy and delivery of x-ray contrast. [1], [2], [14], [15], [16], [17], [18], [19], [20], [21], [22], [23], [24], [25], [26], [27] and [28] The more the instrument becomes looped as it advances into the small bowel the greater the difficulty in getting instruments to emerge from the biopsy channel. This particularly applies to instruments with a long rigid tip such as a heater or bipolar probes and balloons, rather than snares and laser fibers.

Biopsy Endoscopic forceps–type biopsy has now largely replaced the use of a suction-fired biopsy capsule such as the Crosby capsule as a means of taking small bowel biopsies. The advantages of the endoscopic method are speed, ease, patient comfort, and reliability. Enteroscopic biopsies can reduce the chances of proximal duodenal inflammation and shorter villi in the bulb causing confusion when examining for celiac disease. Enteroscopic biopsy might offer advantages in the workup of patients with malabsorption, particularly if focal specific mucosal abnormalities have been seen in the proximal jejunum on a small bowel x-ray contrast series.
Jejunal Feeding Tube Placement Push enteroscopy has also been used in a variety of ways to place jejunal feeding tubes. Push enteroscopy has been used to carry a transgastric jejunal tube through a previous gastrostomy into the jejunum. [17], [18] Nasojejunal feeding tubes have been placed using the Seldinger technique. [20] The push enteroscope is placed into the jejunum initially and then a guidewire, such as a 0.35 mm-diameter 400-cm–long guidewire, is advanced through the endoscope's biopsy channel. The endoscope is removed, leaving the guidewire in place. A feeding tube is advanced over the wire and then rerouted from the mouth through the nose by passing it back through another tube passed through the nose and retrieved from the back of the pharynx. This method has been combined with a sewing method for attaching the jejunal feeding tube to the stomach to prevent displacement. [1]
Direct Percutaneous Endoscopic Jejunostomy Placement By using push enteroscopy, the "pull" technique for the placement of percutaneous gastrostomies has been extended to permit direct percutaneous jejunostomies. [1], [17], [20], [21] This technique has also been used to place jejunal tubes for small bowel enemas [22], [23] as well as to obtain cholangiograms in patients after Roux-en-Y hepaticojejunostomy. [1], [12], [23]
Polypectomy Polypectomy can be performed in the small intestine via the push enteroscope using snares. [1], [17] Surveillance of patients with a polyposis syndrome can be performed with push enteroscopy, allowing biopsy and polypectomy of larger lesions. Removal of large jejunal hamartomatous polyps in the Peutz-Jeghers syndrome has become part of the screening of this autosomal dominant condition with a malignant potential. The more proximal lesions are relatively easy to remove, but endoscopic removal is not yet possible for all lesions in the jejunum.
Diagnosis and Treatment of Gastrointestinal Bleeding The major indication for push enteroscopy lies in the evaluation and treatment of patients with obscure gastrointestinal bleeding. Reported yields have varied from 3% to 65%. Messer and colleagues [22] reported finding the bleeding site in 20 of 52 patients (38%) with obscure bleeding. Findings included angiodysplasias in 9 and small bowel tumors in 11. Foutch and associates [9] also reported a yield of 38% in their report of examinations of 39 patients. Angiodysplasias were the most common finding, accounting for 80% of the diagnoses. Davies and colleagues [1] reported finding a possible cause of bleeding in 45% of cases referred with occult bleeding. Chong and colleagues [24] reported finding a possible cause of bleeding in 64% of 55 patients using the newer push enteroscopes in combination with an overtube. In addition to diagnosis, push enteroscopy allows cauterization of bleeding sites. Using bipolar cautery, the Foutch group was able to fulgurate angiodysplasias in 11 of 12 patients. Control of bleeding was obtained in 8 of the 11 treated patients. Askin and Lewis [25] assessed the long-term effectiveness of push enteroscopic cauterization of bleeding arteriovenous malformations in 89 patients. Of these patients, 61 were cauterized and 28 were not. The group that was cauterized required significantly fewer blood transfusions than the noncauterized group. In another series [14] of 50 patients undergoing therapeutic push enteroscopy, bleeding was terminated in all patients with isolated angiomas and reduced in more than half of the patients with multiple jejunal angioma as well as in some malignant tumors. In addition, one bleeding duodenal ulcer, three gastric angiomas, linear erosions in a hiatus hernia, two Dieulafoy ulcers, and three watermelon stomachs were found, were treated with bipolar probe or laser, and had no further bleeding. [14] This group had a significantly reduced transfusion requirement when compared to their precauterization status. Heater probes and bipolar probes as well as monopolar probes and laser fibers are available in lengths to fit the newer push enteroscopes.

Complications

Complications are uncommon with push enteroscopy, which is probably nearly as safe as gastroscopy. Most of the complications appear to be associated with the use of a metal-tipped overtube. These include a Mallory-Weiss tear, pancreatitis most likely secondary to papillary trauma, a pharyngeal tear, and three cases in which long strips of gastric mucosa were torn off during advancement of the overtube. [2], [23], [26] These complications with overtubes occurred prior to the addition of a Gortex tip. Some series describe severe patient discomfort, which is usually due to stretching the stomach as a loop is formed along the greater curve while trying to transmit forward pressure to advance the tip in the small bowel.

SONDE ENTEROSCOPY

Sonde enteroscopy uses a long and extremely flexible fiberoptic instrument propelled through the intestine by peristalsis following inflation of a balloon at its tip. [29], [30], [31], [32], [33], [34] and [35] This instrument, in contrast to a push enteroscope, has no biopsy or therapeutic capability and no tip deflection. The endoscopic examination is performed during withdrawal. The instrument allows views of the distal jejunum and ileum, which cannot be reached by push-type enteroscopes. Mucosal visualization is somewhat limited due to the lack of tip deflection capability and occasional uncontrolled instrument withdrawal. Visualization is incomplete even when total small bowel intubation is achieved. Abdominal palpation, inflation and deflation of the tip balloon, and pulling or not pulling on the endoscope at the nose offer some degree of control over the intralumenal view. Lewis and Waye [29] estimated that approximately 50% to 70% of small bowel mucosa is observed during a standard examination. The ileum is reached in about 75% of examinations with 10% reaching the ileocecal valve. The concordance when sonde enteroscopy was compared with intraoperative enteroscopy performed with a colonoscope was 77% in 23 patients with bleeding.

Technique

Pioneers of this technique positioned a sonde enteroscope within the jejunum by passing the instrument transnasally, placing the patient in the right lateral decubitus position and following the patient with sequential fluoroscopy. Endoscopic techniques were subsequently applied to reduce the time the enteroscope took to pass through the stomach into the jejunum. [29] The sonde enteroscope is passed transnasally; then a gastroscope or push enteroscope, passed orally, grasps a suture tied to the tip of the sonde enteroscope with biopsy forceps while both instruments lie within the stomach. The push instrument is advanced into the small bowel, pulling the sonde enteroscope along. Once within the jejunum, the balloon of the sonde instrument is inflated, anchoring it in place as the push enteroscope is removed. Care has to be taken to prevent frictional force, exerted by pulling the larger scope backward, from pulling the sonde enteroscope through the pylorus. The advantage of this technique is that it permits total to near-total small bowel intubation within 8 hours and thus allows the procedure to be performed on an outpatient basis. The original technique averaged 24 hours. Withdrawal times range from 45 to 60 minutes. With present standard transnasal sonde enteroscopes, the new technique of placement has become generally accepted. Some centers use orally passed enteroscopes that are either allowed to pass naturally through the pylorus or are passed over a previously positioned guidewire. [29]

Video recording of the whole procedure with rapid playback helps to reduce the chances of missing lesions. Arranging for a nurse or assistant to visit the patient every 30 minutes to check that all is well and push 6 more inches of the enteroscope into the patient allows the enteroscope to be placed in the duodenum in the morning and removed in the afternoon. A sonde enteroscope is sometimes positioned immediately following push enteroscopy if the latter examination fails to identify the cause of obscure bleeding.

Diagnostic Capability

Sonde enteroscopy identified a small bowel site of bleeding in 33% of 60 patients with obscure gastrointestinal bleeding. [29] In a series of 504 patients with obscure gastrointestinal bleeding, combined push and sonde enteroscopy documented findings in 42% of patients; [31] 18% of the lesions were found in the region covered by push enteroscopy distal to the area examined by standard upper endoscopy and 26% were found in the remaining bowel examined by sonde enteroscopy. Vascular ectasias comprised 80% of the pathological abnormalities found overall, and small bowel tumors accounted for 10%. Several of the tumors discovered occurred in patients after a negative small bowel series. [33] Similar experience using sonde enteroscopy (without prior push enteroscopy) has been reported by Barthel and colleagues with a yield of 27.8% in 18 patients, [34] by Gostout and colleagues with a yield of 26% in 35 patients, [30] and by Morris and colleagues with a yield of 38% in 65 patients. [36]

Complications

The main drawback is the length and discomfort of the procedure, which makes it an unpopular examination with patients, nursing staff, and doctors. Perforations have been described due to balloon overinflation. [36]

INTRAOPERATIVE ENTEROSCOPY

With sonde enteroscopy not routinely available, intraoperative enteroscopy was probably the most common form of total small bowel endoscopic examination. [37], [38], [39], [40], [41], [42], [43], [44], [45], [46], [47], [48], [49], [50] and [51]

Technique

Colonoscopes are usually used for this examination, though a push enteroscope can also be used. The instrument does not need to be sterile, because the technique either involves peroral intubation of the small intestine, or the endoscope is placed into nonsterile bowel through an enterotomy, in which case it can help to place the endoscope in a sterile plastic sheath. It may be helpful to advance the endoscope into the proximal jejunum through the mouth prior to laparotomy, since once the abdomen is open it may be difficult to advance the instrument around the ligament of Treitz because the endoscope forms a loop along the greater curve of the stomach that is not constrained by the anterior abdominal wall. With oral intubation using an adult colonoscope, the endotracheal tube cuff may need to be deflated to permit passage of the wide caliber endoscope. Once the colonoscope has been positioned in the proximal jejunum, laparotomy is performed. It can be helpful to place a noncrushing clamp across the ileocecal valve to prevent distention of the colon with insufflated air because colonic distention can lead to difficulties with subsequent abdominal closure.

The examination is carried out by an endoscopist and a surgeon; the endoscopist looks through the endoscope using minimal air insufflation while the surgeon holds the endoscope tip inside the small bowel so as to inspect a short segment ahead of the endoscope. The surgeon then advances the endoscope into another segment. The view is best seen by dimming the overhead lights, also allowing the surgeon to look at the transilluminated bowel, which can be helpful in finding angiodysplasia. Once examined both internally and externally, the small bowel is pleated onto the shaft of the endoscope and the next section of bowel is examined. Care has to be taken not to overstretch the mesentery on colonoscopes, which are rather stiff for this use. [27] Active bleeding within the small bowel may diminish the effectiveness of this examination. Examination has to be performed during intubation and not on pull-back since mucosal trauma occurs with the pleating-causing artifact that may be confused with the appearance of angiodysplasia. [37] A technique of “reverse transillumination” to help differentiate trauma from vascular ectasias in this setting has been described. [38] This may allow visualization of the feeding vessel of the vascular ectasia. Using nonvideo endoscopic instruments, the endoscopic light source is turned off and the operating room lights are focused on the intestine. Abnormalities identified at enteroscopy are marked with a suture placed on the serosal surface of the small intestine. At the end of the examination, the endoscope is withdrawn and the surgeon can resect the abnormalities identified by the sutures.

An alternative technique is to perform an enterotomy through which a sterilized endoscope or an endoscope covered by a sterile plastic sheath is placed. The enterotomy is generally performed in the mid–small bowel, allowing both proximal and distal intestinal intubation, but it can be performed in the cecum if vascular ectasias are suspected in the cecum or distal small bowel. Retrograde intubation of the small bowel can be performed after the cecum has been inspected. The colonoscope is advanced by the surgeon through the ileocecal valve and up the small intestine.

Diagnostic and Therapeutic Use

Intraoperative endoscopy has been used for a variety of indications [37], [38], [39], [40], [41], [42], [43], [44], [45], [46], [47], [48], [49], [50] and [51] but is probably the endoscopic method most widely used in identifying small intestinal sites of bleeding. [37], [38], [39], [40], [41], [42], [43], [44], [45], [46], [47] and [48] Intraoperative enteroscopy can be successful in identifying the site of blood loss in selected patients with reported yields of 83% to 100%. Vascular ectasias are the most common nonpalpable cause of bleeding, but radiation enteritis, ulceration, malignancies, strictures, and polyps (e.g., multiple polyps in Peutz-Jeghers syndrome) [49], [50] and [51] may require endoscopic identification. Hemostasis can be achieved at intraoperative enteroscopy either by resection of the bleeding lesion or by transendoscopic ablation of the bleeding lesion, usually with a thermal endoscopic method.

In one study involving 71 patients, laparotomy and intraoperative enteroscopy was more successful in defining the source of gastrointestinal bleeding. [38] Preoperative sonde-type enteroscopy may be most useful in recognizing patients with diffuse vascular ectasias in order to avoid operating on such patients.

Complications

Prolonged ileus, sepsis, and perforations (the endoscopist and surgeon should listen for a hissing sound that indicates that perforation has occurred) are common sequlae of operative enteroscopy.

WIRELESS CAPSULE ENTEROSCOPY

Small bowel endoscopy is especially limited by problems of discomfort and failure to advance enteroscopes far into the small bowel. The invention of the transistor made the design of electronic swallowable radiotelemetry capsules possible for the study of gastrointestinal physiological parameters. These capsules were first reported in the late 1950s and included measurements of temperature, [52] pressure, [53] and pH. [54] The development and testing of a new type of radiotelemetry capsule endoscope, which is small enough to swallow (11 × 30 mm) and has no external wires, fiberoptic bundles, or cable has been described and tested [55] (Fig. 139-2). By using a short focal length lens and a CMOS—complementary metal oxide silicon chip—images are obtained as the optical window of the capsule sweeps past the gut wall, without requiring air inflation of the gut lumen. [56], [57]

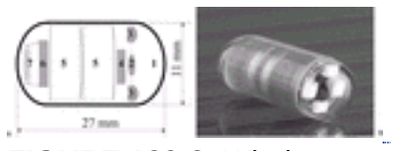

FIGURE 139-2. Wireless capsule endoscope **A:** Schematic diagram. *1*, Optical dome; *2,* Lens; *3*, Illuminating light-emitting diodes (LEDs); *4*, Complementary metal oxide silicon chip (CMOS) imager; *5*, Battery; *6*, ASIC transmitter; *7*, Antenna. **B:** Photograph.

The capsule endoscope is propelled by peristalsis though the gastrointestinal tract and does not require a pushing force to propel it through the stomach, small bowel, or colon. Because the gut is a hollow tube it is unimportant whether the capsule points forward or backward as it passes through.

The video images are transmitted using radiotelemetry (operating in UHF band) to an array of aerials attached to the body. The aerial belt allows image capture and enables the continuous triangulation of the capsule location in the abdomen so that the whole trajectory can be shown on the workstation monitor to help in locating pathologies detected by the capsule imager. The images are stored on a small portable recorder carried on the belt and are subsequently downloaded for analysis. The system allows more than 8 hours of continuous recording of images of the gastrointestinal tract. The patient need not be confined to a hospital or clinic environment during the examination and is free to continue his or her daily routine.

The first human volunteer [55] and patient [58] studies revealed that the capsule was easily swallowed and caused no discomfort. The capsule, propelled by peristalsis, successfully reached the cecum in less than 2 hours. The image window remained clear throughout all of the transmissions with transmission times of up to 6 hours.

Trigonometric analysis of signal strength allowed continuous monitoring of anatomic position of the capsule endoscope.

There is the potential to link this device with radiotelemetry signals indicating the presence of pH, *Helicobacter pylori,* or other relevant physiological or pathological parameters, biosensors, or optical biopsy methods. It is likely that a similar device will form the basis of any robotic attempts to move imaging devices by remote control in the human body. The capsule may provide a better method to examine the small bowel, especially in patients with recurrent gastrointestinal bleeding. Provisional results suggest that this device is nearly as sensitive and specific as push enteroscopy in a randomized study. [59] Unlike all other forms of nonsurgical enteroscopy it can supply images painlessly from the entire small intestine.

CONCLUSION

Minor technical advances in endoscope design and increased use by clinicians have resulted in enteroscopy becoming more useful for diagnosis and therapy. There are still limitations, both in viewing and treating the small bowel, particularly from the distal jejunum to the proximal ileum; these require innovative engineering and clinical understanding if solutions are to be found that will allow enteroscopy to be as successful as upper gastrointestinal endoscopy and colonoscopy have become.

CHAPTER 140

Jerome D. Waye and Christopher B. Williams

COLONOSCOPY AND FLEXIBLE SIGMOIDOSCOPY

INSTRUMENTATION

Flexible fiberoptic technology began to be used for visualization of the colon several years after fiberoptic gastroscopy was introduced in 1957. The first commercially available fibercolonoscope, the Overholt Coloscope appeared in the early 1960s. Modern colonoscopes, whether fiberoptic or video, give a brilliant, high-resolution, color view of the mucosa through wide-angle (140-degree) optics. The 20- to 30-fold magnification at 5-mm distance rivals the close-up view of a dissecting microscope, but colonoscopes provide excellent distant views as well. Tip angulation in four directions to 160 to 180 degrees allows angulation around most acute flexures. Retroflexion (i.e., J configuration) is possible in the proximal colon or rectum, thus minimizing the risk of missing significant lesions in capacious areas that could not be seen with older, less maneuverable instruments. The length of the instruments varies from the 65-cm flexible sigmoidoscope to the 165-cm colonoscope. The instruments range in shaft diameter from 1-cm pediatric colonoscopes to 15-mm adult instruments. Instrumentation and suction channel sizes range from 2.7 to 4.2 mm in diameter. In most ways, a colonoscope is similar in design to a gastroscope, but it has a more flexible shaft to accommodate the various colonic bends encountered. Smaller-diameter pediatric colonoscopes or standard gastroscopes, which are more maneuverable in the colons of babies and small children, also have a place in examining ileostomies and fixed or strictured adult colons. Their ability to retrovert in the capacious portions of the colon can also make some difficult polypectomies easier. Zoom colonoscopes have the capability of image magnification to levels similar to a dissecting microscope. Enhanced maneuverability is possible with an instrument of variable stiffness. [1] High-resolution optical chips afford greater definition of the visual image.

A full range of endoscopic accessories is available for colonoscopes, including biopsy forceps, electrocoagulating hot-biopsy forceps, cytology brushes, washing and spraying catheters, sclerotherapy needles, a range of dilating balloons and bougies, and various polypectomy snares and retrieving devices. Other standard techniques can be applied, such as the introduction of balloons or tubes over a guidewire and insertion of self-expanding stents for obstructing cancer. Thermal therapeutic devices such as the heater probe, bipolar electrocoagulation, argon plasma coagulator, or laser are as applicable to the lower gastrointestinal (GI) tract as they are to the upper GI tract. Some endoscopists use an overtube as a splinting or stiffening device to control looping in the sigmoid colon or as a temporary stent to facilitate rapid withdrawal and reinsertion of the colonoscope.

Blind rectal ultrasound probes can assess invasion in tumors of the anorectal area. Direct-vision, ultrasound-bearing colonoscopes may also have a role in tumor staging. Small ultrasound probes may be passed through the colonoscope's instrument channel to enable ultrasound as desired at any point throughout the colon [2] (e.g., before removal of sessile lesions, to check the relation of the colon wall to surrounding organs before electrocoagulation).

ANATOMIC BASIS OF COLONOSCOPY

The ease or difficulty of colonoscopy in a given patient is related to the degree to which the supporting mesenteries fuse to the posterior abdominal wall during fetal development. Although the descending and ascending colon become fixed retroperitoneally, in about 10% to 15% of patients they remain mobile on mesocolons similar to the normal anatomy of the sigmoid and transverse parts of the colon. The consequence for the endoscopist is that these colons are mobile and can move around freely and unpredictably within the abdomen, being uncontrollable by the various straightening or rotation maneuvers that are effective with conventional colonic anatomy.

There are no fixed anatomic landmarks between the anus and the ileocecal valve, but there are geographic clues which often are helpful (but may also be misleading). At about 17 cm, the colonoscope leaves the capacious rectum and enters the narrower, extraperitoneal part of the sigmoid colon (Fig. 140-1). The sigmoid has frequent circular haustral infoldings—which may be especially exaggerated with diverticular disease—into which the instrument tip impacts if steering is not accurate.

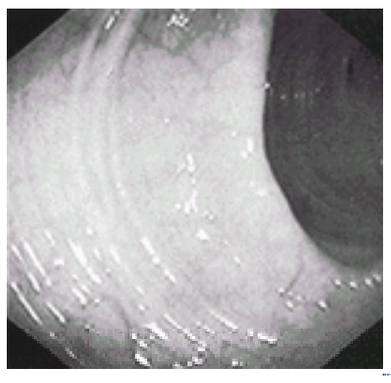

FIGURE 140-1. In the sigmoid colon, the circular outline with the light reflex over arcs of circular musculature clearly indicates the center of the lumen for close-up endoscopic steering purposes.

In contrast to the zigzag path of the sigmoid colon, the descending colon is usually a short, tubular segment. An acute angulation of the instrument tip at the junction of the sigmoid and descending colon may afford a clear view of the tubular descending colon, but forward progress may be impeded by loops in the instrument caused by the tortuous and convoluted sigmoid colon.

The transverse colon (Fig. 140-2; see also Color Fig. 140-2) frequently shows a triangular configuration as a result of its three longitudinal muscles, or teniae coli, that act as tethering boundaries to air distention. The liver is a fairly predictable landmark with the flat, bluish-gray surface and sharply defined edges caused by the balloonlike, air-filled colon contacting the hepatic surface (Fig. 140-3; see also Color Fig. 140-3).

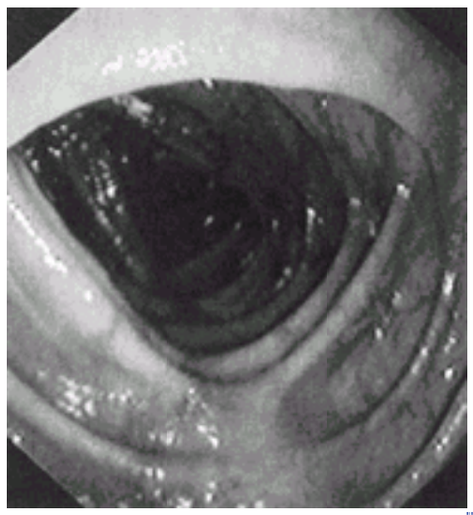

FIGURE 140-2. (See Color Fig. 140-2.) Transverse colon shows the characteristic triangular outline resulting from the relative thickness of the three longitudinal teniae coli. The circular muscle is much thinner.

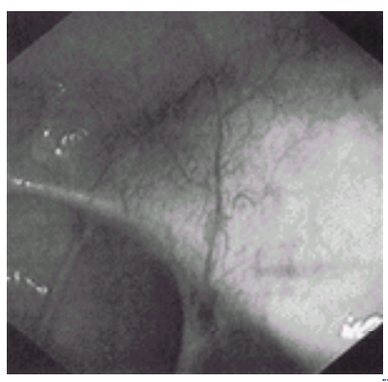

FIGURE 140-3. (See Color Fig. 140-3.) Hepatic flexure shows the dark impression of the liver. Similar discoloration can be caused by other extracolonic viscera at the splenic flexure or in the distal colon. Note the longitudinal impression of a tenia and the transverse haustral folds.

Upon entering the ascending colon, the superior lip of the ileocecal valve may appear in the distance as a short flat segment on the most proximal circular haustral fold (Fig. 140-4; see also Color Fig. 140-4). The upper lip may have a notched bulge or may appear thickened by fat accumulation. Most often the opening into the ileum is slitlike on the inferior side of the fold. The appendiceal orifice, a less definite landmark, is seen as a crescent-shaped slit or a circular convolution of folds at the blind saccular cecal pole (Fig. 140-5; see also Color Fig. 140-5). Multiple, pale reddish, 1- to 2-mm circular halos are often seen in proximity to the appendix when using the videoendoscope. These represent lymphoid follicles. [3]

FIGURE 140-4. (See Color Fig. 140-4.) Ileocecal fold shows the characteristic notch on a flattened fold. The notch denotes the superior lip of the ileocecal valve. The opening is just proximal to and below the notch, and cannot be seen without marked angulation of the instrument tip.

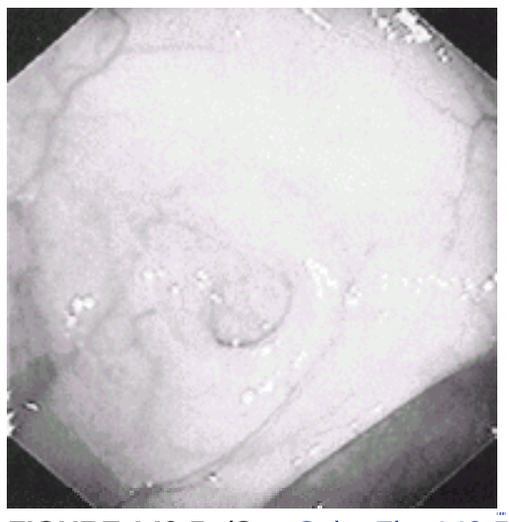

FIGURE 140-5. (See Color Fig. 140-5.) The appendix orifice is variable in configuration. Here, the orifice is round, but it may also be seen as a crescent-shaped slit. It is usually rather insignificant in appearance. The internal aspect remains the same after appendectomy.

The ileal mucosa has a granular appearance when the ileum is air-filled, and short frondlike villi are visible in pools of fluid. The granular appearance is caused by multiple light reflections from the individual villi. One- to 3-mm nodules of lymphoid tissue, sometimes aggregated into 10- to 15-mm plaques of Peyer patches are normal in the terminal ileum, and particularly prominent in children. By contrast, the normal colorectal mucosa is smooth and shiny, although with deflation, fine transverse innominate grooves may show, especially with surface dye spray.

Throughout the colon, a fine, interlacing, vascular pattern is visible through the transparent overlying epithelium. When the normal vascular pattern is hidden by mucosal congestion, visible as diffuse redness of the surface, a pathological process must be considered, but biopsies are needed to differentiate between inflammatory change and traumatic or reactive hyperemia. Opacity of the surface can also be caused by thickening that occurs after chronic colitis or by edema. In the rectum, the vascular pattern is more pronounced, with larger vessels. Hemorrhoidal veins may appear wide and tortuous. A U-turn (i.e., retroflexion) maneuver in the rectum should always be attempted to afford a view of the rectal ampulla, the dentate line (Fig. 140-6; see also Color Fig. 140-6), and internal hemorrhoids, [4] but the rigid anoscope gives a superior view of this area by dilating it maximally.

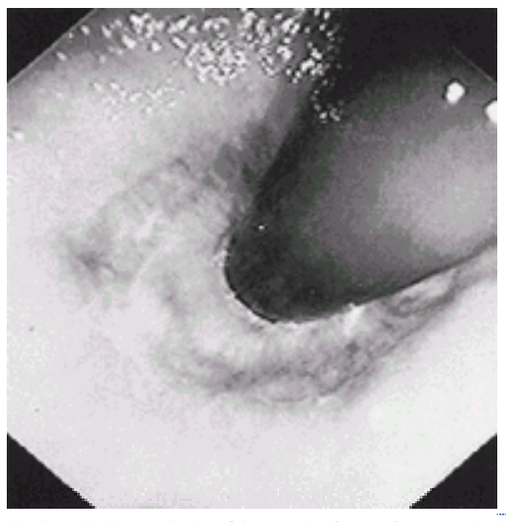

FIGURE 140-6. (See Color Fig. 140-6.) Retroversion of the endoscope in the rectum is a useful maneuver to find or remove small polyps in the distal part of the rectal ampulla. The dentate (pectinate) line is serpiginous at the junction of the squamous mucosa of the anal canal and the columnar rectal mucosa.

Localization During Colonoscopy

The position of the colonoscope can be approximately judged by a combination of factors: the length of instrument inserted, the characteristic appearances of certain areas, including the sharply defined blue color of the liver, the fluid-filled splenic flexure area, and the triangular, air-filled, transverse colon. Most instruments are bright enough to transilluminate the abdominal wall where the bowel approximates to the surface at the splenic flexure (left midaxillary line), transverse colon, or cecum. Fluoroscopic guidance is rarely used, but some find it helpful in the endoscopist's learning phase and in a few difficult cases.

The magnetic imager [5] is a new localizing device whereby small electromagnets can be inserted into the colonoscope shaft, either during manufacture or with a catheter-type wand. External sensors can detect the energy and plot an image of the exact shape and location of the endoscope. There is no radiation, and the computer-generated image is similar to that obtained fluoroscopically. Alternatively, the transabdominal impression of the endoscopist's palpating fingers may often be seen from within. Transillumination or endoscopically visible indentation by finger palpation in the right iliac fossa, however, does not necessarily indicate that the tip of the instrument is located in the cecum, because the instrument tip may stretch almost any portion of the colon into the right lower quadrant during colonoscopic intubation. For instance, mobile portions of the bowel, such as the sigmoid or the midpoint of the transverse colon, can be pushed toward the right iliac fossa.

All localizing judgments that depend on landmarks or palpation can be mistaken. For instance, using the length of scope inserted, in a long or mobile colon, 80 cm of shaft may be looped in the proximal sigmoid; whereas in the same patient during withdrawal, the instrument may be straightened so that the splenic flexure is 40 cm from the anus, and the hepatic flexure (or even the cecum) can be reached with 50 to 60 cm of instrument. The only definitive landmark is the ileum seen through the ileocecal valve, but even this may be difficult to locate, and the valve can be effaced after severe or long-standing inflammatory disease.

Because of the absence of absolute landmarks throughout the colon, even if the endoscopist has reported success in total colonoscopy with identification of the ileocecal valve and cecal pole, there is still the possibility of being grossly mistaken about the location of the instrument tip and in the anatomic localization of pathological findings. [6] Even experienced endoscopists can occasionally mistake the splenic flexure for the hepatic flexure or the hepatic flexure for the cecum, and thereby mislead the surgeon as to the site of an obstructing tumor. [7]

In the absence of fluoroscopy, any lesion seen by colonoscopy can be marked with an intramural deposit of carbon particles using sterilized india ink or a newly developed pure carbon suspension, injected through a long, flexible, injector needle, either for subsequent surgical localization or to enable the endoscopist to find the area on a subsequent examination. [8] A gray-blue, submucosal stain of carbon permanently remains at the injection site. Injection of vital dyes such as methylene blue, indocyanine green, or indigo carmine are rapidly absorbed, disappearing within hours or days. [9] It is possible to mark the proximal extent of tip progress with metal clips, [10] but this technique is often not clinically useful.

BOWEL PREPARATION

Total colonoscopy is rarely possible in the unprepared colon. Patients with profuse watery diarrhea are sometimes mistakenly thought not to require preparation and are often found to have an opaque mucosal coating of fecal material that obscures adequate view of the surface. Even patients with a surgically defunctionalized bowel produce inspissated mucoid residue and require cleansing. A patient with massive colonic bleeding may effectively cleanse the colon of fecal material, but often a residual coating of blood obscures mucosal events during the colonoscopic examination.

Limited Preparation

When it is necessary to examine only the distal colon segments, an adequate preparation can consist of one or two evacuant enemas of tap water, saline, or, more usually, a small-volume hypertonic phosphate or other proprietary enema, given 15 to 60 minutes before the examination begins. This allows enough time for proper bowel clearance but is not so long that proximal contents move distally. Limited bowel preparation assumes normal colonic ability to empty the whole left colon rapidly by mass action. This may not happen in patients with diverticular disease or strictures. In these individuals, even limited examination must usually be preceded by full bowel preparation.

Full Preparation

A wide variety of bowel preparations are available. [11] Ideal attributes for bowel preparation include pleasant taste and avoidance of excessive volume, cramps, or the need for enemas. Certain modifications of medication and diet are necessary. Oral iron medications must be stopped 4 to 5 days before colonoscopy because the formation of organic iron tannates in combination with dietary green vegetable residue renders colon contents black, sticky, and difficult to clear. Constipating agents such as codeine or loperamide should be discontinued 12 hours before colonoscopy. It has been suggested that aspirin and other antiplatelet drugs or anticoagulants be discontinued 7 days before examination to reduce the risk of immediate or delayed bleeding should polypectomy be performed, but this may not be necessary since clinical experience has not borne out any excess bleeding risk in patients on aspirin. [12] No matter what the preparation regimen, colon cleansing is enhanced by a clear or full-liquid diet for 24 to 48 hours before the examination.

Purgative Regimens

Purgative regimens are still the most commonly used form of bowel preparation. Their advantage is that the colon, after a contact laxative such as senna, or bisacodyl, is stimulated to evacuate most of the bowel contents. Disadvantages are that the evacuation stimulus can cause severe cramping abdominal pain, that the cecal region is often poorly cleared, and that some solid residue often remains distally. Therefore, enemas or oral osmotic agents may be required to supplement the cleaning effect of the purgative. More recent bowel cleansing methods do not require enemas. [13]

Osmotic purges can be used as an alternative to enemas, either adding to or supplementing the oral purgative with up to 2 L of an agent such as magnesium salts (e.g., citrate, sulfate) or a nonabsorbed carbohydrate (e.g., mannitol, lactulose, sorbitol). Magnesium sulfate has strong purgative and osmotic effects but also an unpleasant taste; the milder but citrus-flavored magnesium citrate is generally preferred. Mannitol has been the most widely used of the carbohydrate solutions. Its sweet taste can be reduced by cooling, and the likelihood of nausea is prevented by preadministration of an oral antiemetic prokinetic agent such as domperidone or metoclopramide 30 minutes before administration. Five percent mannitol is isotonic, and 2 L are drunk slowly over 1 hour or more. The use of mannitol or other carbohydrate preparations risks explosion during electrosurgical procedures because of the production of hydrogen gas resulting from fermentation by intestinal bacteria. This risk can be effectively eliminated by insufflation of carbon dioxide during the procedure or by meticulously aspirating gas and reinsufflating air before electrosurgery. A low-volume sodium phosphate preparation is commonly used for endoscopy preparation and has been well received by patients. [14] Taken orally the evening before and 4 hours prior to colonoscopy, 45-mL aliquots of sodium phosphate produce a vigorous catharsis. [15] Cleansing enemas are not required. Fluid balance shifts, absorption of sodium, or hyperphosphatemia may cause deleterious effects, especially in the presence of cardiac or renal disease. The noxious taste may be circumvented by dehydrated sodium phosphate in pill form. [16]

Balanced electrolyte solutions, administered in a volume of 4 L orally or by nasal tube, result in an acceptable bowel preparation. The salty, oily taste and required large volume cause about 10% of patients to stop drinking the solution, thereby failing to prepare their colon adequately. Newer formulations with flavoring have improved palatability and may improve patient compliance. Although packaged instructions advise minimal dietary restrictions, better results can be expected from a 24-hour full liquid diet. Simple saline solution (0.9% sodium chloride) is effective and arguably safe for preparation of the majority of patients, but potassium losses and electrolyte fluxes can be avoided by appropriate additional ingredients.

The regimen chosen for whole-colon preparation necessarily varies according to circumstance, patient preference, and clinical indication. Patients need to sleep and must be able to travel without fear of incontinence, so the timing of preparation must also be adjusted according to the time of examination and travel arrangements. [17] Frail, ill, and elderly patients may require modified preparation, sometimes on an inpatient basis if cooperation is uncertain. If obstruction is a possibility, oral preparations may be dangerous or at least should be spread out over a longer period. In almost all circumstances, a patient fit for total colonoscopy is fit for full-bowel preparation. Compromise in reducing the regimen may result in poor preparation and in only being able to perform a limited examination or a less accurate colonoscopy.

Whichever of the different purgative regimens is chosen, it must cause profuse, clear, fluid diarrhea. A more vigorous preparation may be required for the patient with chronic constipation or severe diverticular disease or a patient whose bowel was not properly cleansed with a previous regimen. It is desirable that patients continue to drink fluids up to the time of the examination, and ingest at least some of the preparation fluid within a few hours.

Medication

Sedation Sedation is unnecessary for some examinations, especially those that are limited, or those in patients after sigmoid colon resection or in whom a previous procedure is known to have been easy. A great deal also depends on the patient's attitudes and on local custom. Endoscopists in some countries rarely sedate, whereas those in other countries almost always do. Some routinely use general anesthesia administered by an anesthesiologist, [18] although this may add to the risk of complications by removing feedback from the patient relating to pain from loops or difficult electrosurgical procedures. Using less sedation makes for easier change of position and greater safety. Using no sedation allows the patient to leave rapidly and unescorted after the procedure. Endoscopists who never use sedation may have a lower success rate in total colonoscopy. [19] Some stretching of peritoneal attachments is inevitable, at least transiently, during colonoscopy. This causes gnawing or acute unpleasant visceral pain. Coupled with air distention and the sensation of rectal fullness simulating the desire to defecate, this can make a slow examination difficult to bear for some patients who are mildly or not sedated, although others tolerate it easily. Pain during colonoscopy can usually be rapidly diminished or eliminated by reducing the loops responsible for stretching the mesentery, or by aspirating air, but sometimes further doses of analgesic agents are needed. Normal diet, activities, and medication can usually be resumed as soon as the mild stress of the examination and the effects of medication are over.
Antispasmodics Antispasmodics (glucagon, 0.5–1 mg IV; hyoscine- *N*-butyl bromide, 20–40 mg IV) are thought by some to increase the difficulty of insertion by rendering the colon atonic and therefore more likely to stretch and loop, but they eradicate circular muscle spasm and may increase the accuracy of examinations for small lesions such as polyps or angiodysplasias. [20] Some endoscopists use antispasmodics routinely.
Antibiotics A prosthetic heart valve, history of endocarditis, surgically constructed or congenital systemic-pulmonary shunt, or synthetic vascular graft less than 1 year old places a person at high risk for infection with various procedures. Even in these persons, however, there is insufficient data to strongly recommend antibiotic prophylaxis for colonoscopy with or without biopsy or polypectomy. [21] Antibiotics are not recommended for colonoscopy with or without biopsy or polypectomy in patients with cirrhosis and ascites, immunocompromised patients, those with prosthetic joints or pacemakers, or patients with a history of rheumatic valvular dysfunction, mitral valve prolapse with insufficiency, hypertrophic cardiomyopathy, or for most congenital cardiac malfunctions. If antibiotics are deemed necessary, the usual doses are ampicillin 1 g and gentamicin 80 mg IV 10 to 30 minutes before the procedure.

COLONOSCOPY PROCEDURE

Position and Position Changes

The left lateral position is most commonly used for flexible sigmoidoscopy and colonoscopy, mainly because it gives convenient access to the perineum for insertion. However, colonoscopic examinations can be, and in some centers are, performed in other positions, including lithotomy, knee-chest/elbow, and right lateral positions. Especially if a large-volume fluid preparation regimen has been used, position changes can modify both the configuration of the colon and of the air and fluid within it because of the effects of gravity. When forward progress can no longer be accomplished, a change in the patient's position will aid tip advancement in two thirds of cases. [22]

Insertion of the Endoscope and Flexible Sigmoidoscope

Digital examination of the anorectum is used to lubricate the area generously and to palpate any lesion. A local anesthetic gel may reduce anal discomfort. When

there is rectal stenosis, a fistula, or abnormal anal sensitivity, it may be desirable to use a small-diameter pediatric instrument or a gastroscope. The technique for flexible sigmoidoscopy is the same as for the first part of a colonoscopy, except that it is less important to avoid looping, because the proximal colon is not to be intubated. Characteristically, there is a red-out when the instrument enters the rectum, because the tip abuts on the rectal mucosa. Simultaneous air insufflation and instrument withdrawal are required to disimpact it; and angulation or rotational movements are useful to find the rectal lumen. Movements of the instrument tip should thereafter be slow and deliberate, taking care to steer toward the lumen before pushing inward, so as to avoid constantly losing the view. When the lumen cannot be seen, continuing to push the instrument shaft into the rectum stretches the sigmoid colon into unnecessary and painful loops and rarely results in tip advancement. Once impacted against a haustral fold the tip tends to remain stationary while the rest of the scope flexes into a loop.

Slide-by is a term describing the maneuver when the tip is against the mucosal surface, no part of the lumen can be seen, and the instrument is pushed forward causing the mucosal vessel pattern to visibly slide across the lens. This maneuver should be avoided but is permissible for short distances and only when the instrument is known to be pointing in the correct direction; if tip movement stops and the mucosa blanches, additional pressure risks perforation, and the instrument must be withdrawn to locate the lumen. Withdrawal and disimpaction of the tip is a routine procedure that should be performed every time the view is lost for more than a few seconds.

Diverticular disease is often associated with thickened rings of circular muscle or fixation of the sigmoid colon by pericolic adhesions from previous inflammatory episodes. The resulting distortion and angulations can make it difficult to locate the lumen and coax the instrument through, because the tip is not free to maneuver normally. In a few cases, the angulations are so acute that a small-diameter pediatric colonoscope or a standard gastroscope with the capability for greater tip deflection may allow passage through diverticular disease where the standard colonoscope cannot be passed. Despite the technical problems in intubation, endoscopic examination of diverticular disease can be clinically valuable, mainly because the distorted appearances seen on barium enema may make it impossible to exclude malignancy on radiologic grounds. Similar bowel fixation and angulation may occur after hysterectomy as a result of postoperative adhesions between the sigmoid colon and anterior aspect of the pelvic cavity.

If any pathology is seen during flexible sigmoidoscopy, a biopsy can be easily and safely performed. However, electrosurgery for polyp removal is contraindicated after the limited bowel preparation for flexible sigmoidoscopy because of the significant hazard of explosive gas mixtures.

Total Colonoscopy

The fundamentals of insertion technique are the basis of rapid, relatively pain-free, accurate total colonoscopy. Difficulty during intubation of the proximal colon or passage around the hepatic flexure is invariably related to failure to straighten the colonoscope in the distal colon before attempting the last part of the insertion. Looping in the sigmoid colon is a continual and recurrent problem throughout a colonoscopy but especially when it is necessary to push harder to transmit force around a looped colonoscope to reach the cecum.

During a colonoscopy, there are only a limited number of options available to the endoscopist. These include pushing the instrument in or pulling it out; twisting the shaft to the right or the left; insufflation or withdrawal of air; using tip controls to steer up, down, right, or left; use of abdominal pressure to reduce loops; and changes of patient position. The difference between the slow endoscopist who reaches the cecum infrequently after a traumatic examination and a fast endoscopist who examines the whole colon in over 95% of patients within an average time of 10 minutes is the ability to use the various options logically, quickly, and sequentially without repeating a nonproductive maneuver over and over again.

During the intubation phase, the instrument controls must be continuously manipulated using torque to keep an adequate view of the lumen while the endoscopist concentrates on visual detail to locate and find the direction when it is briefly lost, and backs off quickly if the tip impacts into a bend or fold. The endoscopist can feel when the instrument is passing freely and can be advanced or when it is becoming snarled and should be withdrawn before pushing in again. The biggest mistake of the inexperienced endoscopist is to think that a good view of the lumen is an unqualified signal to push, especially when looped in the sigmoid with a view of the descending colon; pushing under these conditions often results in an expanding sigmoid loop with resultant pain but without tip progress.

Some sigmoid loops, such as the spiral a-loop configuration that may form in the sigmoid colon, are favorable, because they allow the instrument to proceed into the descending colon without forming acute angulations; others, such as the N-loop, which more frequently occurs in the sigmoid, put the tip into an acute angulation at the descending colon junction, making this area difficult and painful to pass through. Fluoroscopy is not necessary to ascertain the presence of a loop, because it is apparent that a loop is forming whenever the shaft is pushed in more than the tip advances. Additionally, once a loop is stretched on its mesentery, additional pushing hurts the patient. Conversely, when the colonoscope shaft is straight, with the colon shortened or pleated over it rather than stretched, only a light touch is needed on the instrument with 1:1 correspondence between shaft and tip during push-pull and rotational movements. When there are no excessive loops, tip angling using the dial controls is also easy and full. Conversely, when the tip is maximally deflected using both control knobs and the lumen is at an acute angle, this indicates that the scope is in a loop configuration. The best maneuver is to withdraw and straighten the shaft, and if that cannot be accomplished, short in-and-out thrusts of the scope often result in forward tip movement.

Because of the multiple bends, folds, and twists of the large bowel, it is inevitable during a colonoscopy that the instrument will loop or start to loop on many occasions. After each advance, by pulling back and restraightening the shaft, the colon is effectively shortened and pleated over the instrument, which is progressively advanced on a “three-steps-forward-and-two-steps-back” basis.

It is usually not possible to keep the instrument straight or the patient completely comfortable all the time because of the unpredictability of the sigmoid colon. There may be a period of difficulty or looping before the tip reaches the fixed retroperitoneal part of the descending colon or the splenic flexure, where the shaft can be fully straightened by pulling back with clockwise rotation to only 50 cm from the anus. Unfortunately, because of the variability of the anatomy and attachments of the sigmoid and descending colon, this first part of a colonoscopy is the most difficult part of the procedure.

Passing the splenic flexure into the transverse colon is usually easy if the sigmoid has been straightened and can be held straight. After maximal shaft withdrawal, the combination of gentle shaft advancement with clockwise twist maintained, simultaneous abdominal pressure over the sigmoid, and avoidance of tip overdeflection usually allows progress into the transverse colon. Overaggressive pushing tends to reform the loop in the sigmoid, and overangulation impacts the tip into the flexure (i.e., the inverted “J” or “walking stick handle” effect). If, after several attempts, the tip does not advance, the instrument should be withdrawn and restraightened; rotating the patient into the right lateral position almost invariably causes the splenic flexure to drop downward, allowing the instrument to slide more easily around to the midtransverse colon. With the patient in the right lateral position, the midtransverse colon often sags down into a rather acute bend, providing a good point at which to withdraw and restraighten the colonoscope once again and also to rotate the patient onto the back or the left lateral position before insertion into the proximal colon.

In the proximal transverse colon or hepatic flexure region, and thereafter in the even more capacious ascending colon, deflation is extremely helpful in advancing the instrument and shortening the distance to the ileocecal region. Aspiration of air causes the colon to deflate concentrically so that the diameter is smaller, but it also results in shortening the colon longitudinally. A few additional maneuvers may be helpful in assisting total intubation, such as rolling the patient into the prone or supine position or asking the patient to inspire to lower the diaphragm. The more difficult it is to reach up or around the hepatic flexure and down to the cecal pole, the less likely it is that aggressive forward pushing will work. The longer and more mobile the colon is, the more certain it is that force will generate loops that will absorb all the motive power applied. With attention to technique and patience, even a redundant colon often shortens to only 50 to 60 cm at the hepatic flexure, permitting the tip to slip down the last few centimeters with ease. Advances in technology have permitted electromagnetic imaging devices to visualize, in real time, the three-dimensional localization of the colonoscope without x-ray involvement, which may significantly change current practice. [5]

Ileocecal Region

Even experienced endoscopists can be mistaken in thinking that a capacious hepatic flexure is the cecal pole, or that tonic contraction of the ileocecal fold represents the appendiceal orifice. The appendiceal orifice is seen often merely as a crescent-shaped slit or a circular convolution of folds. When a crescent orifice is seen, the apex of the crescent almost invariably points toward the ileocecal valve. With the tip in the cecum and the crescentic orifice clearly visible, deflection of the tip in the direction indicated by the apex of the curve will align the scope with the ileocecal valve orifice. Withdrawal of the shaft and deflection of the up/down control dial in the direction of the appendix curve when the first large fold is encountered will often result in ileal intubation. Alternatively, withdrawing the colonoscope 10 cm or so back up the ascending colon and looking for the telltale inward bulge of the valve on the ileocecal fold, which is the first encircling fold back from the cecal pole, is another method to permit the endoscopist to determine where to angulate and enter the ileum. Even so, ileal intubation can be difficult and may require several minutes combined with skill and patience. The anatomy is variable, and both colon and colonoscope can rotate or move during attempted insertion. Some ileocecal valves

show prominent pouting lips; others, however, are the merest slit on the reverse side of the ileocecal fold, which may require visualization by attempting retroversion of the bending section of the colonoscope within the cecal pole.

Terminal Ileum

A skilled endoscopist can enter the terminal ileum with reasonable ease in approximately 80% of cases [23] and can almost invariably obtain a blind forceps biopsy through the valve in the remaining patients. Failures arise mainly when deformity or scarring make angulation impossible or the opening too narrow, but poor bowel preparation and loops in the instrument can be contributory problems. Endoscopic assessment of the mucosa of the terminal ileum is straightforward. Although the polypoid lymphoid follicles that are frequently present may cause the radiologist to mistakenly diagnose Crohn's disease and consider cobblestoning, these nodules and the surrounding mucosa are covered with normal pink mucosa with a granular surface in air or with small villi visible underwater.

The endoscopic view of the terminal ileum is usually limited to 5 to 10 cm. There is rarely a serious indication to attempt further insertion, because ileal Crohn's disease almost invariably involves the terminal part of the ileum, and other lesions such as ileal angiodysplasia are exceedingly rare; a Meckel diverticulum is not endoscopically accessible because it is located 1 m proximally. If deep ileal intubation is attempted, 30 to 50 cm is usually the limit of what can be seen because of the acute angulations that occur in the small bowel.

Role of the Assistant

Colonoscopy must not be performed by one person alone. A properly trained and observant GI assistant is an absolute necessity for the proper performance of colonoscopy. The assistant's functions extend beyond the confines of the endoscopic procedures itself to include setting up the room before the procedure, recording endoscopic photographs, noting biopsy specimens, and filling out requisition forms for the histopathologist. All equipment that may possibly be necessary for the procedure must be assembled and available before the examination. The endoscopic assistant monitors the patient and assists with accessories. If polyps are encountered, the snare and patient return-plate must be plugged into the electrocautery apparatus, which requires setting the proper diathermy levels and testing to ensure that all equipment is functioning properly. During the examination, additional lubricant, gloves, and abdominal pressure may be provided from time to time during various phases. The assistant orders and prepares the necessary pre-endoscopic medications and is responsible for maintenance of the emergency cart, which must include antidotes for the various medications used, cardiac drugs, resuscitation equipment such as an Ambubag, endotracheal tubes and laryngoscopes, intravenous solutions, and oxygen. The cleaning, care, and maintenance of all the endoscopy equipment is in the hands of the assistant, who is responsible for mechanical cleaning and disinfection procedures. Most colonoscopists prefer to advance and withdraw the shaft of the instrument with the right hand, while the left hand manipulates the dial controls as well as the air-water and suction buttons. However, some colonoscopists prefer a two-person technique, whereby the assistant advances the instrument while the endoscopist handles the control portion of the colonoscope.

THERAPEUTIC PROCEDURES

Colonoscopy makes possible a range of therapeutic procedures. Polypectomy is the most obvious, but electrocoagulation, laser photocoagulation, or injection therapy of vascular lesions (e.g., telangiectasias, angiodysplasias, hemangiomas) are all routine. [24] Laser photodestruction also makes possible the ablation of some tumor masses and large sessile polyps if conventional surgical or snare polypectomy techniques are inappropriate. [25] The argon plasma coagulator is a relatively new monopolar device that delivers thermal energy to the colon wall in a noncontact fashion. It is useful for arteriovenous malformations, radiation telangiectasias, and fulguration of residual adenomatous tissue at the base of piecemeal polypectomy sites. [26]

Snare polypectomy of pedunculated or sessile polyps is efficient, rapid, and relatively safe. By constricting the tissue within the closed snare wire, low electrical power (often only 15– 20 watts) is sufficient for transection, with localized tissue heating. Because the colon mucosa is insensitive to thermal injury, the patient should feel nothing during polypectomy or electrocoagulation unless full-thickness heating is occurring, which causes the patient to warn of peritoneal pain at an early stage, before actual damage has occurred. If small (2 to 5 mm) polyps are found, simultaneous biopsy and electrocoagulation with electrically insulated hot-biopsy forceps can be performed. This rapid procedure ensures that a histological specimen is obtained. An alternative technique for small sessile polyps is cold resection, or cheese-wiring across the base by closing the snare in the absence of current. [27] Snared tissue can be retrieved for pathological analysis by aspiration through the instrument channel into a filtered suction trap or into a gauze tissue placed at the connection of the suction tubing with the endoscopic umbilical cord. Larger polyps can be retrieved whole using the snare loop or other grasping devices, although this may necessitate several reinsertions of the endoscope for multiple polyps. A metal basket or nylon-mesh net allows retrieval of several polyps or fragments from the right colon.

Except for polyps with an extremely broad base, almost all benign-appearing polyps encountered can be removed endoscopically. Pedunculated polyps are removed with snare application around the pedicle. Pure coagulating current at low power is used by most endoscopists following snare-loop tightening, providing controlled and localized tissue heating for blood vessel obliteration. [28] Thicker stalks with increased risk of immediate or delayed bleeding can be preinjected with an epinephrine solution to ensure hemostasis before snaring both flat and broad-stalked polyps with early invasive colon carcinoma may be successfully resected by submucosal injection polypectomy (SIP) technique, whereby the polyp is elevated by a fluid injection (3 to 10 [or up to 40] mL of saline or diluted epinephrine solution) into the submucosa prior to transection. [29] A viscous solution of sodium hyaluronate may also be successfully employed. [30] If the polyp is very large and snare placement is difficult, it may be useful to remove segments sequentially until the base can be easily visualized and complete transection can be accomplished. Even very large pedunculated polyps may be removed in piecemeal fashion. Polyps that usually cannot be removed endoscopically are those that cover a substantial area of the colonic surface (i.e., more than 30% of the circumference), extend over two interhaustral folds, are obviously malignant, or involve the appendiceal orifice. [31]

Every effort should be made to retrieve all the resected portions of each polyp and to submit them to the pathologist for histological evaluation. Because of the force of gravity, polyps have a tendency to fall into fluid pools or crevices that hide them from view, making retrieval difficult. There are various techniques for polyp retrieval. Although in clinical circumstances, only about 94% of transected colon polyps are recovered for full histopathological interpretation, those most likely to be lost are small and of little clinical significance.

Tube placement in patients with pseudoobstruction (Ogilvie syndrome) or postoperative ileus can be accomplished by passing a decompression catheter over an endoscopically placed guidewire after withdrawal of the colonoscope, [32] or by carrying the tube up alongside the endoscope during insertion. Immediate decompression occurs, but because of the frequency of redilation, it is wise to leave the tube in situ until it is expelled spontaneously, signaling restoration of normal propulsive contractions. Volvulus can be reduced by placing a wide-caliber tube beyond the twisted segment, provided the colon is not gangrenous, in which case surgery is mandatory. Foreign bodies can be successfully removed endoscopically from all levels of the large bowel. Balloon dilation is possible, usually with through-the-scope (TTS) balloons inserted under direct vision into a stricture, with or without prior guidewire placement. [33] The controlled radial expansion (CRE) balloons exert maximal dilating force over a range of sizes according to the degree of pressure applied. An appropriate-size balloon gives sufficient dilation for most circumstances with minimal risk of splitting the stricture. These balloons have the advantage of allowing passage over an endoscopically positioned guidewire, with correct insertion and dilation observed either endoscopically or on fluoroscopy. Other techniques for stricture dilation include incision into the stricture with electrocoagulation by a needle-knife, the slightly protruded tip of a polypectomy snare, or a papillotome; these methods are however, useful only for relatively thin, short strictures.

Short strictures, such as those after right hemicolectomy for Crohn's disease or when postoperative complications result in localized anastomotic narrowing, respond very well to endoscopic dilation. A single dilation can be permanently effective or can last for a few weeks to many months, depending on the presence of any inflammatory condition likely to cause restenosis. [34] Postoperative anastomotic stenoses may be dilated widely during the first examination because there is usually considerable fibrosis around the anastomotic site which makes the occurrence of free perforation unlikely. Primary strictures in inflammatory bowel disease unrelated to surgery, however, do not have the same surrounding cicatricial reaction, and the initial dilation should be limited to not greater than twice the diameter of the stricture to avoid perforation. Frequently, the lumenal narrowing in Crohn's disease is related to active inflammation with circular muscle spasm and so is rarely ameliorated by attempts at endoscopic dilation techniques. Self-expanding metal stents effectively dilate malignant strictures, and are usually permanently embedded into the tissue once inserted. They may be used for decompression prior to surgery or for symptom palliation. [35]

INDICATIONS

Flexible Sigmoidoscopy

Flexible sigmoidoscopy should be the procedure of first choice for examination of the rectum and sigmoid colon. It is useful for evaluation of complaints that most

likely are caused by conditions affecting the lower bowel, and for population-based screening for colon and rectal cancer, and should replace rigid proctosigmoidoscopy except when the rigid instrument is used for screening examinations of the rectum on grounds of cost, expediency, and the ease of taking larger biopsy specimens. [36] The rigid proctoscope (i.e., anoscope) is preferred for assessment of hemorrhoids and anal canal pathology, which are often poorly seen with a flexible instrument, even in retroversion.

Flexible sigmoidoscopy alone may be considered sufficient examination in patients with minor disturbance of bowel habit, obvious hemorrhoidal bleeding such as blood dripping into the toilet bowl following defecation, or localized left iliac fossa pain. With minimal discomfort and no sedation, the rectum, sigmoid colon, and often the descending colon or splenic flexure can be examined.

Colonoscopy

Colonoscopy can be performed in any patient fit for barium enema and for a similarly wide range of indications (Table 140-1). With the increasingly widespread availability of endoscopic skills and improvements in instrument technology, colonoscopy can often be regarded as a first-line procedure not preceded by barium enema. A prior barium enema rarely helps the endoscopist, because the configuration on x-ray films gives little indication as to how easy or difficult the colonoscopy will be. Most patients find barium enema a more unpleasant experience than colonoscopy because of the sustained inflation required in the double-contrast barium enema (DCBE) [37] and perhaps also because of the sedative-analgesic medications often given for colonoscopy.

- Evaluation of abnormality on barium enema likely to be clinically significant, such as a filling defect or a stricture
- Evaluation of unexplained gastrointestinal bleeding (including occult bleeding)
- Unexplained iron-deficiency anemia
- Screening and surveillance for colonic neoplasia
- Chronic inflammatory bowel disease of the colon if more precise diagnosis or determination of the extent or activity of disease will influence immediate management
- Clinically significant chronic diarrhea of unexplained origin
- Intraoperative identification of a lesion not apparent at surgery (e.g., polypectomy site, location of a bleeding site)
- Treatment of bleeding from such lesions as vascular malformation, ulceration, neoplasia, and polypectomy site
- Foreign body removal
- Excision of colonic polyp
- Decompression of acute nontoxic megacolon or sigmoid volvulus
- Balloon dilation of stenotic lesions (e.g., anastomotic strictures)
- Palliative treatment of stenosing or bleeding neoplasms
- Marking of a neoplasm for surgical localization

Modified from ref. 86.

TABLE 140-1 Indications for Colonoscopy

High-Yield Indications

Abnormal Barium Enema X-Ray The highest diagnostic yield of endoscopic pathology is in patients with tumor, polyps, stricture, or mucosal disease diagnosed on DCBE. Colonoscopy provides histological confirmation or confident exclusion of a questionable abnormality, [38] and allows immediate therapy where appropriate.
Colon Polyps: Benign and Malignant Nearly all polyps can be snare-resected during the procedure, and some radiologically diagnosed carcinomas prove to be benign lesions that are manageable endoscopically. Even with an apple-core lesion on x-ray films, colonoscopy can confirm the histology of the lesion, and in the absence of obstruction, also rule out synchronous polyps and cancers. Five percent of pedunculated or broad-based polyps removed endoscopically are found histologically to contain invasive carcinoma with malignant cells traversing the muscularis mucosae into the submucosal layer. The biologically benign entity in which malignant cells are present only superficial to the muscularis mucosae should not be described as “carcinoma in situ”; but rather by the more innocuous term, *severe dysplasia*. Surgical resection is not necessary in pedunculated polyps with invasive carcinoma if there is a sufficient margin (1–2 mm) between the limit of invasive carcinoma and the resection line on multiple sections, if the carcinoma is well or moderately well differentiated, and if there is no lymphatic or venous invasion. [39], [40] There is controversy as to whether these endoscopic and histological principles should be applied to the local removal of sessile malignant polyps or whether surgery should be recommended unless the patient is a poor operative risk. Because malignant polyps and polypoid carcinomas tend to occur in older, frail patients, and surgery rarely yields resectable lymph nodes without evidence of distant metastases, there is an increasing tendency to use conservative endoscopic management, even in lesions failing to meet the previously outlined criteria, unless the patient is an excellent surgical risk. [41] The use of a permanent colonic tattoo makes it possible to localize a malignant polypectomy site with accuracy in the event that surgical resection is necessary [8] or for subsequent surveillance after an interval of a few months before entering a normal follow-up regimen. [42]
Rectal Bleeding of Undetermined Etiology Rectal bleeding, especially if sustained, dark, or mixed in the stools, is frequently caused by tumor or mucosal pathology. In the subgroup of patients with visible rectal bleeding in whom a barium enema and sigmoidoscopy are normal, about 10% of referral patients have cancer, 15% to 20% have polyps (Fig. 140-7; see also Color Fig. 140-7), and up to 50% have some kind of a visible abnormality, including traumatized, inflamed, or ulcerated mucosa. Blood loss or anemia, particularly in elderly persons, remains the highest-yield indication for colonoscopy. Total colonoscopy should be performed rather than DCBE in the assessment of rectal bleeding, whether overt or occult, because of the obvious bonus of color view in seeing blood, altered blood, or bleeding points, which can be flat and totally invisible on x-ray films. It may also be possible to treat the cause of bleeding endoscopically. [43]

FIGURE 140-7. (See Color Fig. 140-7.) Smooth sessile adenoma is located in the descending colon.

Acute colonic bleeding. Acute colonic bleeding of overwhelming proportions may require surgery and perioperative bowel irrigation with on-table colonoscopy, [44] but bleeding of lesser severity may stop spontaneously. [45] Ten percent of patients admitted to an intensive care unit with a tentative diagnosis of acute colonic bleeding will have an upper GI source, [43] which must be considered in all instances. In most cases of acute bleeding, an attempt at conventional colonoscopy examination is indicated before resorting to angiography, scintigraphy, or other investigational techniques. If possible, oral or nasal tube electrolyte bowel preparation is started immediately after the patient presents because blood coating makes localization of the bleeding site very difficult without preparation or if enemas reflux blood proximally. Colonoscopy should be performed as soon as practical, because the aim is to examine the bowel while fresh bleeding continues. [43] Waiting even an hour or two may miss the opportunity for diagnosis and allow degradation of blood into a dark unpleasant mess. If there is bleeding, adequate visualization can be maintained by changing the patient’s position during the examination. Expertise is needed in this situation, but a cause for bleeding should be apparent in more than half of all cases, and treatment may be possible by polypectomy, electrocoagulation, injection therapy, or other means. [46] Postpolypectomy hemorrhage should be managed by immediate colonoscopy without preparation, since the site of bleeding is known. [47] An algorithm for the approach to acute lower GI bleeding has been published. [43]
Anemia Iron-deficiency anemia or a positive fecal occult blood test should be evaluated by colonoscopy rather than DCBE because flat lesions such as angiodysplasia or minor inflammatory change cannot be diagnosed radiologically. Even if radiographs appear normal, endoscopy is known to find significant numbers of radiologically missed lesions such as cecal carcinomas. In anemic patients, gastroscopy and colonoscopy can be performed at the same visit. The object of

endoscopy in anemic patients is mainly to rule out carcinoma or vascular anomalies with certainty; about 80% have negative examinations, but the endoscopic opinion of normality is considerably more certain than a negative x-ray film result.

Chronic Diarrhea Patients with long-standing bowel diarrhea require an accurate examination with histological biopsies routinely taken and other specimens as appropriate. Rectal evaluation is adequate in many patients, but total colonoscopy and ileal examination complete the investigation and sampling process in one definitive test. Microscopic or collagenous colitis can occur despite normal endoscopic appearances; therefore, biopsy specimens must be taken in any patient with chronic diarrhea or increased bowel frequency. [48] However, the normal colonic mucosa frequently harbors inflammatory cells, and great care should be taken to avoid misinterpretation and overdiagnosis of inflammatory bowel disease when none is truly present, based on an inexperienced pathologist's report of acute or chronic inflammation on biopsy specimens. Collagenous colitis is diagnosed histologically from a thickened intraepithelial collagen layer. Ischemic colitis has a range of appearances, from slight reddening and friability, to varying degrees of ulceration, to frank gangrene; the diagnosis is often possible by combining the typical history of sudden onset of pain, bleeding, and diarrhea with endoscopic evidence of a perisplenic distribution.

Inflammatory Bowel Disease Often, the mucosal appearances are sufficient to make immediate assessment of the extent and type of colitis. [49] Crohn's disease, in particular, shows a rather characteristic pattern of small aphthoid ulcers with intervening normal mucosa quite unlike the generalized redness of early ulcerative colitis. More advanced inflammatory disease of any type, including ulcerative colitis, Crohn's disease, tuberculosis, or amoebic colitis, can be nearly indistinguishable from each other because of the colon's limited range of responses to various diseases that affect the mucosal surface. [50] Once the diagnosis of inflammatory bowel disease has been established, there are only a few indications for follow-up colonoscopy besides malignancy surveillance, unless there is a marked change in symptoms.

Cancer Surveillance or Prevention

The long period preceding cancer during which a focal adenomatous polyp is visible gives the opportunity for visualization, biopsy, and destruction of precancerous lesions, even at sizes of 1 to 2 mm. [51] Accuracy is possible, because color makes it easy to distinguish which small excrescences are fecal, which are air bubbles, and which are polyps. A syndrome of flat adenomas has been described. [52] These adenomas may have a tendency to degenerate into carcinoma while still relatively small in diameter. [53] Detecting their presence may be enhanced by zoom colonoscopy or by dye spraying or "chromoendoscopy." [54]

The recommendations of an expert multidisciplinary panel, published in 1997, [55] included offering colonoscopy every 10 years to asymptomatic persons of average risk who are 50 years of age or older. In addition, the panel suggested annual fecal occult blood tests in this population, with colonoscopy as the investigation of choice if the occult blood test is positive. A flexible sigmoidoscopy is recommended every 5 years, followed by colonoscopy to remove polyps, biopsy cancers, and to examine the rest of the bowel should an adenoma or cancer be seen. Colonoscopy is indicated for any patient with a positive fecal occult blood test and in those who are at increased risk for polyp and cancer formation, including those with first-degree relatives with either colorectal cancer or an adenomatous polyp, in whom screening should begin at age 40. [55] People with a family history of familial adenomatous polyposis whose genetic testing is positive or indeterminate should be offered flexible sigmoidoscopy every 12 months beginning at puberty. [55] Family history of hereditary nonpolyposis colorectal cancer (HNPCC) should trigger an examination of the entire colon every 2 to 3 years starting between the ages of 20 and 30 years.

The interval between surveillance examinations after removal of adenomatous polyps or an operation for colorectal cancer is a matter of debate, [56] but the expert panel [55] has made the following recommendation: Removal of an adenomatous polyp larger than 1 cm in diameter or of multiple polyps requires repeat colonoscopy 3 years after the initial examination, and if that is negative or reveals only a single small tubular adenoma, the surveillance interval can be increased to 5 years. In special circumstances, such as a polyp with invasive cancer, large sessile adenomas, or numerous adenomas, a shorter follow-up interval may be necessary. In patients who have had a colorectal cancer surgically resected with a curative intent, if total colonoscopy had not been performed preoperatively, a complete colon examination should be completed within 1 year of the resection. If this or the preoperative examination was normal, subsequent colonoscopy is indicated in 3 years, and if normal, every 5 years.

Surveillance examinations in patients with extensive ulcerative colitis [57] or Crohn's colitis [58] normally start 8 years after onset of disease and are repeated at 1- or 2-year intervals, with 10 or more biopsy specimens taken at representative sites around the colon. The endoscopist is alert for any nodular, indurated, or plaquelike lesions in the colon, but varying degrees of low- or high-grade dysplasia may be found in relatively normal-looking mucosa.

Intraoperative Colonoscopy

The most common indication for intraoperative colonoscopy is to localize the site of a previously endoscopically resected malignant polyp (not necessary when preoperative tattooing is performed). The site may heal completely in 3 weeks, leaving no external sign of its location, but it can often be endoscopically identified as a scar on the mucosal surface. Another indication is to assist the surgeon in identifying which colonic segment is the source of massive lower GI hemorrhage. The presence of a large volume of blood can completely obscure intralumenal vision. Blood can be rapidly flushed out of the colon by a large-volume saline lavage instilled through a cecostomy and removed with a rectal tube. [48]

Low-Yield Indications and Circumstances When Colonoscopy Is Not Indicated

Conditions manifesting with functional symptoms such as long-standing constipation, bloating, or chronic abdominal pain, may be investigated by x-ray examination if there is no occult or overt colonic bleeding (Table 140-2). On the other hand, the older adult patient may be unable to cooperate with the need to retain barium, resulting in a poor radiographic examination. Bowel symptoms in patients older than 70 years of age may be better investigated by colonoscopy than barium enema. [59]

- Chronic, stable, irritable bowel syndrome or chronic abdominal pain
- Acute diarrhea
- Metastatic adenocarcinoma of unknown primary site in the absence of colonic signs or symptoms when it will not influence management
- Routine follow-up of inflammatory bowel disease
- Upper gastrointestinal (GI) bleeding or melena with a demonstrated upper GI source

Modified from ref. 66.

TABLE 140-2 Diagnostic Colonoscopy Is Usually Not Indicated or Has a Low Diagnostic Yield in the Following Circumstances

A flexible sigmoidoscopy may be the examination of choice when the patient presents with an acute diarrheal syndrome, since the view of the distal colon mucosa often (but not always) mirrors the findings in the remainder of the colon. Other than surveillance for malignancy, repeated colonoscopy for routine follow-up of patients with established inflammatory bowel disease provides little clinically useful information. Colonoscopy need not be performed in the patient with overt GI bleeding in whom an active upper GI source has been demonstrated. Similarly, there is no indication for colonoscopy in the patient with an adenocarcinoma where the primary site of the tumor is unknown, unless the result of colonoscopy will influence the management of the patient.

CONTRAINDICATIONS AND RISKS

Colonoscopy is a relatively stressful physiological experience and a strong vagal stimulus that can produce dysrhythmias, minor electrocardiographic disturbances, and a degree of hypotension; therefore, it is contraindicated for several weeks after myocardial infarction. [60] Both the air pressure involved in distention of the colon and the unavoidable stretching during passage around loops and bends have the potential to increase any existing risk of perforation. Because of this, colonoscopy is contraindicated in the acute or abscess phase of diverticulitis. Severe acute episodes of ulcerative, Crohn's, ischemic, or infective colitis have generally been considered a contraindication for colonoscopy, but some reports suggest that, with due expertise and care, it is safe and may be of value in therapeutic decision making in these situations. [61]

Therapeutic maneuvers increase the hazards of colonoscopy. Balloon dilation in a sick patient may justify antibiotics. Polypectomy carries a small risk of immediate primary bleeding or of delayed secondary hemorrhage for up to 29 days after the procedure. The likelihood of delayed bleeding is especially increased in patients with a coagulopathy or in those taking anticoagulants or antiplatelet therapy. When medical conditions prohibit discontinuation of coumadin, the patient may be

admitted to the hospital for the substitution of heparin for oral anticoagulation. Once the coagulation parameters have returned to normal levels, the heparin dosage should be stopped 4 hours before colonoscopy with polypectomy. If a clean polypectomy has been performed without bleeding, heparin may be restarted 4 hours after the procedure, and oral anticoagulants reinstituted 12 to 24 hours later although the possibility of delayed hemorrhage will remain. The patient must remain on heparin until prothrombin levels have returned to the therapeutic level. If polypectomy is associated with bleeding, an attempt should be made to withhold heparin for 8 to 12 hours if it is considered that the patient can safely remain off anticoagulants for that period. Low-molecular-weight heparin has been used during periods of coumadin discontinuation but this has not been supported by clinical investigations. [62]

Polypectomy can result in perforation by cutting through the bowel wall or by applying sufficient thermal energy to burn through and necrose the full thickness of the colon, resulting in a perforation delayed for between several minutes to many days after the polypectomy. The colon wall is extremely thin, with the normal mean colon wall thickness being about 2.2 mm. [63] Some features of a full-thickness thermal injury to the colon wall, including localized pain, fever, and leukocytosis, may occur 6 to 24 hours after polypectomy. This is known as the postpolypectomy or transmural burn syndrome, [64] and must be distinguished from a perforation. Transmural damage is localized and self-sealing when bowel loops, mesentery, omentum, or other adjacent peritoneal surfaces become adherent, so that conservative management with antibiotics and bed rest is usually sufficient.

When signs of frank perforation occur after colonoscopy, it is safest to advise immediate surgery. If only a small amount of free air is present on a postendoscopy x-ray film and the patient has no symptoms, it may be safe to treat the patient conservatively, with antibiotics but without surgery. In any event, a surgeon should always be involved in observation of the patient and in deciding whether or not surgery is indicated. [65]

Current morbidity and mortality rates for colonoscopy are unknown but are certainly higher than those for barium enema. Reviews from the late 1980s and 1990s indicate that the perforation rate is about 1 in 2500 colonoscopies, [66] with a mortality of 1 in 15,000 colonoscopies; most deaths occur after inappropriate conservative management of suspected perforation. [64] The complication rate is inevitably higher in therapeutic colonoscopy than in diagnostic colonoscopy.

The bleeding rate after polypectomy varies from 0.26% to 1.5%, [66] but likely can be reduced with better attention to hemostatic techniques such as the sole use of coagulating current [28] and slow transection. The use of cutting current may be associated with a higher bleeding incidence. [67] Injection or other means of endoscopic therapy for immediate control of bleeding should avoid the small number of cases in which angiographic or operative intervention was previously necessary. Unexpected x-ray demonstration of free air in the abdominal cavity (pneumoperitoneum) of symptomless patients submitted to routine abdominal x-ray after colonoscopy has been reported. Surgeons also report the existence of hematomas, serosal splits, and manifestations of local colonic trauma in patients coming for laparotomy soon after colonoscopy. These facts serve as a reminder to all endoscopists, particularly those in the learning phase, to be cautious, to be considerate of the patient, to avoid oversedation, and to be prepared to abandon a colonoscopy that appears unreasonably traumatic.

COMPARISON WITH BARIUM ENEMA

Colonoscopy has become a procedure of first choice for most colonic investigations. The ability of the barium enema to diagnose advanced cancers is comparable to that of colonoscopy, but it is less accurate for early colon cancers and polyps. [68], [69] In contrast, it is estimated that it is unusual to miss a polyp = 1 cm in diameter during colonoscopy. [70]

Unfortunately, patients with very long and mobile colons or with advanced diverticular disease who are difficult to endoscope are also difficult for the radiologist. Barium enema can be performed following failed or difficult colonoscopy, but endoscopy is impossible in the presence of barium; it is therefore logical to attempt colonoscopy first in most circumstances, providing that each technique is equally available and that the criteria for performing primary colonoscopy are present.

Technical difficulties of colonoscopy in patients with severe constipation and megacolon make them best managed by modified barium technique, sometimes with no bowel preparation, whereas patients who have reduced mobility, rectal incontinence, prolapse, or stomas are best examined by colonoscopy because of technical difficulty in obtaining proper filling and coating with x-ray contrast material. Barium enema is particularly effective in assessing the configuration and gross morphology of the colon, especially when there are multiple strictures or fistulae that may be impassable or invisible to the endoscopist. The colon in idiopathic or acquired megacolon and Hirschsprung's disease may be almost impossible to prepare and offensive and difficult to endoscope, whereas radiology provides the necessary assessment of colon configuration. In elderly patients with symptoms suggestive of diverticular disease, x-ray can exclude serious pathology in most cases; in the same patients, unless the endoscopist is expert, colonoscopy can be relatively slow, traumatic, and more hazardous, although the endoscopic examination may be more diagnostic. [59]

When colonoscopy proves unreasonably difficult, endoscopy can be abandoned, aspirating residual air as far as possible and proceeding to immediate DCBE. Using CO_2 rather than air insufflation for colonoscopy is an advantage because in 15 minutes there is total absorption of residual CO_2, leaving the radiologist a nondistended bowel that is easy to fill and coat with barium. [71], [72] Endoscopic biopsies can be performed safely before DCBE, [73] and in all probability hot biopsies and snare removal of small stalked polyps may also safely precede the x-ray examination.

Barium enema films are easily stored and retrieved for review and comparison with subsequent examinations, a feature not available with colonoscopy. Videotapes can be recorded continually or intermittently during colonoscopy, but there is no method for endoscopic photographic mapping of the large bowel. Watching 20 to 40 minutes of a colonoscopic videotape is a tedious task that is not likely to be a standard part of any endoscopic review.

VIRTUAL COLONOSCOPY (COMPUTED TOMOGRAPHY OR MAGNETIC RESONANCE COLOGRAPHY)

A computer reconstruction of a rapidly performed abdominal spiral computed tomography (CT) scan provides a simulated tubular view of the intestinal lumen. Infoldings (haustrae), outpouchings (diverticula), and intraluminal protuberances (polyps) can be identified. The process is noninvasive, requiring a single breath-hold while the colon is maximally air-inflated. Cancers and most polyps over 10 mm in diameter can be identified, [74] but smaller polyps are often overlooked when compared to findings at conventional colonoscopy. [75] Retained stool may give a false-positive reading, and flat mucosal lesions are difficult to identify. Technological developments will increase the accuracy of this tool which will require further evaluations before assigning this radiologic procedure a role in the screening algorithm. The use of air as a contrast medium instead of barium means that the "virtual" examination has the ability to either precede or follow the endoscopy.

LIMITATIONS OF COLONOSCOPY

It is pertinent to mention that the endoscopist is capable of gross errors in localization and occasionally of missing large lesions. Blind spots for the endoscopist occur in certain areas, such as the rectal ampulla and flexures (especially the mobile sigmoid-descending colon junction), behind acute bends, and in regions of spastic muscle contractions. Adhesions or strictures can render the endoscope tip immobile and make a proper view for targeted biopsies impossible. Large polyps on long stalks can be missed by the endoscopist because they move around and may spring out of the field of view as the colonoscope is pulled back. Poor preparation and redundant or mobile colons also make the endoscopic examination less accurate.

Careful inspection for possible abnormalities is important on the way in as well as during the withdrawal phase of a colonoscopy because the view of the stretched colon is quite different from that obtained when the bowel is shortened. Several passes may be needed to see all aspects of an angulated or convoluted area properly. There is no room for complacency by the endoscopist over the accuracy of colonoscopy; it takes dexterity and integrity to be sure that an optimum examination has been performed. It can be assumed that 5% to 10% of the mucosal surface is not seen during colonoscopy. This explains the significant detection of lesions up to 5 to 10 mm in diameter during check colonoscopies usually performed within 1 year (or even on the same day) [70] of a previous colonoscopy and polypectomy to establish a "clean colon" that is free of adenomas. It has been estimated that 27% of adenomas in the size range of 1 to 5 mm are missed on colonoscopy, as are 13% of adenomas in the range of 6 to 9 mm, and 6% of those over 10 mm. [70] Colonoscopy can miss colonic cancer in the intramucosal lesions of chronic ulcerative colitis, within strictures, or where there is submucosal involvement by extrinsic neoplasm or metastases.

In addition to diagnostic difficulties, the mechanical limitations of colonoscopy are relevant. An expert manages up to 98% to 99% total colonoscopy, especially if there is no stricture or stenosing lesion to prevent insertion. Less expert endoscopists achieve only up to 70% to 75% total [76] colonoscopy and are more likely to be slow, inaccurate in diagnosis and localization, and more prone to trauma and complications. The lack of proper means of teaching colonoscopy skills limits its clinical

application worldwide.

COSTS

Colonoscopy is highly cost-effective. The instrumentation involved is inexpensive compared to x-ray. A colonoscope should last for at least 500 examinations before major repair or replacement becomes necessary. The actual physician time involved per procedure is greater for colonoscopy than for the barium enema, during which examination films may frequently be taken by a technician. The overall cost is approximately equal if an x-ray and flexible sigmoidoscopy–first schema is compared to a colonoscopy-only approach for the investigation of patients with lower GI symptoms. Many patients with an abnormal sigmoidoscopy or barium enema demonstrating a lesion or probable pathology will require a subsequent colonoscopy for confirmation, polypectomy, or biopsy; whereas only a few with the colonoscopy-first approach will require a barium enema. [77], [78]

FUTURE DEVELOPMENTS

Videocolonoscopy will allow improvements in image resolution as well as potential for computer enhancement and related developments that should improve diagnostic accuracy, localization, and ease of instrument handling. Advances in bowel preparation should permit comfortable clearance in a few hours instead of the 24- to 48-hour preparations currently used. Developments in safe, short-lived analgesia should make insertion easily tolerated while allowing normal activities soon afterward such as driving or returning to work. Computerized interactive teaching models will permit education in manipulative and interpretive skills without imposing an undue burden on and risk to patients during the endoscopist's early training phase. [79], [80]

Development of other diagnostic and therapeutic modalities will allow the endoscopist to apply miniaturized imaging probes to areas of interest and to ablate lesions more completely and safely than can be performed at present. For instance, ultrasound probes passed through the instrumentation channel help to determine the presence and depth of penetration of malignancy. [2], [81] Optical coherence tomography (OCT) uses light instead of sound waves to achieve an "optical biopsy" of the mucosa and submucosa. [82] A new technology is emerging to record spectrophotometric measurements of tissue fluorescence by a sensing device passed through the accessory channel. [83] Differentiation between neoplastic and normal tissue by their inherent differences in level of tissue excitation by laser stimulation may be sufficient for diagnostic purposes or will enable directed biopsy of abnormal areas. [84] With improved photosensitizing agents and laser photocoagulation or locally injected immunotherapeutic agents, colonoscopy should be able to make further inroads into territory that is currently considered the domain of the surgeon.

Wireless "capsule" endoscopy [85] has been developed for small bowel exploration, where peristalsis is the propulsive force for movement. The narrow caliber lumen is sufficiently illuminated by the light to produce a diagnostic visual image. Several inherent differences in the large bowel are impediments to adapting the capsule to colonoscopy: the diameter is wide and the light will be insufficient for adequate visualization; peristalsis is relatively slow in the colon; air insufflation is required to distend the bowel; the capsule tends to tumble and its movements cannot be controlled; and there is no therapeutic capability. Some or all of these factors can be overcome in the future, which may see the development of robotic therapeutic capsules armed with snare, forceps, scissors, and clips.

The future seems limitless, but for now, the colonoscope is the best imaging system for the colon, and has the additional ability to perform therapy including injection, biopsy, decompression, and polypectomy.

CHAPTER 141

Stuart Sherman and Glen A. Lehman

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY, ENDOSCOPIC SPHINCTEROTOMY AND STONE REMOVAL, AND ENDOSCOPIC BILIARY AND PANCREATIC DRAINAGE

Endoscopic cannulation of the major papilla with imaging of the pancreatic duct and biliary tree (endoscopic retrograde cholangiopancreatography [ERCP]) was first successfully accomplished with an end-viewing duodenoscope and reported in 1968. [1] Subsequent development of side-viewing endoscopes with a catheter-deflecting elevator greatly facilitated the technique. Diagnostic studies were supplemented by the first endoscopic sphincterotomies in 1973. [2], [3] Techniques of biliary stone extraction, nasobiliary tube placement, and biliary stent placement soon followed. These developments permitted less invasive diagnostic and therapeutic maneuvers in the pancreatic duct and bile duct previously limited to open surgical and percutaneous techniques.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

Indications/Contraindications

The role for diagnostic ERCP alone is diminishing as other less invasive/noninvasive imaging techniques (e.g., endoscopic ultrasound, magnetic resonance cholangiopancreatography) become more widely used. Imaging of the ducts without anticipated therapy is clinically helpful in a few clinical settings where other noninvasive or less invasive procedures are negative and the clinical suspicion for pancreaticobiliary disease remains high, such as cholestasis without a dilated duct and chronic abdominal pain with concern for chronic pancreatitis. ERCP is indicated in those clinical settings in which there is significant suspicion of an obstructing, inflammatory, or neoplastic pancreatobiliary lesion, which if detected or ruled out, would alter clinical management. A general classification of indications is listed in Table 141-1.

Suspected Biliary Ductal Disorder
Jaundice or cholestasis of suspected obstructive origin
Acute cholangitis
Gallstone pancreatitis
Clarification of biliary lesion seen on other imaging test
Biliary fistula
Suspected Pancreatic Ductal Disorder
Pancreatic cancer
Mucinous or cystic neoplasm
Unexplained recurrent pancreatitis
Chronic pancreatitis with unrelenting pain
Clarification of pancreatic lesion on other imaging test
Ascites or pleural effusion of suspected pancreatic origin
Pancreatic pseudocyst or fistula
To Direct Endoscopic Therapy
Sphincterotomy
Biliary drainage
Pancreatic drainage
To Direct Endoscopic Tissue/Fluid Sampling
Biopsy, brush, fine-needle aspiration
Bile/pancreatic juice collection
Preoperative Ductal Mapping
Malignant tumors
Benign strictures
Chronic pancreatitis
Pancreatic pseudocysts and ductal disruptions
Mucinous or cystic tumors of pancreas
To Perform Manometry
Sphincter of Oddi
Ductal

ERCP, endoscopic retrograde cholangiopancreatography.

TABLE 141-1 Indications for ERCP

There are few, if any, true contraindications for ERCP. The only truly absolute contraindication is refusal of the patient to undergo endoscopy or the patient's inability to cooperate during the procedure for whatever reason. Even in the latter circumstance, ERCP can be performed under general anesthesia when the study is considered essential for the patient's management. Most contraindications are relative and in such settings, the degree of risk must be balanced against the potential benefit. In many settings—such as acute cholangitis with bile duct stones, malignant biliary strictures, and pancreatic pseudocysts—diagnostic ERCP should not be done unless simultaneously accompanied by a drainage procedure (surgical or endoscopic). ERCP in patients with severe acute pancreatitis, especially with necrosis (when gallstones or trauma are not the etiology), is considered a relative contraindication as bacterial contamination of the pancreatic bed can occur. Other relative contraindications include an unstable cardiopulmonary disease or severe coagulopathy. Patients with co-morbid life-threatening conditions can frequently have their ERCP performed in the intensive care unit (ICU) (with or without fluoroscopy) if deemed medically necessary. For example, in patients with septic shock from bacterial cholangitis, biliary drainage can be lifesaving.

Preparation

Preparation for ERCP involves assembly of a skilled team that includes physician(s), nursing personnel, and a radiology technician. A quality fluoroscopic unit is

needed. A wide variety of catheters, guidewires, stone extraction balloons and baskets, sphincterotomes, stents, drainage catheters, lithotripters, and tissue sampling devices should be available.

Patient preparation includes an updated history and physical and recent complete blood count, serum liver chemistries, serum amylase and/or lipase, coagulation studies, and noninvasive imaging of the upper abdomen, with abdominal ultrasound or a computed tomography (CT) scan. Special risk factors such as anticoagulant therapy, bleeding disorders, prosthetic heart valves, and allergies must be addressed.

Informed consent for ERCP must be obtained. It is both legally and ethically necessary to apprise the patient and family of the risks, benefits, and alternatives of ERCP. Table 141-2 lists the potential complications of diagnostic and therapeutic ERCP and their relative frequency. While legal standards continue to evolve, we recommend that patients not only be informed of the potential complication frequencies but that they also be told that a severe complication may possibly result in a prolonged hospital stay, ICU monitoring, or open surgery and may very rarely result in permanent disability or death. Complication rates vary according to patient and procedure risk factors as well as the disease process being evaluated and treated. [4], [5] Patients with uncomplicated biliary stones, malignancy, or chronic pancreatitis have lower complication rates, while patients with recurrent pancreatitis and sphincter of Oddi dysfunction have two- to threefold higher complication rates. Procedure techniques associated with higher complication rates include repeated cannulation attempts, repeated pancreatic duct injections, pancreatic parenchymal acinarization, and precut sphincterotomy. Attention to details of the technique and patient selection can minimize but not eliminate complications. Early recognition and treatment of complications helps to limit morbidity.

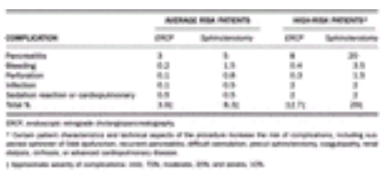

TABLE 141-2 Approximate Frequencies of Complications from ERCP and Sphincterotomy (%)

ERCP can be performed with fiberoptic or videochip instruments that have similar performance characteristics. Video systems offer the advantage of television monitor viewing by all persons in the endoscopy suite. This offers better teaching capabilities and allows better coordination between the endoscopist and nursing assistants. For Billroth II patients, we generally start with a standard side-viewing duodenoscope, but an end-viewing endoscope is occasionally needed. In patients with a long Roux-en-Y gastroenterostomy, a 220-cm enteroscope will reach the site of pancreatic duct or bile duct drainage in approximately half of patients. [6] The lack of a catheter-deflecting elevator and limited compatible accessories make end-viewing endoscopy difficult in these settings.

Technique

The patient is positioned in a prone to slightly left lateral decubitus position on a fluoroscopic table. An antiperistaltic drug (e.g., glucagon or atropine) to inhibit duodenal motility is commonly needed. Initially, a brief endoscopic examination of the esophagus, stomach, duodenum, and major duodenal papilla is done. The finding of a large ulcer or neoplasm may cancel the need for ERCP. Other findings such as varices, a pseudocyst pressing on the gut wall, or edema of the medial wall of the duodenum help to quantitate or localize disease processes. The major papilla is usually located on the medial aspect of the mid-descending duodenum. Prior to attempts at cannulation, fluoroscopic visualization (or a “scout film” radiograph prior to starting the procedure) of the field of interest should be performed to look for calcifications, masses, and old contrast material. The major papilla is then cannulated, usually with a 5F plastic catheter. Orientation of the catheter tip toward the 11 to 12 o’clock position will more likely enter the bile duct; orientation of the catheter toward the 3 to 5 o’clock position will more likely enter the pancreatic duct. Cannulation may be done by gentle impaction of the catheter tip in the papillary orifice. Deep cannulation (greater than 1 cm penetration of the catheter into the duct) more securely establishes an intraductal position which allows contrast injection, fluid aspiration, patient position changes, and endoscope position changes without loss of access to the duct.

Standard contrast media (e.g., meglumine diatrizoate) at a 50% to 60% concentration (full-strength) is used for pancreatography, while 25% to 30% (half-strength) concentration is recommended for cholangiography. Biliary stricture detail is better defined with full-strength contrast, however. Nonionic and lower osmolality contrast media, which are more expensive, offer no safety advantage. Contrast media injection is done with continuous fluoroscopic monitoring. The extent of ductal filling should be correlated with the clinical need to know the ductal anatomy. Complete pancreatography involves filling of the main duct and side branches to the tail. High-resolution fluoroscopy is required to see such detail. In settings where there is excess overlying gas or obesity, underfilling of the pancreatic duct is recommended to avoid acinarization (instillation of contrast media into the pancreatic parenchyma). For an extremely dilated duct, initial aspiration of fluid will allow better contrast visualization without overdistention of the duct. Complete cholangiography requires filling of the peripheral intrahepatic radicles. The left lobe is more dependent in the prone position and fills preferentially. Right lobe filling may require tilting the patient’s head down 15 to 20 degrees on the fluoroscopy table, more forceful injection (a balloon occlusion catheter is helpful), or turning the patient to the supine position. Contrast media mixes slowly with gallbladder bile and final films are best taken in the supine position after endoscope withdrawal (and additional time for mixing with gallbladder contents). Occasionally, delayed gallbladder films taken 4 to 12 hours after completion of the procedure allow for passage of intraluminal gas, giving better diagnostic film quality. In settings of tight biliary strictures, limited contrast filling upstream should be done until catheter access above the stricture is achieved. Similarly, limited pseudocyst filling should be done unless immediate drainage is certain. Several views of each ductal position are recommended both in the limited filling and more completely filled state.

Sphincter of Oddi manometry (SOM) usually is performed at the time of ERCP. All drugs that relax (e.g., anticholinergics, nitrates, calcium channel blockers, glucagon) or stimulate (e.g., certain narcotics, cholinergic agents) should be avoided for at least 8 to 12 hours prior to SOM and during the manometric session. SOM is performed using a low-compliance infusion pump system and a 5F catheter.

Endoscopic sphincterotomy (ES) of the bile duct is commonly performed prior to removing bile duct stones or placing a biliary stent. A pull-type (traction) sphincterotome is advanced into the bile duct and its position confirmed on fluoroscopy. The sphincterotome is pulled back until 5 to 7 mm of cutting wire are passed into the papillary orifice. The instrument is bowed to apply gentle tension in the 11 to 12 o’clock direction. Cautery current at 40 to 60 watts is applied in less-than-one-second bursts to stepwise cut 80% to 90% of the intramural portion of the bile duct. Although blended current is most commonly used, pure cut current may be associated with a lower incidence of pancreatitis without increasing the rate of sphincterotomy induced bleeding. [7] Adequacy of the sphincterotomy is judged by pulling a bowed sphincterotome through the incised sphincter. Small papillae and papillae associated with diverticula may require smaller cuts. Minor bleeding may occur but usually stops spontaneously. Bleeding that limits the endoscopic view should be controlled by hydrostatic balloon tamponade, bipolar cautery, or epinephrine injection.

Precut sphincterotomy involves cutting the papilla to gain deep intraductal access to the biliary tree. This technique should be limited to experienced endoscopists and applied in patients only when there is a high clinical suspicion of obstructive pathology (e.g., jaundiced patient with dilated bile duct on ultrasound) after standard techniques fail. Precutting can be achieved by impaction of a short-nosed, pull-type sphincterotome into the papillary orifice with sequential shallow cephalad cuts until the biliary orifice is identified. Similar sequential shallow cuts can be made with a needle knife. We prefer to place a 3F to 4F, 8-cm long, unflanged polyethylene stent into the pancreatic duct first, if possible, and use the stent to guide needle knife cutting.

Radiology

Figure 141-1 shows a normal pancreatogram. The main duct contour is typically S-shaped but numerous other configurations are common and normal. The upper limits of normal for main duct diameter are 5 mm in the head, 4 mm in the body, and 2 mm in the tail. Side branches are delicate with terminal branching. The accessory duct extends from the genu at the head/body main duct junction to the minor papilla. The minor papilla has a patent orifice in approximately 85% of patients. Pancreas divisum is discussed later in the chapter.

FIGURE 141-1. A normal pancreatogram obtained by placing a metal-tipped cannula (*solid arrow*) in the duct of Wirsung. Note the gradual tapering of the main pancreatic duct and the delicate side branches. The duct of Santorini (*open arrows*) is filled by its connection with the main duct.

A normal cholangiogram is shown in Figure 141-2. The upper limits of normal diameter for the common bile duct is 10 mm. The cystic duct commonly joins the common duct approximately halfway from the hilum to the papilla, but this junction may be quite variable. The intrahepatic radicles have a treelike branch pattern with marked variation in distribution.

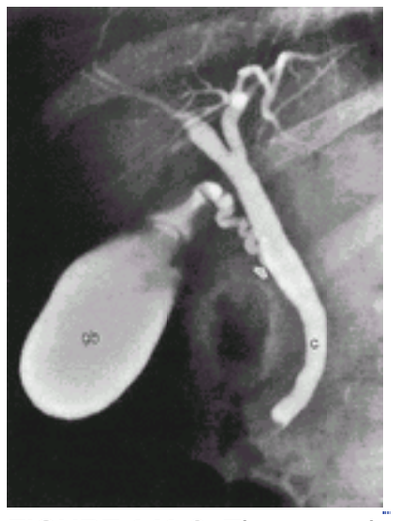

FIGURE 141-2. The normal common bile duct (*c*) becomes the common hepatic duct proximal to the insertion of the cystic duct (*arrow*). The common hepatic duct bifurcates into the right and left hepatic ducts. The cystic duct has a spiral shape owing to the valves of Heister and connects the gallbladder (*gb*) to the bile duct.

Cannulation Success Rates

The papilla is readily identified by experienced endoscopists in nearly all patients with normal anatomy. Difficulties in finding the papilla may arise in cases of large papillary tumors, duodenal stenosis, edematous folds caused by acute pancreatitis, or if the papilla is located inside a diverticulum. Initial cannulation success rates with ductography vary from 80% to 95% depending on operator experience, anatomy, and disease state. Cannulation is easiest in patients with biliary stones but more difficult in patients with periampullary neoplasms, sphincter of Oddi dysfunction, and chronic pancreatitis with obstructing stones. In experienced centers, cannulation success rates exceed 95% even in difficult cases where a prior attempt at cannulation failed. [8], [9] Such high success rates require supplemental use of precut sphincterotomy and minor papilla cannulation in 10% to 25% of cases. In patients with a Billroth II gastrojejunostomy, the success rate should be greater than 80% when the procedure is performed by an expert.

Endoscopic Findings

Duodenal diverticula (usually periampullary) will be present in 10% to 20% of patients. Patients with ductal stones may have edema, enlargement, or inflammation of the major papilla. If a stone has recently passed, as is common in gallstone pancreatitis, the papillary orifice will appear enlarged or lacerated. Stones impacted in the terminal bile duct invariably cause bulging of the papilla but a stone visible in the papillary orifice is uncommon. Pancreatitis commonly causes edema of the medial aspect of the descending duodenum, including the papillae. Pancreatic neoplasms may cause (mass effect) compression from the duodenal bulb down to the major papilla. Duodenal mucosal invasion in pancreatic head cancers occurs in approximately 10% of patients. Tumors of the papilla usually appear as fleshy enlargements with or without ulceration. Pseudocysts will cause compression of the stomach or duodenum in approximately one third of cases.

Complications of ERCP/ES

Complications of ERCP/ES are undesirable outcomes related to some portion of the procedure or sedation required for the procedure. Unsuccessful cannulation, stent placement, stone removal, or making an incorrect diagnosis are failures of the procedure, but generally not included as complications. Table 141-2 lists the more common complications for diagnostic and therapeutic ERCP. Since 1991, a more uniform classification of complications and their severity has been developed. [10]

BILE DUCT STONES

The introduction of ES by Classen and Kawai [2], [3] in 1974 initiated a change in the management of bile duct stones. Before that time, laparotomy with common bile duct exploration was the main therapeutic recourse for the patient with choledocholithiasis. With improvements in equipment and accessories, growth in numbers and skill of biliary endoscopists, and the introduction of laparoscopic cholecystectomy, the clinical settings in which endoscopic management is applied to common duct stones have been broadened considerably (Table 141-3).

1. Postcholecystectomy (no T-tube in)
2. Postcholecystectomy (T-tube in)
Symptomatic patient with immature T-tube tract
Failed T-tube extraction
3. Gallbladder in situ
Elderly patient
Patient with high operative risk
Patients choosing nonoperative management of gallbladder stones
Before laparoscopic cholecystectomy (where laparoscopic common bile duct exploration is unavailable or not selected)
4. Severe gallstone pancreatitis with biliary obstruction
5. Acute cholangitis

ERCP, endoscopic retrograde cholangiopancreatography.

TABLE 141-3 Indications for ERCP and Sphincterotomy for Choledocholithiasis

Methods of Stone Extraction

Standard (Basket and Balloon Catheters) Following identification of a common duct stone, a sphincterotomy is usually performed. The length of the cut is dictated by the length of the endoscopically visible intramural bile duct and by the size of the stone. Balloon catheters are most useful for extracting one or more relatively small stones (<10 mm) in a nondilated duct. They are not as effective for extracting larger stones or small stones in a markedly dilated bile duct since the balloon will often slide past the stone. A major advantage of the stone retrieval balloon (as compared to the basket) is that it cannot become impacted, although the stone can. Catheters with balloons that inflate to 8 to 18 mm are commercially available. The catheter is advanced through the sphincterotomy into the bile duct proximal to the

stone using fluoroscopic guidance. The balloon is then inflated to the diameter of the duct and gentle traction is applied to deliver the stone through the sphincterotomy. Passage of the balloon catheter over a guidewire is often helpful to allow frequent easy catheter passage through the sphincterotomy without trauma, to position the balloon proximal to the stone without pushing the stone proximally, and to avoid repeated cystic duct entry. Stone retrieval baskets with different configurations, length/width, wire types, and number of wires are commercially available. Settings where a basket may be preferred over a balloon include larger stones (>10 mm), intrahepatic stones, smaller stones in a dilated duct, and stones that are larger than the downstream duct (e.g., stone proximal to a stricture) (Fig. 141-3). The basket is advanced through the sphincterotomy and partially or fully opened alongside or above the stone taking care not to push the stone up the duct. The basket is then moved to and fro with the stone adjacent to the widest portion of the basket. Once captured, the stone is removed with gentle traction. Usually there is resistance at the sphincterotomy orifice. By deflecting the scope tip down, extra force in the correct axis is applied, often allowing for successful stone removal. Vigorous pulling on the endoscope is sometimes necessary but has the potential of causing a duodenal tear.

FIGURE 141-3. A Dormia basket has been used to capture a stone (*S*) that is approximately 12 mm in diameter. Two smaller stones (*s*) are seen in the dilated common bile duct, distal to the stone retrieval basket.

In experienced centers, common duct stones can be successfully removed in 80% to 90% of patients after sphincterotomy using standard baskets and balloon catheters. [11], [12] and [13] Difficulty of clearing or failure to clear the common duct of stones may occur for a variety of reasons. In most cases, stone size is the major determinant of success. In one series, [14] stones less than 10 mm in diameter (*n* = 21) were all removed successfully, whereas only 3 of 25 (12%) larger than 15 mm were cleared via stone extraction with balloons and baskets. Stones greater than 15 mm are generally considered to be large; equally important, however, are stone factors such as number, consistency, shape, and location, and ductal factors such as contour, diameter at the level of and distal to the stone, and the presence of coexisting pathology such as a stricture or tumor.

Lithotripsy Techniques A variety of lithotripsy techniques (mechanical, electrohydraulic, laser, and extracorporeal shock wave lithotripsy [ESWL]) and dissolution therapies have been used to facilitate the retrieval of stones not removable by standard methods. [15], [16] The simplest endoscopic adjunct for the management of common duct stones that have failed to be removed by conventional baskets and balloons is the mechanical lithotripter or crushing basket. It is a safe, effective, low-cost procedure that can be performed at the time of the initial ERCP. Although mechanical lithotripters have been available for more than 15 years, the design improvements made over the last several years have been considerable and made these devices relatively easy to use. Using this technique, the stone is captured in a strong wire basket that has been advanced through a metal sheath. Longitudinal traction is then applied by turning a crank handle withdrawing the basket into the metal sheath, resulting in stone fragmentation or wire breakage. There are two types of mechanical lithotripters commercially available. The first is a metal sheath (e.g., Soehendra mechanical lithotripter) that is advanced over a standard basket after the basket handle has been cut and the endoscope removed. This technique is fairly simple once the stone is captured but has the disadvantages of destroying a basket with each use and requiring endoscope removal (and replacement to remove the fragments). This lithotripter is particularly useful for basket impaction and should, therefore, be available for all stone cases. The second lithotripter is a through-the-scope model that has a three-layer system consisting of a basket, plastic sheath, and a larger metal sheath. Using this model, the stone is captured in standard fashion while the metal sheath is in the endoscope channel. If lithotripsy is necessary for stone removal, the metal sheath is advanced and the stone crushed against it. In experienced centers, mechanical lithotripsy allows for removal of more than 85% to 90% of difficult bile duct stones, which are refractory to standard extraction techniques. [17], [18], [19] and [20] Failures of mechanical lithotripsy are typically due to inability to engage the stone within the basket and rarely to insufficient shearing power to fragment the stone. Lithotripsy techniques using ESWL or intracorporeal (laser or electrohydraulic) modalities are acceptable adjuncts to standard endoscopic management in attempting bile duct clearance. [21] The choice between these methods or surgery largely depends on availability as they are usually concentrated in tertiary centers. Intracorporeal lithotripsy can be achieved by producing a shock wave directly on the surface of the stone with either a flexible electrohydraulic probe or a flexible quartz fiber to deliver light from a laser. Both techniques require a fluid medium that is delivered coaxially along the probe or through a nasobiliary tube (NBT). Because of the risk of bile duct injury (electrohydraulic has a greater risk of injury than the pulsed dye laser), intracorporeal lithotripsy is usually performed under direct endoscopic control using the mother-baby endoscope system. In this technique, a small caliber endoscope (baby scope) is advanced through the working channel of the duodenoscope (mother scope) into the bile duct. The laser fiber or electrohydraulic probe is advanced through the working channel of the baby scope and apposition with the stone is assured under direct vision. Laser lithotripsy has been possible under fluoroscopic guidance with the development of a device (smart laser) that can identify bile duct stones by analyzing backscattered light, interrupting the pulse in case of tissue contact. [22] Complete duct clearance rates with intracorporeal lithotripsy techniques range from 80% to 90%. [23], [24], [25], [26] and [27] The main advantages of electrohydraulic lithotripsy over laser technology are its low cost and portability; however, the potential risk of bile duct injury is greater. ESWL is used to treat bile duct stones in a fashion similar to renal and gallbladder applications. Most centers use machines that require fluoroscopy to target the stones and rely on injection of contrast material through an NBT, [28] but some centers have reported good visualization of the stone in 90% of patients with ultrasound imaging. [21], [29] Complete stone clearance can be expected in approximately 80% of patients, but it usually requires a number of ESWL and endoscopic sessions. [21], [28], [29] and [30]

Dissolution Therapy Contact dissolution of biliary stones has been attempted by perfusing the bile duct with solvents administered via an indwelling NBT, percutaneous transhepatic catheter, cholecystostomy tube, or T-tube. The results with these agents (monoctanoin and methyl- *tert*-butyl ether) have been disappointing due to incomplete stone dissolution and the potential for complications from these solvents. [31], [32] Due to their low efficacy and high morbidity, contact dissolution has not assumed an important role in patients with refractory bile duct stones.

Stents and Nasobiliary Tubes When stone extraction is incomplete or failed, biliary drainage should be established to prevent stone impaction and cholangitis. In most situations, this therapy serves as a temporizing measure allowing for improvement in the patient's clinical condition pending repeat attempts at stone removal. The stent (or NBT) is placed so that one limb is above the stone and the other is in the duodenum (in the case of an NBT, the end of the tube is brought out the patient's nose and connected to a drainage bag) (Fig. 141-4). Most authorities recommend double-pigtail stents, although favorable experience is reported with straight 10F stents. [33], [34], [35], [36], [37] and [38] NBTs allow for repeat contrast injection without the need for another ERCP to visualize the biliary tree. However, they are often poorly tolerated, frequently dislodged by a confused or uncooperative patient, and out-of-hospital tube management is not optimal. Endoprostheses are better tolerated but migration or occlusion may occur, leading to recurrent symptoms of biliary obstruction and cholangitis.

FIGURE 141-4. A nasobiliary tube (NBT) has been placed to provide temporary biliary drainage in this patient with multiple small common bile duct (*CBD*) and gallbladder (*GB*) stones. An NBT traverses the stomach (*S*) and forms a loop in the duodenum (*D*) before entering the papilla (*arrow*).

Biliary stenting not only serves to drain the bile duct but may aid in mechanically fragmenting the stone facilitating subsequent attempts at endoscopic removal. [39], [40] The addition of oral dissolution therapy may also soften and reduce the size of the stone, aiding endoscopic removal. In a study by Johnson and colleagues, [41] 9 of 10 patients with nonextractable stones treated with ursodeoxycholic acid plus stenting had clearance of their bile duct after a mean of 2.7 follow-up procedures in contrast to none of 12 patients treated with stenting alone and a mean of 5.3 follow-up procedures. Long-term internal stenting was believed to be a good palliative measure in elderly and high-risk patients with nonextractable bile duct stones. In several reports, the rate of late complications (primarily cholangitis) was 12% to 15%. [33], [34], [36], [37], [39] The enthusiasm for this approach has been tempered by the results of a study [38] in which 34 complications occurred in 23 of 58 patients (40%) stented for a median of 36 months (range, 1–117 months). There were 9 (16%) biliary-related deaths occurring at a median of 42 months. The rate of late complications was shown to increase proportionally with time (16% at 1 year and 50% at 4 years). The authors advised that permanent stenting be restricted to patients unfit for elective surgical, endoscopic, or percutaneous treatments and in patients with short life expectancy. This recommendation was supported by the results of a randomized study of endoprosthesis insertion versus standard duct clearance techniques in a group of high-risk patients with symptomatic stones. [42] DePalma and Catanzano [43] retrospectively compared the results of endoscopic biliary stenting ($n = 31$) with those of surgery ($n = 37$) in 68 patients over 70 years of age with failed endoscopic bile duct clearance. Although early complications were significantly less frequent in the stented group (12.9% vs 29.7%; $P < 0.0005$), the complications (35.5% vs. 8.1%; $P < 0.001$) and biliary mortality (9.6% vs. 0%) during long-term follow-up were significantly more common in the stented group.

Endoscopic Balloon Dilation of the Biliary Sphincter for Stone Removal Because of the significant risks and unknown long-term effects of sphincter ablation, some authorities have suggested that small common duct stones should be removed after papillary balloon dilation. The main theoretical advantages of not cutting the sphincter are that acute complications might be less frequent and by preserving sphincter function, long-term complications (a particular concern in younger patients undergoing laparoscopic cholecystectomy) may be avoided. Bergman and colleagues [44] reported 36 biliary tract complications in 22 patients (among 93 patients) followed for a mean of 15 years after sphincterotomy and stone removal. The same group [45] later found that, after biliary sphincterotomy, the function of the biliary sphincter was permanently lost and was associated with bacterial colonization, presence of cytotoxic components in the bile, and chronic inflammation of the biliary ductal mucosa. In contrast, manometric studies have suggested recovery of sphincter function within a few weeks of balloon dilation of the sphincter. [46] In this technique, the papilla is dilated with an 8- to 10-mm hydrostatic balloon. Following dilation, the stones are removed using stone retrieval balloons, baskets, or mechanical lithotripsy. Initial reluctance to use this technique arose because of concern for a high risk of postprocedural pancreatitis and cholangitis. A prospective randomized trial comparing ES ($n = 101$) to papillary balloon dilation ($n = 101$) for removal of common duct stones achieved complete stone removal in one endoscopic session in 89% (9% required additional sphincterotomy) after balloon dilation and 91% after sphincterotomy. [47] Mechanical lithotripsy was more frequently required in the balloon dilation group (31% vs. 13%; $P < 0.005$). Early complications were similar for the two groups (17% vs. 24%; $P = 0.29$). Seven percent of patients in each group developed post-ERCP pancreatitis. In another randomized study in patients with Billroth II anatomy, balloon dilation was found to be as effective as sphincterotomy for stone removal with fewer complications. [48] These favorable results for balloon dilation stand in marked contrast to the preliminary results of a multicenter randomized trial conducted in the United States. [49] In this study of 177 patients, procedure success was similar in the balloon dilation (94%) and ES (100%) groups. However, procedure time was significantly longer (51 minutes vs. 40 minutes; $P = 0.011$) and overall morbidity was significantly greater (12% vs. 1%; $P = 0.006$) in the balloon dilation group. Among the 11 episodes of pancreatitis in the balloon dilation group, four were graded severe; two patients died. In another randomized study comparing the two techniques, the frequency of recurrent bile uct stones and cholecystitis at one year were similar. [50] Moreover, at one year after balloon dilation, the common bile duct pressure, sphincter of Oddi basal and peak pressure, and sphincter of Oddi contraction frequency were significantly lower than predilation values. These results suggest that balloon dilation should probably not be used routinely but should be reserved for patients at high risk for sphincterotomy complications such as patients with uncorrectable coagulopathy. [51], [52]

Interface of ERCP and Laparoscopic Cholecystectomy

Laparoscopic cholecystectomy has become the standard, accepted, and preferred technique for the treatment of gallbladder stones. This approach is associated with less postoperative pain, reduced hospitalization time, shorter convalescence, and better cosmetic results than open cholecystectomy. However, the laparoscopic management of common duct stones is much more complex than cholecystectomy alone, requiring advanced surgical skills and sophisticated instrumentation, and it is not widely available. Thus, ERCP plays an integral role in the treatment of common duct stones in the laparoscopic cholecystectomy era. The timing and need for ERCP in relation to the laparoscopic cholecystectomy is dependent on the likelihood of stones being present (low, medium, and high), the skill of the endoscopist, and the ability of the laparoscopist to perform common duct exploration. [53] There appears to be little value to routine ERCP prior to laparoscopic cholecystectomy in patients with a low likelihood of having bile duct stones. When comparing the low yield of detecting clinically important anatomic variants and unsuspected bile duct stones with the generally accepted 3% to 7% ERCP complication rate, the use of routine ERCP prior to cholecystectomy cannot be justified. [54] Patients judged to have a high likelihood of harboring duct stones are likely to benefit from preoperative ERCP and stone extraction (if stones are present). [53] Patients in the medium-risk group create a diagnostic and therapeutic dilemma that must be resolved based on the skills of the endoscopist and laparoscopist at each particular center. Endoscopic ultrasound, magnetic resonance cholangiopancreatography (MRCP), and spiral CT cholangiography appear to have a high sensitivity and specificity for stone detection; however, these imaging modalities [55], [56], [57], [58] and [59] are operator-dependent and limited to select centers. The value of these noninvasive and less invasive techniques in the evaluation of patients with a medium risk of bile duct stones needs further evaluation.

Ultimately, a single laparoscopic procedure that treats both cholelithiasis and choledocholithiasis in a single setting would be the best approach in the majority of patients. This approach appears to be cost-effective and associated with a shorter hospital stay than a two-stage procedure (preoperative ERCP with sphincterotomy followed by laparoscopic cholecystectomy). [60], [61] and [62] When these laparoscopic skills become widely disseminated, the use of ERCP will be relegated to its well established role in the open cholecystectomy era: the treatment of acute cholangitis, severe gallstone pancreatitis, retained common duct stones, and complications of biliary surgery.

Acute Gallstone Pancreatitis

In Western countries, gallstone disease is the leading cause of acute pancreatitis, accounting for 34% to 54% of the cases. [63] Most patients with acute gallstone pancreatitis (AGP) have a mild attack and can be treated conservatively. However, case fatality in severe pancreatitis remains unacceptably high, approaching 10%. In the open cholecystectomy era, urgent surgical intervention for severe AGP did not gain general acceptance because of the increased morbidity and mortality associated with this approach. [64], [65] Coincident with these surgical reports were uncontrolled endoscopic series reporting the efficacy and safety of ERCP and ES in the setting of AGP. [66], [67] Although the results were encouraging, the studies varied in their criteria for patient selection and timing of ES in relation to the acute attack (many were performed in the recovery phase when surgery is also safe). These early series prompted the three randomized controlled trials, [68], [69] and [70] which now serve as the basis for the endoscopic treatment of AGP. The therapeutic principle for ES in AGP is simply removal of the obstructing calculus and reestablishment of bile and pancreatic juice flow. [71]

In a randomized prospective controlled trial from the United Kingdom, 121 AGP patients either received conventional therapy (i.e., gut rest, analgesics, intravenous fluids, and antibiotics) or underwent urgent (within 72 hours after admission) ERCP with ES and stone extraction (if stones were present in the common bile duct at ERCP). [68] Patients were stratified by the predicted severity of their attacks sing the modified Glasgow system. Choledocholithiasis was found in 25% of patients with predicted mild attacks and 63% with predicted severe attacks. The four important findings were:

1. ERCP could be safely performed in the setting of gallstone pancreatitis.
2. There was a significant reduction in the major complications of patients who underwent urgent ERCP and ES.
3. The reduction of morbidity was only apparent in those patients with predicted severe attacks (61% vs. 24%; $P = 0.007$).
4. There was a significant reduction in the hospital stay for those with severe attacks treated with urgent ERCP and ES (median, 9.5 days vs. 17 days, $P = 0.03$).

The mortality rate was improved, but the difference was not statistically significant.

A second randomized controlled study was performed by the Department of Surgery at the University of Hong Kong. [69] One hundred ninety-five patients with acute pancreatitis were randomized to early ERCP (within 24 hours of admission) or conservative therapy. Although the methodology, patient selection, and the assessment of the severity of the acute pancreatitis used in this study differed from the United Kingdom study, the results in the subgroup of patients with gallstone pancreatitis ($n = 127$) were quite similar. Patients with mild pancreatitis had a similar morbidity and mortality regardless of the therapy. In contrast, patients with predicted severe attacks undergoing endoscopic therapy had a lower complication rate (54% vs. 13%; $P = 0.003$) and a lower mortality rate (18% vs. 3%; $P = 0.07$) than patients

treated conservatively.

The third study [70] was a prospective multicenter randomized controlled study from Germany in which 238 patients with AGP and no evidence of severe biliary obstruction (severe biliary obstruction defined as a bilirubin >5 mg/dL) were randomized to ERCP with ES and stone extraction or conservative therapy within 72 hours of symptom onset. This study attempts to address the major criticism of the United Kingdom and Hong Kong studies: the need to exclude patients presenting with concomitant cholangitis because these patients are known to benefit from ERCP. The two treatment groups did not differ significantly for mortality (11% vs. 6% overall mortality; 8% vs. 4% AGP mortality; ERCP vs. conservative therapy) or overall complications (46% vs. 51%; ERCP vs. conservative therapy) regardless of the predicted severity of the pancreatitis. However, respiratory failure was more frequent in the ERCP group (12% vs. 5%; $P = 0.03$), and jaundice was more frequent in patients who received conservative treatment (11% vs. 1%; $P = 0.02$).

Although all three studies conclude that there was no difference in outcomes for patients with mild pancreatitis treated conservatively or by ERCP, only the study from Germany suggested that early ERCP was of no benefit in patients with severe gallstone pancreatitis. Although ERCP is clearly indicated in patients with AGP complicated by cholangitis or biliary obstruction, its role in the setting of severe AGP alone warrants further investigation. A metaanalysis [72] of these three published studies and an abstracted randomized study [73] revealed a statistically significant reduction in morbidity from 38% to 25% and mortality from 9% to 5% in the ERCP/ES group compared with the conservatively treated group. A subgroup analysis based on the severity of pancreatitis was not reported in this metaanalysis.

Acute Cholangitis

Cholangitis is a potentially life-threatening disease that results from bacterial infection of obstructed bile. Systemic toxicity occurs when the intraductal pressure is sufficiently elevated to cause reflux of the bacteria or endotoxin into the blood. [74] Thus, obstruction plays a key role by both increasing intraductal pressure and promoting bacterial overgrowth as a result of bile stasis. The most common cause of acute cholangitis is choledocholithiasis, which occurs in approximately 80% to 90% of unselected cases. [74] Other diseases less commonly associated with cholangitis include malignant obstruction of the bile duct, choledochal cysts, iatrogenic conditions (e.g., postoperative biliary stricture), papillary stenosis, biliary parasites, and the sump syndrome.

Therapy for cholangitis must be individualized because of the spectrum of severity of illness. Antibiotic therapy should be initiated promptly. Analysis of bile and stone cultures indicates that *Escherichia coli, Klebsiella* spp., *Enterobacter* spp., *Enterococcus* spp., and *Streptococcus* spp. are the most commonly isolated bacteria. [75] The antibiotic selected should preferably penetrate an obstructed biliary tree. [75] The majority of patients will respond to conservative management, allowing for a more elective approach to biliary decompression. [76] Urgent decompression is indicated if improvement is not seen within a few hours of initial resuscitation. [77] The latter group will, invariably, have a fatal outcome if conservative treatment is continued. [78]

The options for bile duct decompression include surgical, percutaneous, and endoscopic methods. Endoscopic intervention is now accepted as a definitive therapy for acute cholangitis. The advantages of ERCP are that it can delineate the cause of obstruction, facilitate sampling of bile for cultures, and decompress the biliary tree in a relatively short time with low morbidity. Biliary decompression is the goal of therapy and can be complete (e.g., stone removal) or temporary (e.g., placement of a stent without stone removal) pending more definitive management (this will allow stabilization of an unstable patient). The endoscopic procedure consists of a sphincterotomy with stone extraction or biliary drainage with an NBT or endoprosthesis.

Technical Considerations Ideally the patient should be stabilized or made as stable as possible prior to performing ERCP. Patients with respiratory compromise can have their ERCP performed while on ventilatory assistance. Although the procedure is best performed in a dedicated fluoroscopy room, unstable patients should undergo the ERCP in the ICU. A mobile fluoroscopy unit can be used but reports indicate that ductal decompression can be performed without fluoroscopic assistance in an ICU. [79] Since the intrabiliary pressure is increased in acute cholangitis, contrast injection should be limited to reduce further systemic seeding of bacteria. Enough contrast should be injected to define the anatomy and the cause of obstruction. Alternatively, the bile duct should be aspirated completely of infected bile prior to contrast injection. Aspirated bile should be cultured. In a stable patient, definitive therapy can be performed. In an unstable patient, the length of the procedure should be limited. In such cases, a stent or NBT should be placed and once the patient is stabilized, more definitive therapy can be performed. NBTs are available in a variety of diameters with and without pigtail tips and duodenal a-loops (to maintain the duodenal position). NBT placement is performed in several steps. Following cannulation of the bile duct, a guidewire is advanced through the catheter into the intrahepatic biliary tree. [80] The cannula is withdrawn over the guidewire, keeping the guidewire in position. The NBT is advanced into the biliary tree over the guidewire and the tip usually positioned in an intrahepatic duct. The endoscope is then slowly withdrawn over the NBT by coordinated efforts of the endoscopist and assistant. While watching fluoroscopy, the endoscopist is advancing the NBT and the assistant withdraws the endoscope at 1- to 2-cm increments keeping the NBT in the same position. Although the NBT now emerges through the mouth, it is preferable to bring it out through the nose using a transfer tube. The NBT is taped to the cheek or forehead of the patient and its tip is connected to a drainage bag. Biliary endoprostheses are generally made of polyethylene and are available in a variety of diameters and shapes. The Amsterdam or barbed straight stents are most commonly used for long-term therapy because they offer the best flow characteristics and the longest patency rates. Plastic stents larger than 8.5F require use of a large diameter working channel (e.g., 4.2 mm) duodenoscope. Metal expandable stents, which offer superior bile drainage, are discussed later in the chapter. Double pigtail or straight stents can be used to prevent stone impaction. The equipment needed for endoprosthesis placement include guidewires, guide catheters, pusher tubes, and stents of varying diameters, lengths, and shapes. The initial steps of placing a biliary endoprosthesis are the same as for placing an NBT. After selective biliary cannulation is performed, a guidewire is advanced proximal to the obstruction. The catheter is removed while keeping the guidewire in position. When placing larger diameter stents (usually 10F and 11.5F), stricture dilation (if a stricture is present) with a hydrostatic balloon or dilating catheter may be necessary. If the stent is larger than 7F, a guide catheter (usually 6F) is advanced over the guidewire to stiffen the system to facilitate stent placement. The stent is then advanced over the guidewire and guide catheter using a pusher tube. Through coordinated efforts of the assistant and endoscopist, the tip of the stent is positioned above the stricture (if present) or stone, with the distal end in the duodenum. The stent is deployed by removing the guide catheter and guidewire while keeping the pusher tube against the tip of the stent. Delivery systems that allow passage of the stent, guide catheter, and pusher tube as a single unit have been developed, simplifying stent deployment. The ideal position of the endoprosthesis is for the proximal barb to be located at least 1 to 2 cm above the superior margin of the stricture or stone and the distal end of the endoprosthesis to protrude 1 cm into the duodenum, with the barb preferably at the level of the papilla.

Results The high morbidity and mortality associated with surgical and percutaneous therapy for acute cholangitis prompted evaluation of the safety and use of endoscopic management. [81], [82] and [83] In a retrospective analysis, Leese and colleagues [84] reported on 71 patients with cholangitis due to stones treated by early decompression either surgically ($n = 28$) or by ES ($n = 43$). Early surgery was associated with significantly higher 30-day mortality (21% vs. 5%) and morbidity (57% vs. 8%) than sphincterotomy. The endoscopic group was significantly older and had more medical risk factors than the surgical group and there were no significant differences in the severity of cholangitis. Leung and associates [76] reported their experience in a retrospective analysis of 105 patients with acute calculous cholangitis who did not respond to conservative management and underwent urgent endoscopic decompression at a mean of 1.5 days after admission. Thirty-nine percent of patients had coexisting medical problems, 85% had Charcot triad, and 40% were in shock at the time of admission. Endoscopic drainage was successful in 102 patients (97%). Ninety-seven percent of patients responded with striking improvement of abdominal pain and 93% had resolution of fever within 3 days. The overall 30-day mortality was 5%. Among those in shock, 2 out of 4 drained after 72 hours died, compared with 3 out of 38 drained before 72 hours. There were no deaths in the group without shock irrespective of the timing of drainage. The mortality of 5% compares favorably with that of urgent surgical intervention, which has been reported to be greater than 40% in some series. [85] The ERCP complication rate was 5% and was limited to 5 postsphincterotomy bleeding episodes managed by endoscopic techniques. The safety and efficacy of endoscopic therapy were corroborated in a large retrospective study of 947 patients with cholangitis due to stones ($n = 898$) or stricture ($n = 49$). [86] In a randomized prospective study, Lai and colleagues [87] compared the safety and efficacy of biliary decompression by surgical and endoscopic techniques in 82 patients with severe cholangitis due to stones. Patients treated with laparotomy and common bile duct exploration had a significantly higher morbidity (64% vs. 34%) and mortality (32% vs. 10%) compared to those treated with endoscopic therapy. These and other studies clearly demonstrate the efficacy and safety of biliary decompression either as a definitive therapy or as a temporizing measure pending more definitive intervention once the patient is stabilized.

BILIARY DRAINAGE PROCEDURES

Benign Biliary Strictures

Postoperative Postoperative stricture(s) of the extrahepatic bile duct occur after 0.25% to 1% of cholecystectomies. [88] Most such lesions present as abnormal liver tests, obstructive jaundice, and cholangitis within 2 to 3 months postoperatively, although a much more delayed presentation may occur. In contrast, when the common duct has been completely occluded with a clip, progressive jaundice will become obvious early in the postoperative period. The cholangiogram commonly shows a short, smooth narrowing near the cystic duct stump and surgical clips with proximal duct dilation (Fig. 141-5). Strictures greater than 2 cm in length, those with clips placed securely across the duct, or those associated with resected segments of duct require operative management. Irrespective of the site or pathogenesis of the strictures, the primary aim of endoscopy is to pass a guidewire through the stricture to permit passage of dilators (balloon or catheter) and stents.

Sphincterotomy prior to stricture manipulation permits greater instrument maneuverability. The preferred treatment of short, simple strictures is balloon dilation to 6 to 10 mm with ultimate placement of two to three 10F plastic stents across the stricture and extending into the duodenum. The stricture is redilated and stents are exchanged at 3- to 4-month intervals for 8 to 12 months until the stricture profile is nearly as open as the downstream adjacent duct. The goals of treatment are to render the patient free of symptoms and to achieve sustained normalization of the liver tests after the stents are permanently removed. Because strictures can recur many years after therapy, the long-term outcome following endoscopic intervention is of critical concern. In three uncontrolled endoscopic studies [89], [90] and [91] a good to excellent result was achieved in 70% to 80% of patients followed for an average of 4 years. Assessment of good to excellent outcomes was based on resolution of symptoms and normalization or significant improvement in biochemical tests and radiographic findings. Two long-term follow-up studies of endoscopic stenting of biliary strictures have been reported. [92], [93] Bergman and colleagues [92] reported late complications (median follow-up of 9.1 years) in 34% of 44 patients undergoing biliary stenting with two 10F stents for a maximum of one year. Restenosis at the site of the original stricture occurred in 20% of patients. Costamagna and colleagues [93] undertook a more aggressive endoscopic approach. Each patient received as many large-diameter stents as necessary (based on stricture tightness and bile duct diameter) to eliminate the stricture. Stents were exchanged electively at 3-month intervals and were removed upon complete stricture resolution. There were no symptomatic recurrent biliary strictures among the 40 patients completing the stenting protocol during a 49-month follow-up period. In a nonrandomized study, Davids and associates [94] compared the outcome of 35 patients treated surgically (biliary-enteric anastomosis) and 66 patients managed with endoscopic balloon dilation and stenting (stents changed every 3 months for 1 year). The mean follow-up interval for the surgical and endoscopically treated patients was 50 and 42 months, respectively. Eighty-three percent of patients in both groups attained good to excellent results. The total morbidity rates (surgery, 26%; endoscopy, 35%) and stricture recurrence rates (17% for both groups) were similar for the two groups. Collectively, these data support the use of endoscopic therapy in patients with postoperative biliary strictures. Surgically fit patients who fail initial endoscopic therapy or have recurrent strictures are best managed by a bilioenteric bypass. Although metal expandable stents offer prolonged patency compared to plastic stents, their use for treating benign postoperative biliary strictures should be discouraged. Dumonceau and associates [95] reported mucosal hyperplasia and Wallstent occlusion in all six patients who underwent this therapy.

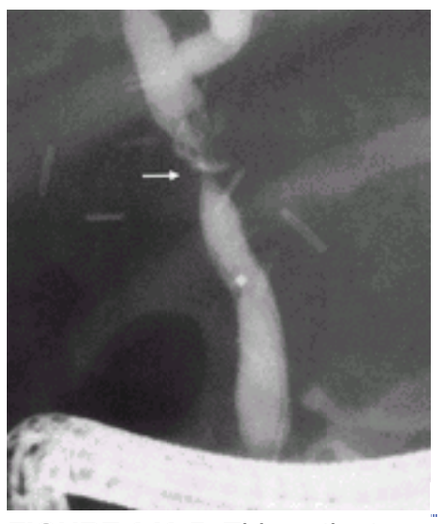

FIGURE 141-5. This patient presented with obstructive jaundice 2 months after laparoscopic cholecystectomy. The cholangiogram shows a common bile duct stricture (*arrow*). Note the clips in the region of the common duct.

Endoscopic techniques have been used to treat biliary strictures complicating orthotopic liver transplantation. [96] Such strictures are often treated in a fashion similar to strictures occurring after other biliary tract surgeries. Anastomotic strictures appear to be more responsive to endoscopic therapy than strictures occurring at nonanastomotic sites. [96]

Distal Common Bile Duct Strictures Secondary to Chronic Pancreatitis Intrapancreatic common bile duct strictures have been reported to occur in 3% to 46% of patients with chronic pancreatitis (Fig. 141-6). Deviere and colleagues [97] evaluated the use of biliary stenting in 25 patients with common bile duct obstruction and significant cholestasis (alkaline phosphatase greater than two times the upper limits of normal) secondary to chronic pancreatitis. Nineteen patients had jaundice, and seven presented with cholangitis. The patients were treated with ES followed by insertion of one or two 10F biliary stents placed across the stricture. The stents were changed when clinical or ultrasonographic evidence of blockage was present. Cholestasis, hyperbilirubinemia, and cholangitis resolved in all patients following stent placement. The late follow-up (mean, 14 months; range, 4 to 72 months) on 22 patients was much less satisfactory. One patient died 1 month after treatment from acute cholecystitis and postsurgical complications, whereas a second died 10 months after stenting of sepsis that was believed to be caused by stent blockage or dislodgment. Stent migration occurred in 10 patients and stent blockage in 8, resulting in cholestasis with or without jaundice ($n = 12$), cholangitis ($n = 4$), or no symptoms ($n = 2$). These patients were treated by stent replacement or surgery ($n = 7$). Ten patients continued to have a stent in place (mean follow-up, 8 months) and remained asymptomatic. Only 3 patients required no further stents because of resolution of their biliary stricture. Other authors have also reported a low stricture resolution rate ranging from 11% to 28%. [98], [99] and [100] The results of the aforementioned studies stand in distinct contrast to those of Vitale and associates [101] who reported that 20 of 25 patients undergoing plastic biliary stenting for a median period of 13.3 months remained stent-free without stricture recurrence during a 32-month follow-up.

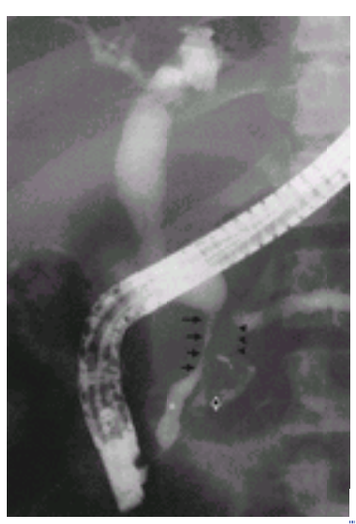

FIGURE 141-6. Chronic pancreatitis-induced common bile duct stricture. The cholangiogram shows a 2-cm common bile duct stricture (*closed arrows*) with proximal dilation. Note the pancreatic duct stone (*open arrow*) and stricture (*arrowheads*).

Because of the disappointing results with plastic stents and the concern for the high morbidity associated with surgically performed biliary drainage procedures in alcoholic (frequently debilitated) patients, the use of uncoated expandable metal stents was evaluated. [102] Twenty patients were treated with a 34-mm long metal stent that becomes 10 mm in diameter when fully expanded. The short length of the stent was chosen so that surgical bypass (e.g., choledochoduodenostomy) would still be possible if necessary. Cholestasis ($n = 20$), jaundice ($n = 7$), and cholangitis ($n = 3$) resolved in all patients. Eighteen patients had no further biliary problems during a follow-up period of 33 months (range, 24 to 42 months). Two patients (10%) developed epithelial hyperplasia within the stent resulting in recurrent cholestasis in one and jaundice in the other. These patients were treated endoscopically with standard plastic stents, with one of these patients ultimately requiring surgical drainage. The authors concluded that this therapy could be an effective alternative to surgical biliary diversion but that longer follow-up and controlled trials will be necessary to confirm these results. The studies cited here and others indicate that plastic biliary stents are a useful alternative to surgery for short-term treatment of chronic pancreatitis-induced common bile duct strictures complicated by cholestasis, jaundice, and cholangitis. This therapy should also be considered for high-risk surgical patients. However, the long-term efficacy of this treatment is much less satisfactory because stricture resolution rarely occurs; operative intervention appears to be a better long-term solution for this problem in patients of average risk. More data on the long-term outcome, preferably in controlled trials, are necessary before the expandable stents can be advocated for this indication. Trials of membrane-coated metal stents and removable coil spring stents are awaited.

Primary Sclerosing Cholangitis

Cholangiographic imaging is the gold standard for diagnosing primary sclerosing cholangitis (PSC), although conditions that mimic PSC must be excluded (Table 141-4). In the variant, small duct PSC, the cholangiogram is normal. [103] Both percutaneous transhepatic cholangiography (PTC) and ERCP can be used to show the characteristic changes of PSC. The choice between PTC and ERCP will depend on local and regional expertise and availability. However, where available, ERCP is the preferred modality because:

- the often small fibrotic ducts of PSC may be difficult to puncture via the percutaneous route
- ERCP has a better safety profile
- the pancreatic duct and cystic duct, which may be involved in up to 20% of PSC patients, can be examined at ERCP.

Neoplasms
Metastatic carcinoma
Cholangiocarcinoma
Lymphoma
Cirrhosis
Polycystic Liver Disease
Caroli Disease
Multiple Hepatic Abscesses
Systemic Fungal Infection
Bacterial Cholangitis
Secondary Sclerosing Cholangitis
Associated with bacterial infection and impacted intrahepatic ductal stones
Associated with congenital immunodeficiency syndromes, opportunistic infections (e.g., cytomegalovirus)
Acquired Immunodeficiency Syndrome (AIDS)
Associated with cytomegalovirus, *Cryptosporidium*, papillary stenosis
Graft-Versus-Host Disease
Hepatic Arterial Ischemia
Posttraumatic
Postsurgical (including intentional or inadvertent ligation of hepatic artery and complications from liver transplantation)
Associated with intraarterial 5-fluorodeoxyuridine (5-FUDR)
Preservation injury of biliary tract in the donor liver
Chronic allograft rejection in liver transplantations

TABLE 141-4 Conditions Producing Cholangiograms That May Mimic Primary Sclerosing Cholangitis

PTC is reserved for ERCP failures and patients with altered anatomy. The role of MRCP and spiral CT cholangiography in the diagnosis of PSC awaits further study. [104]

The classic cholangiographic features in PSC are diffuse multifocal strictures of the intrahepatic and extrahepatic bile ducts (Fig. 141-7). [105] These strictures are usually short with intervening normal or dilated segments giving a beaded appearance. Other frequent findings on the cholangiogram include pseudodiverticula, mural irregularities, and biliary stones and "sludge." [106], [107]

FIGURE 141-7. This patient has primary sclerosing cholangitis involving the extrahepatic and intrahepatic ducts. There are multiple strictures of the common bile duct (*open arrows*) and intrahepatic ducts (*arrowheads*).

The rationale for endoscopic intervention is based on the hypothesis that progressive liver disease and deterioration of liver function may be aggravated or accelerated by back pressure from dominant strictures and stones or debris when present. It is further hypothesized that relief of obstruction may halt, delay, or even reverse progression to cirrhosis and liver failure. [108] Because no medical therapy has been definitively proven effective for PSC, a trial of endoscopic therapy in symptomatic patients seems reasonable. The indications for considering endoscopic management in PSC are the treatment of jaundice or pruritus, symptomatic cholangitis, deteriorating serum hepatic chemistries, and, when the concern for bile duct cancer is high, for purposes of tissue sampling. The most favorable candidates for therapy are those patients with a dominant extrahepatic stricture with or without stones and limited or no intrahepatic involvement. Such ideal anatomy is uncommon.

Endoscopic Techniques If therapeutic skills are not readily available, care should be taken to avoid injecting more than 2 to 3 cc of contrast media proximal to high-grade strictures. Not uncommonly, contrast media will take the path of least resistance and enter the cystic duct and gallbladder; intrahepatic filling is therefore limited. Preferably, a balloon catheter is then manipulated above the cystic duct takeoff, and higher-pressure injection of the intrahepatic radicles is performed with the balloon inflated. Moreover, since the risk of post-ERCP cholangitis in PSC may be as high as 20% to 30% following diagnostic and therapeutic procedures (particularly in patients where obstructed segments are not decompressed), antibiotic prophylaxis has been advocated. All therapeutic procedures aim at improving bile flow. The endoscopic techniques that may be used to achieve this goal are ES, stone/sludge removal, stricture dilation with balloons and catheters, placement of stents and NBTs (with or without instillation of corticosteroids and saline lavage), and combinations of therapy. Many authorities advocate performing ES as this will permit easier access to the biliary tree for other therapeutic maneuvers. Moreover, the sphincter may be involved in the fibrotic process. A potential disadvantage of sphincterotomy is the destruction of the natural barrier between the duodenum and the biliary tree, which protects against bacterial and food contamination. Endoscopic stricture dilation and stenting have been reported in PSC patients since the early 1980s. The techniques have been standardized. Guidewires must first be advanced proximal to the stricture. This may be quite difficult in the PSC setting because of the irregular, high-grade strictures and the presence of pseudodiverticula. Perforation and false passages can occur relatively easily. Such perforations and false passages rarely seem to cause clinical problems, probably because they were made distal to the dominant stricture and the pressure in the bile duct at these sites is low. Once perforation or a false tract is created, however, further attempts to pass the guidewire through the natural stricture are often fruitless. We often put the patient on antibiotics and repeat the ERCP in a few days to a week depending on the clinical situation. Forceful pushing of wires and catheters should never be done. The development of hydrophilic guidewires has facilitated the passage of high-grade strictures. Once the guidewire has been advanced through the stricture, a dilating catheter or balloon can be used to dilate the stricture. The decision of which dilating instrument to use is a personal one as there are no studies that compare the two devices. However, while the diameter of the dilating catheter is dependent on the accessory channel size, no such limitation (for the most part) exists for dilating balloons. Strictures are generally dilated to match the size of adjacent normal ducts (i.e., 2 to 6 mm for intrahepatic ducts and 6 to 10 mm for extrahepatic ducts). Newer higher-pressure balloons permitting inflation to 10 to 12 atm have decreased the frequency of failure to obliterate the stricture waistline but probably carry a higher risk of duct perforation. Another option advocated by some authorities is placement of an NBT. The NBT can be advanced through the stricture and left in place. For the first few days, the drain is used simply for drainage. During this interval, the strictures open up by continuous pressure and movement of the NBT, creating space around the NBT. The catheter can then be used for instillation of saline or drugs (e.g., corticosteroids). Temporary biliary stenting has been advocated by some authorities particularly when dilation fails to

improve stricture patency sufficiently. Others suggest that stents should be avoided owing to the high incidence of cholangitis.

Results The goals of endoscopic intervention in PSC are to relieve jaundice and pruritus, treat cholangitis and theoretically delay the onset of biliary cirrhosis, and buy time prior to liver transplantation. Interpretation of the reported results of endoscopic therapy is difficult because there are no randomized controlled trials, therapies are not uniform, treated patients have variable anatomy, the definition of success varies, studies are generally small, the course of untreated PSC is variable, and there is no long-term follow-up. Johnson and colleagues [109] treated 35 symptomatic PSC patients (29 with cholangitis and 6 with jaundice alone) by dilation (balloon or catheter) with or without biliary stenting. During a mean follow-up period of 24 months, there was a significant reduction in the frequency of hospitalization for cholangitis, bilirubin, and stricture score. Cholangitis occurred shortly after treatment in six patients; five of the six had a biliary stent placed. As a result, these authors recommended avoiding biliary stents in PSC. A retrospective review of 85 PSC patients who underwent 175 ERCP procedures (75 diagnostic and 100 therapeutic) showed that endoscopic therapy was associated with a 15% major complication rate (7% pancreatitis and 8% cholangitis). [110] Clinical follow-up (median, 31 months) was obtained in 50 of 53 patients who underwent 85 therapeutic procedures. Twenty-eight patients improved clinically, while 21 felt the same, and one felt worse. Serum liver chemistries obtained within 3 months of the endoscopic intervention were significantly improved compared with pretreatment values. Overall, 41 of 53 patients (77%) had improvement of their clinical symptoms, liver function tests, or cholangiograms. Van Milligen de Wit and associates [111] reported results of stent therapy in 25 patients with PSC and dominant extrahepatic strictures. Stents were exchanged or removed electively at 2- to 3-month intervals or because of symptoms attributable to stent clogging. Endoscopic therapy was technically successful in 21 patients (84%). In these 21 patients, the results of all serum biochemical liver tests improved significantly within 6 months of stent therapy. During a median follow-up of 29 months (range 2 to 120 months) after stent removal, 12 patients (57%) remained asymptomatic with stable biochemical liver tests and 4 (19%) had clinical and biochemical relapse of disease that responded favorably to repeat endoscopic therapy. Early procedure-related complications occurred in 14% of the procedures. The value of short-term endoscopic stenting (mean, 11 days; range, 1 to 23 days) for 32 patients with dominant strictures has been reported by Ponsioen and colleagues. [112] Cholestatic symptoms improved in 83% and there were statistically significant reductions in abdominal pain, fatigue, and pruritus. Serum liver chemistries were significantly improved. Eighty percent of patients were free of reinterventions at 1 year and 60% at 3 years. Procedure-related complications occurred in 15% but there were no episodes of cholangitis. The authors advocated this technique because of its efficacy and it overcame the complications associated with stent occlusion. Kaya and colleagues [113] reported that stenting after balloon dilation (median stenting interval of about 4.5 months) of dominant strictures provides no additional benefit and is associated with more complications than balloon dilation alone. Baluyut and colleagues [114] found that repeated endoscopic treatments to maintain bile duct patency were associated with a significantly higher observed 5-year survival than predicted by the Mayo Clinic survival model. The value of saline lavage and infusion of steroids via NBT has been studied in small series with inconclusive results. [115], [116] Cholangiocarcinoma is a dreaded complication of PSC, occurring in 9% to 15% of patients. [103] The risk appears to be greatest in those patients with long-standing ulcerative colitis and cirrhosis. Surprisingly, studies suggest that there may be an inverse relation between the duration of PSC and the risk of cholangiocarcinoma. [117], [118] Sudden worsening of jaundice should raise the possibility of the development of cholangiocarcinoma. Cholangiographic findings that suggest malignant transformation include markedly dilated ducts of ductal segments proximal to a stricture, the presence of a polypoid mass, and progressive stricture formation. [106] Comparison with previous ERCP results is essential to signal the presence of complicating cholangiocarcinoma because with PSC uncomplicated by malignancy the cholangiographic appearance frequently remains static for years. [106] Unfortunately, early diagnosis of cancer is difficult because we lack a sensitive, specific serologic marker and bile duct tissue sampling is relatively insensitive. However, tissue sampling of any suspicious lesion found at ERCP is indicated. Although the use of ERCP in helping to make the diagnosis of PSC is clear, its therapeutic efficacy in improving the course of the disease appears highly likely but not definitively established. Clearly, symptomatic patients with dominant extrahepatic strictures are the best candidates for therapy.

Biliary Fistulae

Biliary fistulae most commonly occur as a complication of cholecystectomy, common bile duct exploration, inadvertent operative injury of the bile duct, or as a consequence of a local infection. Rarely, biliary fistulae result from long-standing untreated biliary tract disease. With more widespread use of laparoscopic cholecystectomy, the incidence of bile duct injury, including biliary fistulae, has increased. [119], [120] and [121] Bile leakage from the cystic duct remnant is among the most common injuries reported as a complication of laparoscopic cholecystectomy. The most common cause for cystic duct leaks involves imprecise application of clips on the duct or their subsequent dislodgment during the procedure. [122], [123], [124] and [125] Biliary fistulae may also arise from the intrahepatic ducts and common duct. The duct of Luschka, if present, is quite vulnerable to transection during cholecystectomy. [126] Clearly, distal obstruction from stone, stricture, or papillary stenosis increases the ductal pressure proximally and may promote and maintain the biliary fistula.

Postoperative bile duct leaks usually manifest within a week after surgery. [125], [127], [128] In a series [128] of 62 patients with postcholecystectomy leaks, presenting symptoms included abdominal pain in 89%, abdominal tenderness in 81%, fever in 74%, nausea and vomiting in 43%, and jaundice in 43%. Only 2% presented with a clinically detectable mass or ascites. Biochemical testing is usually nonspecific with variable elevations of the serum hepatic chemistries and white blood cell count.

A high index of suspicion for bile duct injuries after laparoscopic cholecystectomy should be maintained for any patient who fails to follow a smooth, uneventful postoperative course. Patients with suspected biliary fistulae often undergo abdominal ultrasound or CT scan to look for evidence of a biloma and HIDA scan to diagnose the leak. [53] However, direct cholangiography (most often by ERCP) is the most sensitive test to detect a biliary fistula. [128]

The treatment options for biliary leaks include percutaneous or endoscopic placed biliary drains or stents, and surgical drainage and repair of the leak. Patients with large bilomas should undergo percutaneous drainage (unless surgery is performed) of the fluid collection. Endoscopic therapy has been shown to be a definitive therapy in this setting with low morbidity. Patients with leaks from the cystic duct, duct of Luschka, and T-tube tract are optimal candidates for endoscopic treatment. However, patients with injuries of the common bile duct, common hepatic duct, and intrahepatic ducts can also be managed by endoscopic techniques.

The primary goal of endoscopic therapy is to decrease the pressure gradient between the bile duct and duodenum, allowing drainage of bile along the path of least resistance and away from the site of leakage (to allow the defect to seal). This can be accomplished with biliary sphincterotomy alone, stenting alone, NBT alone, or any combination thereof (Fig. 141-8). [53], [121], [127], [128], [129], [130], [131], [132], [133] and [134] Foutch and colleagues [135] compared the various endoscopic treatment options in 23 patients with biliary leaks arising from the cystic duct (*n* = 13), common duct (*n* = 6), and duct of Luschka (*n* = 4). Patients were treated by sphincterotomy alone (*n* = 4), stent alone (*n* = 6), sphincterotomy and stent (*n* = 12), and sphincterotomy and NBT (*n* = 1). The biliary fistula closure rate was 100% and was complicated by minor bleeding in one patient. Davids and associates [134] reported their results of endoscopic management for postoperative biliary fistulae in 55 patients. A sphincterotomy alone was performed when there was a cystic duct stump or hepatic radical fistula but no distal common bile obstruction. Residual stones were removed using conventional techniques. A 10F stent was placed when there was a history of operative biliary trauma, when a benign or malignant stricture was present, or when the common duct could not be completely cleared of stones. The biliary tract and site of leakage were visualized during ERCP in 98% of patients. Endoscopic treatment was attempted in 49 of 54 patients. Five patients had total bile duct obstruction caused by a clip or ligature and could not be treated endoscopically. Successful drainage was achieved in 48 of 49 patients. An excellent outcome (clinical and radiologic resolution of the biliary fistula) was achieved in 43. Despite adequate therapy, five patients had continuing sepsis resulting in death. Although no significant factors predictive of a favorable outcome could be defined, the clinical condition of the patient at the time of referral seemed to be of importance. All poor responders had been admitted to the ICU prior to endoscopic treatment.

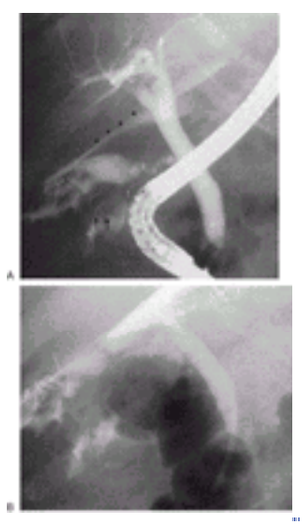

FIGURE 141-8. This patient underwent laparoscopic cholecystectomy for acute cholecystitis. She presented 10 days later with fever, chills, and abdominal pain. **A:** The cholangiogram shows contrast extravasation (*closed arrows*) from a residual gallbladder remnant (*open arrow*). Note subhepatic contrast collection (*arrowheads*). **B:** Endoscopic sphincterotomy was performed, and a 7F stent was placed with the tip of the stent proximal to the cystic duct takeoff.

Patients with clinically evident leaks not identified on cholangiography may have a disconnected duct. Kalacyi and associates [136] showed that MRCP may be helpful in identifying the upstream bile duct and the site of injury.

A sphincterotomy alone can be sufficient treatment for many patients with obstructed bile ducts with associated leaks when the cause for obstruction (papillary stenosis or choledocholithiasis) can be treated with such therapy. [137] However, sphincterotomy as a single treatment has failed when leaks were large. [138] Experience with NBTs to treat biliary leaks is limited, but available data from several investigators have been favorable. [138], [139] Since most fistulae seal in a few days, NBT placement is a reasonable option. The advantages of the NBT include the ability to monitor closure of the leak with repeat cholangiography, maximum decompression can be applied with suction, and the tubes are easily removed without the need for a second endoscopic procedure. However, the risk of infection when improperly cared for, poor patient acceptance and discomfort, and potential electrolyte disturbances from external drainage have been cited as potential disadvantages of this approach. [53] Furthermore, the documentation of closure seen on cholangiogram may not correlate with long-term healing of a disrupted duct. [135]

Biliary stents are a very effective therapy for resolving biliary leaks. The observation from several uncontrolled studies that patients treated with stents alone experience equally good outcomes compared to patients treated with a combination of stents and sphincterotomy suggests that sphincterotomy can be avoided in patients with otherwise unobstructed ducts. [134], [135] Therapeutic efficacy for 7F stents has been high. However, Foutch and associates [135] reported a 22% failure rate with 7F stents; these fistulae resolved by upsizing the stent to 10F. Larger caliber stents are certainly preferred when a concomitant stricture is present. In most reported series, stents were inserted with the proximal end positioned above the leak site. [134], [135] It is assumed that the stent can partially mechanically occlude the leak site favoring more rapid closure. However, Bjorkman and colleagues [133] reported 100% fistula closure rate in 15 patients after placing one short (2 to 3 cm) 10F stent with the stent tip distal to the leak site. The results of this study confirm the importance of eliminating the transpapillary pressure gradient. Most studies that monitor drain output or reassess the fistula by repeat cholangiography report rapid closure of the fistula in most cases with cessation of bile extravasation in 1 to 7 days. [138] The precise time when the fistula site is permanently closed however is difficult to determine from reported series.

The available data suggest that biliary fistulae are likely to heal regardless of the therapy used to decrease the pressure gradient in the direction of the duodenum. Randomized studies comparing sphincterotomy, internal stent, and NBT will be necessary to determine which of these therapies is the safest, most reliable, and most cost-effective management option. Biliary fistulae associated with bile duct strictures will require long-term stenting, preferably with large bore stents (10F and 11.5F stents).

Malignant Bile Duct Obstruction

A variety of palliative options can be offered to the patient with malignant obstructive jaundice including surgical, percutaneous, endoscopic, and medical therapy (chemotherapy and radiation therapy). Certainly the surgically fit patient with a resectable tumor after staging should be offered the option of surgical resection for cure. In the high-risk patient or the patient with an unresectable tumor, endoscopic placement of polyethylene stents has become a widely accepted method of management. [140] Soehendra and Rejinders-Frederix [141] first described endoscopic biliary stenting in 1980. Since then, many advances in stent technology have been made. Despite these developments, stent patency remains a major problem with 10F stents becoming occluded after 3 to 6 months. [142], [143] The problem with stent occlusion has been studied intensively but attempts at altering bile composition with choleretic agents, reducing bacterial load with antimicrobial agents, changing stent material, or influencing mucin production with aspirin have failed to prolong stent patency. [144], [145] and [146] Because deposition of sludge (leading to stent occlusion) may depend on flow rate through the stent, change in stent diameter may influence the process of stent clogging. Theoretically, a small increase in stent diameter may result in an appreciable increase in flow. The limiting factor for insertion of larger plastic biliary stents is the size of the instrumentation channel of the duodenoscope. With today's endoscopes, plastic stents up to 12F can be placed. The question of whether bigger is better still cannot be definitively answered for plastic stents. In some studies, stent patency was significantly longer for large diameter plastic stents than small diameter ones. [147] Others have found no prolongation of stent patency and more complications when larger stents are used. [148] The divergent results of these studies may be explained by study design, patient selection criteria, and sample size.

There is considerable debate as to whether patients with strictures involving the bifurcation require ductal decompression of both the right and left intrahepatic systems. [140] Advocates of a single stent argue that ductal decompression of one lobe improves symptoms of cholestasis and allows jaundice to resolve. [149] Proponents of decompressing both sides of the liver point to the 30% to 40% incidence of cholangitis, increased mortality, and death from sepsis when only one lobe is drained. [150] Our approach to hilar strictures is as follows: Once a guidewire is advanced into an intrahepatic duct, bile is aspirated to limit systemic seeding of any resident bacteria when contrast is injected. Only enough contrast should be injected to define the stricture anatomy. If a good stentable duct is identified, that lobe is drained. When draining only one lobe of the liver, it is imperative to limit contrast injection to the lobe to be drained and avoid manipulation of the other lobe. The other lobe should be stented if the patient develops cholangitis or symptoms of cholestasis persist. Two studies support this approach. [151], [152] and [153] De Palma and associates [152] randomized 157 consecutive patients with malignant hilar obstruction to undergo unilateral or bilateral hepatic duct drainage. In the intention-to-treat analysis, unilateral drainage was associated with significantly higher rates of successful drainage (defined as decreases in bilirubin to less than 75% of the pretreatment values within one month) and lower early complication rates (primarily because of lower rates of cholangitis). Thirty-day morality, late complications, and median survival were similar for the two groups. MRCP can help select the liver lobe to be drained thus avoiding contrast medium injection into the contralateral lobe. [154]

The success rate of plastic stent insertion is about 90%, and it is higher in patients with distal than proximal tumors. [155] If endoscopic stent placement fails, percutaneous drainage or a combined endoscopic radiologic procedure (rendezvous procedure) can be performed. If contrast was injected into the biliary tree, such therapy should be performed urgently to prevent cholangitis. In the surgically fit patient, particularly if duodenal obstruction is present, surgical bypass is a reasonable option. Relief of symptoms can be expected in nearly all patients following successful deployment of a plastic stent. Stenting not only resolves jaundice and pruritus, but also is associated with improvements in quality of life. [156], [157]

Early postprocedure complications, which have been reported in 10% to 20% of patients in most studies, are related to the sphincterotomy or to the insertion of the stent itself. The most frequent early complication is cholangitis, reported to occur in as many as 10% to 15% of patients, and is probably due to the introduction of bacteria during the procedure into the stagnant bile proximal to the stricture. [10], [158] The risk of cholangitis is higher if incomplete drainage is obtained.

The main late complication of biliary stenting is cholangitis as a result of stent occlusion. Stents placed for hilar obstruction appear to occlude faster than stents placed for more distal obstructing lesions. [155], [159] Patients with symptomatic stent occlusion will require stent change and possibly hospitalization for therapy of cholangitis. As a result, some authorities have advocated prophylactic stent changes with the hope of avoiding cholangitis. Sherman and colleagues [159] have demonstrated that nearly 50% of patients undergoing stenting with 10F or 11.5F plastic biliary stents die prior to stent occlusion. Thus, patients with a short life expectancy would be subjected to unnecessary procedures if prophylactic stent changes were performed. Using computer modeling, Tarnasky and associates [160] suggested that indicated stent exchanges are more cost-effective compared to prophylactic stent change at any interval. Prat and associates [161] reported that symptom-free survival was longer for patients undergoing planned stent exchange every 3 months but offered no cost advantage compared to patients undergoing stent exchange for symptomatic occlusion. Preliminary results of a randomized trial comparing scheduled stent change every 4 months to symptomatic stent change revealed no difference in the number of ERCPs per patient, number of stents per patient, mortality rate, need for metal stenting, frequency of surgery, mean stent survival, frequency of cholangitis, and time to death. [162]

One of the major advances in stent technology was the development of the metal expandable stent. Expandable metal stents may offer improved biliary drainage because of their large diameter and small surface area with prolonged patency rates. There are several types of expandable metal stents available, characterized by different insertion devices, methods of deployment, radial forces, and metal composition. To date, most experience has been gained with the Wallstent. This stent is easily inserted over a well-positioned guidewire and successfully deployed in more than 95% of cases. The Wallstent is mounted on a 7.5F delivery device and shortens and expands to 8 to 10 mm as it is deployed. Four prospective, randomized trials [163], [164], [165] and [166] (three endoscopic and one percutaneous) have shown that the metal expandable biliary stent occludes less frequently and less rapidly than the conventional 10F and 11.5F plastic stents. This translated into a reduction in hospitalization requirements (for cholangitis and stent change) and an overall cost savings for the metal stents. Since metal stents are more costly initially, and since approximately half of the patients in most plastic stent series will need a second stent, identification of patients who are likely to outlive their first plastic stent (and

warrant a metal stent) is a major challenge for the managing physician. In a study from Amsterdam, [163] the stent patency curves of Wallstents and plastic stents ran parallel during the first 3 months after stent insertion. After that time the curves diverged in favor of the Wallstent. Therefore, based on data from this study, the authors recommended that only patients with a life expectancy of more than 3 months are potential candidates for use of an expandable metal stent. An additional indication for use of metal stents can be found in the small group of patients who suffer rapid and repeated obstruction of plastic stents. These patients have not been well studied and can, at present, not be identified at the initial stenting session.

When palliation is the goal of therapy for patients with malignant bile duct obstruction, how does endoscopic decompression compare to percutaneous and surgical drainage procedures? In a randomized study comparing percutaneous drainage to endoscopic drainage, [167] endoscopic stenting was associated with more frequent successful drainage (81% vs. 61%; $P < 0.05$), a lower complication rate (19% vs. 67%; $P < 0.05$), and a lower 30-day mortality (15% vs. 33%; $P < 0.05$). Median survival was similar for the two groups (23 vs. 16 weeks). Three prospective, randomized trials [168], [169] and [170] have compared endoscopic to surgical drainage for malignant distal biliary obstruction. Endoscopic stenting and surgery were equally effective palliative treatments with endoscopic treatment having a lower early complication rate and mortality, but a higher risk of late complications, such as stent blockage and gastric outlet obstruction. None of these studies demonstrated a difference in survival rates between treatment groups.

Tissue Sampling at ERCP ERCP frequently provides the first opportunity to obtain a histological or cytologic specimen from an unexplained biliary or pancreatic stricture. A variety of tissue sampling techniques are available to the endoscopist at the time of ERCP. These include bile and pancreatic juice cytology, brush cytology, intraductal forceps biopsy, intraductal fine-needle aspiration, stent cytology, and juice and tissue evaluation for aneuploidy, tumor markers (e.g., CEA, CA 19-9), p53 immunoreactivity, and K *-ras* oncogene mutations. Aspiration of bile or pancreatic juice is the easiest method of obtaining tissue when evaluating biliary and pancreatic strictures for malignancy. Unfortunately, the results have been largely disappointing, with cancer sensitivities in the 6% to 32% range [171], [172], [173] and [174] and frequent findings of acellular specimens. The desmoplastic nature of certain tumors or failure of the neoplasm to invade the ductal epithelium are likely responsible for these results. [174] It has been suggested that endoscopic manipulation of the stricture (e.g., dilation) [175], [176] prior to bile collection may increase tumor exfoliation, making more malignant cells available for diagnosis. However, this has not been confirmed by others. [177] Brush cytology is the most commonly applied method of tissue sampling and most extensively studied. While the technical success rate is high (90% to 95%), most studies demonstrate cancer detection rates in the 20% to 60% range. [171], [178], [179], [180], [181], [182], [183] and [184] Sawada and colleagues [185] have shown that brushing the pancreatic duct may increase the diagnostic yield of brush cytology (compared to brushing the bile duct) in pancreatic cancer. However, pancreatic cancers often disrupt the duct and prevent passage of the brush through the tumor in more than 25% of patients. In an attempt to improve on the sensitivity of brush cytology, other methods have been used. Howell and colleagues [186] originated use of the ERCP endoscopic needle aspiration (ENA) technique and reported a cancer detection sensitivity from biliary samplings of 62% in patients with biliary strictures (including 53% in pancreatic cancer and 80% in cholangiocarcinoma). These impressive results for ENA were not found in three subsequent [177], [183], [187] reports where the sensitivity was 26%, 30%, and 27%, respectively. Endobiliary forceps biopsy allows examination of tissue specimens below the bile duct epithelium. The results of six prospective studies have been encouraging, [171], [177], [179], [180], [183], [188] with a cancer detection rate among 415 patients of 58%. Stents placed for palliation can be removed and sent for cytologic evaluation of adherent cells, as exfoliated malignant cells may become entrapped in the Biofilm and sludge of an occluded endoprosthesis. A few small studies have evaluated this approach, with a wide range of sensitivity results. Foutch and associates [174] reported a sensitivity of 36% (4 of 11 patients), while Leung and associates [189] reported a sensitivity of 79% (11 of 14 patients). Devereaux and colleagues [190] reported a cancer detection rate of only 11% among 101 patients with biliary strictures (57 were confirmed to be malignant). Unfortunately, this method is impractical because the diagnosis of cancer is delayed until the stent is removed. Although it would be preferable to have one technique that would have a cancer detection rate similar to that seen with biopsy of upper gastrointestinal and colonic neoplasms, this goal has not been reached in the pancreaticobiliary tree. Investigators have therefore evaluated the added sensitivity of combining a number of tissue sampling techniques. Jailwala and colleagues [183] reported their results of the cumulative sensitivity of triple tissue sampling at one ERCP session with brush cytology, fine-needle aspiration, and forceps biopsy in 104 patients with malignant bile duct obstruction. Tissue sampling sensitivity varied according to the type of cancer; the highest yield was seen in patients with ampullary cancer. The combination of techniques was superior to individual methods, as the addition of a second or third technique increased cancer sensitivity rates in most instances. It is clear that the cancer detection sensitivity of these standard techniques individually is suboptimal. Methods to improve this sensitivity are therefore being evaluated. Preliminary studies suggest that the yield may be increased by evaluating aspirated fluid and tissue for aneuploidy [191] and tumor markers such as CEA and CA 19-9. Investigations have suggested that the evaluation of tissue or fluid for K *-ras* mutations is more accurate than cytology in the diagnosis of pancreatic cancer. [192], [193], [194] and [195] However, some authors [194] have identified K *-ras* mutations in patients with chronic pancreatitis reducing the specificity of this test. Further study is warranted to determine the role of these new techniques in the assessment of pancreatic and biliary strictures.

Sump Syndrome

The sump syndrome is an infrequent complication of a side-to-side choledochoduodenostomy. Some degree of stenosis of the surgical anastomosis is usually present. Cholangitis, pain, and pancreatitis may occur as food, stones, or other debris accumulate in the common bile duct in the bypassed segment. The reported median time interval between surgery and the appearance of symptoms was 5 years and 6 years between surgery and the diagnosis of sump syndrome. ES with removal of the debris has been shown to be an effective treatment. [196], [197] and [198] Although it may be possible to extract debris and stones through the choledochoduodenostomy, obviating the need for sphincterotomy, this approach puts the patient at risk of recurrent symptoms.

Choledochal Cysts and Anomalous Pancreatobiliary Union

Choledochal cysts are uncommon anomalies of the biliary tree manifested by cystic dilation of the intrahepatic or extrahepatic ducts. [199], [200] These cysts are most often classified by the scheme proposed by Todani and associates. [201] Type I cysts, which involve only the extrahepatic biliary tree, are the most common form, accounting for 80% to 90% of all choledochal cysts. [202] In this form of the anomaly, the cystic duct generally enters the choledochal cyst and the right and left hepatic ducts and the intrahepatic ducts are normal in size. Type II cysts are extrapancreatic bile duct diverticula and make up 2% of reported cases. [203] Type III cysts, accounting for 1.4% to 5% of cases, are choledochoceles and most often involve only the intraduodenal part of the common bile duct but occasionally the intrapancreatic portion. [204] Type IV cysts are subdivided into type IV A, multiple intrahepatic and extrahepatic cysts, and type IV B, multiple extrahepatic cysts. Type IV A cysts account for approximately 19% of reported cases, whereas type IV B cysts are much less common. [205] Finally, the type V cyst, or Caroli disease, consists either of single or multiple intrahepatic cysts. This form of cystic disease within the liver communicates with the biliary system as opposed to fibrocystic disease in which cysts filled with bile do not communicate with the biliary system. [206]

An anomalous pancreaticobiliary union is considered to be present when the common channel is greater than 15 mm in length. In this situation, the pancreatic duct and bile duct junction is outside the duodenal wall and proximal to the sphincter of Oddi promoting reflux of pancreatic juice into the biliary tree. Pancreatic juice reflux has been postulated to be involved in the pathogenesis of carcinoma, which occurs in 2.5% to 17% of patients with choledochal cysts. [207], [208], [209], [210], [211] and [212]

Surgery is the recommended treatment for most patients with choledochal cysts. [212], [213], [214] and [215] Cholangiography is the gold standard for diagnosing choledochal cysts. Although ERCP and PTC are invasive, they can thoroughly assess the cyst anatomy, site of biliary origin, extent of intrahepatic and extrahepatic disease, associated biliary tract anomalies, and complications (e.g., bile duct strictures, stones); and they shed light on possible therapeutic intervention, either definitive or temporizing pending surgery. ERCP is often the preferred modality because it provides detailed evaluation of the pancreatic duct and the pancreaticobiliary union, and is very useful in the diagnosis of type III choledochal cysts (choledochocele).

ERCP has become the procedure of choice to evaluate and treat most patients with type III choledochal cysts. [216] Patients with choledochoceles will commonly present with biliary symptoms (biliary colic, cholestatic jaundice, jaundice) or unexplained pancreatitis prompting ERCP evaluation. The endoscopic features of a choledochocele include:

- the intramural segment of common bile duct protrudes into the duodenum in continuity with an enlarged papilla
- the papilla is soft and smooth
- ballooning of the papilla is noted with contrast injection
- on contrast injection, a cyst-filled structure is apparent on fluoroscopy and in continuity with the common bile duct
- no impacted stone is present.

Several small series have reported the use of endoscopic cyst unroofing and sphincterotomy for both pancreatic and biliary indications. [216], [217], [218], [219], [220] and [221] Ladas and associates [216] identified 15 symptomatic choledochocele patients among 1019 (1.5%) referred for ERCP. Twelve patients were treated by endoscopic

therapy. During long-term follow-up (mean, 26 months; range, 4 to 56 months), 10 of 12 patients were asymptomatic with normal liver tests. One patient had a mild episode of cholangitis and one developed a carcinoma in the choledochocele. This unusually high frequency of choledochoceles may represent overdiagnosis, since several of these patients appeared to have only bile duct and ampulla of Vater dilation associated with ductal stones (not true choledochoceles). Although the risk of cancer in these patients is uncertain, it appears appropriate to recommend long-term follow-up in patients treated by endoscopic therapy alone. How this follow-up should be pursued remains to be clarified. Elton and colleagues [220] described a variant of a choledochocele which they called the dilated common channel syndrome. These patients have enlarged common pancreatobiliary channels which were believed to have developed because of papillary stenosis. Among 77 patients treated with unroofing and sphincterotomy, 77% had complete and long-lasting resolution of symptoms.

The management of anomalous pancreaticobiliary union in the absence of a choledochal cyst is unclear. Because of the high risk of gallbladder cancer, prophylactic cholecystectomy has been recommended by some. [211] In one series [222] of 15 patients with an anomalous pancreaticobiliary union (7 had choledochal cysts) and recurrent pancreatitis or abdominal pain treated by ES, 13 had resolution or reduction in the frequency of pancreatitis and pain. Ng and colleagues [223] similarly reported pain and pancreatitis resolution in five of six patients with a long common channel following endoscopic therapy. It is not yet known whether patients with anomalous junctions without choledochal cysts treated by sphincterotomy need surveillance for cancer.

PANCREATIC DRAINAGE PROCEDURES

Chronic Pancreatitis

Pancreatic duct pressure is generally increased in patients with chronic pancreatitis regardless of the etiology and whether or not the main pancreatic duct is dilated. [224] The aim of endoscopic therapy (and decompressive surgical therapy) for patients with chronic pancreatitis presenting with pain or clinical episodes of acute pancreatitis is to alleviate the obstruction to exocrine juice outflow. Certain pathological alterations of the pancreatic duct, bile duct, or sphincter lend themselves to endoscopic therapy. The techniques (e.g., sphincterotomy, dilation, stenting) and instruments (e.g., sphincterotome, dilating balloon, pancreatic stent) used to treat biliary tract disease have been adapted for use in the pancreatic duct.

Data in this area are often difficult to interpret because of the heterogeneous populations with one or more pathological processes being treated (e.g., pancreatic duct stones, strictures, pseudocysts) and because of the multiple therapies being performed in a given patient (e.g., stricture dilation, stone extraction, bile duct, or pancreatic duct ES). Controlled studies have not been reported to date.

Pancreatic Strictures Benign strictures of the main pancreatic duct may be a complication of previous embedded stone or consequence of acute inflammatory changes around the main pancreatic duct. [225] In Cremer and colleagues' [225] large referral population, only 10% of the patients presented with a stricture without associated calcified pancreatic stones. Pancreatic duct strictures can be treated by stent therapy. If stents larger than 7F are to be used, patients often require both a pancreatic and bile duct sphincterotomy followed by stricture dilation. For optimal results, the therapy must address both the pancreatic duct stricture and duct stones. The best candidates for stenting are those with a distal stricture (in the pancreatic head) and upstream dilation.
Pancreatic Stent Placement Technique The technique for placing a stent in the pancreatic duct is similar to that used for inserting a biliary stent. A guidewire must be maneuvered upstream to the narrowing. Hydrophilic flexible tip wires are especially helpful. Most pancreatic stents are just standard biliary stents with extra side holes at approximately 1-cm intervals to permit better side branch juice flow. In general, the size of stent should not exceed the size of the normal downstream duct. Therefore, 4F to 7F stents are commonly used in small ducts, whereas 10F to 11.5F stents can be used in advanced chronic pancreatitis and grossly dilated ducts. A pancreatic sphincterotomy (major or minor papilla) is often performed prior to (or after) placing a pancreatic stent. [226], [227], [228], [229] and [230] This is done with a standard pull-type sphincterotome or by using a needle-knife to incise the sphincter over a previously placed stent. Some authorities favor performing a biliary sphincterotomy prior to the pancreatic sphincterotomy because of the high incidence of bile duct obstruction and cholangitis, reported by one group, if this is not done. [231] Such complications were not found by others and have been infrequent in our experience. [226], [227] and [228], [232] Performing a biliary sphincterotomy first, however, can expose the pancreaticobiliary septum and allow the length of the cut to be gauged more accurately.
Efficacy of Stenting The results of pancreatic duct stent placement (usually with ancillary procedures) are detailed in Table 141-5. [225], [233], [234], [235], [236], [237], [238], [239], [240] and [241] Successful stent placement was achieved in 82% to 100% of patients. Sixty-six percent of patients were reported to benefit from therapy during an 8- to 39-month follow-up period. Quantification of the degree of improvement is often poorly defined. Partial or complete symptom improvement after stenting suggests that intraductal hypertension was an etiologic factor. Continued symptom relief after stent removal indicates adequate dilation of the narrowing. Differentiation of these two types of improvement is not clarified in some reports.

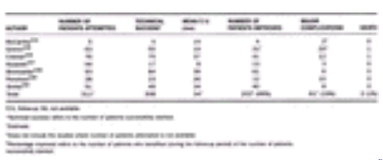

TABLE 141-5 Selected Series Reporting the Results of Pancreatic Duct Stenting for Dominant Strictures

Unfortunately, because the stricture persists in the majority, compliance with long-term use of such plastic stents (i.e., multiple stent changes) would be difficult. As a result, Cremer and colleagues [242] evaluated the expandable metal stent (18F, 23 mm in length) in 29 patients. After 6 months, mucosal hyperplasia resulted in stent occlusion in most patients.

Pancreatic Ductal Stones

It has been postulated that increased intraductal pressure proximal (upstream) to an obstructed focus within the pancreatic duct, as with pancreatic duct stones, is one of the potential mechanisms responsible for attacks of acute pancreatitis or exacerbations of chronic abdominal pain in patients with chronic pancreatitis. [236], [243] Reports indicating that endoscopic (with or without ESWL) or surgical removal of pancreatic calculi results in improvement in symptoms support this notion. [231], [243], [244], [245], [246], [247], [248], [249], [250], [251], [252], [253], [254] and [255] In one series, [249] 32 patients with pancreatic duct stones underwent attempted endoscopic removal. Of these patients, 72% had complete or partial stone removal and 68% improved after endoscopic therapy. Symptomatic improvement was most evident in the group of patients with chronic relapsing pancreatitis (versus those presenting with chronic continuous pain alone; 83% vs. 46%). Factors favoring complete stone removal included:

- three or fewer stones
- stones confined to the head or body of the pancreas
- absence of a downstream stricture
- stone diameter of <10 mm
- absence of impacted stones.

After successful stone removal, 25% of patients had regression of the ductal changes of chronic pancreatitis and 42% had a decrease in the main pancreatic duct diameter. The only complication from therapy was mild pancreatitis in 8%. These data suggest that removal of pancreatic duct stones may result in symptomatic improvement. A longer follow-up will be necessary to determine the stone recurrence rate and whether endoscopic success results in long-standing clinical improvement.

Smits and associates [251] treated 53 patients with pancreatic duct stones primarily by endoscopic methods alone (8 had ESWL). Stone removal was successful in 42 patients (79%), complete in 39, and partial in 3. There was initial relief of symptoms in 38 (90%). Three of 11 patients (27%) with failed stone removal had improvement in symptoms suggesting, as do results of Sherman and colleagues, [249] that some of the clinical response may be related to other therapies performed at the time of attempted stone removal (e.g., pancreatic sphincterotomy). During a median follow-up period of 33 months, 13 patients had recurrent symptoms due to stone recurrence. The stones were successfully removed in 10 (77%). No factor evaluated (etiology of pancreatitis, presentation with pain or pancreatitis, presence of single or multiple stones, location of stones, presence or absence of a stricture) was shown to predict successful stone treatment (defined as complete or partial removal of stones resulting in relief of symptoms).

Cremer and colleagues [252] reported complete stone clearance was achieved in only 18 (45%) of 40 patients with pancreatic duct stones who were treated by endoscopic methods alone, but immediate resolution of pain occurred in 77% of these patients. During a 3-year follow-up, 63% remained symptom-free. Clinical steatorrhea improved in 11 of 15 patients.

ESWL can be used to facilitate fragmentation and stone removal when endoscopic therapy alone fails. [231], [246], [250], [253], [254], [255], [256] and [257] Thus, this procedure is complementary to endoscopic techniques and improves the success of nonsurgical ductal decompression. Patients with obstructing prepapillary concrements and upstream ductal dilation appear to be the best candidates for ESWL. In the largest reported series, [231] 123 patients with main pancreatic duct stones and proximal dilation were treated with the electromagnetic lithotripter, usually before pancreatic duct sphincterotomy. Stones were successfully fragmented in 99% resulting in a decrease in duct dilation in 90%. The main pancreatic duct was completely cleared of all stones in 59%. Eighty-five percent of patients noted pain improvement during a mean follow-up of 14 months. However, 41% of patients had a clinical relapse due to stone migration into the main pancreatic duct, progressive stricture, or stent occlusion. Similar results were reported by Sauerbruch and colleagues [246] in 24 patients using a kidney lithotripter. Complications in series using ESWL were primarily related to the endoscopic procedure. Pancreatoscopy with laser and electrohydraulic lithotripsy of pancreatic duct stones has been successfully performed in small numbers of patients. [258]

Overall, the endoscopist is encouraged to remove pancreatic duct stones in symptomatic patients when they are located in the main duct (in the head or body) and are thus readily accessible. The available data suggest that the clinical outcome after successful endoscopic removal is similar to surgical outcome, with lower morbidity and mortality. [259] However, to date, no comparative trials have been done.

Pancreatic Pseudocysts and Fistulae Pancreatic pseudocysts are defined as encapsulated collections (without an epithelial lining) of pancreatic juice, either pure or containing necrotic debris or blood, which are situated either outside or within the limits of the pancreas from which they arise. [260] A pancreatic pseudocyst arises as a consequence of acute pancreatitis, chronic pancreatitis, or pancreatic trauma. [261] The optimal candidates with pseudocysts for endoscopic drainage have a single mature cyst without pancreatic necrosis, residual adjacent inflammation, or portal hypertension. More complex patients are generally best managed by a multidisciplinary approach with input from surgery, medicine, and interventional radiology. Two endoscopic approaches can be applied depending on whether the cyst communicates with the pancreatic duct. [236], [260], [262], [263], [264], [265], [266], [267], [268] and [269] Cysts communicating with the ductal system can be drained by a transpapillary approach. [262], [263], [265], [266], [267] and [268] The proximal tip of the prosthesis generally has been placed in the cystic cavity. [260] A pancreatic duct sphincterotomy may be required. Noncommunicating pseudocysts can be treated by direct cystoenterostomy via the stomach (endoscopic cystogastrostomy) or duodenum (endoscopic cystoduodenostomy) (Fig. 141-9). The aim of therapy is to create a communication between the cystic cavity and the gastric or duodenal lumen. Two prerequisites should be fulfilled before attempting this treatment: bulging due to the cyst should be obvious during upper endoscopy and the distance between the cyst and the lumen should not exceed 1 cm. [260] This distance can usually be assessed by CT scan, ultrasound, or endosonography, but when the compression is visible, usually the cyst to lumen distance is less than 1 cm. Also, the cyst wall should be mature. A double or triple lumen, beveled tip needle-knife is used to burrow a hole (usually using blended current) into the cyst cavity. A cystoenterotome is commercially available. [270] Many authorities advocate contrast injection via needle puncture of the cyst wall to identify a safe entry site before diathermic puncture. [271] The complication rate of this procedure may also be reduced by using the Seldinger technique without electrocautery. [272] A guidewire is advanced into the cyst and looped 360 degrees to secure positioning. Puncture should be performed perpendicularly to the cyst wall, and thus a duodenoscope is preferred. The newly created tract is then balloon dilated to 8 to 10 mm. Vigorous flow of pseudocyst fluid into the gut lumen generally occurs and this must be aspirated to maintain the endoscopic view. Two or more double-pigtail stents are then placed, bridging the cyst and the intestinal lumen. When significant debris or necrotic tissue is present, a nasocystic drain should be considered to allow for lavage of the cyst cavity. It is appropriate to maintain the patient NPO and on IV broad-spectrum antibiotics for 1 to 3 days if the cyst is >6 cm or contains debris. Diabetics, patients with debris in the cyst, and immunosuppressed patients may need a longer NPO interval as oral intake permits food and a greater concentration of bacteria to enter the residual cyst. The pseudocyst size is followed with ultrasound or CT scan at 4- to 6-week intervals. After resolution (usually in 1 to 2 months), the stents are endoscopically removed. If not done initially, pancreatography is performed to identify and allow treatment of ductal disease, such as stricture or stones, in an attempt to decrease pseudocyst recurrence. Pseudocysts recur in 10% to 20% of endoscopically managed cases, especially in patients with duct cut-off on pancreatogram. Table 141-6 shows the results of endoscopic management from large centers.

TABLE 141-6 Results of Endoscopic Management of Pseudocysts

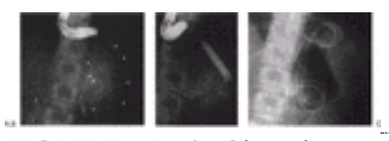

FIGURE 141-9. Chronic pancreatitis with a 7-cm nonresolving pseudocyst. **A:** Puncture of the pseudocyst via transgastric approach. Contrast injection reveals filling of a 7-cm pseudocyst (*arrowheads*) containing filling defects (*arrows*). Note the pancreatic calcifications (*open arrows*) in the region of the pancreas. **B:** The tract between the stomach and pseudocyst is dilated with a 10-mm hydrostatic dilating balloon. **C:** Two 10F, double-pigtail stents were placed, bridging the stomach and pseudocyst.

These excellent results certainly support the use of endoscopic therapy in appropriate candidates. When compared to other endoscopic techniques, this procedure has a relatively high bleeding and perforation rate. Bleeding complications are decreased by use of a hydrostatic balloon (not sphincterotome) to enlarge the tract orifice or by initial puncture with a needle catheter instead of the needle-knife. Nevertheless, the overall complication rate probably compares favorably to surgical series. Coordination with the surgeon is necessary when performing this procedure.

PANCREAS DIVISUM

Pancreas divisum, the most common congenital variant of pancreatic ductal anatomy, occurs when the ductal systems of the dorsal and ventral pancreatic ducts fail to fuse during the second month of gestation. With nonunion of the ducts, the major portion of the pancreatic exocrine juice drains into the duodenum via the dorsal duct and minor papilla. It has been proposed that a relative obstruction to pancreatic exocrine juice flow through the minor papilla could result in pancreatic pain or acute pancreatitis in a subpopulation of patients with pancreas divisum. [273], [274] While several epidemiologic studies dispute the relation of pancreas divisum and pancreatitis, two lines of evidence favor this association:

1. Histological studies and pancreatograms have demonstrated signs of chronic pancreatitis isolated to the dorsal pancreas.
2. Several reports have indicated that symptoms may be relieved by facilitating dorsal duct decompression endoscopically or surgically.

Endoscopic attempts to decompress the dorsal duct in patients with symptomatic pancreas divisum have been performed primarily by dilation, stent insertion, or minor papilla sphincterotomy. [234], [275], [276], [277] and [278] Lans and colleagues [276] reported their results of a randomized controlled trial of long-term (12 months) stenting of the minor papilla in patients with recurrent pancreatitis ($n = 19$). Follow-up continued for at least 12 months after stent removal. Stented patients had fewer hospitalizations and episodes of pancreatitis ($P < 0.05$) and were more frequently judged to be improved (90% vs. 11% for controls, $P < 0.05$). While symptomatic improvement following this therapy has been encouraging, multiple stent changes are generally required and the risks of stent-related complications are considerable. Ertan [277] reported that 21 of 25 patients (84%) with pancreas divisum developed stent-induced ductal changes after stenting periods of 6 to 9 months.

A “more permanent” enlargement of the minor papilla orifice is possible from sphincterotomy. Lehman and colleagues [278] attempted to evaluate the efficacy of minor papilla ES for patients with pancreas divisum ($n = 52$) presenting with disabling pancreatic-type pain ($n = 24$), idiopathic acute recurrent pancreatitis ($n = 17$), or chronic pancreatitis ($n = 11$). A short 4F to 7F stent was placed in the minor papilla and then a 3- to 6-mm sphincterotomy was performed over the stent using the

stent as a guide for cutting and a bridge to prevent edema-induced closure of the cut. The stent was then removed in approximately 2 weeks. The mean duration of symptoms was 5.1 years, and follow-up averaged 1.7 years with all patients being observed at least 6 months after therapy. While 76.5% of the acute recurrent pancreatitis group improved following therapy, only 26% of the chronic pain group ($P = 0.002$) and 27% of the chronic pancreatitis group ($P = 0.01$) benefited. Similarly, as compared to the chronic pain and chronic pancreatitis groups, the acute recurrent pancreatitis group had a significant reduction in the mean pain score and number of hospital days per month required for severe pain or pancreatitis. These discordant results in responsiveness to therapy for the acute recurrent pancreatitis group versus the chronic pancreatitis and chronic pain group were noted in several surgical series evaluating dorsal duct decompression [279], [280] and other endoscopic series. [281], [282] Pancreatitis complicating therapy occurred in 13% but, in general was mild and managed conservatively. Stent-induced dorsal duct changes occurred in 50%. One elderly patient died from complications of a pancreatic abscess that developed after a failed attempt at minor papilla stent placement. Results of these studies suggest that patients with pancreas divisum with acute recurrent pancreatitis are good candidates for endoscopic therapy while patients with chronic pancreatitis or chronic pain alone do not do as well.

CHAPTER 142

Cyrus E. Rubin and Mary P. Bronner

ENDOSCOPIC MUCOSAL BIOPSY—A MEMORIAL TO RODGER C. HAGGITT, M.D.

Rodger Haggitt passed away on June 28, 2000. This revised chapter is dedicated to him and presents his approach to gastrointestinal biopsy pathology. The sources of this chapter are Dr. Haggitt's prior published versions of this chapter and his other previously published and unpublished work. We also relied on the memories of his closest disciples, collaborators, residents, and other professional colleagues.

Dr. Haggitt early recognized the great clinical importance of endoscopic biopsy. He therefore taught himself how to interpret these small tissue samples and correlate their histological picture with the clinical findings. He developed his skills "on the job," learning much from his patients, fellow pathologists, and consulting gastroenterologists. To an extraordinary degree his approach combined common sense, diagnostic skill, and critical clinical judgment. He was blessed with a superb analytical mind. He was also an unusually able teacher of both pathologists and clinicians and it is our hope that this chapter will keep those teachings and his memory alive.

This chapter describes the clinicohistological approach to gastrointestinal (GI) endoscopic biopsy diagnosis. The endoscope is an excellent tool for visualizing gross mucosal lesions some of which, such as a varix, are obvious diagnostically, but most of which, such as erosions, ulcers, or masses, require biopsy for a specific diagnosis. The normal endoscopic surface appearance of the mucosa does not reveal whether its full thickness is normal or abnormal histologically. When an endoscopic diagnosis of "esophagitis, gastritis, or colitis" is based on subjective endoscopic impressions on which there is poor interobserver consensus, such as "reddening, edema, or granularity," the histology commonly turns out to be completely normal. On the other hand, an endoscopically normal appearing mucosa may

on occasion reveal unsuspected lesions such as dysplasia or infectious processes histologically. For example, every patient with normal appearing colonic mucosa and undiagnosed diarrhea merits at least two rectal and perhaps some proximal biopsies to rule out lesions such as collagenous colitis, lymphocytic colitis, quiescent ulcerative colitis, or Crohn's disease, all of which may not produce endoscopic changes. Because the endoscopic surface mucosal appearance may be misleading, the authors believe, as did Dr. Haggitt, that the mucosa should always be sampled according to a standard protocol during every diagnostic endoscopy.

To interpret the histopathology of endoscopic biopsies accurately, the GI pathologist must know and recognize diagnostic criteria for a broad spectrum of medical and surgical conditions and correlate them with the clinical findings to formulate the diagnosis. Knowing the clinical background of the patient who has been biopsied is essential for an accurate diagnosis because similar histological pictures may be seen in different diseases. To facilitate biopsy interpretation by the pathologist, a detailed endoscopic report should accompany every biopsy request and should include pertinent clinical history, physical findings, relevant diagnostic studies, and an endoscopic photograph of any important findings.

Four factors determine the usefulness of endoscopic biopsy:

1. The skill and diligence of the endoscopist who takes the biopsy.
2. The training and motivation of the technicians who process the biopsies.
3. The specialized experience, training, and skill of the GI pathologist who interprets the biopsies.
4. The quality and quantity of interaction between gastroenterologists and pathologists.

TECHNICAL CONSIDERATIONS

Diagnostic accuracy is greatly enhanced if biopsy samples are large enough, sufficient in number, correctly oriented, separately labeled, optimally fixed, step-serial sectioned, and appropriately stained. Dr. Haggitt said that approximately half the consultations sent to him from pathologists and gastroenterologists were prompted by defects in tissue processing and biopsy technique. In this regard, the suggestions given in the following paragraphs may be helpful.

A 3.4-mm diameter "jumbo" biopsy forceps passed through a large-channel endoscope yields specimens that are twice as large as those taken with standard-size forceps through a smaller endoscope. Smaller diameter endoscopes are now available with larger channels permitting passage of the larger forceps. Large biopsies can be taken safely using the "turn and suck" technique. [1] Larger biopsies are the best for diagnostic purposes because they are easier to orient, contain proportionately less crush artifact, permit more precise evaluation of architecture, and are more likely to detect small, infrequent lesions on serial sectioning. Proper use of a large biopsy forceps is not associated with a higher risk of complications than use of smaller versions. When removing a small lesion by "hot" biopsy or with an electrocautery snare, excessive cauterization can easily distort the tissue beyond recognition or rarely cause perforation. Saline injection submucosally in a sessile lesion can make electrocautery snare removal less dangerous without impairing histological quality.

Endoscopists tend to err on the side of taking too few biopsies for optimal diagnostic accuracy. The specific number of samples that should be obtained depends on whether the disease being evaluated is patchy or diffuse in distribution, and whether it is endoscopically visible and excisable, like a polyp, or invisible, like many dysplasias.

Correct orientation of biopsies is essential for obtaining sections perpendicular to the mucosal surface. Such sections are needed for precise evaluation of villous and crypt architecture, a sensitive but nonspecific indicator of abnormality in a wide variety of mucosal diseases. Ideally, the endoscopy assistant should orient the fresh biopsy onto a substrate which is then placed into fixative. To do this, the specimen is first teased out of the biopsy forceps and placed mucosal surface down on a gloved fingertip; it is then carefully unfolded with a blunt-ended probe to uncover its cut side, which is then gently pressed onto the substrate; the fingertip is then rolled off of the lumenal surface using the side of the probe to keep the specimen attached to the substrate. The mounted biopsy is then dropped into the fixative. Videotapes demonstrating these techniques, produced by Dr. Wilfred Weinstein and Boston Scientific (Natick, MA), may be obtained at no cost by calling toll-free 1-800-225-3226. A less satisfactory alternative is to drop the unmounted biopsy into the fixative without orientation and have a trained technician orient the fixed biopsy in the histology laboratory. If pseudomembranous colitis or amebiasis is suspected, the biopsy should be dropped directly into fixative with minimal manipulation to preserve the adherent diagnostic membranes or amebae.

The cut surface of larger pieces of tissue removed with electrocautery snares can be recognized for orientation by the presence of a fulguration artifact. After preliminary fixation, larger polyps should be divided perpendicular to the cut surface through their long axis so that the center of the polyp can undergo adequate further fixation.

Finally, the locations of biopsy sites should be clearly indicated by placement of the samples in separately labeled bottles of fixative. This simple step not only provides accurate clinicopathological correlation but also guides the endoscopist in rebiopsy of suspicious areas, or the surgeon if resection is indicated.

Despite its wide use, formalin alone is not an ideal fixative. Because of the delicate nature of formalin fixation, the tissue is not protected from the disruptive effects of tissue processing. In addition, formalin provides poor definition of nuclear detail and uneven shrinkage. As formalin requires a minimum of 24 hours for adequate fixation, [2] most tissue is not fixed long enough because of the pressure for rapid turnaround time. Inadequate formalin fixation is a major contributing factor to the generally low quality of histological preparations available in the United States. The advent of microwave rapid processing may solve this problem.

To address these concerns, some pathologists use Bouin or B-5 solution or other formalin-based fixatives containing metallic cations such as mercury, copper, and zinc, or acids such as picric and acetic. These fixatives penetrate tissue more rapidly and precipitate and denature tissue proteins; this hardens the tissue and enables it to better withstand the harsh treatment of embedding and sectioning. The better preservation of nuclear detail provided by these fixatives facilitates the diagnosis of dysplasia and cancer. Decreased shrinkage minimizes artifactual tissue distortion. We use a modified Bouin solution called Hollande solution, which preserves red cell membranes and the eosinophil granules. Specimens should be fixed in Hollande solution for a minimum of 2 hours, but not for more than 3 days because they will become brittle. After sufficient fixation these biopsies can be washed with water and stored in alcohol prior to processing at a later, more convenient time.

We recommend partial serial sectioning of all GI biopsies. From 3 to 5 different biopsy specimens can be oriented on edge together in the same block and at least 10 to 20 sections can be included in each of two ribbons cut from the central, best-oriented portion of the block. Three slides are usually made. Sectioning perpendicular to the mucosal surface provides well-oriented glands, crypts, and villi, whose architecture and surface nuclear maturation are easier to assess, facilitating the diagnosis of dysplasia. Step-serial sectioning helps detect focal lesions like granulomas and dysplasia. Also, biopsies not optimally oriented on the initial sections may be interpreted on deeper cuts. Personal experience has shown that this approach is feasible as a routine procedure in both university and community hospitals if endoscopists and histology technicians are trained and sufficiently motivated.

We routinely stain our biopsies with hematoxylin and eosin (H & E) as well as a HEABS stain (H & E, Alcian blue at pH 2.5, and saffron). The Alcian blue stains acid mucin in goblet cells of intestinal metaplasia of the stomach and Barrett specialized metaplasia. The bright Alcian blue stain marks the occasional malignant signet cell containing acid mucin that may focally invade the lamina propria or deeper layers of the submucosa. Saffron helps identify the collagen deposition characteristic of diseases such as collagenous colitis, chronic ischemia, solitary rectal ulcer syndrome, or collagenous sprue. It may also help differentiate collagen from edema in the lamina propria. We substitute a Genta stain [3] for the HEABS stain in gastric biopsies. The Genta stain is an H & E combined with a silver and Alcian blue stain at pH 2.5. When the Genta stain is performed properly, it helps the pathologist detect *Helicobacter pylori* (HP) with minimal effort and is morphologically diagnostic because of recognizable black dots at each end of its orange body. The Genta stain is difficult to perform well; the Alcian yellow stain is a reasonable alternative. [4] H & E alone may detect the organisms, especially when the critical combination of fixation and hematoxylin is used, but special stains are most helpful when organism load is low. Immunolocalization of various antigens is useful in classification of tumors, hormone secretion, and lymphoid surface antigens. DNA-based assays can now be applied even after use of special fixatives if heavy metal ions are removed by Lugol iodine. [5]

Confusing artifacts affecting mucosal histological study may be induced by rough handling of biopsy specimens or by improper tissue processing. Double-cupped endoscopic biopsy forceps remove specimens by avulsion causing some intramucosal hemorrhagic and crush artifact, especially at the edge of the biopsy where normal cells may be squeezed together mimicking inflammation, fibrosis, dysplasia, or even carcinoma.

Most errors in biopsy diagnosis are related to overinterpretation of normal variations or to unappreciated artifacts.

DYSPLASIA

Esophageal squamous carcinoma, esophageal adenocarcinoma, gastric and cardia adenocarcinoma, and colonic adenocarcinoma occur more frequently in patients with specific diseases predisposing to cancer or in environments where such diseases are more common (e.g., Barrett esophagus predisposes to esophageal adenocarcinoma). Therefore, endoscopic screening for dysplasia or early carcinoma is warranted in such patients.

Glandular Dysplasia

Dysplasia is defined as an unequivocal neoplastic alteration of the epithelium that remains confined within the basement membrane of the gland within which it arose.[6] When dysplastic columnar epithelium proliferates to form a grossly visible polyp, the term *adenoma* may be applied. Dysplasia is recognized histologically by a combination of nuclear and architectural abnormalities.

Dysplastic columnar epithelium has cytologic abnormalities similar or identical to those seen in carcinoma (Fig. 142-1): cytoplasmic mucus is usually reduced or absent. Dysplastic epithelial nuclei are enlarged, often hyperchromatic, variable in size, shape and contour, and may contain prominent or multiple nucleoli; nuclear crowding and stratification are often present. Because of confounding reactive changes, the diagnosis of dysplasia should be made with caution when the mucosa is actively inflamed (Fig. 142-2). The presence of dysplasia should be seriously questioned if the neoplastic nuclear changes do not extend to include epithelia of the mucosal surface [6], [7] (see Fig. 142-1). Dysplastic glands may retain their normal architecture, or more frequently become irregular or even grossly distorted with intralumenal epithelial budding and back-to-back glands [7] (Fig. 142-3).

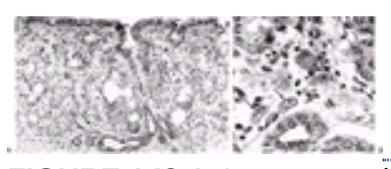

FIGURE 142-1. Low-power (**A**) and high-power (**B**) views of Barrett esophagus with no visible lesion by endoscopy but with high-grade dysplasia and intramucosal carcinoma by biopsy. Marked distortion of the glandular architecture and prominent nuclear abnormalities are seen. Invasion of the lamina propria by individual glandular epithelial cells represents intramucosal carcinoma (*arrows*).

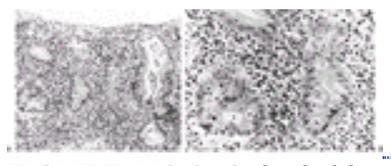

FIGURE 142-2. Colonic biopsy specimen in active ulcerative colitis. **A:** Notice the polymorphonuclear leukocytes within the crypt epithelium, the crypt abscess, the distortion of the crypt architecture, the basal lymphoplasmacytosis, and the marked chronic inflammatory infiltrate within the lamina propria. **B:** Reactive epithelial changes that can be confused with dysplasia are seen. Notice the occasional polymorphonuclear leukocytes within the crypt epithelium with enlarged, crowded, stratified nuclei containing numerous mitotic figures.

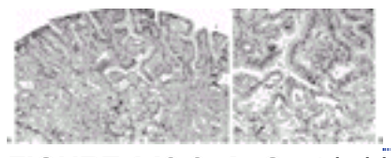

FIGURE 142-3. A: Gastric biopsy specimen shows high-grade dysplasia without invasion in its upper portion, but with gross distortion of glandular architecture forming a complex network of glandlike spaces deeper in the biopsy specimen (*arrow*). **B:** The architectural distortion is better seen at higher magnification of the area with an *arrow* in **A,** and the cytologic abnormalities of the nuclei lining the distorted glands can be better recognized. This gross distortion of the architectural pattern suggests possible invasion of the lamina propria.

Histologically, the degree of abnormality (atypia) within dysplastic mucosa forms a continuous spectrum from slight to marked. In certain situations it may be useful prognostically to grade dysplasia as low or high, based upon the degree of deviation from normal. This will be discussed subsequently.

Among experienced observers there is good inter- and intraobserver agreement on interpretation of high-grade dysplasia (HGD) [8] (Fig. 142-4). The nuclear abnormalities are more pronounced than those seen in low-grade dysplasia (LGD) with more marked nuclear enlargement and more irregular nuclear membranes. In HGD the nuclei may vary markedly in size, shape, and staining characteristics. There is usually loss of nuclear polarity (i.e., some of the elongated neoplastic nuclei that were originally oriented perpendicular to the basement membrane may round out or rotate from a vertical o a more horizontal or jumbled orientation). Invariably, the nuclear changes extend to the epithelial surface, where they are also enlarged and neoplastic in appearance. Goblet cell mucus is usually diminished or absent. Architectural distortion is almost always present and may be marked. Crypts or glands exhibit branching and lateral budding. One may see bridging epithelium extending across glands or crypts to form a cribriform “back-to-back” pattern with epithelial cells of adjacent acini touching one another without intervening lamina propria. A filiform epithelial configuration may also be seen at the mucosal surface. It may be difficult to differentiate HGD from invasive cancer (see Fig. 142-3), if architectural distortion is sufficiently severe, if back-to-back glands are growing into one another, if ill-defined abortive glands are present in the lamina propria, or if the limited depth of the biopsy specimens makes it impossible to determine whether glands are invading into the submucosa [7] (Fig. 142-5). In such situations, an appropriate diagnostic description might be “marked distortion of crypt or glandular architecture such that carcinoma can not be excluded.”

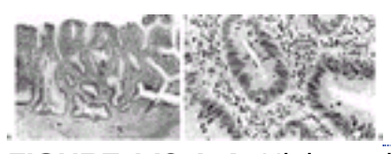

FIGURE 142-4. A: High-grade dysplasia complicating chronic ulcerative colitis. Notice the distorted glandular architecture, almost complete absence of goblet cell mucus, and marked crowding and stratification of nuclei. **B:** At higher power the cytologic abnormalities can be readily identified. The nuclei are markedly enlarged compared with the size of the nuclei in the lamina propria and they vary markedly in size and shape. A beginning loss of nuclear polarity also is seen.

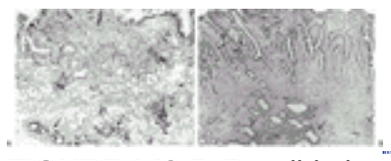

FIGURE 142-5. Possible invasive cancer in a biopsy specimen from a patient with Barrett esophagus. The corresponding area in the surgical specimen shows definite submucosal invasion. **A:** The upper portion of the biopsy specimen above the muscularis mucosae shows only high-grade dysplasia, whereas in the lower portion of the specimen, slightly dilated, darkly stained glands (*arrows*) extend into a widened and splayed muscularis mucosae. Because of the limited depth of the specimen, and the frequent noninvasive trapping of glands into previously ulcerated areas of Barrett esophagus, invasion through the muscularis mucosae into the submucosa cannot be confirmed, but was suspected. **B:** The surgical specimen from the same area clearly shows the dilated glands invading into the submucosa (*arrows*).

In general, there is less agreement on the diagnosis of LGD [8] (Fig. 142-6). The crypt architecture in low-grade dysplasia tends to be preserved, and distortion if present, is mild. The nuclei may be stratified, particularly near the base of the crypts, but the enlargement, hyperchromatism, and crowding is less severe than that seen in HGD. Cytoplasmic mucin is not necessarily diminished. Diagnosis of LGD still requires that the enlarged neoplastic nuclei extend to the epithelial lumenal surface but nuclear polarity is maintained. [7]

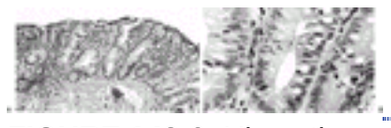

FIGURE 142-6. Ulcerative colitis with low-grade dysplasia. **A:** Notice the relatively well-preserved crypt architecture and the mild chronic inflammatory infiltrate within the lamina propria. There is no evidence of active inflammation. Notice the decreased number of goblet cells and nuclear crowding and stratification involving the crypts and extending to the surface epithelium. **B:** At high-power magnification of the crypts, the nuclear enlargement, hyperchromatism, crowding, and stratification can be readily seen. Notice some dystrophic goblet cells that fail to communicate with the lumenal surface. Such goblet cells are characteristic but not diagnostic of dysplasia.

Squamous Dysplasia

Squamous dysplasia of the esophagus has a similar nuclear neoplastic appearance to that seen in dysplasia of GI organs lined by columnar epithelium. The mucosa has an increased number of epithelial cells per unit area. The nuclei of these epithelial cells are pleomorphic, crowded, hyperchromatic, and overlap each other. The basal epithelial layer often does not “mature” by flattening horizontally and reducing its nuclear size as it approaches the superficial epithelium at the lumenal surface. The cells often assume a jumbled rather than a layered appearance. Squamous dysplasia of the esophagus is rare in the United States without an accompanying endoscopically apparent squamous carcinoma (Fig. 142-7). Most of the epithelial changes that mimic squamous dysplasia are caused by the benign regenerative and inflammatory response of esophagitis.

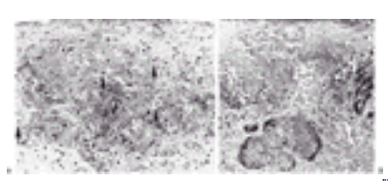

FIGURE 142-7. Esophageal squamous dysplasia and early carcinoma. **A:** Squamous dysplasia. The papillae of the lamina propria are irregular and the mucosa has an increased number of epithelial cells per unit area. The nuclei of these epithelial cells are crowded and hyperchromatic and overlap each other. The cells fail to mature while they move toward the lumenal surface, and numerous mitotic figures are present at all levels of the mucosa (*arrows*). **B:** An esophageal biopsy specimen from another mucosal area of the same patient shows both esophageal squamous dysplasia and early invasion of the lamina propria. This section shows tongues of dysplastic squamous epithelium extending into the lamina propria, some of which have become detached to form discrete nests of early invasive carcinoma.

In both columnar and squamous mucosa throughout the GI tract one must be especially careful in diagnosing dysplasia in inflamed, eroded, or ulcerated tissue infiltrated with polymorphonuclear leukocytes. The nuclear changes caused by inflammation or regeneration may be impossible to differentiate from dysplasia of any grade (see Fig. 142-2). Such changes are often seen in biopsy specimens near the edge of a benign ulcer. When uncertain in such cases, the diagnosis “indefinite for dysplasia” is appropriate. Repeat biopsy evaluation after successful treatment of inflammation can avoid this confusion and lead to the correct diagnosis.

Endoscopic biopsy surveillance for cancer is based upon several assumptions regarding dysplasia: the first assumption is that dysplasia is a histologically recognizable precursor of cancer. As mentioned previously, HGD is a diagnosis with an interpretation that is usually reproducible but the diagnosis of low-grade or indefinite for dysplasia is less so. It may also be difficult to differentiate HGD from early invasive carcinoma because biopsies often do not reach deeply enough into the submucosa to assess invasion through the muscularis mucosae (see Fig. 142-5). In the stomach and esophagus single epithelial cells invading the lamina propria indicate that HGD has progressed to intramucosal carcinoma except in the colon, but these cells are often difficult to identify with certainty. The diagnosis of intramucosal carcinoma is not made in the colon and the reasons for this exception are discussed later in the chapter under “Colonic Polyps.” Examining serial sections may demonstrate the ectopic position within the lamina propria of single invasive epithelial cells (see Fig. 142-1). Considering the difficulty in diagnosing dysplasia or early carcinoma, it is wise to seek an opinion from a second pathologist with considerable experience in the diagnosis of GI dysplasia and cancer before major clinical decisions. More objective techniques such as flow cytometric quantification of DNA may complement the histological diagnosis of dysplasia. [9] However, given the present state of knowledge, it is our belief that clinical decisions should still be based primarily on the histological appearance.

The second assumption is that cancers develop from dysplasia. There is evidence to support this assumption. [10], [11] How soon and often the dysplasia will become cancer in different patients is unpredictable. Prospective data on the natural history of these diseases is accumulating, but much work remains to be done.

The third assumption is that early malignancy can be detected by prospective surveillance while it is still curable by surgical excision. There are prospective studies that support this assumption. [12], [13] It is accepted clinical practice in the United States to place certain patients with Barrett esophagus, colonic adenomas, ulcerative colitis, or Crohn’s disease in surveillance protocols. Older adult patients from certain geographic areas with intestinal metaplasia of the stomach may also merit surveillance because of their increased likelihood of developing intestinal-type adenocarcinoma of the stomach. Some have questioned whether close surveillance is worth the time, effort, expense, and discomfort involved in detecting a relatively low number of patients with dysplasia or early curable carcinoma. Obviously it is worthwhile for those patients whose lives are saved but other, better techniques are needed to select subsets of patients whose high cancer risk warrants the cost and effort of such close surveillance. [14]

ESOPHAGEAL CANCERS

Esophageal Squamous Carcinoma

A history of treated squamous carcinoma of the mouth, pharynx, or nose merits a screening esophagoscopy for esophageal squamous dysplasia (see Fig. 142-7); if found, the patient should undergo frequent and extensive biopsy surveillance. Other rare predisposing diseases such as longstanding achalasia, lye strictures, Plummer-Vinson syndrome, and tylosis may merit screening esophagoscopy. Screening for esophageal squamous dysplasia or early carcinoma is generally not justified in the United States because of its decreasing frequency in many of ethnic groups. When one discovers squamous dysplasia with an early carcinoma of the

esophagus, one must remember that, unlike Barrett adenocarcinoma which is confined to the columnar epithelium, squamous dysplasia is characteristically multifocal throughout the length of the squamous esophagus. Thus, total esophagectomy is mandatory for possible cure.

Esophageal Adenocarcinoma

Adenocarcinoma is now far more frequent than squamous carcinoma of the esophagus in the United States. Barrett-specialized metaplasia is almost always the precursor of these esophageal adenocarcinomas. [15] Barrett is an acquired condition in which chronic reflux of gastric juice erodes the normal stratified squamous esophageal lining and it is replaced by metaplastic columnar epithelium defined by the presence of goblet cells. [7] This metaplasia is potentially precancerous regardless of how short or long the involved esophageal segment may be [7], [16] (Fig. 142-8). Barrett-specialized metaplasia comprises a spectrum of epithelial changes in which the diagnostic sine qua non is the presence of goblet cells containing acid mucus that stains intensely with Alcian blue at pH 2.5. [7], [17] The appearance of the columnar cells between the goblet cells varies from normal gastric surface or foveolar cells containing neutral mucus, to others containing mildly acid mucin staining lightly with Alcian blue, to cells resembling intestinal absorptive cells except for poorly developed brush borders. Barrett-specialized metaplasia is most commonly of the incomplete type. Complete intestinal metaplasia is composed of normal goblet and absorptive cells with Paneth cells at the bottom of some of the crypts. This is the common type of intestinal metaplasia seen in the stomach (Fig. 142-9).

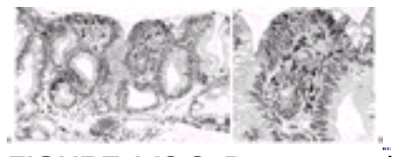

FIGURE 142-8. Barrett esophagus with low-grade dysplasia. **A:** The dysplastic glands to the right of center are irregular in size and shape, and have decreased mucus production. To the left and right, the characteristic goblet cells of the nonneoplastic, Barrett-specialized metaplastic epithelial precursor still can be identified. **B:** Observe the crowding, stratification, and enlargement of the dysplastic nuclei that extend to the lumenal surface. The changes are less severe than those seen in high-grade dysplasia, and there is maintenance of nuclear polarity, where the long-axis of the nuclei remain perpendicular to the basement membrane.

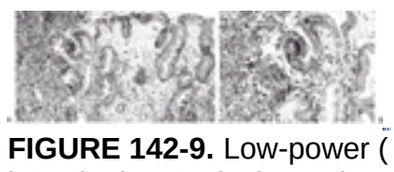

FIGURE 142-9. Low-power (**A**) and high-power (**B**) views of advanced *Heliobacter pylori*–caused multifocal intestinalized pangastritis (MIP) with decreased glands, intestinal metaplasia, and an associated adenocarcinoma. In the right half of the illustrations, the normal gastric glands have been replaced by complete intestinal metaplasia, as evidenced by the goblet cells and normal absorptive cells. To the left in **A** and **B,** sheets of malignant-appearing cells infiltrate the lamina propria.

Thirty-three percent of patients with nonerosive gastroesophageal reflux disease without endoscopic evidence of Barrett esophagus may have intestinal-type goblet cells right at the squamocolumnar junction if both the squamous and columnar epithelium are present in the same biopsy. [18] Biopsies 1 to 2 cm below the esophagogastric junction rarely have goblet cell foci. [18] This common finding of intestinal metaplasia at the normally located esophagogastric junction in gastroesophageal reflux disease should not be called Barrett esophagus because it will stigmatize patients with a false diagnosis of Barrett that will impair insurability.

Barrett esophagus and “columnar-lined esophagus” have been incorrectly considered identical. They are not. Almost all patients with Barrett esophagus have a hiatus hernia lined with normal gastric mucosa. If a biopsy is taken above the diaphragm within a hiatal hernia that is mistaken for tubular esophagus, it will show gastric surface and foveolar columnar epithelium covering fundal or cardiac glands (Fig. 142-10, Fig. 142-11). This should not be misinterpreted as Barrett “columnar” epithelium because what has been biopsied is stomach within a hiatus hernia and does not represent Barrett specialized metaplasia of the esophagus with its precancerous potential. The normal tubular esophagus in its distal 2 or 3 cm may have some cardiac (see Fig. 142-11) or fundal glands covered by columnar epithelium and these too must not be confused with Barrett-specialized epithelium with its goblet cells.

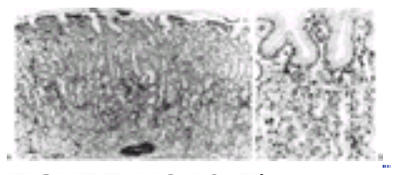

FIGURE 142-10. Biopsy specimen of a typical hiatal hernia pouch. **A:** The gastric fundal (oxyntic) glands are normal. The surface is covered by normal gastric surface mucus cells that dip into normal shallow foveolae. **B:** The lamina propria contains no recognizable inflammatory infiltrate, and numerous parietal cells are visible in the normal oxyntic glands (*arrows*).

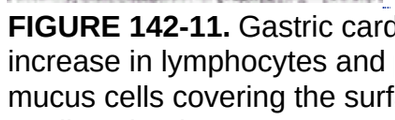

FIGURE 142-11. Gastric cardiac mucosa. **A:** The surface epithelium, foveolae, and glands are lined by cells producing mucus. The lamina propria contains a mild increase in lymphocytes and plasma cells, a feature found in the majority of biopsy specimens from this portion of the stomach. **B:** The appearance of the epithelial mucus cells covering the surface and lining the foveolae at higher magnification illustrates the lengthened columnar cells that are characteristic, but not diagnostic, of cardiac glands.

How can potentially curable adenocarcinoma be detected in Barrett esophagus? The first rule is to recognize that dysplasia and early intramucosal carcinoma (see Fig. 142-1) are usually grossly invisible. [10] The second rule is to methodically and repeatedly biopsy the whole length of Barrett specialized metaplasia within the tubular esophagus from the lower esophageal sphincter to the upwardly displaced squamocolumnar junction. Large, properly processed, and expertly interpreted biopsy specimens increase diagnostic sensitivity and specificity. The finding of dysplasia in Barrett esophagus provides an opportunity to prevent a uniformly fatal adenocarcinoma, yet the proper course of action is unclear when only HGD is found after extensive biopsy. There are three reasons for this uncertainty:

1. The older patient with dysplasia is often a poor surgical risk for esophagectomy.
2. The partial esophagectomy of all the columnar epithelium that eliminates metaplasia still has a sizable mortality, except when performed by exceptionally experienced and skillful surgeons. Even then, there is significant morbidity.
3. How long dysplasia takes to become carcinoma is unpredictable in each individual case.

Recent data on the natural history of Barrett dysplasia by the Seattle and the Hines VA groups indicate that the dysplasia diagnosed at its onset during careful biopsy

surveillance may take a mean of 6 years or longer to progress to early carcinoma that is still surgically curable. [12], [13]

Grading of dysplasia in Barrett esophagus has been shown by prospective study to be the single most important indicator of cancer risk. This is another benefit of endoscopic biopsy surveillance. [12]

If only HGD without adenocarcinoma is found after the extremely thorough sampling of Barrett mucosa recommended in the Seattle protocol, esophagectomy to exclude an undetected carcinoma may not be necessary provided the patient undergoes this compulsive biopsy surveillance at least annually. In our protocol we sample four quadrants of the involved esophagus at 2 cm levels beginning below the lower esophageal sphincter within gastric fundal mucosa, and extending upward throughout the tubular esophagus lined by Barrett-specialized metaplasia to beyond the ora serrata, where columnar epithelium joins the squamous lined esophagus. Any visible lesions are separately and additionally biopsied. In patients with HGD who remain in annual surveillance, the interval is shortened to 1 cm including areas of squamous surface overgrowth. Curable, intramucosal or early adenocarcinoma can be detected by such compulsive annual endoscopic biopsy surveillance. For surgical treatment, the entire columnar-lined portion of the esophagus must be removed, but the squamous-lined portion of the esophagus need not be excised. Alternatives to excision such as endoscopic photoablative treatment are being tested and show promise.

BENIGN ESOPHAGEAL DISEASES

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is one of the most common diseases. It is usually caused by regurgitation of gastric or duodenal contents into the esophagus that injures or even destroys its squamous lining. When the endoscopic appearance of esophagitis has progressed to erosion, ulceration, or stricture, the histological diagnosis of esophagitis is usually obvious because the biopsy specimen shows erosions and active inflammation with intraepithelial polymorphonuclear leukocytes (Fig. 142-12). If the mucosa is intact endoscopically in a patient with reflux symptoms, as is often the case, it may be difficult to find diagnostic histological abnormalities by endoscopic biopsy.

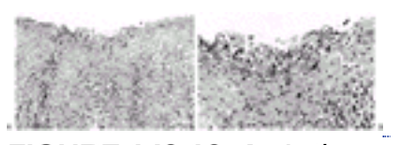

FIGURE 142-12. A: Active esophagitis in gastroesophageal reflux disease in which polymorphonuclear neutrophils and lymphocytes infiltrate the surface of the squamous mucosa and the lamina propria, obscuring the interface between the mucosa and the underlying lamina propria. **B:** Prominent epithelial hyperplasia of the basal layer is evidenced by the enlarged, hyperchromatic, and more numerous nuclei seen best at higher magnification.

Thus, the main problem in diagnosing GERD in patients with reflux symptoms is that many have a normal endoscopy without evidence of esophagitis even by biopsy. Some believe that histological evidence of hyperplasia of the squamous epithelium indicates reflux injury. In squamous hyperplasia, there is lengthening of the papillae of the lamina propria and thickening of the basal layer (Fig. 142-13). Furthermore, there is a significant correlation between the severity of reflux as measured by the 24-hour pH score and the length of the papillae. [19] Unfortunately, squamous hyperplasia as a histological indicator of esophagitis is not useful clinically for several reasons:

Most biopsy specimens taken with the standard-sized forceps are too small to orient for accurate architectural diagnosis of hyperplasia.
More than half of normal persons without GERD have squamous hyperplasia in the distal 2.5 cm of their tubular esophagus and one fifth have it proximally. [20]
Fifteen percent of patients with obvious symptoms of reflux and other positive tests for reflux show no histological evidence of active inflammation or hyperplasia. [21]

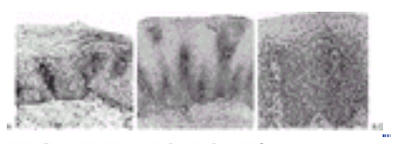

FIGURE 142-13. Biopsy specimens of normal and hyperplastic esophageal mucosa. **A:** Normal squamous mucosa of the esophagus. The papillae of the lamina propria extend through approximately 50% of the thickness of the mucosa, and the basal zone occupies a small portion of the mucosa. **B:** Hyperplasia of the mucosa is indicated by lengthening of the papillae of the lamina propria, some of which extend close to the lumenal surface (*arrow*). In addition, the basal zone is markedly hyperplastic and occupies more than 25% of the thickness of the mucosa. **C:** A profound degree of hyperplasia can be seen with the basal zone occupying two thirds of the thickness of the mucosa and with papillae of the lamina propria extending a similar distance through the mucosa (*arrow*). Note the architectural uniformity wherein the squamous papillae extend to the same depth within the lamina propria. This combined with the epithelial cytologic uniformity are the best features to differentiate benign squamous hyperplasia from dysplasia.

Some believe that the presence of several eosinophils per individual section of squamous epithelium indicates reflux esophagitis. We do not, because data published by Dr. Haggitt on 91 patients indicated that eosinophils did not correlate with a 24-hour pH score unless they were abundant (>6 eosinophils/biopsy). [22]

Active esophagitis with infiltrating polymorphonuclear leukocytes can progress to erosion or ulceration, or it can heal with reepithelialization or with stricture. The eroded squamous epithelium may regrow, or be replaced by specialized metaplastic columnar epithelium (i.e., Barrett esophagus).

Even in those patients with reflux symptoms who have the eroded endoscopic appearance of esophagitis, the histological picture is nonspecific and one must also consider a variety of rare systemic conditions such as eosinophilic gastroenteritis, collagen vascular disease, Stevens-Johnson syndrome, and bacterial stasis. Also, a carcinoma can masquerade occasionally as erosive or ulcerative esophagitis. Thus, esophageal biopsy of erosive esophagitis by endoscopy is not done to confirm GERD but rather to exclude infection, Barrett esophagus, or neoplasia.

Esophageal Infections

Esophageal infections are rare in immunocompetent persons, but immunocompromised hosts are susceptible to cytomegalovirus (CMV), herpes simplex virus (HSV), varicella zoster virus, or *Candida* organisms, all of which have a diagnostic histological pattern [23], [24] (Fig. 142-14). A spectrum of endoscopic appearances is possible with these infections. Biopsies, brushings, and viral cultures are indicated to make these specific diagnoses. Such infections are increasing in frequency due to the immunosuppression caused by acquired immunodeficiency disease (AIDS), or several iatrogenic causes such as chemotherapy or pharmacological prevention of rejection after organ transplantation.

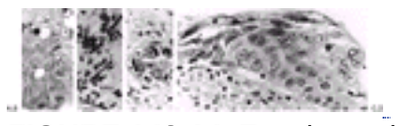

FIGURE 142-14. Esophageal biopsy specimens from various opportunistic infections. **A:** Hematoxylin and eosin (H & E) stained, high-power magnification illustrates esophageal squamous mucosa in which there are budding yeasts (*arrowhead*) and infiltrating pseudohyphae of *Candida* organisms (*arrow*). **B:** Periodic acid-Schiff

stain for carbohydrates highlights pseudohyphae of *Candida* organisms (*arrow*) more clearly than an H & E stain. **C:** A high-power photomicrograph of esophageal mucosa in which cytomegalovirus is present. The *arrowhead* indicates a diagnostic inclusion body with a surrounding halo within the nucleus of an enlarged mesenchymal cell. This cell and the one marked by the arrow also contain granular cytoplasmic inclusions. **D:** The characteristic findings of herpes simplex virus infection: ground-glass nuclei, a Cowdry type A inclusion body (*arrow*), and multinucleated giant cells (*arrowhead*).

Fungal esophagitis is most commonly caused by *Candida albicans* and *Candida tropicalis.* Other fungi are rare. They occur primarily in immunosuppressed, diabetic, or antibiotic-treated patients. They may also be seen in otherwise healthy subjects. *C tropicalis* is more virulent than *C albicans* because of its increased invasiveness. [25] The budding yeasts and pseudohyphae of *Candida* organisms may be recognized in tissue stained with H & E, but are seen far more easily in biopsy specimens stained with periodic acid-Schiff (see Fig. 142-14A, Fig. 142-14B). A few yeast forms within surface debris are extremely common and probably represent oral contamination. The presence of pseudohyphae within the tissue indicates invasive infection, but their presence only in adherent exudate does not exclude it, especially if clinical evidence suggests dissemination.

CMV may be found in the endothelial cells and fibroblasts in the granulation tissue in the base of ulcers and erosions, but also may be identified within columnar epithelial cells (see Fig. 142-14C). Isolated enlarged cells containing CMV may be time-consuming to find histologically but careful histological examination is equal to, or superior to, ancillary techniques for its detection, such as immunohistochemistry. The characteristic features of CMV are cytomegaly with a large viral intranuclear inclusion occupying most of the nucleus except for a surrounding halo and granular inclusions in the cytoplasm. CMV esophagitis alone, or in combination with *Candida* and herpes is relatively common in AIDS. The accurate diagnosis of CMV is important because without early treatment it may be fatal but early effective therapy is available. No single technique for diagnosis of CMV has a very high sensitivity; thus, a combination of diagnostic modalities such as shell viral centrifugation culture and in situ hybridization with specific DNA probes may also be used if the findings on histological examination with H & E staining are uncertain and clinical suspicion is high. [26]

Herpes simplex virus (HSV injury) shows a diagnostic histological picture in the surface squamous epithelium of the esophagus (Fig. 142-14D). Herpetic ulcers are very painful, shallow, sharply punched out, and often surrounded by relatively normal mucosa. Biopsies should be taken from the squamous epithelium at the immediate edge of the lesion in order to be diagnostic. Cells infected by HSV are smaller than those infected with CMV and contain a smaller intranuclear viral inclusion (Cowdry type A). Ground-glass nuclei are made up of multiple small eosinophilic particles producing a smudged appearance; multinucleated giant cells and ballooning degeneration of infected squamous cells may also be seen. HSV type I causes most herpetic esophagitis but it cannot be distinguished on morphologic grounds from the rarer HSV type II or from varicella-zoster. Immunocytochemical staining and in situ hybridization using DNA probes can separate these three organisms.

Less common pathogens may be seen in the immunosuppressed patient such as *Mycobacterium tuberculosis, Mycobacterium avium-complex,* histoplasmosis, or toxoplasmosis. In some patients with AIDS, there is no apparent cause for the esophagitis or ulcer but there is speculation that the human immunodeficiency virus (HIV) itself may be etiologic because it has been detected in the epithelium and lymphocytes of the GI tract. [27]

Other Benign Esophageal Conditions

A variety of other benign conditions are diagnosable by endoscopic biopsy. The most common is the clinically unimportant entity of glycogenic acanthosis. This condition is diagnosed by biopsy of small white nodules or plaques that can be shown to contain squamous epithelium whose cytoplasm is distended with excess cytoplasmic glycogen. The glycogen can be identified by periodic acid-Schiff–stained particles that disappear after glycogenolysis with diastase.

Other rare esophageal diseases that are difficult to diagnose by endoscopic biopsy alone include sarcoidosis, Crohn's disease, Behçet disease, graft-versus-host disease, and the esophageal lesions seen in patients with bullous skin disease.

Esophageal injury caused by prolonged direct mucosal contact with tablets or capsules taken in therapeutic doses occurs frequently. [28] The histological appearance of ulcers and strictures induced by pills is nonspecific but one may see prominent infiltration of eosinophils, or spongiosis and necrosis of squamous epithelium. Birefringent crystalline material may be seen in alendronate-induced injury, [29] and crystalline iron in ferrous sulfate-induced disease. [30] Esophageal erosions and ulcers were found in 20% of patients with arthritis taking nonsteroidal antiinflammatory drugs (NSAIDs), [31] but esophageal injury by NSAIDs may be less common than such injury in other parts of the GI tract.

Benign Esophageal Tumors

Clinically significant benign esophageal tumors are uncommon. The most frequent benign tumor is submucosal leiomyoma, which arises from the muscularis mucosae but it may require a deeper biopsy for diagnosis than is usually provided. A squamous papilloma is a papillary growth composed of fingerlike projections covered by lamellated benign squamous epithelium; it is usually located in the distal third of the esophagus (Fig. 142-15). Inflammatory fibroid polyps contain active inflammation and eosinophils in a prominent fibrovascular stroma; these can become quite large and can be mistaken grossly for carcinoma. A submucosal tumor of polygonal cells filled with abundant, variable-sized granules is almost certainly a granular cell tumor (Fig. 142-16). Lipomas may also be difficult to diagnose by biopsy because they are mostly submucosal.

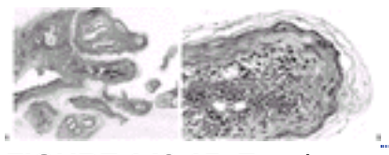

FIGURE 142-15. Esophageal biopsy specimen of a squamous papilloma. **A:** Papillary (fingerlike) projections are characteristic. **B:** The central fibrovascular cores of the papillae are covered by lamellated, benign, squamous epithelium.

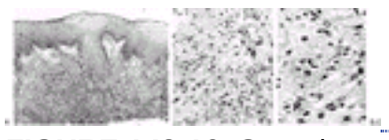

FIGURE 142-16. Granular cell tumor of the esophagus. The lamina propria (**A**) contains sheets of enlarged polygonal cells with granular cytoplasm in **B** and **C**.

GASTRIC CANCERS

Gastric Adenocarcinomas

There are three types of gastric adenocarcinoma: intestinal-type adenocarcinoma, diffuse adenocarcinoma of the stomach, and cardia adenocarcinoma.

Intestinal-type adenocarcinoma is the most common worldwide, although it is decreasing markedly in frequency in the Western world. It is called intestinal-type because it forms glands that resemble those of colonic cancer. It arises in a multifocal intestinalized pangastritis caused by HP (see Fig. 142-9). In an unpublished 15-year longitudinal study [32] of 122 elderly, high-risk Japanese-Americans with intestinal metaplasia undergoing extensive prospective endoscopic surveillance every 3 years, metaplasia progressed to dysplasia followed by intestinal-type adenocarcinoma in 10 patients; in 8 of these patients, the cancer was discovered while surgically curable. The two incurable carcinomas were in patients who failed to return on time for scheduled follow-up. Thus, early intestinal-type adenocarcinoma of

the stomach can be detected even in the United States during close surveillance of a selected population.

Diffuse adenocarcinoma of the stomach is less common. It does not form glands but is made up of diffusely infiltrating single malignant epithelial cells (Fig. 142-17). It offers a diagnostic challenge to pathologists because it can be easily under-diagnosed or over-diagnosed. The infiltrating malignant cells may be sparse, hidden within the lamina propria, and deceptively bland. They may mimic collections of macrophages or xanthelasma within the lamina propria. Histochemical stains for mucin may help identify goblet cells or immunohistochemical markers for cytokeratin can be useful in identifying these infiltrating malignant cells in the lamina propria as epithelial.

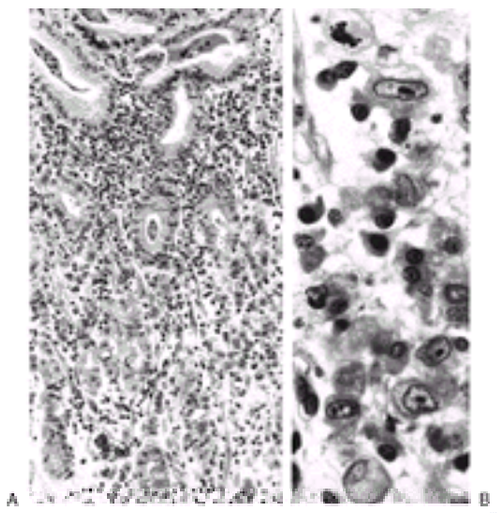

FIGURE 142-17. Gastric biopsy specimen of a minute lesion of diffuse adenocarcinoma that was barely visible endoscopically. **A:** Low-power magnification illustrates how subtle diffuse adenocarcinoma of the stomach can be. The inflamed lamina propria contains infiltrating malignant cells that are difficult to recognize because they are interspersed with inflammatory cells. **B:** The high-power view makes these infiltrating, malignant cells more apparent.

Cardia adenocarcinoma is the third type of gastric adenocarcinoma and it is located in the uppermost stomach involving the gastroesophageal junction. It has clinical and epidemiologic features in common with Barrett esophageal adenocarcinoma, [33] the most rapidly increasing carcinoma in Caucasian American males. [34] Cardia carcinomas and short-segment Barrett adenocarcinomas are probably the same entity. The tumors probably originate in a short distal segment of Barrett-specialized metaplasia that can be easily missed during endoscopy for reflux esophagitis unless several biopsies are always taken at an irregular or jaggedly serrated esophagogastric junction. The finding of even one biopsy with unequivocal dysplasia on initial endoscopy is a red flag indicating the need for extensive and repeated sampling to be certain that early cancer has not been missed. We have diagnosed several early curable cardia carcinomas in this manner (Fig. 142-18).

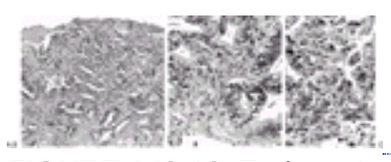

FIGURE 142-18. Early, potentially curable adenocarcinoma of the gastric cardia. **A:** At low-power magnification both high-grade dysplasia and a focus of intramucosal carcinoma (*single arrow*) are present. Residual goblet cells suggest the presence of Barrett-specialized metaplastic epithelium (*double arrows*). **B:** The area previously marked with double arrows shows the enlarged goblet cells that define this dysplastic epithelium as originating from Barrett-specialized metaplasia (*arrowheads*). **C:** In the area marked in **A** with a *single arrow*, malignant cells infiltrating the lamina propria are evident. This patient is alive and well 5 years after local surgical resection of this lesion. Lymph nodes were free of tumor, and the carcinoma did not extend beyond the mucosa.

Gastric Lymphomas

Gastric lymphoma, while far less frequent than adenocarcinoma, is well worth diagnosing while confined to the stomach, especially because low-grade lymphoma of the mucosa-associated lymphoid tissue (MALT) (Fig 142-19) is reversible and potentially curable by a pharmacological regimen for HP eradication. [35] Histologically, it may be difficult to differentiate HP gastritis from low-grade B-cell gastric (MALT) lymphoma. The diagnostic challenge is to distinguish MALT lymphoma from the reactive lymphoid hyperplasia that commonly accompanies HP-induced gastritis. MALT lymphoma is characterized by a dense lymphoid infiltrate, often accompanied by eosinophils and plasma cells. The lymphocytes resemble small, cleaved lymphocytes or monocytoid B-cells. The lymphoid cells infiltrate the gastric epithelium to produce lymphoepithelial lesions, and ultimately destroy the epithelium (see Fig. 142-19). These lymphocytes are thought to be derived from a mantle zone-like B-cell unique to MALT. [36] Histological evaluation remains the most sensitive and specific method for the diagnosis of low-grade lymphoma of MALT. [38] The demonstration of light chain restriction by immunohistochemistry can establish the presence of a clonal proliferation, but the sensitivity of this technique is relatively low, as only about 40% of cases contain detectable cytoplasmic immunoglobulin by immunohistochemistry. Unfortunately, polymerase chain reaction (PCR) analyses for heavy chain rearrangement are also relatively unreliable diagnostically because of detection of small clonal populations that are probably reactive in nature in gastritis with no morphologic or clinical evidence of lymphoma. [39], [40]

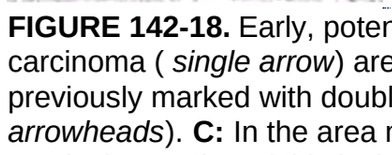

FIGURE 142-19. Gastric mucosa-associated lymphoid tissue (MALT) lymphoma. **A:** Low-power picture could be confused with *Helicobacter pylori* gastritis, but there is a lymphoid infiltrate, a reduction in the number of glands, and lymphoepithelial lesions (*arrow*). **B:** High power of a lymphoepithelial lesion shows small, cleaved lymphocytes infiltrating and destroying the epithelium (*arrows*).

Substantial evidence implicates HP as an etiologic factor in MALT lymphoma. Evidence of HP is present in over 90% of gastric MALT lymphoma cases and the HP infection precedes the lymphoma. Thus, it is not surprising that HP eradication is followed by regression in many patients with these low-grade lymphomas. [35], [37] A reasonable approach to the patient with gastric MALT lymphoma may be eradication of HP with subsequent endoscopic follow-up, with surgical resection reserved for refractory complications (bleeding, gastric outlet obstruction, or high-grade lymphoma). A predominance of large malignant lymphoid cells indicates high-grade transformation, a condition almost always unresponsive to HP eradication alone. How often regression of MALT lymphoma is permanent after HP eradication will require longer prospective studies than are currently available.

Lymphomas can develop after solid organ and bone marrow transplantation. The majority are B-cell Epstein Barr virus-driven proliferations. Histologically, these disorders vary from polyclonal plasmacytic hyperplasia to immunoblastic lymphoma, a monoclonal, frankly malignant lymphoma. Involvement of the GI tract is not uncommon and has been reported to be more common in patients receiving cyclosporine.

Gastric Carcinoid and Enterochromaffin Cell-like Tumors

Microscopically, carcinoids show monotonously similar small round cells growing in cords, glands, or nests, which invade the lamina propria and submucosa (Fig. 142-20). Gastric endocrine cell hyperplasia when it becomes endoscopically visible is considered to be a carcinoid. It is seen in a variety of conditions with a chronically elevated serum gastrin, such as the fundal atrophy of pernicious anemia, Zollinger-Ellison syndrome, or less commonly HP-induced intestinalized pangastritis. Gastric carcinoids associated with hypergastrinemia are indolent and rarely metastasize. Sporadic carcinoids not associated with hypergastrinemia commonly behave much more aggressively, making this distinction important.

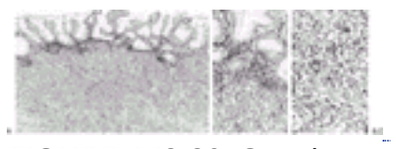

FIGURE 142-20. Gastric carcinoid. **A:** Small nests, glands, and sheets of neoplastic cells have replaced most of the mucosa and invade into the muscularis mucosae and submucosa. **B:** A higher magnification reveals nests of carcinoid cells in the lamina propria beneath the gastric pits. **C:** At the highest magnification the small, round, uniform nuclei with the finely stippled chromatin pattern characteristic of carcinoid can be seen.

Gastric Gastrointestinal Stromal Tumors

Gastrointestinal stromal tumors (GIST) are much more common in the stomach than in the rest of the GI tract. They were originally considered to be of smooth muscle differentiation. They are now recognized to share the phenotype of the interstitial cells of Cajal and as such express the *c-kit* protooncogene product for which a diagnostic immunohistochemical test exists. [41], [42] Grossly, these tumors commonly have surface ulceration. Microscopically GIST is submucosal and deeper in location and does not arise from the muscularis mucosae, as do the esophageal and anorectal true leiomyomas. The tumors may be composed of spindled or epithelioid cells. They may have a vacuolar pattern and other highly variable morphology. They can be benign or malignant and it is difficult to predict their behavior with certainty, although size and mitotic activity, invasion of the lamina propria, or small cell cytology are of help. It is important to diagnose GIST because treatment with the ligand of the *c-kit* receptor, or stem cell factor, is dramatically effective in previously untreatable malignant GIST. [43]

Intramural Extramucosal Tumors

Other rare lesions include intramural, extramucosal tumors derived from muscle, fibrous tissue, nerve, or fat. Endoscopically all may show bridging mucosal folds extending from the top of the tumor to the surrounding mucosa, an appearance reminiscent of the flying buttresses of an ancient cathedral. It is often difficult during biopsy to sample deeply enough of these extramucosal lesions to provide a diagnosis. Many ulcerate and bleed; obstruction occurs in some. A variety of vascular tumors may be seen. Pancreatic nests occasionally are evident on gross inspection.

Kaposi Sarcoma

Kaposi sarcoma in AIDS presents endoscopically as multiple violaceous, flat, macular lesions or as nodules that may have a surface that resembles a strawberry or elephant hide, or infrequently as volcano lesions with superficial erosions at their peaks. It is often missed by shallow biopsies, although experienced endoscopists often suspect the diagnosis grossly in patients with HIV infection. The diagnostic histological picture is one of spindle cells containing clusters or individual hyaline, eosinophilic, cytoplasmic inclusions and erythrocytes within slit-like openings between the streaming spindle cells [44] (Fig. 142-21).

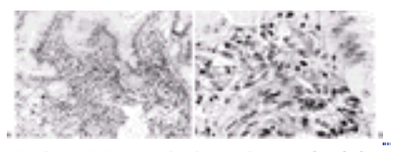

FIGURE 142-21. Gastric biopsy specimen from a patient with Kaposi sarcoma. **A:** The lamina propria contains infiltrating spindle cells of the sarcoma and a dilated vessel at the bottom. The arrow marks the area shown at higher power (**B**). Observe the spindle cells that compose the lesion and the red blood cells in the slitlike spaces between individual spindle cells. The *arrowheads* denote intracytoplasmic hyaline inclusions that are highly characteristic of Kaposi sarcoma. Note the mitotic figure immediately to the right of the arrowheads.

BENIGN GASTRIC DISEASES (Table 142-1)

TABLE 142-1 Diffuse Benign Gastric Mucosal Abnormalities

Gastritides

Gastritis is an inflammatory lesion and contrasts with gastropathy, another common benign gastric mucosal lesion that does not contain much or any inflammation. The classification of gastritis has been greatly advanced because of the recognition that HP causes most of the gastritides, and NSAIDs most of the gastropathies.

The gastric mucosa infected by HP shows neutrophilic infiltration of the gastric epithelium, primarily near the base of the foveolar pits and in the upper part of the glands. Neutrophilic infiltration indicates active inflammation but it should not be designated “acute gastritis” which has a chronologic implication. More appropriate terminology for describing chronic inflammation with neutrophilic epithelial infiltration in the lamina propria separating the foveolae is “chronic active gastritis.” Careful

inspection of the apical region of the surface and pit (foveolar) epithelial cells almost always (=90%) shows HP within the mucus layer, between it and the surface of the epithelial cells, attached to the surface of the epithelial cells, or between epithelial cells. The surface and pit epithelium may show evidence of injury. Lymphoid follicles within the lamina propria are highly characteristic of HP infection. [45]

The construction of a useful classification of gastritis presents many problems: First, there is poor correlation between the endoscopic and histological appearance of the gastric mucosa. Endoscopically normal mucosa may show significant biopsy abnormalities. Conversely, the endoscopic diagnosis of "gastritis" is often made when the endoscopist sees reddening which presumably reflects hyperemia of the mucosa that usually proves normal histologically. [46] Histological evidence of HP gastritis is highly likely to be present (specificity high) if the endoscopist sees antral nodularity, but the nodularity is not present in most adults with HP gastritis (sensitivity low). [46] Thus, the endoscopist should be encouraged to describe observed gross changes rather than to attempt the histological diagnosis of gastritis through the endoscope. Secondly, the topographic distribution of gastritis is important in its classification, but is rarely well documented because of inadequate endoscopic biopsy sampling. Thirdly, ethnic, geographic, and environmental factors appear to be decisive in determining the type of gastritis that a population develops, but these differences are rarely considered in its classification. Finally, there is the problem in classifying two types of coexisting gastritis. For example, in a patient with a benign gastric ulcer it may be impossible to determine the etiologic and histological contribution of NSAIDs that the patient is taking as opposed to HP with which the patient is infected.

These aforementioned problems have resulted in a lack of consensus on the classification of gastritis. The "Sydney" system for classifying gastritis was an attempt to resolve this lack of consensus; [47] however its histological division, if used as recommended, is exceedingly complex, purely descriptive, and not particularly helpful in everyday practice. A group of individuals interested in the pathology of gastritis has attempted to make the Sydney system more user friendly, [48] but it remains a descriptive method of reporting, rather than a nosologic classification correlating clinically different gastric diseases with different histological patterns of gastritis.

Many of the problems in classifying gastritis are caused by different ways of handling the earlier term "chronic nonspecific gastritis." In our opinion, the subdivisions of HP-caused gastritis proposed by Correa [49] make the most sense, and we shall use them with some nosological and histological modifications to reflect our beliefs regarding the relation between the different patterns of gastritis and different diseases. In our present state of knowledge, it is our opinion that all classifications are provisional. Our classification of gastritis patterns is a modification of Correa's. [50] We agree with the classification *diffuse antral-predominant gastritis* (DAG) with HP. We break the *multifocal atrophic gastritis* (MAG) classification of Correa into two different categories: [50] *multifocal intestinalized pangastritis* (MIP) with or without HP and *nonulcer pangastritis* (NUP) with HP. In addition there is the autoimmune gastritis of pernicious anemia— *diffuse corporeal atrophic gastritis* (DCAG) without HP.

In the United States and many other Western countries, the most common pattern of HP gastritis is DAG, a classification that is widely accepted. The presence and extent of intestinal metaplasia (IM) within the antral pyloric gland mucosa in DAG varies in different geographic areas and ethnic groups of the U.S. The antrum is almost always infected by HP and shows a diffuse chronic, active inflammatory infiltrate that expands the lamina propria between the foveolae, pushing the glands apart and basally so that there is an apparent decrease in the number of glands (Fig. 142-22A). Some call this atrophic gastritis; however, there is no real decrease in the number of glands in diffuse antral gastritis, as they will return in their original density and normal position after eradication of HP (see Fig. 142-22B). The gastritis of DAG may extend to varying degree from the antrum along the lesser curvature, but almost all fundal glands in DAG are *free of intestinal metaplasia* and have less gastritis than that present in the pyloric glands of the antrum. A strong association between DAG and both duodenal and juxtapyloric ulcers has been noted, and the risk of intestinal-type gastric adenocarcinoma is low in this setting. However, one must remember that only a minority of patients with any type of HP gastritis, including DAG, develop ulcers. Eradication of HP heals any ulcers that may be present, reverses the gastritis, but has no effect on any intestinal metaplasia that may be present.

FIGURE 142-22. Diffuse antral-predominant gastritis (DAG) associated with duodenal ulcer before (**A**) and after (**B**) successful eradication of *Helicobacter pylori.* **A:** Prominent interfoveolar inflammation with the pyloric glands pushed basally. **B:** A marked reduction in the number of mononuclear cells in the interfoveolar lamina propria. The pyloric glands of the antrum have resumed their normal position, and the antral mucosa has returned to an almost normal appearance.

Both MIP and NUP have gastritis involving the antrum and fundus. In addition IP contains extensive multifocal IM in both antrum and fundus but NUP has less or none. MIP may be associated with benign gastric ulcer and intestinal-type adenocarcinoma (see Fig. 142-9) but NUP is not. Neither NUP nor MIP is associated with duodenal ulcer.

In the United States, MIP is now far less common than DAG although it may be seen more frequently in certain minority populations [51], [52] (i.e., Native Americans and probably Hawaiians, African Americans, and immigrants from Eastern Europe, Asia, and South America). Thus, although HP is strongly associated with MIP, ethnic, environmental and dietary factors are important, if not essential, for its development. The antral and fundal pangastritis of MIP (Fig. 142-23) is histologically like that seen in NUP and in the DAG antrum. As Stemmerman and Hayashi have shown, [53] the multifocal intestinalized gastritis in MIP begins along the lesser curvature at the junction between the antral pyloric glands and the fundal glands. It then spreads proximally and distally and is the most intestinalized and progressive of the HP gastritides. In some patients IM is the precursor of dysplasia which becomes gastric adenocarcinoma of the intestinal type. The risk of this cancer is proportional to the extent of the intestinal metaplasia. [54] In other patients the IM is associated with benign gastric ulcer that does not become malignant with the passage of time. [32] The HP gastritis and the benign gastric ulcers of MIP are reversed by HP eradication (see Fig. 142-23), but the IM and intestinal-type adenocarcinoma are not. [32] Claims that IM is reversible are probably based on inadequate sampling. When MIP is advanced and intestinal metaplasia is extensive, HP may disappear. Until long-term, prospective data with multiple gastric biopsies are available it will remain unknown whether early treatment by dietary modification or eradication of HP will prevent development of MIP with intestinal metaplasia, benign gastric ulcers, dysplasia, and intestinal-type adenocarcinoma.

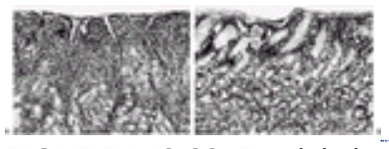

FIGURE 142-23. Fundal glands of the gastric body in multifocal intestinalized pangastritis (MIP) before (**A**) and 8 months after (**B**) *Helicobacter pylori* eradication. **A:** Note the inflammatory infiltrate in the upper half of the mucosa pushing the parietal and chief cells of the fundal glands basally. **B:** Note the complete restitution of normal fundal glands after *H pylori* eradication. Other focal areas of intestinal metaplasia (not illustrated) did not reverse their metaplasia after *H pylori* eradication.

We call the second type of pangastritis NUP because gastric ulcers, duodenal ulcers, and intestinal-type adenocarcinoma are rarely if ever seen and there is considerably less IM than in MIP. NUP has not been studied extensively because it is difficult to justify endoscopy with extensive biopsy in individuals with a normal upper endoscopy and few if any symptoms. Nevertheless, limited longitudinal data suggest that untreated NUP progresses more slowly than MIP and is present in many asymptomatic patients who are infected with HP. [3] The pangastritis of NUP is reversible after HP eradication. Whether NUP can ever evolve into MIP is unknown.

DCAG is not caused by HP and is confined to the fundal gland area. This is a genetically determined, progressive autoimmune destruction of the parietal cells, but the pyloric glands of the antrum are unaffected except for occasional concomitant HP antral gastritis. These patients develop an autoantibody directed to the proton pump on the canalicular membrane of the parietal cell. As the glands are progressively destroyed, they are usually replaced by intestinal metaplasia or less frequently by pyloric gland metaplasia, by pancreatic acinar metaplasia, or by nothing at all (atrophy). Destruction of the fundal glands results in achlorhydria and loss of intrinsic

factor, both of which are manufactured in the parietal cells. When gastric acid is low, gastrin secretion increases, predisposing to gastric enterochromaffin cell-like (ECL) hyperplasia and carcinoids. The lack of intrinsic factor prevents normal ileal absorption of vitamin B_{12} leading to the eventual development of pernicious anemia. As the gastritis progresses and the parietal and chief cells are destroyed, the extent of metaplasia or gland loss increases and the inflammatory infiltrate diminishes producing a picture sometimes referred to as gastric atrophy.

The older term “superficial” gastritis does not appear in the previous classification because it refers to a grade of gastritis rather than to a single histological pattern or nosological category; thus it has no independent clinical or histological significance. A substantial body of evidence indicates that HP is a causative agent also of acute epidemic gastritis with hypochlorhydria. We speculate that acute HP gastritis evolves into either DAG, MIP, or NUP, depending upon environmental influences. HP is also an important factor in the development of gastric or duodenal ulcer as well as intestinal-type adenocarcinoma. Only half of benign gastric ulcers are infected with HP in the United States and the other half are associated mostly with NSAIDs. One suspects that even when HP gastritis is present in gastric ulcers, many of these ulcers are caused by superimposed NSAID injury. The frequency of gastric ulcers caused by NSAIDs, and of duodenal ulcers caused by HP-DAG, is increasing in those areas where benign gastric ulcers and intestinal-type adenocarcinomas caused by HP-MIP are decreasing in frequency. Although all HP infected patients have gastritis, the majority will never develop an ulcer or cancer. The histological patterns of DAG, MIP, or NUP may be present without HP if the patient recently ingested an antibiotic because HP may disappear shortly after the start of an antibiotic.

To differentiate the four patterns of gastritis with certainty in our opinion requires at least six representative biopsies of the stomach. To save money, the six biopsies can be mounted three each in two blocks because most laboratories charge by the block. The biopsies in the first block should contain two from the lesser curvature of the antrum near the pylorus, and one from the mid-greater curvature of the stomach in an area of heavy folds. The three additional biopsies in the second block should contain one from the upper greater curvature, one from the middle of the crescentic fold that marks the angulus, and one from the lesser curvature 2.5 cm proximal to the angulus. Foci of intestinal metaplasia in four of the six biopsies suggest the diagnosis of MIP and differentiate it from NUP, which tends to have less than two biopsies (or no biopsies) with intestinal metaplasia. The DAG pattern is diagnosed when there is diffuse pyloric gland gastritis of the antrum and a lesser degree of gastritis in fundal glands that are *free of intestinal metaplasia.*

Although it has been said that 90% of patients with duodenal ulcers have DAG with HP infection, this number is decreasing because of widespread treatment of HP. Those patients with a duodenal ulcer and no HP-DAG most frequently are taking NSAIDs which causes an erosive, reactive gastroduodenopathy with ulcerations (duodenal ulcer and gastric ulcer). On rarer occasions, the duodenal ulcer is caused by Crohn’s disease, gastrinoma, or short bowel syndrome, or is idiopathic.

Intestinal metaplasia is subdivided histologically into two types: Complete intestinal metaplasia contains goblet cells, Paneth cells and absorptive cells with a well-developed brush border resembling those seen in the small bowel. Incomplete intestinal metaplasia also contains goblet cells, but the cells between the goblet cells may resemble gastric surface cells or altered absorptive cells that may secrete either sialomucins or predominantly sulfated mucins. Incomplete intestinal metaplasia that contains epithelium that secretes sulfated mucins may be more closely associated with increased risk of cancer, but this relationship has been challenged. We believe that subtyping of intestinal metaplasia need not be performed for diagnostic purposes.

A spiral bacterium that differs from HP may be found in the gastric mucosa of some patients with active gastritis. The organism originally named *Gastrospirillim hominis,* is longer and has more spirals than HP and appears to be a significant but uncommon cause of gastritis. Studies of the 16S ribosomal RNA gene sequences of this organism show that it is closely related to *Helicobacter,* and it is now called *H heilmannii.*

Gastropathies

Reactive, erosive gastropathies are caused by agents or factors that injure the gastric mucosa without producing a pronounced inflammatory infiltrate like that seen in the gastritides. NSAIDs are the most common cause. [55]

The mechanism by which reactive, erosive gastropathy develops is not completely understood; however, increasing evidence suggests that microvascular injury to the mucosa by NSAIDs plays an important role in addition to any direct effect by the NSAIDs on the epithelium. Early erosions are remarkably similar histologically to mild ischemic changes with superficial zonal necrosis and hemorrhage.

The lesion adjacent to an ulcer or erosion in reactive gastropathy is characterized by prominent foveolar hyperplasia with little or no gastritis and no HP infection. In foveolar cell hyperplasia there is elongation of the gastric pits with a “corkscrew” or serrated appearance of the longitudinal profiles of the pit lumen (Fig. 142-24). The individual hyperplastic foveolar cells may be normal, as they often are near the edge of an NSAID gastric ulcer, or they may have decreased amounts of mucus and large hyperchromatic nuclei especially in a healing erosion or ulcer.

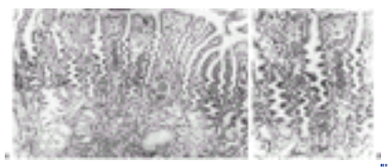

FIGURE 142-24. Reactive gastropathy near the edge of a gastric ulcer associated with ingestion of nonsteroidal antiinflammatory drugs. **A:** Notice the foveolar hyperplasia, as evidenced by the corkscrew or pleated configuration of the elongated gastric foveolae (*arrows*). The lack of gastritis is indicated by the paucity of polymorphonuclear leukocytes within the interfoveolar lamina propria. **B:** The foveolar hyperplasia with its lengthened corkscrew configuration is illustrated at higher magnification (*arrow*). Notice the nuclear crowding and decreased quantity of mucus in the foveolar epithelium, but maintenance of basal uniform-sized nuclei. No *H pylori* were present.

Many patients with reactive gastropathy also develop mucosal petechiae and erosions. In these patients, multiple subepithelial hemorrhages (petechiae) and hemorrhagic gastric erosions are seen endoscopically. Sometimes the entire mucosa may appear to be bleeding. Such an endoscopic appearance is caused by a reactive, erosive gastropathy not by an HP gastritis. Endoscopic biopsy may show histological evidence of widespread superficial subepithelial hemorrhage [56] in addition to erosions (Fig 142-25). Active inflammation is usually mild or absent. The erosions may have an appearance of superficial ischemic necrosis with pseudomembranes. Healing erosions may show foveolar hyperplasia with regenerative epithelial alterations. This pathological picture of erosions and superficial hemorrhage has multiple causes: injury from drugs, especially NSAIDs and alcohol; stress from burns, trauma, or severe illness; ischemia from shock or atherosclerotic narrowing of the celiac axis or its branches; and trauma from previous passage of tubes or endoscopes.

FIGURE 142-25. Gastric fundal mucosa in reactive, erosive gastropathy. **A:** There is a focus of erosion (*open arrows*) of the surface epithelium with fibrinopurulent exudate adherent to the mucosal surface. Notice the absence of active inflammation within the gastric mucosa proper. **B:** Adjacent to the erosion, a focus of subepithelial hemorrhage can be seen and is marked with *arrowheads* at higher magnification.

With the passage of time the hemorrhagic and necrotic erosions may extend through the muscularis mucosae into the submucosa to become an acute ulcer. These can bleed or perforate. An ulcer is differentiated from an erosion because it penetrates through the muscularis mucosae into the submucosa and an erosion does not. Unlike in ulcers, resolution of the erosive lesions results in complete, rapid healing of the mucosal defects. The rapid regeneration of the mucosa that occurs in

erosive, reactive gastropathy may produce foveolar hyperplasia with atypical nuclei, and this picture can be misinterpreted as dysplastic or malignant. For this reason, one should be very cautious about making the diagnosis of neoplasia in a biopsy that shows necrosis or granulation tissue. As Dr. Haggitt taught: parietal cells within a worrisome regenerative gastric epithelial process strongly suggest benignancy. Also, because subepithelial hemorrhage is an artifact frequently resulting from the trauma of taking a biopsy, such hemorrhage alone must involve a relatively large area of the mucosa in order to be suggestive of erosive, reactive gastropathy.

When present, gastric ulcers that develop on the background of reactive gastropathy are usually caused by NSAIDs and differ from those seen in patients with DAG and MIP because they are surrounded by HP-free, relatively uninflamed mucosa. In fact, any gastric ulcer surrounded by mucosa that has little or no inflammation should be considered an NSAID-associated ulcer until proven otherwise. Because the prevalence of HP infection is so high and because NSAID therapy is so widespread, it would be surprising if the two did not coexist. When this is the case, it is not possible to recognize an NSAID-induced gastric ulcer superimposed on a preexisting HP gastritis. An increasing proportion of benign gastric ulcers in the United States are probably caused by NSAIDS, whether or not there is an accompanying HP gastritis. There is controversy about whether or not HP gastritis predisposes to NSAID damage to the gastric mucosa.

The reactive gastropathy seen after gastrectomy is a special problem presumably caused by regurgitation into the gastric remnant of injurious bile containing alkaline pancreatic secretions. This “bile reflux gastropathy” is usually worse in the peristomal area. The enlarged and hyperchromatic nuclei in the hyperplastic stomal foveolae may be confused with dysplasia or even carcinoma. The stomal foveolae may penetrate into the submucosa and form dilated cystic spaces that are seen in the lumen as polyps. A misinterpretation of dysplasia or cancer may be avoided if one notes that nuclear polarity is maintained and there is no nuclear stratification. Dr. Haggitt thought that the presence of parietal cells in these atypical glands is an additional reassurance that the lesion is benign. The rest of the gastric remnant usually shows less severe reactive gastropathy than the stoma but often has severe HP gastritis; it is an inflammatory gastritis without multifocal intestinal metaplasia even after 20 or more years of postgastrectomy reflux. The fundal glands are still present and adenocarcinoma of the stomach is no more frequent than in the unoperated population of the U.S. [57] Except for reactive gastropathy, the fundal gland mucosa is completely normal in those patients without HP infection. Unfortunately, the severity of the gastropathy is not a useful predictor of which symptomatic patients with biliary reflux will improve after a surgical procedure to minimize reflux.

OTHER DIFFUSE GASTRIC DISEASES

Vascular Ectasias

Vascular ectasias of the gastric mucosa may bleed substantially. [58] They are seen more often in patients with cirrhosis or renal failure. Gastric vascular ectasias are composed of dilated mucosal capillaries some of which may contain a fibrin thrombus (Fig. 142-26). They owe their enlargement to increased arteriovenous anastomoses and other vascular abnormalities in the submucosa. [59] Gastric antral vascular ectasia (GAVE), also called watermelon stomach, is probably a related variant recognizable endoscopically as red, linear stripes on the crests of folds in the distal stomach radiating toward the pylorus; they may also show fibrin within dilated mucosal capillaries and features of reactive gastropathy; pronounced fibromuscular proliferation within the lamina propria may suggest mucosal prolapse. [60]

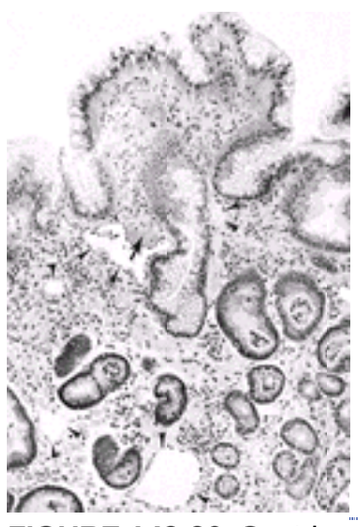

FIGURE 142-26. Gastric antral vascular ectasias (GAVE). Dilated capillaries are present in the lamina propria (*arrowheads*). In one of these, a small fibrin thrombus attached to the capillary wall can be seen (*arrow*).

Infectious Gastritis

Although gastric symptoms play a prominent role in acute gastroenteritis of presumed viral etiology, biopsies from these patients are rarely obtained because of the self-limited nature of most episodes. Other bacterial, fungal, and viral infections of the stomach occur primarily in immunocompromised patients and were described in the section “Esophageal Cancers” (see Fig. 142-14). CMV and *Candida* are the most commonly found infections diagnosed in gastric biopsies. The characteristic cytologic changes of HSV in the squamous epithelium of the esophagus are not seen in the columnar epithelium of the stomach and therefore the virus is more difficult to diagnose. The only acute gastritis caused by bacterial infection other than HP is phlegmonous gastritis. [61] It is rare and principally seen in alcoholics with a history of pharyngitis. This gastritis can be rapidly fatal. It is characterized by marked neutrophilic infiltration and edema, principally in the submucosa, but also affecting the mucosa. Phlegmonous gastritis is usually caused by *Streptococcus* and early treatment with antibiotics can be effective. The rare syphilitic gastritis [62] produces a nonspecific picture of dense plasmacytic infiltration of the mucosa with destruction of glands; if clinically suspected, spirochetes can be demonstrated by suitable stains. Tuberculosis is rare and is seen mostly in patients with AIDS and produces multiple large granulomas containing rare acid fast bacilli and, at times, caseation. Other histologically recognizable gastric pathogens in the immunosuppressed patient include *Cryptosporidium* and *Mycobacterium avium* complex.

Eosinophilic Gastroenteritis

Eosinophilic gastroenteritis is defined as an infiltration of the gastric wall or small intestinal wall with clumps of eosinophils infiltrating the epithelium of patients accompanied by a variety of GI symptoms (usually precipitated by eating) and no evidence of parasitic or extraintestinal disease. [63] An elevated peripheral blood eosinophil count is required for the diagnosis. It usually involves the stomach or small bowel but may also involve the colon or peritoneum. Eosinophils are present normally in the lamina propria of the GI tract; therefore their numbers must be excessive and they should occur in clumps before considering the diagnosis of eosinophilic gastritis. Eosinophilic infiltration is not confined to eosinophilic gastroenteritis but occurs in a wide variety of other inflammatory conditions. For this reason the diagnosis of eosinophilic gastroenteritis should not be made in the absence of an appropriate clinical history. The disease may be patchy; therefore multiple biopsies may be necessary to detect the lesion. If the patient has no GI mucosal involvement, the diagnosis cannot be made by endoscopic biopsy, as is the case with the rarer eosinophilic peritonitis.

Granulomatous Gastritis

Granulomatous inflammation of the stomach occurs in association with systemic granulomatous conditions such as tuberculosis and sarcoidosis, but is most often caused by Crohn’s disease (Fig. 142-27). It also may occur in association with neoplastic disease or with no apparent explanation in the very rare isolated granulomatous gastritis. [64]

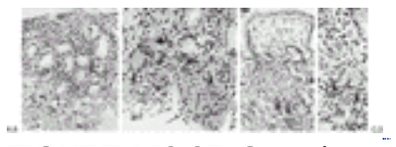

FIGURE 142-27. Granulomatous gastritis in a patient with Crohn's disease. **A:** A discrete epithelioid granuloma is seen (*arrows*) and (**B**) at higher magnification (*arrows*). This granuloma is composed of a compact aggregate of epithelioid histiocytes with a multinucleated giant cell (*arrowhead*). In the stomach such granulomas usually prove to be associated with Crohn's disease. Isolated multinucleated giant cells are present just to the left of the discrete granuloma (*arrowhead*). **C & D:** Multinucleated giant cells (*arrowheads*) can be seen in association with a few epithelioid histiocytes but no discrete granuloma. Giant cells like these in the stomach and duodenum are strongly suggestive of Crohn's disease, unlike in the colon.

A high percentage of patients with Crohn's disease of the small bowel and colon have focal, active inflammation in the stomach. [65] Only about 10% of these patients have epithelioid granulomas, and the majority are clinically asymptomatic. Isolated giant cells in the gastric and duodenal mucosa suggest Crohn's disease; in the colon giant cells are nonspecific and not diagnostic. Seemingly isolated involvement of the stomach by Crohn's disease will usually develop into Crohn's disease of more classic distribution in other organs with the passage of time.

An unusual reason for gastric granulomas is sarcoidosis; diagnosis of this disease requires evidence of a multisystem disease. As mentioned, multiple large granulomas containing necrotic centers suggest the possibility of tuberculosis and warrant a Ziehl-Neelsen stain for acid-fast bacilli.

Varioliform Gastritis

This so-called gastritis is characterized by multiple flat-topped nodules in the gastric mucosa that straddle the mucosal folds and often have an apical erosion. [66] They probably are identical to hyperplastic gastric polyps (described histologically in the section "Gastric Polyps"). This condition has been mislabeled "chronic erosive gastritis." It has been linked to lymphocytic gastritis when it became apparent that lymphocytic infiltration of the gastric surface and pit epithelium was characteristic of some of these lesions. Other patients present with large gastric folds as well as lymphocytic infiltration. The significance of this type of so-called gastritis is not clear, and additional information is needed to clarify whether it is a specific entity or several different ones.

Hypertrophic Gastropathies

Three diffuse gastric mucosal hypertrophies are recognized by their large folds at endoscopy:

- Ménétrier disease
- Zollinger-Ellison syndrome with gastrinoma
- hypertrophic hypersecretory gastropathy.

These lesions may be impossible to sample deeply enough at endoscopy for definitive histological diagnosis. The combination of the endoscopic picture with the clinical information usually makes it possible to arrive at a correct diagnosis.

At endoscopy, Ménétrier disease shows enlarged cerebriform folds covered with thick mucoid secretion especially in the fundus and body of the stomach. The essential histological lesion [67], [68] is foveolar cell hyperplasia, absent parietal and chief cells and a marked increase in mucosal thickness (Fig. 142-28). There is excess secretion of mucus that can cause hypoproteinemia. There can be cystic dilation of the gastric glands and strands of smooth muscle may extend from the muscularis mucosae into the lamina propria. The hyperplastic foveolar cells may have hyperchromatic enlarged nuclei and depletion of cytoplasmic mucus, and can be confused with dysplastic or malignant cells. The fact that adenocarcinoma can complicate Ménétrier disease makes it especially important to exclude this possibility even though it is very rare.

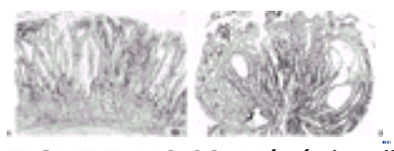

FIGURE 142-28. Ménétrier disease. **A:** A section of the gastric body taken from a resected stomach. The gastric pits or foveolae are strikingly elongated and irregular in configuration. This appearance is produced by a profound hyperplasia of the foveolar cells that extend into the glands and replace the parietal and chief cells so that the body mucosa is now composed exclusively of mucus-producing foveolar cells. **B:** An endoscopic biopsy specimen from a patient with Ménétrier disease. In addition to the marked foveolar hyperplasia that produces a corkscrew appearance of the pits, there are dilated glands, another feature of Ménétrier disease.

At endoscopy in Zollinger-Ellison syndrome with gastrinoma there are large folds and voluminous watery acidic secretion. Parietal and chief cells are proliferating rather than the foveolar cells and this accounts for the hyperchlorhydria, severe peptic ulcer disease, and steatorrhea that may be seen. [69] The presence of many parietal and chief cells rules out Ménétrier disease. Increased parietal and chief cell mass is impossible to quantitate in a biopsy specimen but requires a gastrectomy specimen. The elevation of the blood gastrin level makes the diagnosis.

The endoscopic appearance of the rare hypertrophic, hypersecretory gastropathy is very much the same as that seen in gastrinoma with excess watery acid secretion and numerous parietal and chief cells histologically. Protein loss is variable. Serum gastrin is not elevated and this differentiates this illness from a gastrinoma. These patients may well represent a severe duodenal ulcer diathesis and are probably at the high end of the acid secretory spectrum of duodenal ulcer.

GASTRIC POLYPS

Hyperplastic Polyps

The benign hyperplastic polyp used to be the most common gastric polyp (Fig. 142-29). Fundic polyps now far exceed them in the Western world. Hyperplastic polyps usually are recognized endoscopically because of their characteristic features: they are often less than 1 cm in diameter; sometimes multiple; and distributed on the crests of folds throughout the whole stomach. They may have a sessile, mesa-like shape with an erosion or healed dimple on their top. So-called varioliform gastritis may be a variant of the same lesion. When a solitary or larger hyperplastic polyp develops, it may be pedunculated. An inflammatory polyp is indistinguishable from a hyperplastic polyp except for its increased inflammation. If it is solitary with a smooth eroded surface it is often called a juvenile polyp. Histologically, foveolar hyperplasia, irregular-shaped cystic glands, and edema and inflammation of the lamina propria are typical. Pyloric glands may be present, but parietal and chief cells are infrequent or absent. The inflammatory atypia within the superficial erosion in a hyperplastic polyp may be misdiagnosed as dysplasia but attention to surface cytologic maturation should avoid this error. It is not necessary to remove all multiple small sessile hyperplastic polyps with a snare, but several should be sampled to establish their nature. Hyperplastic polyps that contain adenoma or adenocarcinoma are uncommon but how frequently this occurs is controversial. [70], [71] If a polyp enlarges with the passage of time, or is pedunculated, it should be removed completely for diagnosis.

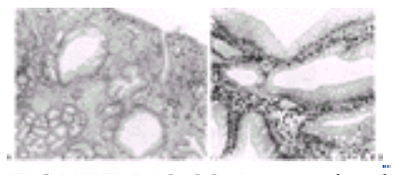

FIGURE 142-29. Hyperplastic gastric polyp. **A:** The low-power view shows the dilated, irregular-shaped gastric glands lined with hyperplastic foveolar cells. Note the inflamed, edematous stroma in which there are numerous dilated capillaries. **B:** Higher magnification shows the hyperplastic foveolar cells lining the glands composing the polyp.

Fundic Gland Polyps

Fundic gland polyps (FGPs) have become the most common gastric polyp in the Western world. They consist of small sessile mucosal elevations in the body of the stomach made up of fundal glands that contain normal parietal and chief cells. Cystically dilated glands are diagnostic; they are lined by parietal and chief cells or gastric surface mucous cells [72] (Fig. 142-30). Fundal gland polyps were first identified in association with familial adenomatous polyposis (FAP) of the colon [73] but those that occur sporadically are far more common; FGPs are benign but some may harbor surface or foveolar dysplasia that may be low or high grade; [74] how significant this is clinically is currently uncertain as gastric cancer is relatively uncommon in FAP. FGPs can disappear spontaneously. The increasing frequency of sporadic FGPs may be explained by the increased use of proton pump inhibitors. The usually small FGP can be totally excised for diagnosis with a large biopsy forceps. Those with dysplasia may require continued endoscopic biopsy surveillance and this surface dysplasia may be a marker for unsuspected FAP. [7], [73], [75]

FIGURE 142-30. Fundic gland polyp of the stomach. **A:** This endoscopic biopsy specimen from a small polyp shows dilated, irregular-shaped fundal glands. **B:** The nature of the cells lining these cystic glands can be recognized; they include parietal cells and chief cells. Although not seen in this particular field, foveolar cells may also be present.

Adenomatous Polyps

In the United States, adenomatous polyps of the stomach are uncommon, usually solitary, and most often located in the antrum. They closely resemble colonic adenomatous polyps histologically and may be tubular, villous, or tubulovillous. The mucosa surrounding gastric adenomas usually demonstrates pangastritis with intestinal metaplasia (MIP). Gastric adenomas are dysplastic precursors to intestinal-type adenocarcinoma and frequently contain a focus of early carcinoma; they may also be associated with carcinoma elsewhere in the same stomach. [7] Strangely, the adenomatous gastric polyps associated with FAP of the colon have a lower than 3% prevalence of carcinoma, unlike the FAP adenomas of the duodenum near the papilla of Vater that are frequently malignant, with a cancer prevalence higher than 12%. [76] Gastric adenomatous polyps should be excised to exclude the diagnosis of focal carcinoma and to prevent their future transformation into adenocarcinoma. Because precancerous dysplasia or early carcinoma may be present in the flat mucosa adjacent to the solitary adenoma, as well as within it, multiple biopsies of the apparently uninvolved surrounding mucosa are also indicated. If the polyp contains carcinoma, and especially if dysplasia is present in the surrounding mucosa, simple endoscopic polypectomy may not be adequate therapy. If an adenomatous polyp is confined to the antrum, as these polyps often are, antrectomy with careful frozen section evaluation of the resection margins may be required.

Polyposis Syndromes

Polyps with foveolar hyperplastic changes similar to those seen in gastric hyperplastic polyps are seen in three other intestinal polyposis syndromes which may involve the stomach: juvenile polyposis, Peutz-Jeghers syndrome, and Cronkhite-Canada syndrome.

Juvenile polyps of the stomach are indistinguishable from gastric hyperplastic polyps; they are part of a generalized *juvenile polyposis syndrome,* [77] in contrast to the *solitary juvenile polyp,* which is benign and confined characteristically to the colon. It is a hamartoma composed of various normal gastric tissues with an inflammatory infiltrate, predominant stromal elements, dilated glands, and usually no adenomatous changes, but a rare adenoma can become a carcinoma. *Peutz-Jeghers syndrome* (PJS) polyps contain an arborized pattern of muscle strands extending from the muscularis mucosae into the lamina propria (Fig. 142-31). Patients with PJS may rarely develop GI cancers, however, associated breast cancers are much more common. [78] *Cronkhite-Canada syndrome* is a rare, acquired, generalized, usually nonneoplastic GI polyposis syndrome. Histologically the polyps resemble juvenile polyps but they are not usually pedunculated; [79] the small bowel and stomach are almost always involved. The nonpolypoid mucosa may also be involved. Patients usually are in their 60s and have diarrhea, protein loss, alopecia, and characteristic skin and nail changes.

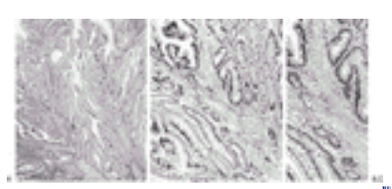

FIGURE 142-31. Small bowel hamartomatous polyp from a patient with Peutz-Jeghers syndrome. Similar polyps may be located in the stomach. **A:** The low-power view shows the complex, branched configuration of the hamartoma. **B & C:** The abnormal arrangement of normal tissue elements is seen. Normal-appearing epithelium lines tubules and covers villi. A thick band of smooth muscle divides the field diagonally. **C:** This smooth muscle band and the normal-appearing epithelium are shown at higher magnification.

Inflammatory Fibroid Polyps

Inflammatory fibroid polyps of the stomach may be pedunculated or sessile and may cause obstruction, [80] especially in the gastric antrum where they are most common and of large size. They are benign proliferations of spindle cells with localized infiltration by eosinophils without an elevated eosinophil count in the peripheral blood. Formerly they were erroneously called eosinophilic granulomas. Inflammatory fibroid polyps usually are asymptomatic until they grow to a size large enough to obstruct the gastric outlet. They are unrelated to eosinophilic gastritis.

Approach to Gastric Polyps

Short of total excision, gastric polyps may be difficult to diagnose histologically. Fortunately, gastric polyps are often pedunculated, and therefore can be easily excised for diagnosis with an electrocautery snare. Sessile lesions that cannot be excised as easily and safely with the endoscope may be diagnosable by multiple large biopsy specimens taken with a snare or by snare removal after they have been elevated from the underlying bowel wall by submucosal saline injection.

SMALL BOWEL CANCERS

Malignant small bowel tumors are the rarest seen in the GI tract (1.5%). Most of these are adenocarcinomas that are found in the duodenum and jejunum. Most have

no known precursor but others are sequelae of celiac sprue, long-term Crohn's disease, or a hereditary polyposis syndrome such as FAP or hereditary nonpolyposis colorectal cancer (HNPCC). Many small bowel carcinomas are periampullary and may be an extension of a pancreatic cancer. Rarely primary periampullary, well-circumscribed carcinomas are potentially curable. Distinguishing neoplasm from an inflammatory process histologically may be difficult in periampullary lesions. Rare lymphomas are associated with Crohn's disease. The malignancies associated with celiac sprue may be adenocarcinomas or T-cell lymphomas. Even more rarely, carcinomas may develop in ileostomies, pouches, and conduits. Primary lymphomas of the small bowel are more common in certain geographic areas including the Middle East where they were first described (see " Flat Lesions with Diagnostic Histology"). Other malignant small bowel tumors include mesenchymal tumors, carcinoids, and metastatic lesions. Duodenal carcinoids differ from other carcinoids because they frequently secrete hormones (gastrin, insulin, somatostatin). Immunocytochemical techniques performed on tissue sections can be helpful in assessing hormone production.

BENIGN SMALL BOWEL DISEASES

Duodenal Nodules

Three types of benign duodenal nodules are seen in the duodenal bulb: Brunner gland nodules, heterotopic gastric mucosa, and benign lymphoid nodules.

Brunner gland nodules are made up mostly of enlarged Brunner glands. They may also involve the mucosa and blunt or flatten overlying villi. Such nodules are frequent, may be multiple, are not adenomas, in that they are not dysplastic, and are usually of no clinical significance.

Heterotopic gastric mucosa in the duodenum is of three types:

1. Gastric surface cell metaplasia replacing some of the epithelium of the intestinal villi. This type is usually not polypoid and is most commonly a variant of normal. Extensive gastric surface cell metaplasia may be associated with excess acid production.
2. Pyloric gland metaplasia occurs as a nonspecific reaction to injury in the small bowel mucosa, particularly in Crohn's disease.
3. Nodules of heterotopic fundal glands may also be seen. They have no clinical significance.

Benign lymphoid nodules may be found in the duodenum and are often of no clinical significance, but they may be a reflection of benign lymphoid hyperplasia which is seen in common variable immunodeficiency (see " Flat Lesions with Diagnostic Histology"). In the latter entity, plasma cells that manufacture the immunoglobulins may be virtually or completely absent.

Small Bowel Adenomas

Adenomas predominate in the duodenum and are frequently periampullary, especially in FAP and HNPCC. They are similar histologically to colonic adenomas. Ideally all adenomas should be excised endoscopically because of their malignant potential. Snare removal of an adenoma of the pancreatic papilla may necessitate placement of a pancreatic stent to maintain drainage.

Other Polyposis Syndromes

Polyps seen elsewhere in the GI tract may also be seen in the small bowel (i.e., gastric-type hyperplastic polyps, adenomas, hamartomatous polyps, and inflammatory fibroid polyps). The Peutz-Jeghers hamartomatous polyps are most common in the small bowel (see Fig. 142-31).

The Proximal Duodenum

The bulb, second, and third portion of the duodenum are easily accessible to endoscopic biopsy. The normal duodenal bulb may differ histologically from the rest of the small bowel. [81] Even when normal, villi in the bulb may be distorted or absent, especially over areas of submucosal Brunner glands penetrating through the muscularis mucosae. The number of plasma cells in the normal bulbar lamina propria is often greater than in the rest of the small bowel. Flattening of villi located over Brunner glands in normal subjects can be differentiated from the abnormal flat biopsy characteristic of celiac sprue by the absence of diffuse chronic inflammation of the lamina propria and the lack of lymphocytic infiltration of the surface epithelium.

Nonspecific duodenitis of the bulb cannot be diagnosed reliably by endoscopic appearance; it requires biopsy to document the presence of polymorphonuclear leukocytes within the epithelium reflecting active injury (Fig 142-32). Nonspecific duodenitis may be a precursor or sequel to duodenal ulcer. Many of the diffuse reactions seen in the stomach are also seen in the bulb, including hemorrhagic erosive lesions, opportunistic and other infections, and eosinophilic or granulomatous inflammation.

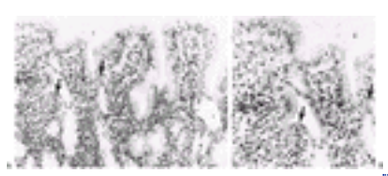

FIGURE 142-32. Active duodenitis. **A:** There are foci of neutrophilic infiltration of glands (*arrows*). Notice the gastric surface cell metaplasia involving most of the surface cell of this biopsy specimen. Two glands just to the right of center contain goblet cells and are normal intestinal glands, whereas the remainder of the glands are lined completely by cells that contain clear mucus and that represent gastric surface cells. Brunner glands that have extended into the lamina propria are seen below; such Brunner glands are also seen in normal biopsy specimens of the duodenal bulb. **B:** Higher magnification shows gastric surface cells more clearly and glands infiltrated by neutrophils, indicating active inflammation (*arrows*).

DIFFUSE PROXIMAL SMALL BOWEL LESIONS (Table 142-2)

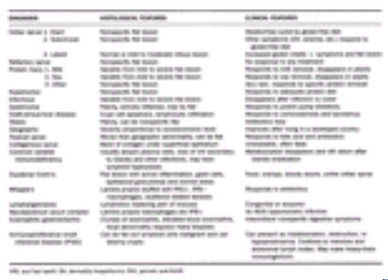

TABLE 142-2 Diffuse Proximal Small Bowel Lesions

Most disease of the small bowel is diffuse, proximal in location, and can be diagnosed by duodenal biopsy. [81] To diagnose these various kinds of disease, we strongly suggest that three or four biopsies be taken from the crest of the valvulae conniventes in the distal descending duodenal loop with a large biopsy forceps. This extra effort maximizes the diagnostic sensitivity for focal lesions and makes it easier to mount and orient the biopsies so that one can best assess villous architecture.

Distal duodenal or proximal jejunual biopsy specimens normally show tall villi in patients in the United States (Fig 142-33), but in some developing countries and in

several diseases, villi may be blunted or even completely absent (flat). The severity of villous architectural abnormality may be variable in the same patient or in different patients with the same disease. Villous abnormalities in some diseases can be diagnosed if they are accompanied by a specific diagnostic histological feature. Other diseases with only nonspecific villous abnormalities may be diagnosed by their response to a specific therapeutic regimen. Although a flat biopsy with absent villi is almost always caused by celiac sprue in the United States, there are a wide variety of much rarer diseases that may have the same histological picture, but which do not respond to a gluten-free diet. For example, the flat biopsy of severe tropical sprue may be indistinguishable from that seen in celiac sprue, but it responds to a combination of folic acid and antibiotics rather than to a gluten-free diet.

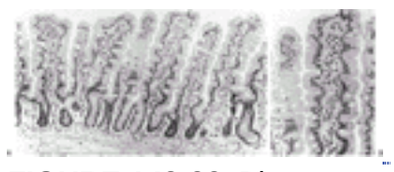

FIGURE 142-33. Biopsy specimen of normal distal duodenum. **A:** The tall, slender villi are about three times as tall as the crypts are deep. Epithelial cells covering the villi consist predominantly of absorptive cells with scattered goblet cells. The nuclei of the surface epithelial cells are lined up in a uniform, picket fence–like arrangement. The lamina propria contains small numbers of lymphocytes and plasma cells are normally seen. **B:** The normal surface epithelium and lamina propria at higher magnification. The slender, fusiform cells in the lamina propria represent smooth muscle cells normally found in the cores of small bowel villi.

Nonspecific Flat Lesions—Celiac Sprue

This disease is termed celiac sprue because in the past the same disease was traditionally called celiac disease in children and idiopathic sprue in adults. [82] There are other satisfactory names such as adult celiac disease and gluten-sensitive or gluten-induced enteropathy. We believe there are three types of celiac sprue: overt celiac sprue, subclinical celiac sprue, and latent celiac sprue.

Patients with *overt celiac sprue* have steatorrhea and it is the hallmark of serious malabsorption. There are two criteria for this diagnosis. The first is the presence of a characteristic but nonspecific flat duodenal mucosal biopsy with abortive or no villi and lymphatic infiltration of the surface epithelium (Fig. 142-34). The second criterion is a dramatic clinical response to a gluten-free diet [83] with a marked improvement in emotional status and a disappearance of steatorrhea. The diagnosis of overt celiac sprue strongly indicates the need for a diet free of wheat, barley, and rye products. This gluten-free diet is a difficult, lifelong undertaking.

FIGURE 142-34. Celiac sprue before and after treatment with a gluten-free diet. **A:** Observe the flat mucosal surface in this biopsy specimen. The villi are effaced, and the crypts have become elongated. The lamina propria contains a prominent infiltrate of chronic inflammatory cells, and lymphocytes infiltrate the surface epithelium. **B:** The appearance of this same patient's mucosa after an absolutely gluten-free period of 3 weeks, during which time the patient was fasting and on total parenteral nutrition. The villi have returned to a normal appearance and the inflammatory infiltrate within the lamina propria and surface epithelium has receded.

Patients with *subclinical celiac sprue* are free of overt malabsorption (steatorrhea). Their proximal small bowel biopsies may have a lesion of variable severity from complete loss of villi to moderate or mild villous abnormalities. The lesion may even be patchy and it is usually confined to the duodenum. The usual reason the small bowel is biopsied to reveal the lesion is the presence of one or several conditions known to be associated with celiac sprue (e.g., dermatitis herpetiformis, [84] diabetes mellitus with steatorrhea, autoimmune thyroiditis, iron deficiency anemia unresponsive to oral iron, hypocalcemia, tetany, osteoporosis, short stature, delayed onset of puberty, arthralgias, infertility, or a family history of celiac sprue). A positive serologic tissue transglutaminase test helps make the decision for biopsy. However, duodenal biopsy and response to a gluten-free diet remain the "gold standards" for diagnosis of celiac sprue.

Latent celiac sprue is very rare. [85] Such patients carry the gene for celiac sprue but the abnormal duodenal phenotype has not penetrated and they have a normal proximal small bowel. Patients with latent celiac sprue eventually may develop steatorrhea and a typical flat lesion after a large dietary gluten challenge of long enough duration. [85]

How does duodenal mucosal morphology guide treatment of celiac sprue? Patients with a flat lesion in overt celiac sprue should be treated by maintaining a lifelong gluten-free diet. Should subclinical celiac sprue with a flat lesion also be treated? In some instances treatment is clearly indicated because the associated disease process which had led to the biopsy is reversible by a sufficiently strict long-term gluten-free diet (e.g. dermatitis herpetiformis, [86] diabetic steatorrhea, and malabsorption of iron). Some clinicians treat because they believe that a gluten-free diet can prevent the dreaded complications of small intestinal lymphoma or adenocarcinoma. Others think that the mere presence of a flat lesion is a "ticking bomb" that may produce a variety of serious, preventable complications of the disease before the patient is aware of them (e.g., osteopenia). Treatment of subclinical sprue with milder duodenal abnormalities may be indicated if the patient has disabling symptoms which seem to respond to a gluten-free diet.

Another question is whether one has to test the efficacy of a gluten-free diet by repeating proximal small bowel biopsies on a gluten-free diet until they become normal. If the patient with treated overt celiac sprue is gaining weight on a diet with a normal caloric content and feels well we think rebiopsy is unnecessary and can be misleading. After institution of a gluten-free diet the mucosa normalizes gradually, beginning distally and progressing proximally. [87] Histological normalization of the proximal duodenum may be dramatic and occur in a short time but occasionally it may take months to years in some patients, and in the rare patient, may never become completely normal proximally. If the residual severe abnormality is delimited very proximally in the duodenum, the patient will be free of malabsorption. [84] The severity of malabsorption is related to the length of small bowel that has lost its normal villi. [84], [87] The reason why the lesion is not completely reversed in some patients is often obscure and one always suspects that the patient inadvertently or purposefully is not adhering to a strict gluten-free diet.

The nonspecific flat lesions of overt celiac sprue (see Fig. 142-34), refractory sprue, severe geographic abnormality (Fig. 142-35), and several other rarer conditions cannot be distinguished from one another histologically. Typically, the flat lesion shows abortive or absent villi, abnormal injured surface epithelium infiltrated by lymphocytes, and increased length of parallel, closely packed crypts with increased numbers of mitotic figures that extend from the crypts toward the surface. The lamina propria is heavily infiltrated predominantly by plasma cells, as well as lymphocytes, eosinophils, macrophages, mast cells, and a few neutrophils. Lymphocytic infiltration is most obvious in the surface epithelium but is present throughout the biopsy, especially within crypt epithelium. Marked active inflammation by neutrophils within crypts and crypt abscess formation is distinctly unusual in celiac sprue. Giant cells or epithelioid granulomas are not seen in celiac sprue and in a flat biopsy usually indicate a missed diagnosis of Crohn's disease (Fig. 142-36).

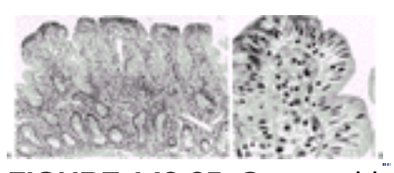

FIGURE 142-35. Geographic abnormality in small bowel morphology. **A:** The villi show a moderately severe nonspecific abnormality in architecture in this biopsy

specimen from an asymptomatic inhabitant of an extremely economically depressed country. **B:** Higher magnification. Note the blunted, shortened villus, the intraepithelial lymphocytes in the surface epithelium, and the prominent infiltrate of lymphocytes and plasma cells in the lamina propria.

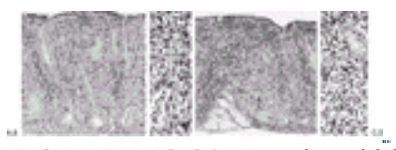

FIGURE 142-36. Duodenal biopsy specimen from a patient with Crohn's disease. **A:** Note the flat mucosal surface and markedly elongated crypts. **B:** The intense chronic inflammatory infiltrate with plasma cells and lymphocytes includes active inflammation with numerous neutrophils that have produced a crypt abscess, shown here at higher magnification. **C:** In another biopsy specimen from the same patient, a focus of granulomatous inflammation is present. A multinucleated giant cell is surrounded by macrophages and neutrophils (*arrow*). **D:** Higher-power magnification of the giant cell shown in **C** (*arrow*).

Nonspecific Flat Lesions—Apparently Unresponsive to Treatment

In *refractory sprue,* the proximal small bowel biopsy looks like untreated celiac sprue histologically, but it does not respond either histologically or clinically to exclusion of gluten from the diet, even when the patient is put on a totally parenteral regimen. Its etiology is unknown.

Some refractory patients with a flat lesion either have or develop *intestinal lymphoma* [88] or *idiopathic ulcerative ileojejunitis.* [89] The prognosis in both of these diseases is poor.

One exceedingly rare adult patient who seemed to us to have refractory sprue with a flat lesion was then found elsewhere to have injury by dietary protein other than gluten. [90] Removal of two proteins from the diet led to regression of the flat histological lesion and the restoration of health. Because the institution of an elimination diet to determine such a rare protein injury is very difficult and rarely rewarding, it should only be undertaken if the patient responds to a totally parenteral diet initially.

Other Nonspecific Flat Lesions With a Specific Therapeutic Response

There are a variety of conditions that have a variable villous abnormality, which may, when severe, be indistinguishable from the characteristic nonspecific flat lesion seen in untreated celiac sprue. *Milk protein injury* is the most common cause of the flat lesion in infants and children. *Soy bean protein* is the next most frequent protein that may be harmful to infants and children. Ingestion of soy bean protein in a susceptible patient leads to a flat lesion and its removal from the diet heals the intestinal lesion and relieves the symptoms. [91] Unlike in celiac sprue, these milk and soy proteins are no longer injurious in adult life. Diets deficient in high-quality protein can cause the disease *Kwashiorkor* with a nonspecific flat lesion, especially when the diet is otherwise adequate calorically. [92] These patients improve after addition of high quality protein to their diet even if gluten is included. In children, various *intercurrent infections* can cause a transient flat lesion. This lesion disappears when the infection recedes. The patchy abnormalities in *Zollinger-Ellison syndrome* [69] are caused by acid peptic injury secondary to excessive secretion of gastrin by a tumor. The injury in this disease is variable in severity but patchy complete loss of villi can occur in some areas of the small bowel with active inflammation and hemorrhage as well as erosions. The mucosa in these patients heals after treatment with proton pump inhibitors and they no longer have ulcers, diarrhea, or steatorrhea.

Acute *graft-versus-host disease* (GVHD) [93] can demonstrate lesions of varying severity from mild villous abnormality and focal lymphocytic and eosinophilic infiltration to complete denudation of the small bowel mucosa. A pathologist with special experience can recognize GVHD by apoptosis dropout, and lymphocytic infiltration of the crypt cells. This lesion may respond to large doses of corticosteroids and cyclosporine or tacrolimus, but severe GVHD can be a fatal disease. *Stasis syndrome* with bacterial overgrowth has a villous lesion of variable severity but it can be completely flat and indistinguishable from the lesion of celiac sprue. [94] Symptoms respond to intermittent antibiotic treatment or to relief of the obstruction if one is present.

The small bowel in inhabitants of some socioeconomically developing countries shows *geographically related abnormalities.* These are nonspecific villous abnormalities of varying severity including the flat lesion indistinguishable from that of celiac sprue with a prominent infiltrate of lymphocytes and plasma cells in the lamina propria and the surface epithelium (see Fig. 142-35). Generally, the severity of the abnormality correlates with the socioeconomic level of the developing country. The abnormality is environmental because it disappears after prolonged residence in a country with a higher socioeconomic level. Patients with *tropical sprue* in certain economically depressed countries tend to have an exaggeration of the nonspecific small intestinal abnormalities seen in their fellow inhabitants. [95] The severity of the villous abnormality varies. Such individuals may have a flat lesion indistinguishable from that of overt or subclinical celiac sprue but they do not respond to a gluten-free diet. Rather, the malabsorption and intestinal lesion respond to folate and antibiotics.

There are rare patients who appear to have *ulcerative colitis and proximal small bowel involvement, including duodenitis.* In these unusual patients, an extensive, nonspecific, flat, actively inflamed lesion of the whole small bowel was demonstrated with severe malabsorption. [96]

Flat Lesions With Diagnostic Histology

Rare cases of sprue are, or become, resistant to gluten elimination and may develop an abnormal band of subepithelial collagen (Fig. 142-37). This disease, *collagenous sprue,* [97] does not respond to a gluten-free diet or any other treatment and has a dismal prognosis. The subepithelial collagen band should be thicker than the diameter of two red cells. One must also avoid a misinterpretation of artifactual thickening of the collagen band caused by tangential sectioning. Other very helpful diagnostic features in collagenous sprue are incorporation of capillaries and inflammatory cells within the matrix of the collagen band and a spiculated interface at the junction of the collagen band with the underlying lamina propria. A number of reports of lymphocytic or collagenous colitis in association with celiac sprue have appeared, and a patient with both collagenous colitis and collagenous sprue has been described.

FIGURE 142-37. Collagenous sprue. **A:** The mucosal surface is flat, the villi are absent, and the crypts are elongated. An abnormally thick layer of collagen lies beneath the surface epithelium (*arrows*). Lymphocytes and plasma cells infiltrate the lamina propria, the collagen, and the surface epithelium. **B:** The markedly thickened subepithelial collagen table (*arrows*) can be better seen at higher power. Note the abnormal surface epithelium.

The flat lesion of *hypogammaglobulinemic sprue* can easily be confused with a nonspecific flat lesion (Fig. 142-38), except that at high-power magnification it is evident that the excess numbers of round cells in the lamina propria are mostly lymphocytes and that the usually numerous plasma cells are virtually or completely absent. [98] This is in marked contrast to the increase in the number of lamina propria plasma cells seen in most other flat lesions. The flat biopsy specimen of hypogammaglobulinemic sprue is usually infected with *Giardia lamblia* and represents one end of the spectrum of the small bowel lesions seen in *common variable immunodeficiency;* the other end is *benign lymphoid hyperplasia.* It too has virtual absence of plasma cells, but, in addition, exhibits large lymphoid nodules or polyps that may or may not have normal villi between them. The most common lesion in common variable immunodeficiency is a mixture of benign lymphoid hyperplasia and abnormal villous architecture of varying severity (Fig. 142-39A). The loss of villi in common variable immunodeficiency is caused by infection with *G lamblia,* [98] an organism easily missed in histological sections (see Fig. 142-39B, Fig. 142-39C) but well visualized in Giemsa-stained smears of mucus adherent to the biopsy specimens (see Fig. 142-39D). Pharmacological eradication of the *Giardia* cures the malabsorption in hypogammaglobulinemic sprue by restoring the villi, but the

humoral deficiency in immunoglobulin A (IgA) and other immunoglobulins remains because the plasma cells that manufacture the immunoglobulins are not restored and are still virtually absent (see Fig. 142-38).

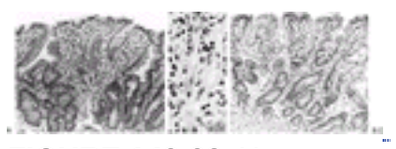

FIGURE 142-38. Hypogammaglobulinemic sprue (a variant of common variable immunodeficiency) before and after eradication of *Giardia lamblia.* **A:** This biopsy sample of the small intestine has a flat mucosal surface with marked elongation of the crypts and an inflammatory infiltrate within the lamina propria. At this magnification, it is indistinguishable from the flat biopsy specimens shown in Figure 142-34 from a patient with celiac sprue. **B:** At higher magnification inspection of the inflammatory infiltrate in the lamina propria reveals mostly lymphocytes with no plasma cells, a finding indicative of hypogammaglobulinemic sprue. *Giardia* organisms were identified in a Giemsa-stained smear made from the mucus adherent to the biopsy specimen. **C:** After treatment for giardiasis, the mucosal villi began to return, and malabsorption disappeared. Virtual absence of plasma cells from the lamina propria was not reversed by eradication of the *Giardia* organisms.

FIGURE 142-39. The typical appearance of a mixed lesion in a biopsy specimen of the small intestine in common variable immunodeficiency. **A:** The biopsy shows mild lymphoid hyperplasia (*arrows*) and an abnormality of the villous architecture. **B:** Longitudinal sections of *Giardia lamblia* are seen (*arrow*). **C:** Pear-shaped organisms (*arrow*) that have been sectioned en face in the paraffin-embedded biopsy. Intracytoplasmic detail is unclear. **D:** Giardiasis is detected most easily in Giemsa-stained smears of mucus adherent to the biopsy. The *arrow* points to a characteristic pear-shaped organism in which two nuclei are barely visible.

An unusual manifestation of *Crohn's disease* may be a flat duodenal mucosa indistinguishable from that seen in celiac sprue [99] (see Fig. 142-34). It is easily confused with celiac or refractory sprue especially if malabsorption is the main symptom and no other usual Crohn's involvement of the GI tract is found. Some indication of the unusual diagnosis of isolated duodenal Crohn's disease is the intensity of the active inflammatory response histologically with polymorphonuclear leukocytes, crypt abscesses, and destruction of glands. If present, the clinical story of fever, cramps, and bloody stools and the lack of response to a gluten-free diet favor the diagnosis of Crohn's disease. If the duodenum is biopsied repeatedly throughout its length endoscopically, epithelioid granulomas or giant cells, as well as focal areas of normal villi may eventually be detected, strongly suggesting Crohn's disease. Other rarer diseases with granulomas are sarcoidosis and tuberculosis or other unusual infections.

In *Whipple disease* [100] (Fig. 142-40), the mucosa is stuffed with macrophages that are negative for acid-fast bacilli but also contains dilated lacteals within the lamina propria. The mucosa may be flat or have residual villi. In the histologically similar disease with many macrophages with which it may be confused— *Mycobacterium avium complex* (MAC)—there are innumerable acid-fast bacilli present within macrophages but no dilated lacteals are seen (Fig. 142-41). MAC is an opportunistic AIDS infection.

FIGURE 142-40. Whipple's disease. **A:** Notice the loss of villi and heavy infiltration of the lamina propria by macrophages with abundant cytoplasm. The clear spaces represent dilated blocked lacteals filled with lipid. The surface epithelium remains essentially normal. **B:** Foamy macrophages at higher magnification are visible. By electron microscopic study, the abundant pale cytoplasm of these macrophages can be seen to contain bacilli and breakdown products of bacterial cell membranes within lysosomes. Note the completely normal surface epithelium (**upper right**).

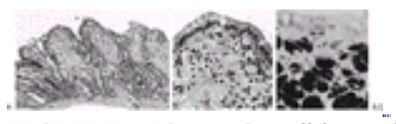

FIGURE 142-41. Small bowel biopsy specimen from a patient with acquired immunodeficiency syndrome (AIDS) who was infected with *Myobacterium avium* complex. **A:** Note the shortened, broad villi and the lamina propria packed full of macrophages. **B:** Macrophages within the lamina propria are seen at higher magnification. With a hematoxylin and eosin stain, this appearance is indistinguishable from that of Whipple's disease except for the absence of dilated lymphatics. **C:** Ziehl-Neelsen stain identifies the acid-fast nature of the bacilli within the macrophages and in the lamina propria.

Lymphangiectasia is usually a congenital disease but it may be secondary to various infiltrating mesenteric lesions. The biopsy varies from normal to flat because of multiple dilated lymphatics distorting the villous architecture (Fig. 142-42).

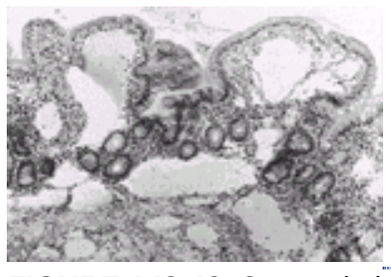

FIGURE 142-42. Congenital lymphangiectasia. The villous architecture in this small bowel biopsy specimen is distorted by dilated lymphatic channels that extend through the muscularis mucosae into the submucosa at the bottom of the photograph. Apart from the dilated lymphatics and distorted architecture, the mucosa is normal.

Eosinophilic gastroenteritis [101] /SUP>of the small bowel is a patchy and rare disease. The small bowel and distal stomach are the most common areas of involvement. There may be large areas of normal villi; thus it often requires multiple biopsies for detection. When the mucosa is free of disease and only the deeper layers of the small bowel are involved it will be impossible to diagnose by peroral biopsy. There are clumps of mucosal eosinophils in the involved areas and an elevated eosinophil count in the peripheral blood. This is a diagnosis of exclusion because collagen-vascular

disease, parasitic infection, and drug and other allergic reactions must be excluded. Also a variable number of eosinophils are present normally in the lamina propria or accompanying any type of inflammation.

Rarely, an *autoimmune enteropathy* can flatten the intestinal mucosa; in this entity, lymphocytes may be seen in the process of destroying crypts and villi; goblet cells may be absent and circulating antigoblet cell antibodies may be demonstrable. Associated thymoma has been reported.

Microvillus inclusion disease [102] is a rare hereditary enteropathy, present from birth onward and compatible with only a short life. Histologically it may resemble the flat celiac sprue lesion but electron microscopy reveals microvilli buried within the cytoplasm of the absorptive cells.

Primary intestinal lymphoma [103] is associated with malabsorption (Fig. 142-43) and is typically a marginal zone lymphoma. It is seen mostly in patients from developing countries and usually is confined to the intestine and its lymph nodes. When the villi are destroyed by this type of lymphoma, the biopsy may be confused at low power magnification with the nondiagnostic flat lesion of celiac sprue. Two features that should prevent this error are the replacement of many of the crypts with the lymphoid infiltrate within the lamina propria, suggesting an invasive process, and the malignant cytologic appearance of the lymphoid infiltrate [103] (see Fig. 142-43). Because in some patients the infiltrating cells may synthesize abnormal heavy chain immunoglobulin, it has been called immunoproliferative small intestinal disease (IPSID). [104] This disease may have a prelymphomatous stage in which there is diffuse infiltration of the mucosa by plasma cells without morphologically malignant lymphoid cells.

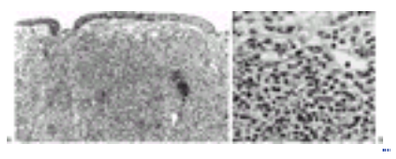

FIGURE 142-43. Primary small intestinal lymphoma (immunoproliferative small intestinal disease). **A:** The absence of crypts is noteworthy and probably reflects the destruction of the glandular architecture by the diffuse infiltrate of small lymphocytes. **B:** At higher magnification, the monotonous, atypical appearance of the lymphoid infiltrate can be readily seen.

Diagnostic Histological Features Despite Normal Villi

There are a few diseases with normal villous architecture that have other diagnostic histological abnormalities. *Amyloidosis* may be suspected when amorphous eosinophilic material is seen in the lamina propria within, or surrounding, vessel walls. This diagnosis is confirmed by staining with Congo red, which causes dichroic birefringence in polarized light (a green and reddish orange color).

The various *storage diseases* have a predilection for ganglion cells, macrophages, or endothelial cells; these cells usually are vacuolated and require special histochemical examination for diagnosis.

If the absence of plasma cells is not recognized, the small bowel biopsy in a patient with *X-linked immunodeficiency* and common variable immunodeficiency can easily be missed because the villi may be normal and it may not be appreciated that the round cells in the lamina propria are lymphocytes rather than plasma cells.

Small Bowel Infections

At least six potentially fatal opportunistic infections with specific histological features are seen in the small bowel of immunosuppressed patients: strongyloidiasis, cryptosporidiosis (Fig. 142-44), candidiasis, CMV, MAC (see Fig. 142-41), and *Isospora belli.* Other infections that may be seen in the duodenum of both immunologically competent and immunosuppressed patients include giardiasis, histoplasmosis, and cryptosporidiosis.

FIGURE 142-44. Cryptosporidiosis in an immunosuppressed individual. It can be seen in both the small and large bowel. **A:** The low-power view illustrates the shortened, blunted villi, the elongated crypts, and an inflammatory process in the mucosa. **B:** Infiltration of the lamina propria and surface epithelium by lymphocytes is evident. Cryptosporidia are barely visible at this magnification (*arrowheads*). **C:** The organisms are best seen in the high-power magnification. They appear as small, round, gray dots adherent to the apical surface of the absorptive cells. Cryptosporidia also may produce disease in immunocompetent persons, but the process is acute and self-limited rather than chronic, as it may be in acquired immunodeficiency syndrome (AIDS).

Other Rare Diseases

Other rare lesions with specific histological features include the abetalipoproteinemia with normal villi and fat-filled, vacuolated, fasting absorptive cells; *chronic granulomatous disease* with normal villi and typical clumps of vacuolated pigmented macrophages in the lamina propria; *Waldenström macroglobulinemia* with variably abnormal villi containing eosinophilic deposits of IgM-specific macroglobulin in the lamina propria; and *severe vitamin B_{12} or folate deficiency,* with its reversible epithelial macrocytosis and mild abnormalities of villous architecture.

TERMINAL ILEAL DISEASE

As experience with biopsy of the terminal ileum has accumulated, diagnostic usefulness has proven somewhat disappointing. It is of limited value in the diagnosis of Crohn's disease; although this disease frequently involves the terminal ileum, surprisingly, diagnostic epithelioid granulomas in this location are very unusual. In Crohn's disease ileal biopsy has proven less accurate than endoscopic, clinical, or surgical impressions. Ulcerative colitis, involving the entire colon, may be accompanied by "backwash" ileitis that can be impossible to differentiate from Crohn's disease. Also, one must avoid a diagnosis of chronic inflammation prompted by over-interpretation of the normal lymphoid aggregates and normal Peyer patches.

Tuberculosis may be diagnosed by histological demonstration of the organisms in granulomas with the Ziehl-Neelsen stain. *Yersinia* infection may be suspected because of its characteristic necrotizing lesions of the gut lymphoid tissue (Fig. 142-45), and PCR detection of this organism in paraffin tissue blocks of the small bowel has been described. [105] Partially obstructive *NSAID-induced diaphragms* of the ileum have been described; [106] characteristically, they are covered with ileal mucosa that has been eroded or ulcerated over the narrowed edge of the diaphragm, where there may also be crypt architectural distortion and active inflammation. Underlying the inflamed mucosa, there often is a shelf of fibromuscular and neural proliferation; transmural lymphoid aggregates that simulate Crohn's disease are also common. Seronegative arthritis may be accompanied by an acute or chronic inflammatory terminal ileal lesion and may resemble, or be associated with, Crohn's disease. [107]

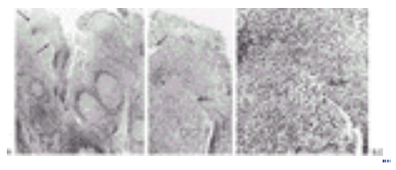

FIGURE 142-45. Yersiniosis of terminal ileum. **A:** The low-power view shows a Peyer patch in which there is erosion of the surface epithelium with adherent exudate (*arrows*). **B:** This erosion is shown at higher power. The margins of the eroded surface epithelium are indicated by the *arrows.* The inflammatory exudate extends into the underlying lymphoid tissue, in which there is a focus of necrosis (*arrowhead*). **C:** The focal necrosis (*arrowhead*) is better seen at higher power.

COLONIC TUMORS, BENIGN AND MALIGNANT

The diagnosis of benign and malignant tumors of the colon and the recognition of precancerous dysplastic lesions depend on endoscopic biopsy. A polyp is any projection from the colonic mucosal surface and is called an adenoma when composed of dysplastic tissue. In contrast, the dysplasia and early carcinoma in ulcerative colitis may not form a grossly visible lesion and is usually found in flat mucosa. The occasional adenocarcinoma seen in various polyposis syndromes also develops from dysplasia. Total excision of polypoid lesions for histological examination is the most reliable method of diagnosis and usually of treatment.

Colonic Polyps

There are four common kinds of colonic mucosal polyps:

- benign hyperplastic polyps
- adenomas with or without adenocarcinoma
- hamartomatous polyps
- inflammatory polyps. [108]

Hyperplastic polyps are the most common nonneoplastic colonic polyp. Only adenomas are neoplastic.

Hyperplastic polyps have no recognized relationship to adenocarcinoma except in the rare (0.3% incidence) *hereditary hyperplastic polyposis* (HHP). The usual hyperplastic polyp is not a marker of an increased probability of adenoma in the more proximal colon except in HHP. There are more than 20 hyperplastic polyps in the distal colon or rectum in HHP. Benign hyperplastic polyps usually are less than 0.5 cm in diameter and are often multiple. Only histological examination can differentiate hyperplastic polyps with certainty from adenomas. The frondlike, serrated, nonneoplastic epithelial surface of colonic hyperplastic polyps is diagnostic (Fig. 142-46). They are considered hyperplastic because they have an increased number of epithelial cells per unit length; the excess number of epithelial cells, squeezed into a shorter distance, buckles and causes serrated glandular profiles. Deeper in crypts, their epithelium may be crowded, depleted of mucus, and confused with an adenoma, especially in tangentially cut sections. The histological appearance of a colonic hyperplastic polyp is different from that of a gastric hyperplastic polyp. Occasionally colonic adenomas may grow in a hyperplastic polyp-like pattern; but their epithelium appears neoplastic and the significance of such lesions is the same as that for any other adenoma.

FIGURE 142-46. Hyperplastic colonic polyp. **A:** This section passes through the junction of normal mucosa and the hyperplastic polyp (*arrow*). The lumen of the normal crypts has a straight appearance whereas the crypt lumina within a hyperplastic polyp has a serrated or stellate profile. **B:** Inspection of the higher power magnification shows that this serrated appearance is caused by crowding of excess numbers of normal, nonneoplastic epithelial cells, causing them to form tufts that project into the lumen and from the lumenal surface.

The most common type of neoplastic polyp is the *adenoma.* Carefully done autopsy studies in which the entire surface of the colon is inspected with a hand lens have shown that the frequency of adenomas is around 50% for males and 40% for females in the United States. [109] Most endoscopic series that report colorectal adenomas, however, find 20% to 30% of individuals have them.

An adenoma is a grossly visible mass of dysplastic epithelium. Dysplasia is defined as neoplastic epithelium (an autonomous new growth of epithelium) that is still confined within the basement membrane of the crypt within which it arose. Because dysplastic epithelium is still confined within its basement membrane, it *cannot* metastasize. Note that all adenomas are, by definition, composed of dysplastic epithelium. Thus, it is redundant to say that “an adenoma has dysplasia.” Some pathologists grade the degree of dysplasia within an adenoma but we do not, nor did Dr. Haggitt, because grading has no prognostic significance regarding future development of additional adenomas or carcinomas.

There are three histological types of adenomas: most common are the tubular adenomas with branched tubules (Fig. 142-47); least common are the villous adenomas that are typically larger and sessile, made up of fingerlike villi and more likely to contain a focus of carcinoma invading the submucosa (Fig. 142-48). Of intermediate frequency are the tubulovillous adenomas that are a mixture of the two types. Histological typing of adenomas is not predictive of future adenomas or carcinomas, but a diameter of greater than 1 cm or an increase in the numbers of polyps is indicative of these. Thus, we see no point in grading the dysplasia of an adenoma or in determining its histological type. Excision is the appropriate treatment for all adenomas.

FIGURE 142-47. Colonic tubular adenoma. **A:** Note the characteristic tubular architecture. **B & C:** Cytologic features of the neoplastic cells lining the tubules. Nuclear enlargement, crowding and stratification, and focal diminution in mucus production are seen. These changes indicate the dysplasia seen in all adenomas.

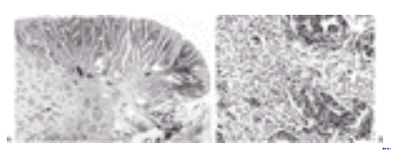

FIGURE 142-48. Electrocautery snare biopsy specimen of a sessile colonic adenoma with invasive carcinoma. **A:** Normal mucosa distorted by electrocautery artifact is shown (**lower right**). The

upper portion of the tissue is composed of villous adenoma, and (**lower left**) an invasive adenocarcinoma infiltrates below the muscularis mucosae into the submucosa. **B:** High-power view of the area marked with an *arrow* in **A** shows the prominent desmoplastic stromal reaction elicited by the invading carcinoma.

"Carcinoma in situ" in an adenoma is a term that should be abandoned. It is defined as cytologically malignant neoplastic epithelium confined within the basement membrane. Note that this definition is synonymous with HGD and thus "carcinoma in situ" *cannot* metastasize. Using the word "carcinoma" for a lesion that is not biologically malignant (because it cannot metastasize) is a great potential source of confusion. It could precipitate an unwarranted laparotomy with segmental resection or impair the patient's insurability. For this reason, most GI pathologists recommend not using the term "cancer" for such dysplastic changes. Rather, adenoma is accurate and sufficient.

"Intramucosal carcinoma" in an adenoma is defined as neoplastic epithelium that has invaded through the basement membrane into the lamina propria, but not through the muscularis mucosae. This is a rare event in the colon, but in the esophagus and stomach, invasion of the lamina propria is a meaningful diagnosis because it is associated with a low, but definite risk of nodal metastasis (approximately 3%). Nodal metastasis from carcinoma confined to the lamina propria in the colon *has never been reported.* Thus, colonic intramucosal carcinoma is *not* a biologically malignant lesion and the World Health Organization has correctly recommended abandoning this term for intramucosal colonic neoplasms. Our approach is not to look for the rare colonic adenoma with intramucosal invasion because it has no more significance than an adenoma alone and both lesions are cured by complete colonoscopic excision.

Adenocarcinoma in an adenoma is neoplastic epithelium that has invaded through the muscularis mucosae *into* the submucosa. Invasion into the submucosa is virtually always associated with a surrounding desmoplastic stromal reaction, which serves as a diagnostic hallmark for invasion and connotes a definite risk of nodal metastasis (see Fig. 142-48).

There are various logical steps in management of an endoscopically resected adenoma containing carcinoma: The first and most important step is to confirm that the lesion is invasive carcinoma. This is not as easy as it seems because "pseudocarcinomatous" invasion, or misplaced epithelium, is a fairly common finding. However, the desmoplastic stromal reaction mentioned previously as being such a characteristic feature of invasive carcinoma is the single most useful criterion to make this distinction (see Fig. 142-48). If the worrisome misplaced glands are surrounded by normal lamina propria, they are not invasive. Also helpful are the rounded appearance of the glands on low power in benign, misplaced epithelium versus the irregular, angulated and infiltrative appearance of invasive adenocarcinoma. Acellular mucin pools within the submucosa are of no differential diagnostic help because they may be associated with both benign misplaced and malignant invasive processes. After determining that the lesion is truly invasive, the pathologist then evaluates the depth of the invasion within the polypectomy specimen. A histological grade is then assigned and the lesion is scrutinized for evidence of lymphatic or blood vessel invasion. The completeness of resection is then evaluated by noting the status of the margin and finally, an estimate of the risk of metastasis can be provided based upon the foregoing information.

Nodal metastasis from a carcinoma in which the invasion extends into the submucosa of the head of a pedunculated polyp or at any level into its stalk is extremely rare, certainly less than 1%. The probability of having positive nodes from cancer arising in a pedunculated polyp becomes significant only with invasion into the level of the submucosa of the bowel wall proper.[110] Sessile adenomas containing invasive carcinoma are less likely to be cured by endoscopic excision because these cancers are more likely to extend into the submucosa of the underlying bowel. The data suggest that the overall risk of nodal metastasis is about 5% when invasion is limited to the underlying submucosa. Poorly differentiated tumors are more likely to have positive lymph nodes than well or moderately differentiated ones. The exact percentage of such cases with nodal metastasis is difficult to determine with certainty because of the small numbers of cases that are poorly differentiated and because of the frequent presence of confounding factors such as lymphatic invasion. If invasion of lymphatic channels is present, there is a high probability of positive nodes, but the exact percentage of such patients with positive nodes is difficult to determine because of small numbers of cases and the presence of confounding factors such as a poorly differentiated tumor. In fact, lymphatic invasion is unusual unless the tumor is poorly differentiated. The presence of carcinoma at the polypectomy margin, if the stalk was transected near its base, implies that invasion into the submucosa of the underlying bowel wall may be present and additional evaluation of the patient to determine whether there is residual tumor left or not needs to be carried out.

Thus, unless the patient has invasion of the tumor into the submucosa of the underlying bowel wall, a poorly differentiated tumor, or lymphatic invasion, resectional surgery appears not to be indicated because of the low risk of nodal metastasis that could potentially be cured by a resection. However, even if positive nodes are resected surgically, the 5-year survival for this Dukes C colon cancer is only approximately 40%. In fact, the 5% risk of nodal metastasis is low enough with invasion into the submucosa that an argument can be made for not proceeding with a surgical resection.

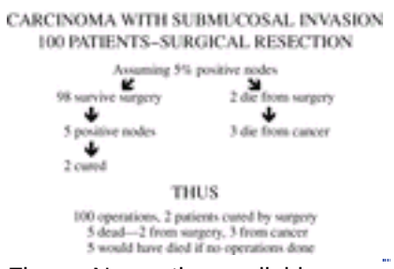

Figure. No caption available.

The status of the polypectomy margin, as an index of prognosis, is also controversial. Morson and colleagues[111] found that if the polypectomy margin was free of the tumor, regardless of the distance from the neoplasm to the electrocautery margin, the prognosis was uniformly favorable. When the carcinoma extended to the electrocautery margin, but when the endoscopist thought that the lesion was completely resected, the prognosis was again favorable. This probably reflects the destruction of an additional zone of 0.2 to 0.3 cm of tissue by the electrocautery during excision. In contrast, when the endoscopist thought that the excision was incomplete or questionable, the prognosis was less favorable. Others have suggested that extension of the carcinoma to within 0.2 cm or less of the margin is an unfavorable prognostic sign. Use of this criterion as an indication for colectomy produces a favorable outcome because the probability of nodal metastasis is distinctly low in this subset of individuals. In Dr. Rodger Haggitt's opinion, if one used extension of the tumor to within 0.2 cm or less of the margin as a criterion for surgical resection, one increased the rate of surgery unacceptably. Thus, careful communication with the endoscopist concerning his or her impression of the completeness of excision is a must in planning the optimal management for a patient with carcinoma arising in an adenoma.

The adenomas of FAP of the colon look the same as those of sporadic adenoma initially, but in the classic form of FAP they are multiple (=100), and in virtually all patients, they progress eventually to cancer if the colon is not removed prophylactically.[112] Patients with FAP have an APC gene mutation. *Hyperplastic polyposis* (HPP) is a far more rare disease than FAP; it is defined by the presence of 20 distal hyperplastic polyps.[113] HPP is often associated with adenomas, some of which contain cancer but there is no family history of colonic carcinoma. Carcinomas in HPP are found throughout the colon. Obviously, these patients need close colonoscopic surveillance. Whether they will need prophylactic colectomy as in FAP remains to be determined. *Hereditary nonpolyposis colorectal cancer* (HNPCC) is caused by a defect in mismatch repair genes. In certain kindreds there may be multiple organ cancers associated with the syndrome. The cancers in HNPCC arise in one or several adenomas rather than in multiple polyps.[113] More than 60% of the cancers are in the right colon and the tumors are both synchronous and metachronous. The colonic pathology is characteristic but not specific for HNPCC: the tumor is diploid, poorly differentiated, mucin producing, or of the signet cell type. There often are dense lymphoid infiltrates and a Crohn's like reaction. Endoscopic surveillance should begin early (5 years prior to the age of the earliest colon cancer in the family) because of the early onset of cancer and the suspicion that some of these tumors progress much more rapidly than sporadic carcinomas. Prophylactic colectomy is also a possible choice for prevention. Surveillance for extracolonic cancers in HNPCC should start at 25 to 30 years of age (uterus, stomach, ovary, etc.).

The hamartomas are an abnormal mixture of benign cells that only rarely contain cancer, and then only arising in dysplastic epithelium or adenomas. The most common hamartoma is the single pedunculated juvenile polyp in a child under 10 years of age (Fig. 142-49). It is less common in older children and adults. *Familial juvenile polyposis*[77] is hereditary and is seen in patients older than 10 years of age, may have multiple polyps involving the whole GI tract, and is associated with an increased risk of carcinoma. The juvenile polyposis of infancy may be fatal but fortunately is rare. The polyps of *Peutz-Jeghers syndrome* (PJS) are more common in the small bowel than in the colon and the polyps of Cowden disease are rare. Histologically, juvenile and Cowden polyps are more cystic and Peutz-Jeghers polyps contain highly ramified branching smooth muscle with a large benign epithelial component (see Fig. 142-31). All are genetic disorders. PJS may have other associated

malignancies, particularly breast cancer. [78]

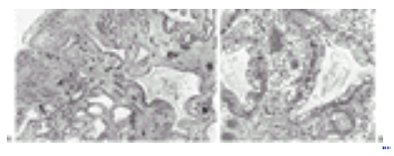

FIGURE 142-49. Juvenile polyp. **A:** The lesion is composed of dilated, irregular-shaped glands (**B**) lined by epithelium of an essentially normal appearance. The lamina propria is inflamed and edematous and contains numerous congested vessels.

Inflammatory or postinflammatory polyps, also incorrectly known as pseudopolyps, are common in areas of healed or partially healed ulcerative colitis or Crohn's colitis and may be found after ischemic or infectious colitis. These polyps often represent islands of variably inflamed residual mucosa in a "sea" of surrounding, previously sloughed, healed mucosa. Inflammatory polyps may have a filiform, sessile, or pedunculated configuration.

Colonic Carcinoma

Most sporadic colonic carcinoma originates in adenomas. Grossly, the lesser the depth of invasion and the absence of nodal metastasis, the better the prognosis (Dukes classification).

Extensive ulcerative colitis of more than 10 years duration predisposes to carcinoma. The coexistence of primary sclerosing cholangitis is an additional risk factor. [114] Such patients should be in an endoscopic biopsy surveillance program to detect dysplasia in nonpolypoid mucosa as an indication for prophylactic colectomy. Histologically, the degree of abnormality (atypia) within dysplastic epithelium forms a continuous spectrum from slight to marked. For clinical purposes, dysplasia is divided into low-grade and high-grade, based upon its degree of deviation from normal colonic epithelium. [6] The problems with dysplasia as a marker of cancer risk are: sampling error, observer variation in diagnosis, and differentiation from inflammatory reactive changes. Dysplasia may be localized to a single, small area of the mucosa, it may be multifocal, or it may be extensive and involve virtually the entire mucosa. We found that 33 biopsy samples are required to achieve 90% confidence that dysplasia would be detected if it were present. [115] We, therefore, recommend at least four biopsy specimens from each 10-cm segment of the colonic mucosa and every 5-cm segment in the rectum, based on the higher incidence of distal carcinoma in ulcerative colitis (i.e., at least one half of colorectal cancers arising in ulcerative colitis occur in the rectum and sigmoid colon). The biopsies from each segment are placed in the same bottle of fixative because we may wish to resample the same colonic area if the findings are equivocal. Thus, in a patient with a 70-cm colon, 32 biopsies would be taken and 8 blocks would be made.

Active inflammation in ulcerative colitis induces reactive and regenerative epithelial changes that can be difficult, and at times, impossible, to distinguish from dysplasia (see Fig. 142-2). For this reason, most experienced GI pathologists are reluctant to diagnose dysplasia in actively inflamed mucosa unless the abnormalities are overt. Reactive epithelium may have crowded, stratified, enlarged, hyperchromatic nuclei and abnormal mitotic figures, but the degree of nuclear atypism typically diminishes toward the lumenal surface—atypism extending onto the lumenal surface suggests dysplasia. In order to recognize abnormal epithelium involving the surface, well-oriented biopsy specimens are necessary. Abundant, eosinophilic cytoplasm is also characteristic of reactive or regenerative epithelial cells. When there is doubt about the significance of epithelial abnormalities, they should be designated as indefinite for dysplasia. If active inflammation is present, posttreatment biopsies may show a dramatic reduction in the intensity of inflammation and resolution of epithelial abnormalities, but dysplasia will be unaffected.

Flow cytometric analysis of DNA content of epithelial nuclei provides objective information about the ploidy status and cell cycle events in populations of cells. Suitable cells/nuclei for analysis can be derived readily from "jumbo" endoscopic forceps biopsies. Such biopsies measure approximately 4 to 5 mm in diameter and can be divided in half, with one half being used for flow cytometric analysis and one half for a histological control. We found aneuploid cells in 22 of 25 patients with dysplasia in ulcerative colitis, while 52 of 53 patients whose biopsies were negative for dysplasia contained only diploid populations of cells. Interestingly, 6 of 13 patients whose biopsies were indefinite for dysplasia contained aneuploid cell populations, and 5 of these patients progressed to develop dysplasia and multiple aneuploidies over relatively short follow-up. [115] The presence of multiple aneuploid populations of cells appears to be highly associated with carcinoma and may indicate high risk for progressing to carcinoma.

Other Colonic Tumors

Lipomas, fibromas, leiomyomas, and Kaposi sarcoma in AIDS are usually submucosal in location and are thus diagnosed less frequently by biopsy. Angiomas can be sampled by hot biopsy but there is some risk of bleeding. Benign, enlarged lymphoid nodules can be mistaken for neoplasms or polyposis; these nodules may be idiopathic or a reaction to infection, or they may be the benign lymphoid hyperplasia of common variable immunodeficiency.

Occasionally tumors metastatic to the colon may be recognizable as such if they retain the characteristic morphologic features of their primary site.

Carcinoids almost always are histologically invasive and have the characteristic appearance of monotonously similar cells with small round nuclei growing in cords, glands, or nests. Many colonic carcinoids that are smaller than 2 cm are indolent and can be resected endoscopically. If they recur or enlarge, segmental resection may be required.

INFLAMMATORY DISORDERS OF THE COLON (Table 142-3)

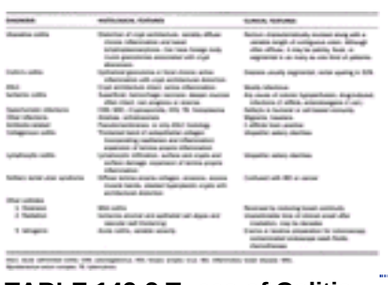

TABLE 142-3 Types of Colitis

An important function of biopsy is to establish the presence and type of colitis in various possible inflammatory disorders of the colon. It is important to emphasize that an isolated increase in the numbers of lymphocytes, plasma cells, and macrophages in the lamina propria is not by itself diagnostic of colitis. There is a wide normal variation in round cell content of the lamina propria. Numerous isolated eosinophils may be seen in the normal mucosa, especially in the right colon, in children, [116] or in patients from the southern latitudes, even within the U.S. [117] The diagnosis of colitis requires alterations in the epithelial cells or in the crypt architecture in addition to an increase in inflammatory cells in the lamina propria. These changes include infiltration of surface, or crypt epithelium by neutrophils, eosinophils, and lymphocytes; decreased mucus secretion (goblet cell depletion); distortion of crypt architecture and reactive nuclear changes, such as enlargement, vesicular chromatin, and prominent nucleoli.

Three causes of bloody diarrhea that may be confused with one another are idiopathic ulcerative colitis (Fig. 142-50), Crohn's disease (Fig. 142-51), and acute self-limited colitis (Fig. 142-52). The term idiopathic inflammatory bowel disease (IIBD) refers to both ulcerative colitis and Crohn's disease. These are both chronic diseases in contrast to acute self-limited colitis which is often of known infectious origin and is both relatively acute and self-limited. The most common reason to biopsy the colon is to help differentiate between these three diseases because their prognoses and responses

to treatment are very different.

FIGURE 142-50. Ulcerative colitis. **A:** The biopsy specimen shows disease in which the inflammatory infiltrate varies in intensity and the distortion of the crypt architecture is mild; the crypt seen in the center of the biopsy sample is branched and contains neutrophils infiltrating its epithelium and lumen. **B:** A biopsy specimen from a patient with severe disease with diffuse inflammation, distortion of the crypt architecture, and basal lymphoplasmacytosis. **C:** Atrophic mucosa in a patient with inactive ulcerative colitis; there is distortion of the crypt architecture but no inflammation.

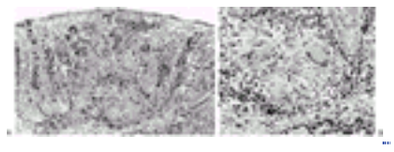

FIGURE 142-51. Crohn's disease of the colon. **A:** This biopsy specimen contains a discrete epithelioid granuloma (*arrows*) composed of multinucleated giant cells and epithelioid histiocytes. **B:** View at higher magnification power. Although inflammation surrounds the granuloma and involves some of the lamina propria, the mucosa at the left side of **A** is essentially normal, emphasizing that Crohn's colitis is commonly focal in distribution.

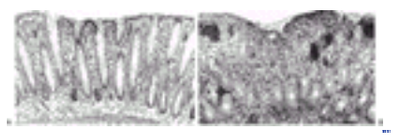

FIGURE 142-52. Acute self-limited colitis in a patient with salmonellosis. **A:** Normal mucosa for comparison with (**B**) the histological appearance of the mucosa in acute self-limited colitis. In acute self-limited colitis, there is no distortion of crypt architecture, and this differentiates it from idiopathic inflammatory bowel disease. The crypts remain as straight, evenly spaced tubules, but there is a mixed inflammatory infiltrate in the lamina propria in which neutrophils predominate over round cells. Accumulation of neutrophils within the crypt lumen to form crypt abscesses is evident, but this is a nonspecific finding seen in all kinds of colitis, as is the absence of mucus secretion in the actively inflamed mucosa.

While both ulcerative colitis and Crohn's disease undoubtedly are at some point in time truly "acute," at the time of onset of the bloody diarrhea there are virtually always histological features of chronicity, even when the duration of symptoms is quite short. [118] From a diagnostic standpoint, the presence of these features of chronicity is often more important than the acute neutrophilic inflammatory component since, in an acute inflammatory background, evidence of chronicity suggests an active IIBD (see Fig. 142-2) rather than an infectious acute self-limited colitis (see Fig. 142-52). In endoscopically normal or near-normal segments of bowel, the presence of histologically detected chronic IIBD changes (see Fig. 142-50) can be crucial to the distinction between ulcerative colitis and Crohn's disease, and thus these apparently "normal" areas must also be biopsied. Histologically a completely normal segment between abnormal segments is more suggestive of segmental Crohn's disease, whereas the presence of residual distortion of crypt architecture in endoscopically normal-appearing areas is in favor of ulcerative colitis which is more often a diffuse process.

The following features suggest chronicity (see Fig. 142-50): crypt architectural distortion, Paneth cell metaplasia (distal to the right colon), and basal lymphoplasmacytosis. Irregularities of crypt shape include branching, foreshortening, and loss of parallelism. Abnormal branching must be differentiated from normal innominate grooves. In the former, two branches of the crypt join to empty at the surface; in the latter, all crypts open independently on the surface of the innominate groove. An occasional branched gland in an otherwise normal mucosa is of no significance, as is branching adjacent to a lymphoid follicle or in proximity to the anus. Foreshortening refers to glands that fail to extend down to a level seen in normal mucosa (i.e., to nearly touch the muscularis mucosae). Loss of parallelism refers to the lack of a "rack of test tubes" architecture seen in optimally oriented normal colonic mucosa.

Marked variation in size and irregular spacing of glands are sometimes best appreciated on portions of specimens tangentially oriented parallel to the surface. Small cross-sectional glands immediately adjacent to mid- and large-size glands suggest crypt architectural distortion.

Crypt architectural distortion may accompany "diversion" colitis following mechanical diverting of the fecal stream and in "pouchitis" within an ileal pouch following ileoanal-pouch anastomosis after total proctocolectomy. Crypt distortion may also be seen in rare infections that linger for a prolonged period of time such as amoebic colitis, occasional cases of *Campylobacter jejuni, Salmonella, Shigella,* and in radiation (Fig. 142-53) or chemotherapeutic damage or chronic ischemia. A segmental colitis mimicking ulcerative colitis but limited to the sigmoid colon may occur in patients with sigmoid diverticular disease. [119] Thus, the pathologist should indicate that the changes likely represent an IIBD, but if the clinical context is not completely known, a "consistent with" modifier is appropriate. Finally, patients with IIBD are at increased risk of infection with the usual bacterial and viral pathogens. These are usually diagnosed clinically through appropriate stool pathogen cultures. One pathogen that may only be detected morphologically is CMV and it should be sought in all IIBD biopsies, particularly those with marked inflammatory activity.

FIGURE 142-53. Colitis after therapeutic radiation. **A:** After radiation the chronic changes in the mucosa are atrophic and may resemble inactive ulcerative colitis. **B:** Fibrosis of the lamina propria and hyalinization of vascular walls are shown (*arrows*). These ectatic vessels with hyalinized walls serve to distinguish radiation colitis from inactive ulcerative colitis. The surface epithelium in this biopsy sample is eroded; this may be an artifact because it is not a consistent finding in radiation colitis. Acute radiation changes, not shown here, may be indistinguishable from ischemia.

Ulcerative Colitis

In the past ulcerative colitis was believed to virtually always affect the colonic mucosa in a diffuse and circumferential manner. The disease usually involves the rectum in continuity with a variable length of colon, and when the entire large bowel is inflamed, the appendix and terminal ileum may be affected as well. There are now numerous reported exceptions to the conventional wisdom regarding the diffuse nature of the disease in ulcerative colitis. In up to one third of cases, patients with well-documented ulcerative colitis may have patchy or focal segmental inflammation. [120], [121] (see Fig. 142-50A) This is usually seen in patients whose disease is or has at one time been in remission.

The pathological findings are essentially restricted to the mucosa and upper submucosa unless there is extensive ulceration, as in fulminant colitis, in which case the inflammation may extend through the bowel wall. Paradoxically, large and deep ulcers are not typical of ulcerative colitis except when the disease is fulminant. A pronounced chronic inflammatory infiltrate consisting of many plasma cells, lymphocytes, and variable numbers of macrophages and eosinophils occupies the lamina propria and may form aggregates near the base of the mucosa (basal lymphoplasmacytosis) (see Fig. 142-50B). In contrast, the neutrophils in active ulcerative colitis tend to be localized to crypt epithelium ("cryptitis") or lumen ("crypt abscess") or marginating in capillaries; they are not found in large numbers in the lamina propria unless crypts are perforated. Numerous eosinophils, however, may be found within the lamina propria or epithelium in IIBD. In active ulcerative colitis, the goblet cell mucin is usually markedly diminished or depleted, even in crypts that are not infiltrated by neutrophils. The crypt epithelium may be hyperplastic with large, hyperchromatic, crowded and stratified nuclei that may closely resemble those seen in dysplastic epithelium, except that the nuclear changes generally mature toward the surface (see Fig. 142-2).

During the resolution phase of active inflammation in ulcerative colitis, the inflammatory infiltrate within the lamina propria may resolve in an irregular manner so that the biopsy shows what appears to be a focal inflammatory process. [120], [121] With quiescence, the neutrophilic infiltrate disappears and the intensity of chronic inflammation gradually diminishes. Biopsies taken during the inactive stage may show a characteristic appearance referred to as "atrophy" and are characterized by reduced numbers of crypts with distorted architectures best recognized by branching (see Fig. 142-50C), or they may be normal, as previously mentioned. The base of the crypt may be separated from the underlying muscularis mucosae by a long distance, and the muscularis mucosae itself may be quite thickened and its bundles of muscle separated from each other by fibrosis. The picture of "atrophic" mucosa is highly characteristic of ulcerative colitis and is seldom seen in Crohn's disease. A closely similar picture may occur in healed ischemia and radiation (see Fig. 142-53) or chemotherapy-induced colitis, so that clinical correlation is important.

Frequently there is a lack of correlation between the endoscopic appearance of the mucosa and its histological appearance. For this reason, the endoscopist should be encouraged to biopsy endoscopically normal-appearing mucosa to document that it is, in fact, normal. In children with ulcerative colitis, focal inflammation or rectal sparing may be present at the initial diagnostic evaluation. [122] Patients presenting with fulminant ulcerative colitis may also have gross and histological rectal sparing. In cases with atypical distributions, particular attention should be given to *all* of the patient's biopsies, especially those from early on in their disease, as time or treatment may influence disease distribution in ulcerative colitis.

Crohn's Disease

Crohn's disease may affect any part of the GI tract from the mouth to the anus. The small bowel alone is affected in about 30% of cases and the small and large bowel together in about 55%. [123] The colon is said to be affected by itself in 15% of cases, but this is probably overestimated. In the most common pattern of involvement, the disease affects the terminal ileum and proximal colon together. Inflammatory lesions of the anus are particularly characteristic of Crohn's disease and may occur even in the absence of inflammation of the colon. In contrast to ulcerative colitis, which it may mimic clinically, Crohn's disease usually affects the colon and the rest of the bowel in a discontinuous manner (see Fig. 142-51). In about half of patients who have colonic involvement by Crohn's disease, the rectum is spared both endoscopically and histologically. Large, linear or serpiginous ulcers surrounded by normal-appearing mucosa are characteristic, as are small, punctate erosions surrounded by a zone of hyperemia (aphthae).

True epithelioid granulomas are the most dependable criterion for the diagnosis of Crohn's disease (see Fig. 142-51). Typically, they are relatively small, compact aggregates of epithelioid histiocytes that contain variable numbers of giant cells. Not infrequently, giant cells cannot be identified. In some granulomas, the epithelioid histiocytes do not form compact nodules but rather "loose" aggregates. Such loose granulomas are more difficult to recognize and are more often related to foreign material, such as mucus, than are compact granulomas. The reported frequency with which granulomas can be identified in biopsies varies markedly between various studies. Possible explanations for this marked variation include the definition of granulomas used, whether or not isolated giant cells are mislabeled granulomas, the number of biopsies obtained, and the number of sections examined. Serial sectioning will significantly increase the yield of granulomas. [124], [125] Microgranulomas are quite small, consisting only of a few histiocytes, and can be easily overlooked. The cytoplasm of epithelioid histiocytes has a typical ground-glass appearance revealed on fine focusing at high power; this appearance reflects the excess cytoplasmic smooth endoplasmic reticulum (E.R.) in epithelioid histiocytes revealed at the higher magnifications of electron microscopy. One must be cautious about what is diagnosed as an epithelioid granuloma in colorectal biopsies. Ruptured crypts release mucin into the lamina propria, and this commonly induces a granulomatous reaction. [126] Such mucin granulomas usually include mature macrophages and foreign body–type giant cells. They can be recognized because of their predominance of giant cells and their orientation about perforated crypts. Mucin granulomas are nonspecific, and they may be seen in Crohn's disease, ulcerative colitis, infections, diverticulitis, and adenomas, among other conditions. Isolated giant cells in the lamina propria occur in similar settings and should likewise not be considered as evidence of granulomatous inflammation in the colon; if located in the basal portion of the mucosa, they are characteristic of IIBD but may be seen in both ulcerative colitis and Crohn's disease. Biopsies from patients with Crohn's disease may also demonstrate aphthous lesions. In the absence of another known cause of aphthous lesions (e.g., *Yersinia enterocolitica*), their presence is very suggestive of the diagnosis of Crohn's disease.

Aphthous-like lesions may also be seen endoscopically in patients who have received sodium phosphates orally or by enema. Histologically, these are prominent lymphoid follicles with reactive changes in the adjacent mucosa. These do not indicate colitis and are a bowel preparation artifact.

Normal areas of colonic mucosa alternating with focal areas of inflammation favors Crohn's disease over ulcerative colitis but ulcerative colitis can become patchy over time, especially with remission and with new immunosuppressive therapies. A variant of untreated ulcerative colitis that must not be confused with Crohn's disease is the "cecal patch" of colitis in which the cecum is discontinuously involved. [121] Occasionally, clinically typical Crohn's disease shows diffuse inflammation that is indistinguishable from ulcerative colitis; unless typical epithelioid granulomas are present, this colitis must be classified as IIBD of indeterminate type. The latter is a diagnosis that we make infrequently. Correlation of clinical activity with biopsy appearance in Crohn's disease is even less dependable than that seen in ulcerative colitis and the typical atrophic appearance of quiescent ulcerative colitis is not often seen in Crohn's disease.

The pathology of postoperative ileoanal pouches in ulcerative colitis overlaps substantially with that of Crohn's disease, and Crohn's like complications are also seen. This does not mean that the original diagnosis of ulcerative colitis was incorrect.

Acute Self-Limited Colitis

Colorectal mucosal biopsy plays an important role in the management of patients with the acute onset of often bloody diarrhea. The endoscopic appearance of acute self-limited colitis is indistinguishable from that of ulcerative colitis. In marked contrast to the histological appearance of acute self-limited colitis (see Fig. 142-52), when a patient with the initial symptoms of IIBD is seen for the first time, even if symptoms have only been present for a few days, the characteristic distortion of crypt architecture and marked, chronic inflammation of the lamina propria are present in colorectal biopsies (see Fig. 142-2). [118], [127], [128] The absence of these key features signifies that the disease process will probably pursue an acute, self-limited course and is, therefore, most likely infectious. [118], [128] In the characteristic picture of acute self-limited colitis crypt architecture is well preserved, and polymorphonuclear leukocytes predominate in a lamina propria that lacks the prominent chronic inflammatory infiltration of IIBD. [118], [128] As in ulcerative colitis, goblet cell mucin may be diminished or absent, neutrophilic infiltration of the crypt epithelium (cryptitis) may be present, and crypt abscesses may be seen. Crypt abscesses associated with a prominent infiltrate of macrophages, producing the appearance of granulomatous inflammation, suggest *C jejuni* infection or *Salmonella.* Pseudomembranes are most commonly seen with *Clostridium difficile*-induced colitis, but are nonspecific and may be seen in other types of colitis, including *E coli* 0157:H7. [129], [130] The latter may produce an appearance that is indistinguishable from ischemic colitis (Fig. 142-54). The changes include, in addition to the other characteristic features of acute self-limited colitis, mucosal hemorrhage, capillary thrombosis, and necrosis.

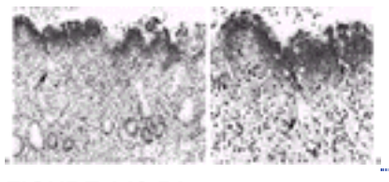

FIGURE 142-54. Ischemic colitis. **A:** The upper part of the mucosa is necrotic whereas the deeper portion remains viable. The *dark band* along the surface of the mucosa represents hemorrhage. The *arrow* points to a crypt basement membrane devoid of epithelial cells because they have become necrotic and sloughed off (crypt ghost). Notice the relatively mild inflammatory infiltrate. **B:** The eroded surface epithelium, superficial hemorrhage, and crypt ghosts (*arrow*) are seen at higher power.

In about half of patients who have acute self-limited colitis that is presumably infectious, the stool cultures and examination for ova and parasites are negative. Thus, the biopsy is quite helpful in determining whether the patient with acute bloody diarrhea has a self-limited process or chronic IIBD. In the general population of the United States, the most common enteric pathogens cultured in the acute self-limited colitides are *C jejuni, Salmonella* species, *E coli* 0157:H7, and *Shigella* species. Cultures are essential for planning appropriate treatment. When none of these pathogens is identified, the causative organism may be an invasive *E coli* that cannot be distinguished from nonpathogenic *E coli* without tissue culture assays or DNA probing.

Ischemic Colitis

Ischemic colitis from vascular hypoperfusion can have a wide variety of causes. [131], [132] Clinically its diagnosis can be difficult and biopsy often is required. In patients with acute ischemic injury, the bowel wall may be friable, but biopsy specimens can be taken safely if done carefully. Black or dusky bowel which may be infarcted should not be biopsied.

The histological hallmarks of ischemic colitis include necrosis of the upper part of the mucosa with sloughing of epithelial cells from the surface and upper regions of the crypts, while the epithelium in the deeper part of the mucosa may remain intact (see Fig. 142-54). A superficial zone of hemorrhage corresponds approximately to the region of necrosis of epithelial cells. Pericryptal basement membranes from which the epithelium has sloughed are called crypt ghosts. Capillary thrombi are prominent. Inflammatory cells, including mostly neutrophils but with a few mononuclear cells, are present but in relatively small numbers unless infection supervenes. The submucosal edema typical of ischemic colitis may produce a bleb that is occasionally removed like a polyp and submitted for histological examination. Such blebs are responsible for the “thumbprints” seen on roentgenograms. In patients with transitory mucosal ischemia, regeneration rapidly occurs and produces changes in the epithelial cells that can be misinterpreted as dysplasia or carcinoma. Ischemic colitis most commonly occurs in the absence of an occlusive vascular lesion. [133]

Patients who develop ischemic lesions of the intestine without vascular occlusion do so because of hypoperfusion of the mesenteric vasculature. [132], [134] The hypoperfusion can be due to a wide variety of causes, but the most common are cardiac failure or arrhythmias, digitalis toxicity, shock, and septicemia. [133] The physiology of the mesenteric circulation is such that a countercurrent exchange mechanism reduces oxygen content in the upper portion of the mucosa while it remains normal in the lower. [135] Consequently, the upper mucosa, which is relatively hypoxic under normal conditions, is particularly vulnerable to the effects of hypoperfusion and may become necrotic while the lower mucosa remains intact.

Ischemic lesions are more common in the colon than in the small bowel, probably because of the vast collateral network in the small bowel. Ischemic colitis may follow three courses depending upon the duration of the ischemic episode and the extent and depth of the lesion. If the ischemia is transitory, only superficial necrosis is produced, and spontaneous healing with no sequelae may occur. Following more prolonged ischemic episodes, the necrosis extends deeper into the bowel wall so that the muscularis propria may be affected. Recovery is usually accompanied by prominent submucosal fibrosis with stricture formation. After prolonged acute ischemia, necrosis of the full thickness of the bowel wall develops, and perforation, peritonitis, and sepsis result in a high mortality rate. Morphologically, one may see all stages at the same time in different biopsies, with necrosis restricted to the superficial mucosa, various depths of mucosal destruction, and ulcers.

Ischemic colitis developing in a younger person or in a patient without apparent predisposing factors, such as cardiac failure or arrhythmia, should suggest a vascular occlusive lesion, such as arteritis, intravascular coagulation, atheroembolism, amyloidosis, volvulus, or thromboangiitis obliterans. [136], [137] Several examples of ischemic colitis that were apparently induced by cocaine have been reported. [138] The mechanism of this ischemia is probably related to the potentiating action of cocaine on norepinephrine. Venous stenosis due to a spectrum of lesions ranging from various types of phlebitis to myointimal hyperplasia may also occur in young people. [139], [140] These mesenteric venoocclusive lesions are of unknown etiology and appear to have a favorable prognosis after resection. Ischemia in young persons taking NSAIDs has been described, as has ischemic colitis in young women taking oral contraceptive agents. In some young patients with ischemic colitis, no apparent cause for the decreased blood flow is ever found. A group of other colitides that probably arise on an ischemic basis and which morphologically resemble ischemic colitis includes: *E coli* 0157:H7, some forms of pseudomembranous colitis, uremic colitis, radiation colitis, and colitis that accompanies some obstructive lesions. [134], [141], [142] and [143]

Infectious Colitides

Sexually transmitted rectal infections include gonorrhea, herpes simplex, chlamydia, syphilis, amebiasis, and the various other enteric pathogenic bacteria. [144] The persisting opportunistic infections in AIDS each have characteristic organisms: Cryptosporidia which may involve the small and large bowel (see Fig. 142-44), MAC, and rotavirus in children. CMV, HSV, tubercle bacilli (Fig. 142-55), and *Histoplasma* species (Fig. 142-56) also are seen. Schistosomal colitis (Fig. 142-56) is an important and extremely common problem in the rest of the world but is only occasionally seen in foreigners or international travelers in the United States. It is diagnosed by finding the characteristic eggs, often within epithelioid granulomas. A section through the edge of a granuloma may miss the egg and be confused with Crohn’s colitis, but inspection of serial sections can overcome this problem. Amebic colitis (Fig. 142-57) in nonendemic areas of the U.S. is seen mostly in travelers, migratory workers, and homosexual men. When amebic colitis is suspected, special care must be taken while obtaining and handling the biopsy specimen to avoid removing adherent mucus containing the amebae. Do not orient such specimens; just drop them into fixative and let the technician attempt orientation after fixation.

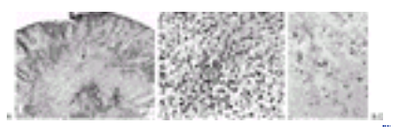

FIGURE 142-55. Colonic tuberculosis in a patient with acquired immunodeficiency syndrome (AIDS). **A:** The biopsy specimen shows inflammation of the colonic mucosa with multiple, large, confluent granulomas. The *arrow* points to a focus of necrosis within a granuloma. **B:** This shows the same biopsy specimen as in panel **A,** at higher power. Necrosis within granulomas should always suggest an infectious agent. **C:** Ziehl-Neelsen stain in which acid-fast bacilli of *Myobacterium tuberculosis* are evident. The tissue response to *Myobacterium avium* complex differs in that granulomas and diffuse granulomatous inflammation with discrete aggregates of epithelioid histiocytes are not seen; rather, there is diffuse infiltration of macrophages with foamy cytoplasm filled with acid-fast bacilli (see Fig. 142-41).

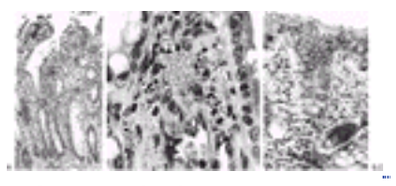

FIGURE 142-56. A: Colonic histoplasmosis in a patient with disseminated histoplasmosis in acquired immunodeficiency syndrome (AIDS). Distorted glandular architecture and an inflammatory infiltrate in the lamina propria are shown. **B:** Inspection of the inflamed lamina propria at higher power reveals a foamy or bubbly appearance caused by numerous *Histoplasma* organisms within the cytoplasm of macrophages. The organisms are seen as clear vacuoles, many of which contain a dark central dot representing the nucleus. **C:** Biopsy specimen from a patient with schistosomiasis. The ovum is clearly identified in the lamina propria and can be diagnosed as a schistosome, but speciation is not possible except in the rare circumstance in which the plane of section passes through a lateral spine of *Schistosoma mansoni.*

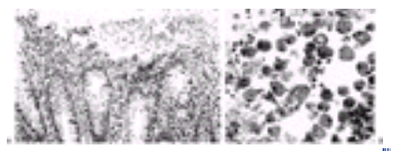

FIGURE 142-57. Amebic colitis. **A:** The mucosa shows diffuse inflammation of the lamina propria and an eroded surface. The material adherent to the surface includes erythrocytes and numerous amebic organisms. **B:** These are seen at high power. The organisms are large cells, measuring approximately 30 µm in diameter. They have a relatively small nucleus compared with the cytoplasmic volume. Phagocytized red blood cells are visible as black round structures within several of the amebae.

The most common antibiotic-related colitis is caused by overgrowth of *C difficile,* which secretes specific toxins. Although colitis caused by *C difficile* usually is called pseudomembranous colitis (Fig. 142-58), only 50% of patients have pseudomembranes at the time of biopsy and pseudomembranes are also seen in other colitides. With or without pseudomembranes, the histological pictures may be indistinguishable from acute self-limited colitis.

FIGURE 142-58. Pseudomembranous colitis caused by *Clostridium difficile.* **A:** This biopsy specimen shows features of an acute self-limited colitis with active inflammation of the lamina propria, erosion of the surface epithelium, and adherent fibrinopurulent exudate (pseudomembrane), but preservation of the crypt architecture. Most of the inflammatory cells are neutrophils. **B:** The erosion of the surface epithelium, the pseudomembrane, and the predominantly neutrophilic infiltration are well illustrated at high-power magnification. This picture has features also seen in ischemic colitis.

Collagenous Colitis

In collagenous colitis there is troublesome, often persistent watery diarrhea, for as long as 15 years, frequently in older women with a normal colonoscopy. [145] On biopsy there is a thickened collagen plate (=15 microns, the diameter of two red cells) located beneath the surface epithelium but not around the crypts (Fig. 142-59). It has a spiculated and irregular appearance due to an incorporation of capillaries and inflammatory cells within the collagen and due to projections of collagen into the underlying lamina propria. This produces a striking contrast to the normal basement membrane which has a uniform straight lower border. These qualitative changes in the collagen plate may be as important as the absolute thickness of the subepithelial collagen in establishing the diagnosis of collagenous colitis. [146] The collagen deposition may be diffuse or patchy and tends to be least prominent in the distal sigmoid and rectum. The superficial lamina propria may be expanded by increased numbers of round cells. Occasionally the rectum is not involved and colonoscopy with more proximal sampling may be necessary for diagnosis. The crypt architecture is almost always well preserved and about half of patients have a focal, mild neutrophilic infiltration of the crypt epithelium which tends to be observed early in the course of disease rather than later. If the neutrophils are prominent, bacterial infection must be ruled out. Lymphocytosis of the surface and crypt epithelium may be present and surface cell damage may be prominent. Collagenous colitis does not have enough inflammatory change or architectural distortion to resemble IIBD. Patchy collagenous thickening however can occasionally be seen in IIBD, ischemic colitis, and other conditions. Rarely amyloid may mimic collagenous colitis.

FIGURE 142-59. Collagenous colitis. **A:** This biopsy specimen shows normal glandular architecture, a possible increase in the number of plasma cells in the upper portion of the lamina propria, and a markedly thickened subepithelial collagen plate. The surface epithelium is abnormal and infiltrated by lymphocytes. **B:** These changes are seen better at higher power. Observe the lacy or reticulated appearance of the thickened subepithelial collagen table, which incorporates inflammatory cells and capillaries.

Lymphocytic Colitis

This is an entity in which patients have diarrhea and other symptoms and a normal appearance on colonoscopy. [147] It is remarkably similar symptomatically to collagenous colitis. However histologically there is no excessive collagen but rather a prominent lymphocytic infiltration of the surface and crypt epithelium with expansion of the lymphocytic content of the lamina propria. Like collagenous colitis, lymphocytic colitis is idiopathic and has preservation of the crypt architecture, so the histological picture is not likely to be confused with IIBD.

The term “microscopic” colitis [148] is applied to both collagenous and lymphocytic colitis as well as to patients with chronic diarrhea of unknown origin in general who have no endoscopic abnormalities. These patients may have mild inflammation on biopsy and are a heterogenous group that has only chronic diarrhea, normal endoscopy, and mild histological inflammation in common. Other causes are various drug-induced injuries. Thus, the term does not refer to a specific disease entity and should be replaced by more specific terminology whenever possible.

Patients with chronic, watery diarrhea and histological findings similar to lymphocytic colitis have been described in an epidemic of diarrhea traceable to a point source. [149] Thus, the histological features of lymphocytic and collagenous colitis seen in patients with chronic, watery diarrhea may reflect reaction patterns to a variety of injuries, rather than specific disease entities.

Other Colitides

There are a variety of other colitides. Diversion colitis usually is a mild colitis that occurs when the colon is excluded from the fecal stream. [150] Restoration of the fecal stream to the diverted colon reverses the process. Radiation colitis has an acute mucosal phase resembling acute ischemia and a more chronic mesenchymal phase with atypical fibroblasts, scarring, and telangiectatic capillaries that may have hyalinized walls. [151] It is an unpredictable process that may become clinically manifest at any time from months to years after irradiation.

Finally, a number of colitides are iatrogenic. Endoscopes may be inadequately rinsed after use of sterilizing solutions or wash water may be contaminated. For example, a microvesicular form of pneumatosis intestinalis can be caused by the accumulation of gas bubbles after inadvertent exposure to hydrogen peroxide (Fig. 142-60A) or by insufflation of gas into microtears in the mucosa during endoscopy. [152] Less dramatic are the changes produced by various methods of cleaning the colon in preparation for colonoscopy. Many cleansing enemas can cause active surface inflammation and edema. [153] A bisacodyl enema may produce a confusing picture that can easily be considered colitic (see Fig. 142-60B, Fig. 142-60C). [154] Gastrografin used as an enema instead of barium is hypertonic and highly irritating.

FIGURE 142-60. Pseudolipomatosis and other artifacts. **A:** Pseudolipomatosis of the lamina propria after inadvertent exposure to hydrogen peroxide left after cleaning the wash channel of the colonoscope. The bubbles in the lamina propria represent gas bubbles caused by the release of nascent oxygen when hydrogen peroxide contacted the mucosa. These bubbles can be differentiated from fat cells because they lack a cell membrane and vary markedly in size. **B:** The mucosa in a patient who has received a bisacodyl enema. The surface epithelium is flattened and contains focal infiltrates of neutrophils (*arrow*). **C:** Focal neutrophilic infiltration of the abnormal surface epithelium at higher power (*arrow*).

A variety of chemotherapeutic agents can cause extensive mucosal injury. This is especially well documented with 5-fluorouracil. [155] Colitis associated with bone marrow transplantation is complex; [93] the early lesion is caused by the preparatory irradiation and chemotherapy and the later lesions represent graft-versus-host reaction or opportunistic infections.

Focal active inflammation is not uncommonly identified in colonic biopsies. Surface apoptosis may also be prominent. The clinical significance of these findings is hard to assess and should probably not be referred to as colitis. These changes may very well be related to bowel preparation.

Solitary Rectal Ulcer Syndrome

Solitary rectal ulcer syndrome [156] (SRUS) is also known by other, perhaps better, terms such as mucosal prolapse and localized colitis cystica profunda. It is a distinct clinical entity and has a characteristic but nonspecific histological appearance (Fig. 142-61). The term is a misnomer because the lesions may be multiple, they may involve the sigmoid as well as the rectum, and usually have erosions rather than ulcers or may lack both. This entity may be confused clinically with the ulcers of Crohn's disease or with ulcerative carcinoma because of the hard lumpy tissue palpable around the ulcer. The thickened tissue may be filled with diffuse collagenous granulation tissue, [157] excess muscle bundles, and lengthened crypts with epithelial hyperplasia.

FIGURE 142-61. Solitary rectal ulcer syndrome. **A:** The biopsy specimen shows erosion of the surface epithelium, obliteration of the lamina propria by fibrosis, granulation tissue and smooth muscle, and gross distortion of the glandular architecture. Hyperplasia of the glandular epithelium also is seen. **B:** At higher power the eroded surface epithelium and obliteration of the lamina propria by collagenous granulation tissue and fibroblasts is better seen. Observe the epithelial hyperplasia that occasionally results in the misinterpretation of these lesions as adenomas or even cancer.

In 10% to 15% of patients, cystic glands penetrate into the submucosa to form so-called colitis cystica profunda; [156] these ectopic glands are benign and have no desmoplastic stromal reaction surrounding them to suggest invasive malignancy. [158] Histologically, there may be gross distortion of crypt architecture and erosion of the surface epithelium with adherent exudate producing a "pseudomembrane." The muscularis mucosae is markedly hypertrophic and disorganized and bundles of smooth muscle and collagen extend high into the lamina propria around the crypts. The epithelium may appear quite hyperplastic and atypical, but it matures as it approaches the surface where the cytologic features of neoplasia are not present.

Other Diagnoses

Other diagnoses by biopsy include melanosis coli, a benign collection of lipofuscin-containing macrophages caused by laxatives, and pneumatosis cystoides intestinalis, marked by gross polyps on colonoscopy that contain gas-filled spaces in the submucosa lined by giant and epithelioid cells. [152]

COST EFFECTIVENESS

Taking a sufficient number of adequately sized biopsy specimens and orienting and processing them in the manner suggested is more costly than routine biopsy. Currently, less comfortable, large-diameter operating endoscopes must be used to take large biopsies; but smaller-diameter endoscopes with larger biopsy channels will be generally available and should remedy this problem. An extra assistant is helpful to orient the specimens correctly without prolonging the procedure but the endoscopy may take longer if more specimens are needed for optimal diagnosis. Step-serial sectioning and special staining also require some extra effort and expense.

Is this compulsive approach worth the effort? We believe that it is for ulcerative colitis [115] and Barrett esophagus surveillance. [7] In the long run our approach may not be more costly. [159] This is because the surveillance interval may be extended in patients who are negative for dysplasia (the majority) because of the high level of diagnostic confidence our approach achieves. In our two teaching hospitals our approach has been self-supporting and has not required subsidization. Those who have been exposed to both approaches firmly believe that the more compulsive technique detects more focal lesions, may be more accurate in the diagnosis of dysplasia and early carcinoma, permits better evaluation of abnormalities of mucosal architecture, and is easier to read.

An incorrect diagnosis of cancer followed by an operation is costly, especially if complications or death occur. Similarly, it is difficult to estimate the cost and distress of the patients and their families that could be avoided if an early, curable cancer had been diagnosed in time. The same considerations apply to more accurate biopsy diagnosis of certain other diseases. The problem is that there may be no way to know which patients need this extra effort at the time of endoscopic biopsy. Ideally all biopsy specimens should be taken and processed as suggested to increase diagnostic accuracy and improve patient care.

Acknowledgments

We gratefully acknowledge the help of two trusted colleagues of Dr. Haggitt, Dr. Henry Appleman and Dr. Pat Dean, who reviewed this chapter to help assure the authenticity of the opinions ascribed to Dr. Haggitt by the authors. We also acknowledge the help of Dr. Haggitt's last two gastrointestinal Fellows: Dr. Victoria Reyes and Dr. Jason Sprouse, and of our faculty colleague Dr. Shari Taylor. Their emotional support and daily help with reading the many biopsies formerly sent to Dr. Haggitt helped preserve the Haggitt tradition during the years following his untimely death. These individuals and three Fellows in gastrointestinal pathology, Dr. Brian Folz, Dr. Tara Mitchell, and Dr. Paul Edmonson also reviewed the chapter for authenticity. We also acknowledge our debt to them.

CHAPTER 143

Sugantha Govindarajan and Maurizio Bonacini

LIVER BIOPSY AND HISTOPATHOLOGICAL DIAGNOSIS

This chapter describes the morphologic changes of various disease processes as one attempts to interpret the needle biopsy of the liver. Attention is drawn to the most important changes one should be aware of while analyzing a liver biopsy to arrive at a diagnosis and differential diagnoses. Sections in other chapters deal with more detailed analysis of these disease processes.

The first step in liver biopsy interpretation is recognition of the lobular architecture differentiating normal from fibrosis, cirrhosis, and noncirrhotic nodular regeneration. Systematic analysis of the hepatic lobule starts with the examination of the portal tract, followed by terminal hepatic veins, and the assessment of the parenchyma and the sinusoidal spaces. Based on this analysis, the following differentiations are made: acute versus chronic; parenchymal versus biliary disease; list of possible etiologic factors; if neoplastic, benign versus malignant; and primary versus metastatic.

TECHNIQUE OF LIVER BIOPSY

The most common method of liver biopsy is transcutaneous (transthoracic or subcostal) with or without ultrasound or computed tomography (CT) guidance. [1,2] Occasionally, biopsies are taken via the transjugular route (useful in patients with severe coagulopathy) or during surgery. [2] Needles used for liver sampling rely either on suction (Menghini, Klatskin, and Jamshidi) or cutting technique (Tru-cut and Vim Silverman). [2] The latter technique is applied with a spring load mechanism (Quick-core or similar) that allows a specific length of tissue, usually 15 to 20 mm, to be retrieved with a minimum of needle manipulation in the liver parenchyma. [3] In cirrhotic livers, cutting techniques result in less fragmented specimens than the suction technique. Most percutaneous liver biopsies result in the retrieval of sufficient liver tissue for diagnosis after a single pass, but more than one pass is required in 4% to 12% of patients. [1,4] The use of real-time imaging (ultrasound more cost-effective than CT) or ultrasound X-marking of the entry site prior to biopsy has significantly decreased the percentage of patients who experience pain requiring analgesia (50%–35%) [1,2,4] as well as the chance of hospitalization. [1] A decrease in mortality has not been shown, [1,4] but the sample size required to show a difference would be exceedingly large.

Patients with coagulopathy (platelets < 60,000 or PT > 4 seconds above normal) can be biopsied transcutaneously after infusion of platelets and fresh frozen plasma, or via the transjugular route. [2] Patients with inherited bleeding disorders such as hemophiliacs can be biopsied transcutaneously, provided they are infused with the appropriate coagulation factors and are followed by experienced hematologists during the peribiopsy period. [5]

Complications of percutaneous liver biopsy that lead to hospitalization are rare and include severe pain (2%), hemoperitoneum (0.04%), hemobilia (0.01%), and sepsis (0.01%). [6,7] Hemo-, pneumo-, or hydrothorax was reported in 0.07% of cases. [6] Perforations of other organs such as gallbladder, lung, colon, kidney, or adrenal gland have all been described. [1,4,6] The vast majority of complications occur within the first 3 hours after biopsy, so a 4- to 6-hour monitoring period is usually carried out, with a friend or family member to take charge of the patient for 24 hours. [7] Death, reported in 1 per 10,000 cases, is always due to massive hemoperitoneum, and most often associated with cirrhosis or malignancy. [6]

The risk of bleeding appears to increase with the number of passes, so only two are customarily allowed. There is little difference in the complication rates that occur with trainees versus attendings [7] and with suction, cutting, or spring-load techniques. [1,4] The role of a lower needle gauge (14G vs. 16 or 18G) or the use of “plugging” devices in the chance of complications is unsettled. [2] As mentioned, the transjugular route is used by interventional radiologists in the most difficult cases, often with advanced liver diseases or bleeding diathesis. [2] Postprocedure complications appear to occur more often than with percutaneous biopsy.

PROCESSING OF LIVER BIOPSY TISSUES

Fixation and processing technique vary from laboratory to laboratory; however, the most commonly used fixative is 10% buffered formalin. For crisp nuclear details and rapid fixation, we use B5 solution containing 6 g of mercuric chloride, 2.074 g of hydrated sodium acetate dissolved in distilled water and mixed with 10 mL of 40% formaldehyde (pH 5.8) at time of use. Embedding in plastic resins such as araldite improves the ability to obtain thin (2–3 μm) sections with greater cytologic details, such as cellular mitochondria or microvesicular fat over paraffin embedding. [8] Besides regular hematoxylin and eosin (H & E) stains, the most useful routine stains are Masson trichrome for collagen (Fig. 143-1; see also Color Fig. 143-1), periodic acid-Schiff (PAS) for glucose, diastase-digested PAS for glycoprotein (i.e., a $_1$-antitrypsin) (Fig. 143-2; see also Color Fig. 143-2), iron stain (Fig. 143-3; see also Color Fig. 143-3), Shikata orcein stain for hepatitis B surface antigen (HB $_S$Ag) (Fig. 143-4), and copper binding proteins (Fig. 143-5), and reticulin stain for identification of cord sinusoidal structures. Other special stains helpful in diagnosis are those for acid-fast and fungal organisms in cases of granulomata, phosphotungstic acid-hematoxylin for fibrin in disseminated intravascular coagulation or necrosis in cases of Q fever, rubeanic acid for copper, and immunoperoxidase stains for viral proteins, a $_1$-antitrypsin, a-fetoprotein, factor VIII, and others.

Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Special Requirements

Frozen sections of fresh or fixed tissue are needed to demonstrate fat with oil red “O” stain in cases of Reye syndrome, fatty liver of pregnancy, and fat-soluble vitamin A in Ito cells in hypervitaminosis A. For quantitative analysis of hepatic copper or iron, a part of the tissue needs to be saved either fixed or fresh frozen prior to processing for paraffin embedding. Electron microscopic examination is not a routine necessity and is used for special studies.

SYSTEMATIC APPROACH TO THE REVIEW OF LIVER BIOPSY

The biopsy section should be reviewed on low-power field to screen all fragments present in the section. At this time, an evaluation of the overall architecture is made. Regularly placed portal tracts and hepatic venules with their proper relationship constitute normal architecture. The portal areas can be expanded with fibrosis. When there are fibrous septa from portal to portal or to perivenular areas with formation of regenerative nodules, a diagnosis of cirrhosis is made (see Fig. 143-1). In nodular regenerative hyperplasia, the parenchyma exhibits regenerative nodules compressing the adjacent hepatic cords without fibrous tissue around them (Fig. 143-6). Collapsed reticulin fibers can be differentiated from true fibrosis by reticulin and trichrome stains. When there is confluent or submassive liver necrosis, there is loss of hepatocytes from hepatic cords resulting in a collapsed or compressed reticulum network. If this occurs in the perivenular region, it can mimic fibrosis (Fig. 143-7). Immediately following the overall assessment of the hepatic architecture, special attention is paid to each of the elements of the hepatic lobule.

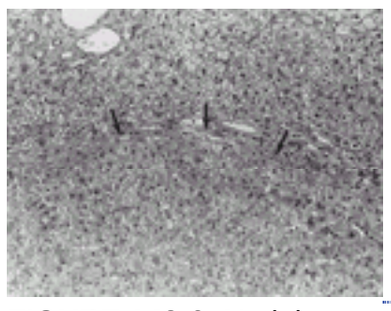

FIGURE 143-6. Nodular regenerative hyperplasia demonstrating regeneration of parenchyma (*arrows*) compressing the surrounding parenchyma without fibrous septa formation. (H & E stain; original magnification ×40.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Portal Areas

Enlargement of the portal tracts can be due to either cellular infiltration or fibrosis. Cellular infiltrate can be of inflammatory reactive changes, such as in a variety of viral, drug-induced, or autoimmune types of hepatitis, or neoplastic infiltrate, such as lymphomas. Inflammatory infiltrates are further categorized as acute with neutrophils, usually seen in acute cholangitis with orientation around the dilated ducts due to biliary obstruction (Fig. 143-8) or diseases such as oriental cholangiohepatitis. Predominant eosinophilic infiltrates, not oriented to the ducts, can be seen in allergic drug reactions (Fig. 143-9; see also Color Fig. 143-9), parasitic diseases, and acute rejection following liver transplantation (Fig. 143-10; see also Color Fig. 143-10). Among the inflammatory infiltrates of mononuclear type, predominant plasma cells are seen in autoimmune chronic active hepatitis (CAH) (Fig. 143-11), mixed mononuclear cells are seen in viral-induced chronic active hepatitis, and cells oriented around the bile ducts are seen in primary biliary cirrhosis. Portal tracts may contain granulomata due to various etiologies, as well as hypertrophic macrophages with phagocytized pigments, such as iron or foreign material. Polarizable talc crystals are often seen in intravenous drug abusers (Fig. 143-12; see also Color Fig. 143-12). The pattern of portal fibrosis varies with the type of disease. For example, in chronic biliary tract diseases, the fibrosis is often periductal, concentric, and lamellar (Fig. 143-13) in nature, while in chronic alcoholic liver disease and in CAH of non-A, non-B type, it is arachnoid with irregular extension into the parenchyma (Fig. 143-14; see also Color Fig. 143-14). Bile ducts are involved in acute as well as chronic disease processes. In acute cholangitis, usually due to mechanical obstruction, there is dilation of the duct with periductal edema and polymorphonuclear leukocytes infiltrating the duct epithelium and within the duct lumina (see Fig. 143-8). In chronic biliary obstruction, there is bile duct proliferation and biliary fibrosis with periductal orientation (Fig. 143-15). Periductal concentric fibrosis is also seen in sclerosing cholangitis (Fig. 143-16). There is chronic inflammatory reaction involving the duct epithelium in early stages of primary biliary cirrhosis (PBC) (Fig. 143-17) and, in the late stage, the ducts are absent. Similar changes are seen in chronic rejection of liver transplantation. Anomalous duct changes include Meyenburg complexes (Fig. 143-18) and cystic disease such as Caroli disease. Paucity of bile ducts is seen in intrahepatic biliary atresia while biliary fibrosis and bile duct proliferation are seen in extrahepatic biliary atresia (Fig. 143-19). Portal veins are thin-walled vascular structures, and are increased in number and dilated in portal hypertension (Fig. 143-20). There is inflammation and thrombosis of portal veins in pyelephlebitis. Primary or metastatic tumors can be seen in the portal venous structures. Hepatic artery can reveal hyalinization in diabetics. Polyarteritis nodosa and giant cell arteritis can produce typical inflammatory reaction involving the arterial wall (Fig. 143-21). There is arterial hypoplasia in congenital hepatic fibrosis. In Osler-Weber-Rendu syndrome there is an increase in abnormal vascular channels suggestive of arteriovenous shunting (Fig. 143-22). There is deposition of amyloid on the arterial wall in systemic amyloidosis.

Terminal Hepatic Venules

Terminal hepatic venules are thin, endothelial-lined vascular spaces without collagen deposition. There is perivenular fibrosis in most types of alcoholic liver disease (ALD) (Fig. 143-23). Endophlebitis with inflammatory reaction of terminal hepatic venules is seen in acute rejection of liver transplantation (Fig. 143-24). In Budd-Chiari syndrome, there is obliteration of the terminal hepatic veins along with hemorrhagic necrosis of the perivenular hepatocytes and dilation of sinusoids (Fig. 143-25).

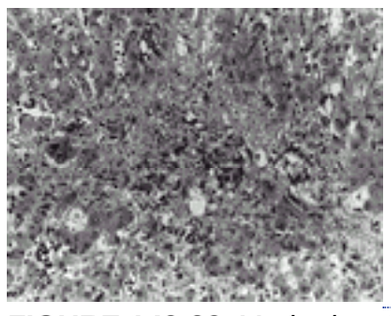

FIGURE 143-23. Marked perivenular fibrosis in alcoholic liver disease. (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

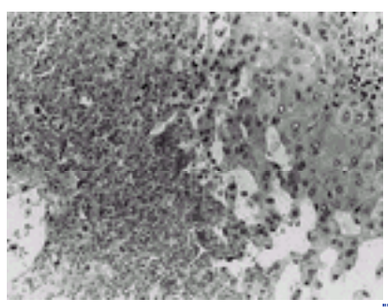

FIGURE 143-25. Budd-Chiari syndrome with perivenular hemorrhage, necrosis, and sinusoidal dilation. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Hepatic Parenchyma

The hepatic parenchyma should be evaluated with orientation to the three zones of Rappaport. Zone 3, or the perivenular zone, is most susceptible to anoxic changes and most drug-induced liver necrosis occurs here. Acute alcoholic injury, as well as acute viral hepatitis, reveals a predominance of zone 3 involvement. Periportal cell necrosis can be seen in some cases of acute type A viral hepatitis, in ferrous sulfate toxicity, and in toxemia of pregnancy. The term *spotty necrosis* is used when there are small scattered foci of hepatocytolysis replaced by a small group of hyperplastic Kupffer cells. Confluent necrosis occurs when a larger number of liver cells, such as an entire zone, is necrotic (Fig. 143-26). Submassive and massive necrosis are more severe forms. In submassive necrosis, entire lobules are involved with sparing of a few periportal hepatocytes, while in massive necrosis, no viable hepatocytes are present (Fig. 143-27). The term granulomatous necrosis is used when the area of necrosis is well circumscribed and is composed of a compact arrangement of macrophages, lymphocytes, and plasma cells (Fig. 143-28). These differ from true granulomata in lacking epithelioid cells and multinucleated giant cells. Coagulative necrosis denotes eosinophilic change of hepatocytes with loss of nuclei and maintenance of reticulin without inflammatory infiltration. This is seen in anoxia (see Fig. 143-26) or toxic necrosis due to halothane or acetaminophen (Fig. 143-29 and Fig. 143-30).

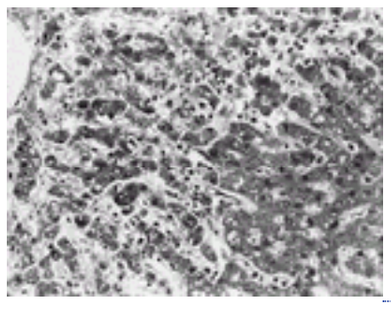

FIGURE 143-26. Confluent necrosis in the perivenular zone due to anoxia. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Parenchymal Inclusions

The most common pigment seen in the liver cells is lipochrome or lipofuscin in the wear- and-tear pigment prominent in zone 3. Hemosiderin pigment is usually seen in periportal hepatocytes (see Fig. 143-3; see also Color Fig. 143-3). Bile can be seen in the hepatocytes and Kupffer cells but often it is associated with canalicular bile plugs. Mallory hyalin is seen as eosinophilic clumpy, ropy material in hepatocytes that are hydropic. It represents aggregates of intermediate filaments. In acute ALD, hyaline necrosis is associated with neutrophilic infiltrates usually in perivenular areas (Fig. 143-31; see also Color Fig. 143-31). Mallory bodies can be seen in periportal hepatocytes in chronic biliary diseases such as primary biliary cirrhosis or chronic obstruction (Fig. 143-32). Another eosinophilic inclusion body that is often spherical but of variable size is a $_1$-antitrypsin globule, which is seen in heterozygous or homozygous deficiency of a $_1$-antitrypsin resulting in an accumulation of the protein in hepatocyte. This is also seen in periportal hepatocytes. These globules are PAS-positive with resistance to diastase digestion (see Fig. 143-2; see also Color Fig. 143-2.). In some cases of ALD, giant mitochondria that are spherical or needle-shaped can be seen in hepatocytes (Fig. 143-33; see also Color Fig. 143-33). Among the viral inclusions, ground glass hepatocytes with excessive HB $_S$Ag in chronic hepatitis B virus (HBV) infection, nuclear and cytoplasmic inclusions of cytomegalovirus (CMV), and nuclear inclusion of herpes simplex are important.

Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Cord Pattern Hepatocytes are arranged in a radial fashion alternating with the sinusoidal blood spaces. In cases of diffuse cell swelling, this pattern is altered. When there is uniform cell enlargement with crisp nuclei and the cells are arranged in a cobblestone formation, it indicates focal regenerative activity (Fig. 143-34). Diffuse cobblestone pattern is seen in persistent viral hepatitis.

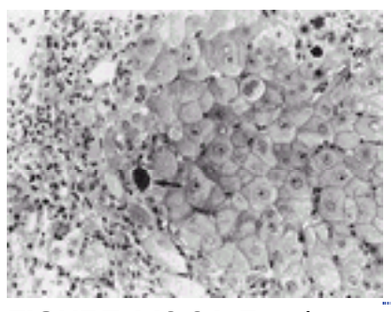

FIGURE 143-34. Focal regeneration with cobblestone arrangement of hepatocytes in chronic active hepatitis. *Arrow* points to acidophilic body. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Nuclear Changes Nuclear changes of hepatocytes include dysplasia, defined as enlargement of a group of cells with high nuclear cytoplasmic ratio (Fig. 143-35). Nuclear polyploidy means irregularity and enlargement of individual cell nuclei. Nuclear membrane invagination and glycogen vacuolization are other frequent changes (Fig. 143-36). Syncytial change represents multinucleated liver cells often seen with neonatal hepatitis (Fig. 143-37).

Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Sinusoidal Spaces and Lining Cells In chronic passive congestion and outflow obstruction, the sinusoids in zone 3 are dilated along with atrophy of hepatocytes (Fig. 143-38). In left-sided heart failure, red cells traverse the space of Disse and enter the hepatic trabecula (Fig. 143-39; see also Color Fig. 143-39). Focal sinusoidal dilation can be seen in space-occupying lesions in the adjacent parenchyma. Collagen deposition in the space of Disse eventually leads to narrowing and occlusion of sinusoidal spaces (Fig. 143-40; see also Color Fig. 143-40). This is commonly seen in ALD, hypervitaminosis A, chronic outflow obstruction including constrictive pericarditis, and inferior vena cava web lesions, as well as in methotrexate toxicity. In amyloidosis, there is deposition of amyloid either as a reticular type or globular amyloid in the space of Disse (Fig. 143-41 and Fig. 143-42). Hypertrophy of Kupffer cells is seen in many inflammatory diseases of the liver, but is most striking in salmonellosis (Fig. 143-43). Stellate cells or Ito cells are located in the space of Disse; they are the storage cells of retinoids (vitamin A metabolites). Through a process of activation, these cells become myofibroblasts causing sinusoidal fibrosis (Fig. 143-44). Peripheral circulating cells are visualized in sinusoidal blood spaces. Atypical cells of mononucleosis, leukemic cells, and cells of hairy cell leukemia can be seen (Fig. 143-45). Fibrin thrombi are seen packed within the sinusoids in disseminated intravascular coagulation and in toxemia of pregnancy (Fig. 143-46; see also Color Fig. 143-46). Sickled red blood cells are often seen in small clumps within the sinusoidals in sickle cell anemia (Fig. 143-47; see also Color Fig. 143-47).

Cholestasis Bile stasis can be within the lobules in dilated biliary canaliculi or in periportal cholangioles or bile ducts. Cholestasis in zone 3 is often associated with biliary obstruction or drug-induced injury (Fig. 143-48), while periportal (zone 1) bile stasis is seen in late stages of primary biliary cirrhosis. Simple cholestasis with no associated morphologic changes of bile ducts is seen in conditions such as benign recurrent intrahepatic cholestasis, benign postoperative cholestasis, pregnancy, and administration of drugs such as estrogen or anabolic steroids, as well as in bacterial sepsis.

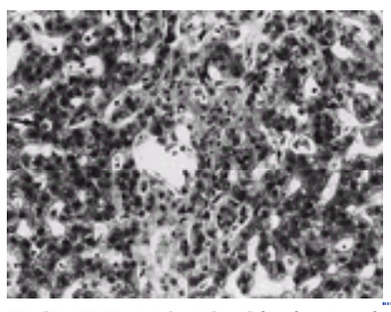

FIGURE 143-48. Cholestasis (*arrow*) in dilated canaliculi in zone 3 in chlorpromazine-induced liver disease. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Fat Two major types of fatty changes can occur in hepatocytes: macrovesicular and microvesicular types. Macrovesicular fat droplets appear as a large vacuole dislocating the nucleus and the cytoplasmic material to the periphery of the cell. Macrovesicular fatty change involving zone 3 is often seen in ALD (Fig. 143-49) and also in diabetes mellitus and in obesity. Steroid-induced fatty change involves all zones. Microvesicular fat, composed of small droplets of fat, sometimes appears as foamy change of the cytoplasm, without displacement of the hepatic nucleus. This is seen in alcoholic foamy degeneration, fatty liver of pregnancy, tetracycline

toxicity, Reye syndrome, and in valproic acid toxicity (Fig. 143-50; see also Color Fig. 143-50).

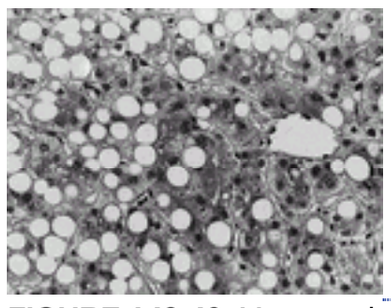

FIGURE 143-49. Macrovesicular fatty change of hepatocytes in alcoholic liver disease. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

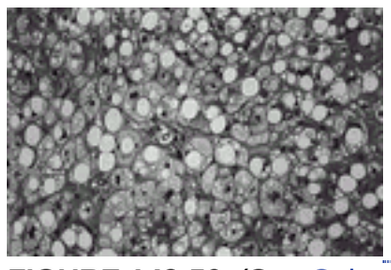

FIGURE 143-50. (See Color Fig. 143-50.) Diffusely enlarged hepatocytes with foamy fatty change in acute alcoholic liver disease. (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Terminal Hepatic Venules and Venous Outflow The most common pathological change of terminal hepatic venule is perivenular and obliterative sclerosis seen in alcohol-induced liver injury (see Fig. 143-23). Similar fibrosis can also be seen in Budd-Chiari syndrome and other causes of outflow obstruction, such as constrictive pericarditis, inferior vena caval obstruction, or web lesions. Endothelialitis or inflammatory cell infiltration of terminal hepatic venules is a feature of acute rejection of liver transplantation (see Fig. 143-24).

SPACE-OCCUPYING LESIONS OF THE LIVER

Primary Tumors—Benign and Malignant

These can be neoplastic lesions, cysts, or abscesses. A CT or ultrasound-guided liver biopsy can result in a sample diagnostic of the lesion present. Cysts and abscesses are usually aspirated. Among the benign solid mass lesions, focal nodular hyperplasia is one of the most common and must be differentiated from liver cell adenoma. [9], [10] Liver cell adenoma does not have a capsule but compresses an adjacent parenchyma (Fig. 143-51). The tumor cells are benign with normal nuclear cytoplasmic ratios, and with lack of portal tracts and terminal veins in the lesions. There are prominent, thick-walled arteries present along the edge of the tumor (Fig. 143-52). Focal nodular hyperplasia has a typical central stellate scar with loose vascularized fibrous tissue containing atypical ductal elements along the periphery of the scar (Fig. 143-53). This lesion also lacks normal portal areas and terminal hepatic veins (Fig. 143-54). Among the primary malignant neoplasms of the liver, hepatocellular carcinoma (HCC) is the most common form. [11] Other forms include cholangiocarcinoma and angiosarcoma. The tumor cells of the majority of typical HCC have a trabecular pattern with increased numbers of cell thicknesses forming fingerlike projections into vascular spaces. These trabeculae are lined by endothelial cells and surrounded by vascular spaces (Fig. 143-55; see also Color Fig. 143-55). The tumor can have focal acinar changes with secretory material in the lumina. Sclerosing hepatic carcinoma is a variant with a dense collagenized stroma (Fig. 143-56; see also Color Fig. 143-56). The fibrolamellar variant has lamellar strands of collagen separating thin cords of large eosinophilic neoplastic hepatocytes [12] (Fig. 143-57; see also Color Fig. 143-57). Cholangiocarcinomas are composed of neoplastic ductal elements surrounded by dense fibrous stroma [11] (Fig. 143-58; see also Color Fig. 143-58). The tumor is clearly demarcated from the surrounding liver.

Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Nodular Regenerative Hyperplasia (NRH)

NRH is a rare form of hyperplasia of liver cells with formation of nodules without fibrous septa. [13] Microscopically, the hyperplastic nodules are better identified on low power exhibiting compression by the surrounding parenchyma (see Fig. 143-6). A reticulum stain outlines these nodules, which can vary from small and microscopic to large, up to 23 cm. Patients with NRH may have evidence of portal hypertension.

Metastatic Tumors

Metastatic tumors in the liver can be easily diagnosed from an ultrasound-guided needle biopsy. The tumor cells usually grow into the adjacent sinusoids, compressing and separating the hepatic trabeculae (Fig. 143-59). Examination of the junction of the tumor and the nontumor is very useful in differentiating HCC from metastatic tumors. In HCC, the tumor cells merge into the hepatic cords where there is a transition from normal to neoplastic cells (Fig. 143-60; see also Color Fig. 143-60). In metastatic tumors, as mentioned earlier, the tumor grows into the sinusoidal spaces.

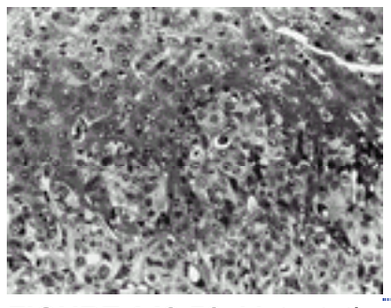

FIGURE 143-59. Metastatic, poorly differentiated adenocarcinoma infiltrating into the sinusoids. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

(H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Granulomas Granulomas are identified in the liver at a rate of 25% of all liver biopsies in most of the large centers. [14] The most common cause of epithelioid granulomas in the liver is sarcoidosis (Fig. 143-61). Among infectious agents causing granulomas in the liver, *Mycobacterium tuberculosis, Mycobacterium avium intracellulare,* Q fever, and brucellosis are most common (Fig. 143-62, Fig. 143-63 and Fig. 143-64). Rare fungal infections such as blastomycosis and coccidiomycosis are the next most common causes. Parasitic infections such as schistosomiasis with hepatic granulomas are common in some endemic areas of the world. Epithelioid granulomas are well circumscribed and comprise multinucleated giant cells, epithelioid cells, and lymphocytes along the periphery. Granulomatous lesions, which are not true granulomas, are small punched out areas of hepatic necrosis with aggregates of macrophages and lymphocytes without epithelioid cell formation. These lesions are seen in viral infections such as CMV, Epstein-Barr virus (EBV), rickettsial infections, such as Q fever, and in liver injury caused by drugs such as Dilantin, allopurinol, Butazolidin, and sulfonamides. Some of these drugs can also elicit an epithelioid reaction with true granuloma formation (Fig. 143-65). Hepatic granulomas can also be associated with Hodgkin disease, postjejunoileal bypass, and PBC (see Fig. 143-17). Some unique features useful in the differential diagnosis of hepatic granulomas include: a central vacuolated space with a fibrin ring in granulomas [15] of Q fever representing the so-called “donut” lesions (see Fig. 143-64); demonstrations of acid-fast and fungal organisms using special stains; the presence of eosinophils in granulomas associated with drug reactions, parasitic diseases, and Hodgkin disease; the presence of remnants of ova in schistosomiasis (Fig. 143-66); and caseation necrosis, rarely occurring in tuberculous granulomas (see Fig. 143-62).

DIFFERENTIAL DIAGNOSIS OF CIRRHOSIS

Based on the morphologic features, cirrhosis of the liver can be classified as alcoholic, nonalcoholic, biliary, and cardiac cirrhosis. Based on the size of the regenerative nodules, a broad distinction is made between micronodular (<3-mm nodules) and macronodular (>3-mm nodules) cirrhosis. A typical alcoholic cirrhosis is a micronodular type diagnosed by the presence of dense, broad fibrous scars with small parenchymal nodules exhibiting sinusoidal collagenosis (see Fig. 143-1; see also Color Fig. 143-1.). Fat, alcoholic hyaline, and other acute changes due to alcohol can be superimposed. Mild chronic inflammatory reaction of nonspecific nature can be present in the fibrous septa without periseptal or parenchymal activity. Cirrhosis due to hemochromatosis, also a micronodular cirrhosis, is characterized by the presence of hemosiderin deposition in the parenchymal cells as well as in the fibrous septa and in bile duct epithelia. There is a striking lack of inflammatory process in this type of cirrhosis. Nonalcoholic cirrhosis, usually of macronodular type, is a broad category where the cirrhosis is the end result of CAH of various etiologies. Fibrous septa are relatively thin and vascularized and reveal prominent chronic inflammatory infiltration. The inflammation extends into the periseptal parenchyma, which exhibits a varying degree of necroinflammatory activity. In biliary cirrhosis, the fibrous septa reveal a characteristic lamellar pattern and extend from portal to portal areas leaving islands of parenchyma. This is best described as a jigsaw puzzle-like appearance (Fig. 143-67; see also Color Fig. 143-67). Cardiac cirrhosis, on the other hand, has a reverse lobular pattern, as the perivenular fibrous areas form septa leaving the portal areas relatively uninvolved.

Following a morphologic identification of the type of cirrhosis, an etiologic diagnosis is attempted. Morphology of alcoholic cirrhosis can also be seen in postjejunoileal bypass liver disease. Among the etiologies of nonalcoholic cirrhosis, chronic HBV infection can be diagnosed by the presence of ground-glass cells (Fig. 143-68) and significant dysplastic changes of the hepatocytes (see Fig. 143-35). Autoimmune hepatitis can be suspected as the etiology if there is a predominance of plasma cells among the portal and parenchymal infiltrates (see Fig. 143-11). In addition, areas of collapse may exist even in the cirrhotic stage in these cases. Wilson disease can be suggested if there is evidence of increased hepatic copper and copper binding protein (see Fig. 143-5). In cases of biliary cirrhosis, absence of bile duct elements with the presence of lymphoid infiltrates in the septa is suggestive of primary biliary cirrhosis while evidence of bile duct proliferation with or without acute cholangitis is suggestive of biliary obstruction leading to cirrhosis. Cirrhosis in infants and children due to a $_1$-antitrypsin deficiency, intra- or extrahepatic biliary atresia, and in cystic fibrosis involving liver also appears biliary in nature. Clinical, laboratory, and radiologic data are needed to arrive at a more accurate etiologic diagnosis of cirrhosis in most cases.

SPECIFIC LIVER DISEASES

Necroinflammatory Diseases

Acute Viral Hepatitis Regardless of the etiology, typical perivenular hepatocytolysis, extreme hydropic swelling of the hepatocytes, marked Kupffer cell hyperplasia, and mononuclear exudative reaction in the parenchyma as well as the portal tracts are found in cases of acute viral hepatitis [16] (Fig. 143-69 and Fig. 143-70). Numerous acidophilic bodies are also present. The acidophilic bodies represent individual hepatocytes undergoing necrosis with cytoplasmic condensation and nuclear pyknosis. Cholestasis may or may not be present. The hepatocytes in zone 1 usually reveal uniform hydropic change suggestive of regeneration. Portal tracts are expanded with inflammation without fibrosis (see Fig. 143-70). Some of the following specific changes are associated with different viral agents: Acute type A hepatitis can exhibit a periportal accentuation of the necrosis. [17] Enteric non-A, non-B (type E) acute hepatitis tends to have prominent acinar changes with hepatocytes arranged around dilated biliary canaliculi resembling rosettes throughout the lobules [18] (Fig. 143-71). In acute hepatitis due to delta (type D) agent, one can demonstrate the presence of hepatitis D antigen (HDAg) by immunoperoxidase. When the necrosis in acute viral hepatitis (AVH) is severe, it involves the entire zone 3 and is called confluent necrosis. When the necrosis involves zones 2 and 3 and part of zone 1 with hepatocytes remaining viable in the periportal zones, it is classified as submassive necrosis. Massive necrosis is the term used when the necrosis involves all zones without any viable hepatocytes.

Chronic Viral Hepatitis

Terminology. Chronic hepatitis is the universal terminology used for all liver biopsies from patients with virologic markers persistent for greater than 6 months with abnormal liver enzymes. Terms such as persistent hepatitis, chronic active hepatitis, chronic lobular hepatitis, and so forth are no longer used by pathologists. The diagnosis of “chronic hepatitis” is further elaborated by adding the name of the etiologic virus (i.e., type B, type C, or type D) and by adding the assessment of necroinflammation and fibrosis in a semiquantitative method, using grades (0–4) and stages (1–4) as proposed by Ludwig. [19] Detailed quantitation assessments have

included many scoring systems; the most commonly used are those devised by Knodell and colleagues, Ishak colleagues, and the Metavir scoring system. [20], [21] and [22] *Knodell scoring* has a total of 18 for necroinflammation including lobular, periportal, and portal inflammation, and a total of 4 for fibrosis (0–4). The *Ishak scoring system* has more details for necroinflammation (0–18) and expanded scores for fibrosis (0–6). *Metavir scoring* is simpler with a combination score for inflammation including periportal and lobular activity (A0–A3) and a fibrosis score on a scale of F0 to F4. The term persistent hepatitis (PH) has been used primarily in cases of chronic "B" infections when the liver biopsy reveals mild expansion of portal tracts with mononuclear inflammatory hyperplasia without periportal extension or fibrosis. The parenchyma reveals diffuse mild hydropic swelling, suggestive of a cobblestone pattern (Fig. 143-72). Ground- glass hepatocytes are usually scattered uniformly among the lobules. Rare foci of necrosis are seen and there is no Kupffer cell activity. This lesion is generally nonprogressive in type B. It is uncommon to have PH when there are chronic B and D co-infections. Rather, progressive chronic hepatitis is seen.

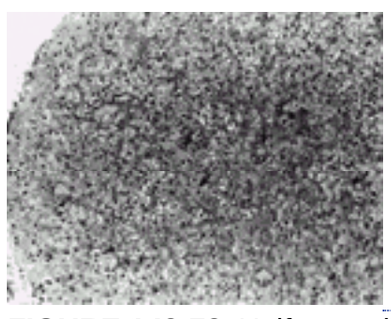

FIGURE 143-72. Uniform cobblestone appearance of parenchyma in chronic hepatitis, type B. A few ground-glass cells are seen (*arrows*). (H & E stain; original magnification ×200.) (Reprinted with permission from Govindarajan S. Liver Biopsy Interpretation. In Kaplowitz N. (ed.). Liver and Biliary Diseases, Second Edition. Baltimore, Williams & Wilkins, 1996.)

The most important morphologic characteristics are portal fibrosis, portal and periportal mononuclear inflammation, and necroinflammatory changes within the parenchyma with an irregular distribution between one lobule and another (Fig. 143-73). There is also regenerative activity in an irregular distribution. Lymphocytes and Kupffer cells are seen cuffing around the target hepatocytes (Fig. 143-74). The degree of necrosis depends on the disease activity, more severe in exacerbations or reactivation and less so in quiescent stages. Fibrosis progresses to cirrhosis and the periseptal inflammatory activity continues with cirrhosis. The term piecemeal necrosis is used to describe the periportal extension of mononuclear inflammation in association with hepatocytolysis involving the limiting plate. In chronic hepatitis B, there is significant nuclear dysplasia (see Fig. 143-35). In cases of chronic hepatitis C, the following unique features are seen in most of the cases: macrovesicular fatty change, mild sinusoidal collagenosis in the periportal areas, prominent lymphoid reaction of portal areas, and moderate to marked atypia of the bile duct epithelium [23] (Fig. 143-75 and Fig. 143-76). In cases of chronic hepatitis B one can stain for the viral proteins such as HB $_{c}$Ag, HB $_{s}$Ag, and HB $_{e}$Ag, using immunoperoxidase methodology. [24] HB $_{s}$Ag is also demonstrable using Shikata orcein stain or Victoria blue (see Fig. 143-4). HDAg is demonstrable by immunoperoxidase techniques in chronic hepatitis D virus infections [25] (Fig. 143-77).

Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Chronic Hepatitis—Autoimmune Etiology In addition to the features of chronic hepatitis already described, the changes unique to autoimmune chronic hepatitis (the term *lupoid hepatitis* is used by some, but should be discouraged as it is not related to systemic lupus erythematosis) are:

- the presence of significant number of plasma cells among the portal and the parenchymal infiltrates (see Fig. 143-11)
- evidence of collapse and striking degree of periportal as well as perivenular necrosis
- trapped hepatocytes in the fibrous portal or septal areas. [26]

Necroinflammatory changes are minimal in patients on steroid therapy with good response.

Other Viral Infections Mononucleosis pattern of hepatitis can be seen in hepatitis due to EBV, CMV, and some cases of hepatitis C virus (HCV). [27] In this form, the hepatocytes are not swollen and the cord pattern is maintained. There is striking sinusoidal lymphocytosis, many of these cells being atypical in nature (Fig. 143-78). There is portal infiltration by the same type of cells. In addition, there is multifocal punched out hepatocytolysis (see Fig. 143-28) without confluent or zonal necrosis. Very rarely, epithelioid granuloma can be seen. In immunocompromised individuals, the CMV infection results in an abundance of virally infected cells with typical nuclear inclusion bodies in the bile duct epithelium or reticuloendothelial cells. In postorthotopic liver transplantation, the CMV infection causes typical microabscess formation with the polymorphonuclear leukocytes (PMNs) surrounding the cells with viral inclusion bodies [28], [29] (Fig. 143-79; see also Color Fig. 143-79). Viral antigen in CMV hepatitis in these cases is demonstrable using immunochemical methods. Herpes simplex infection of the liver is rarely encountered in liver biopsies, since the prothrombin time is too prolonged for a biopsy in these patients. Large, discrete, irregular zones of coagulative necrosis of parenchymal cells with the presence of eosinophilic intranuclear inclusions in the viable hepatocytes at the margins of necrosis is the typical change seen in the liver biopsies [30] (Fig. 143-80).

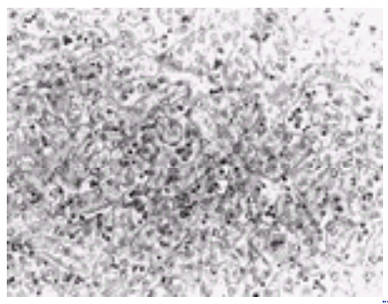

FIGURE 143-78. Striking sinusoidal lymphocytosis of atypical type in Epstein-Barr virus-induced mononucleosis. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Alcoholic Liver Disease

Changes in liver biopsies due to alcohol can be broadly divided into acute cellular damage and its characteristic features, and chronic slowly progressive changes with evidence of chronic liver disease.

Acute Changes The most common form of acute damage is seen as fatty change of macrovesicular type with or without cholestasis. The patients present with large fatty change with or without jaundice. Needle biopsy reveals large vacuoles of macrovesicular fat involving the perivenular hepatocytes (see Fig. 143-49). Occasionally, the entire lobule is uniformly involved. Cholestasis and sinusoidal fibrosis may be seen. Acute foamy fatty change (FFC) represents a variant of acute alcoholic hepatitis. [31] The perivenular hepatocytes are enlarged with foamy or microvesicular fat (see Fig. 143-50; see also Color Fig. 143-50). The nucleus is central in location and the cells may exhibit abnormal giant mitochondria visible as eosinophilic, round bodies (cherry bodies) (see Fig. 143-33; see also Color Fig. 143-33).

Sinusoidal collagen deposition can be prominent in the perivenular zones. FFC can also be seen in association with the classic acute sclerosing hyaline necrosis (ASHN) in patients with alcoholic hepatitis. [32] The morphologic hallmarks of ASHN are:

- hydropic hepatocytes with cytoplasmic Mallory hyaline bodies
- neutrophil reaction around these cells with hyaline necrosis
- sclerosis of the terminal hepatic venules with sinusoidal collagenosis (see Fig. 143-31; see also Color Fig. 143-31).

Other microscopic features, such as fatty change, cholestasis, and portal fibrosis with arachnoid extension, can also be part of this morphology. Other uncommon biopsy findings of acute ALD include lytic necrosis of liver cells in which the hepatocytes are extremely hydropic with lysis and fusion of adjacent cells and acute portal reaction in which there is prominent neutrophilic reaction within the portal tract without any orientation to the bile ducts. These portal tracts often have classic arachnoid fibrosis.

Chronic Alcohol-Induced Liver Damage This primarily manifests as fibrosis. Three forms of progressive fibrosis are seen in the liver. [33] They are:

- portal and perivenular fibrosis leading to fibrous septa formation, resulting in cirrhosis with small regenerative nodules (see Fig. 143-1; see also Color Fig. 143-1)
- diffuse interstitial fibrosis with collagen extending throughout the lobule encircling individual hepatocytes and without parenchymal regeneration or septal formation (Fig. 143-81; see also Color Fig. 143-81)

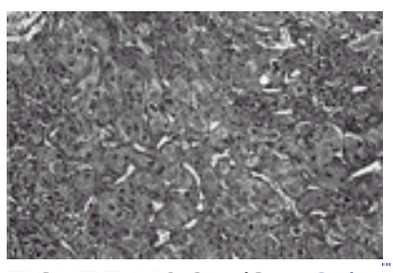

FIGURE 143-81. (See Color Fig. 143-81.) Diffuse interstitial fibrosis in chronic alcoholic liver disease. (Masson stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

- progressive perivenular fibrosis with dense scarlike collagen involving zone 3 with relatively minimal portal fibrosis (Fig. 143-82; see also Color Fig. 143-82).

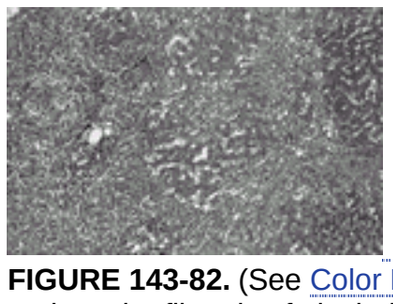

FIGURE 143-82. (See Color Fig. 143-82.) Marked perivenular fibrous scarring with mild portal fibrosis and lack of regenerative nodules in progressive perivenular fibrosis of alcoholic etiology. (Masson stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

In the early stages of development of cirrhosis the fibrous septa appear thin, with larger pseudolobules or parenchymal nodules. There is evidence of prominent intranodular sinusoidal fibrosis. As the disease progresses, the septa become denser and wider, the nodules become subdivided into smaller nodules, with continued sinusoidal fibrosis in the periseptal regions. In advanced stages, there is extensive scarring with islands of parenchymal nodules scattered within. Masson trichrome and PAS stains clearly outline this ratio of the fibrous tissue to the parenchyma. Following an established state of cirrhosis, if there is prolonged abstinence from alcohol, the regenerative parenchymal nodules enlarge, pushing the fibrous septa centrifugally with a remarkable reduction in the amount of collagen both within the parenchyma and the septa. At this inactive stage, it is difficult to identify alcohol as the initial etiologic agent causing cirrhosis. Any of the acute cellular changes described previously can occur superimposed on a cirrhotic or fibrotic liver. The distribution of Mallory hyaline, neutrophilic infiltrate, or fatty change may be irregular and focal, not uniform. When there are additional complications, such as anoxia due to variceal bleeding or general anesthesia, typical coagulative necrosis can be seen within the central zone of the cirrhotic nodules.

Differential Diagnosis Nonalcoholic steatohepatitis (NASH) or nonalcoholic fatty liver disease is unrelated to alcohol or any other recognized etiology for liver disease, but most often progressive liver disease with histological features resembling alcoholic liver disease. [34] These include micro- and macrovesicular steatosis, perivenular and periportal sinusoidal fibrosis with or without necroinflammation, and Mallory bodies. Degree of necroinflammation and ballooning changes (scale of 1–3) as well as fibrosis (1–4) have been graded by a system developed by Brunt and colleagues. [35] Differentiation is made based on clinical and laboratory data. Identical morphologic changes of ASHN can be seen in diabetes mellitus, liver disease secondary to jejunoileal bypass surgery for morbid obesity, and drug-induced reactions in patients receiving amiodorone. [36] Mallory bodies without accompanying neutrophilic reaction can be seen in a number of conditions such as Wilson disease, primary biliary cirrhosis, chronic biliary obstruction, and in livers bearing HCC either in the tumor or nontumor cells. Sinusoidal collagen deposition typical for ALD can be seen in a moderate degree in chronic HCV hepatitis, hypervitaminosis A, and methotrexate toxicity. A much more localized perivenular fibrosis can be seen in venous outflow obstruction such as Budd-Chiari syndrome. Studies of serologic testing for HCV have identified a high prevalence (>50%) of chronic HCV infection among those with ALD. In many of these patients, the liver biopsy reveals features of both ALD and chronic hepatitis of HCV type. There is an increased degree of chronic inflammatory infiltrate in the portal tracts or fibrous septa with spillover to the periseptal parenchyma.

Biliary Diseases

Mechanical Duct Obstruction This is often diagnosed without a liver biopsy. When the various procedures, such as ultrasound, endoscopic retrograde cholangiopancreatography and others, are inconclusive, a liver biopsy is performed. The changes can be divided into parenchymal and portal. Although the predominance of one change over the other varies from patient to patient, the earliest change might be parenchymal cholestasis in the perivenular hepatocytes. This is followed by canalicular dilation with bile plug formation. The hepatocytes become hydropic with a reticular rarefaction of the cytoplasm termed as feathery degeneration. The portal tracts reveal edema with loose fibrous tissue around dilated bile ducts. Portal inflammatory reaction includes PMNs and mononuclear cells. Orientation of PMN infiltration around the bile duct, and within the duct lumen, strongly suggests mechanical duct obstruction (see Fig. 143-8). Prolonged biliary obstruction results in marked cholangiolar proliferation as well as periductal fibrosis (see Fig. 143-13 and Fig. 143-15). Long-standing obstructions can result in disappearance of the ducts resembling PBC. During the acute stage, drug-induced cholangitic and cholestatic reaction, acute viral hepatitis of cholestatic type, impaired regeneration syndrome, changes due to parenteral hyperalimentation, and septic shock should be considered in the differential diagnosis. Biliary fibrosis and cirrhosis follow if there is continued duct obstruction (see Fig. 143-67).

Primary Biliary Cirrhosis (PBC) and Primary Sclerosing Cholangitis (PSC) These are discussed in detail in other chapters. Diagnosis of PBC based on a needle biopsy of liver might be difficult if adequate portal tracts are not present in the specimen. In addition to the classic destructive duct lesions with marked lymphoplasmacytic infiltrates, the presence of granulomas, absence of ducts in small portal tracts, hydropic changes of periportal hepatocytes containing Mallory hyaline and copper-binding protein (Shikata-positive granules), and periportal cholestasis are all helpful morphologic features in diagnosing PBC. [37] A staging system of 1 to 4 has been used by some; briefly, the histological hallmarks of each of these stages are as follows: Stage 1: destructive changes of interlobular bile ducts with or without granulomas.

Stage 2: proliferation of atypical ductules mostly along the periportal areas.

Stage 3: absence of interlobular bile ducts in most of the portal tracts and portal-to-portal bridging fibrosis.

Stage 4: cirrhosis.

However, in many patients, the biopsies reveal changes overlapping between different stages. [38] Diagnosis of PSC is much more difficult in needle biopsies of liver. A wide range of pathological changes from minimal portal fibrosis and inflammatory reaction, changes of biliary obstruction secondary to extrahepatic sclerosing cholangitis to typical, marked, concentric periductal fibrosis with chronic inflammation can be seen [39] (see Fig. 143-16). Radiologic studies are necessary for definitive

diagnosis.

Drug-Induced Liver Diseases

Liver biopsy interpretation should always consider the possibility of drug-induced changes as differential diagnosis. [40] A careful history of drug intake should be considered prior to final morphologic diagnosis.

Parenchymal Changes Parenchymal changes resembling acute viral hepatitis are seen in both isoniazid- and methyldopa-induced hepatic damage (Fig. 143-83). Changes resembling mononucleosis pattern are seen in diphenylhydantoin-, paraaminosalicylic acid-, and, occasionally, in sulfonamide-induced liver diseases (Fig. 143-84). Coagulative necrosis without much inflammatory reaction is seen in acetaminophen- and halothane-induced damage (see Fig. 143-29 and Fig. 143-30). The necrosis is typically in perivenular and midzonal location. Periportal coagulative necrosis is seen in ferrous sulfate poisoning. Fatty change of microvesicular type is caused by tetracycline and valproic acid. This is accentuated in zone 3 resembling alcoholic FFC. Macrovesicular fatty change is most commonly seen with corticosteroid and methotrexate use. Carbon tetrachloride and tritetrachlorethylene toxicity results in fatty change as well as liver cell necrosis without inflammatory changes. Hepatocyte necrosis with Mallory body formation can be seen with amiodarone, perhexilene maleate, and with synthetic estrogen preparation used for prostatic carcinoma. Parenchymal cholestasis in zone 3 without inflammation or necrosis can be seen with use of anabolic steroids and with oral contraceptives. Cholestasis with mild hepatocellular necrosis is associated with total parenteral hyperalimentation, antibiotics such as erythromycin, penicillin, sulfonamides, nitrofurantoin, oral hypoglycemic agents, tranquilizers such as chlorpromazine (see Fig. 143-48), antihypertensive agents, captopril, gold therapy, and some antineoplastic agents. Some of these drugs such as sulfonamides cause granulomatous necrosis in addition to cholestasis. Rare cases of allopurinol-induced submassive hepatic necrosis have been reported. Morphologic patterns of CAH can result from hepatotoxicity from nitrofurantoin, methyldopa, oxyphenisatin, dantrolene, papaverine, and, occasionally, isoniazid. A number of drugs can elicit granulomatous reactions in the liver. Phenylbutazone and sulfonamides cause granulomas resembling sarcoidosis, either portal or parenchymal. Allopurinol, Dilantin, quinidine, nitrofurantoin, methyldopa, Pronestyl, and, rarely, isoniazid can cause a granulomatous reaction, consisting of punched out areas of hepatocytolysis replaced by hyperplastic Kupffer cells, lymphocytes, and other inflammatory cells in a circumscribed fashion resembling a granuloma. Among the drugs causing hepatocyte inclusions, ground-glass appearance can be caused by cyanamide and proliferation of smooth endoplasmic reticulin (SER) resulting in similar appearance by phenobarbital, chlorpromazine, and Dilantin. [41]

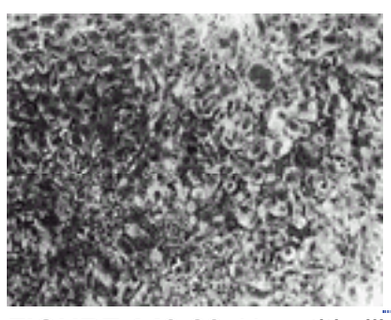

FIGURE 143-83. Hepatitis-like activity resembling acute viral hepatitis in Aldomet-induced hepatotoxicity. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

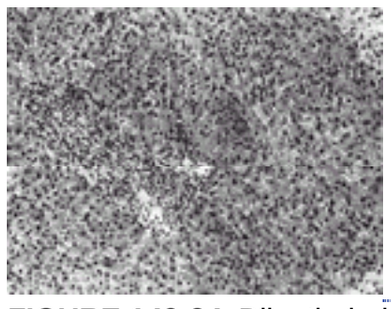

FIGURE 143-84. Dilantin-induced hepatic changes resembling mononucleosis. (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Portal Tract Changes Oral hypoglycemic agents and tranquilizers mentioned previously, as well as allopurinol, can cause variable degrees of portal inflammation and bile duct epithelial abnormalities, resembling mechanical duct obstruction or PBC. Dilantin toxicity results in a mononucleosis pattern along with portal inflammatory reaction with predominance of eosinophils (see Fig. 143-2; see also Color Fig. 143-2.). Allopurinol causes portal eosinophilia with cholangitic reaction.
Vascular Changes These include sinusoidal dilation in oral contraceptive agents, anabolic steroids, and in azathroprine therapy and peliosis hepatis seen in anabolic steroid and methyl testosterone treatment (Fig. 143-85). Venous outflow occlusion with its hepatic morphologic changes can be seen as follows: perivenular sclerosis with sinusoidal collagenosis resembling alcohol is associated with hypervitaminosis A, methotrexate (Fig. 143-86), azathioprine, and certain antineoplastic drugs, such as mitomycin C. Venoocclusive disease with coagulative necrosis and severe congestion in zone 3 is seen in toxicity due to bush tea containing pyrrolizidine alkaloids as well as 6-thioguanine and azathioprine. Hepatic vein thrombosis leading to Budd-Chiari syndrome has been associated with prolonged use of oral contraceptives (see Fig. 143-25).

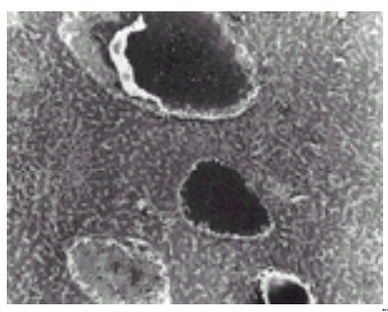

FIGURE 143-85. Peliosis hepatis with blood-filled spaces without endothelial lining. (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

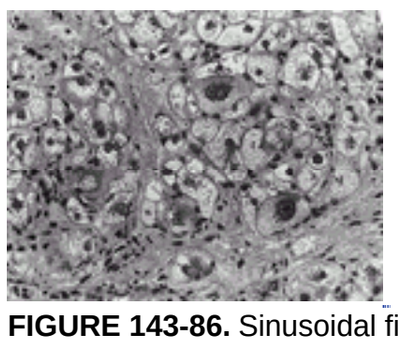

FIGURE 143-86. Sinusoidal fibrosis and nuclear dysplastic changes in methotrexate toxicity. (H & E stain; original magnification ×400.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Liver Biopsy Changes in Systemic Diseases

Hematopoietic System Lymphomas with hepatic involvement reveal monomorphic portal infiltrates of neoplastic lymphocytes (Fig. 143-87). Bile ducts and parenchymal cells are not involved. On the other hand, in Hodgkin disease, the portal infiltrate, including atypical or typical Reed-Sternberg cells, seems to produce destructive lesions of bile ducts (Fig. 143-88). In addition, epithelioid granulomas of nonneoplastic nature are seen in both portal and lobular zones. Cholestasis can also be a prominent feature in Hodgkin disease. Liver biopsies in leukemias reveal immature neoplastic white cells in the sinusoidal spaces as well as in the portal zones (see Fig. 143-45). Hairy cell leukemia exhibits typical leukemic cells in the sinusoidal spaces as well as infiltrating the parenchyma. Sickle cell disease can be diagnosed by identifying clumped red cells as well as sickled cells in the sinusoidal spaces (see Fig. 143-47; see also Color Fig. 143-47). Disseminated intravascular coagulation manifests as fibrin thrombi within the sinusoidal spaces.

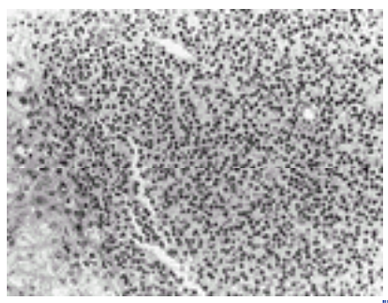

FIGURE 143-87. Portal infiltrate in non-Hodgkin lymphoma. (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Acquired Immunodeficiency Syndrome (AIDS) Liver biopsies in patients with AIDS should be examined for evidence of opportunistic infections commonly seen in these patients. In general, the portal areas are relatively lymphopenic, in spite of the inflammatory processes in the liver [42] (Fig. 143-89). *Mycobacterium avium intracellulare* (MAI) infection in these patients typically results in numerous clusters of bloated Kupffer cells, appearing foamy and containing numerous acid-fast stainable organisms (see Fig. 143-64). No true granulomas are seen. Similarly, fungal infections such as cryptococcosis reveal lack of granuloma formation in the presence of organisms identified by special stains and cultures. Viral inclusion bodies of CMV and herpes simplex involving either the reticuloendothelial cells or duct epithelium cells, or parenchymal cells can be seen. Cryptosporidiosis involving the biliary system can be identified by examining the luminal surface of the duct epithelial cells using special stain such as Giemsa (Fig. 143-90). Sclerosing cholangitis identified in patients with AIDS has been described as a sequela of CMV and cryptosporidiosis of the biliary system. [43] In patients with Kaposi sarcoma elsewhere in the body, liver biopsy can also exhibit the presence of the tumor [44] (Fig. 143-91). Since these patients are on a number of drugs on a long-term basis, hepatotoxic changes due to the drugs should also be considered in the differential diagnosis.

PATHOLOGY OF TRANSPLANTATION

Allograft Rejection

Acute rejection is a more common event seen in varying degree in 70% of allografts; histological characteristics as described by Snover and colleagues [45] include portal inflammatory infiltration, inflammation and destructive changes of interlobular bile ducts, and endothelialitis involving hepatic and portal venous structures (Fig. 143-92). Portal inflammation consists of activated lymphocytes or “immunoblasts,” neutrophils, and eosinophils. These cells are seen infiltrating the epithelial cells of interlobular bile ducts. In addition, the duct epithelium reveals pyknosis of the nuclei, hydropic changes, and disruption of basement membrane. Endothelialitis is exhibited as lymphocytes attached to the venous endothelium and infiltrating through the subendothelium. The hallmark of chronic rejection consists of progressive destruction and eventual loss of bile ducts [46] (Fig. 143-93). In addition, there is perivenular cholestasis and multifocal hepatocytolysis. There is also evidence of obliterative vascular lesions involving hepatic arteries and arterioles. Chronic rejection is less common than acute rejection and occurs in about 4% of graft recipients.

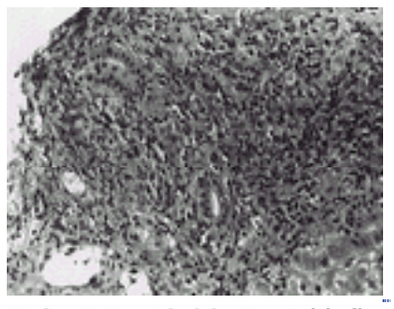

FIGURE 143-92. Portal inflammatory infiltrate, changes of interlobular bile ducts and endothelialitis of portal vein radicles in acute rejection. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

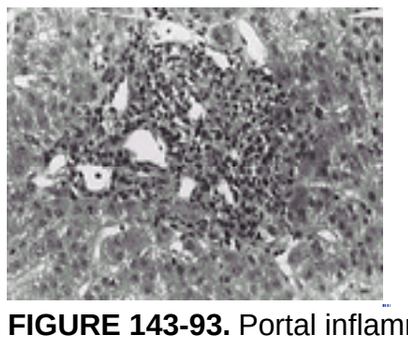

FIGURE 143-93. Portal inflammatory infiltrate with loss of bile ducts in chronic rejection. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Harvest or Preservation Injury

In the majority (54%) of orthotopic hepatic grafts, there is marked ballooning of the hepatocytes in acinar zone 3 (Fig. 143-94). This usually occurs in the first 2 weeks and in some patients as early as 48 hours. This is often associated with cholestasis and high serum ALT levels. Ischemia is considered one of the pathogenetic factors. Ballooning without associated necrosis has better prognosis and is not a sign of graft rejection. Among the other features included under preservation injury are microvesicular fatty change and mild acidophilic degeneration of the hepatocytes.

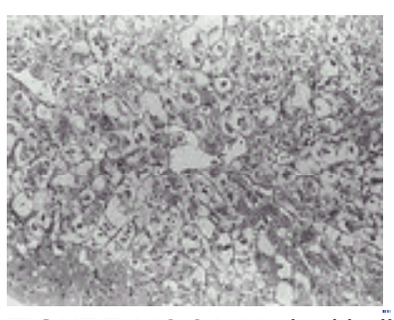

FIGURE 143-94. Marked ballooning of the hepatocytes in acinar zone 3 representing harvest injury. (H & E stain; original magnification ×100.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

CMV Hepatitis

CMV hepatitis in allograft is often associated with parenchymal microabscesses seen as small aggregates of neutrophils in the hepatic lobule. Infected cells have large eosinophilic intranuclear inclusions. Immunoperoxidase stains demonstrate these inclusions clearly.

Recurrent Hepatitis B in Allograft

Liver allograft recipients who had chronic hepatitis B with cirrhosis invariably develop recurrence of hepatitis B infection of the graft. The recurrence usually develops after more than 3 months but can occur earlier in association with an accelerated course. The recurrent HBV infection is similar to that seen in nonliver graft patients. The acute process consists of lobular disarray, ballooning hepatocytes, with necroinflammatory changes (Fig. 143-95). Portal areas reveal inflammatory hyperplasia without any evidence of bile duct epithelial changes or vascular endothelial damage. At this early stage, HB $_{C}$Ag is demonstrable in the hepatocytes by immunoperoxidase stains. Although the acute events can be self-limited, viral infection is never cleared and invariably leads to chronic infection, with progressive increase in the expression of viral antigens in the liver. A unique variant of recurrent hepatitis in the allograft is termed *fibrosing cholestatic hepatitis.* [47] The characteristic pathological changes include periportal fibrosis with thin strands of pericellular collagen, cholestasis, and ballooning of hepatocytes with apoptotic necrosis. There is abundance of HB $_{S}$Ag and HB $_{C}$Ag demonstrable in hepatocytes. Lymphocytic infiltrates are minimal. This morphology has been associated with poor outcome. Development of chronic hepatitis and cirrhosis is the eventual outcome.

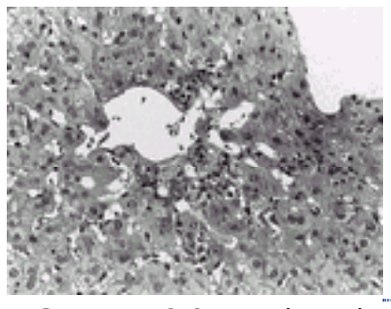

FIGURE 143-95. Perivenular zone with necroinflammatory changes in recurrent acute hepatitis B infection of allograft. (H & E stain; original magnification ×200.) (From Govindarajan S. Liver biopsy interpretation. In: Kaplowitz N, ed. Liver and biliary diseases, 2nd ed. Baltimore: Williams & Wilkins, 1996.)

Recurrent Hepatitis C

Reinfection of allografts is universal but the disease progression varies widely. Acute changes can be seen as early as 80 to 90 days. They include sinusoidal lymphocytosis, acidophic bodies, and lobular disarray. Portal lymphoid aggregates, progressive fibrosis, and changes similar to chronic HCV in nontransplant setting are seen in later stages. A small percentage (2%–10%) of patients with recurrent HCV develop severe fibrosing cholestatic hepatitis similar to that seen in recurrent HBV. [48]

Graft-Versus-Host Disease

Graft-versus-host disease is seen in association with bone marrow transplantation and less often with other solid organ transplantation. [49] In the acute stage, there is evidence of hepatocellular necrosis and endothelialitis. In chronic stages, there is extensive bile duct damage and the interlobular bile duct epithelium shows cytoplasmic vacuolization, nuclear hyperchromasia, and atypia. Destructive bile duct changes resemble PBC.

SUMMARY

Needle biopsy of liver represents a minute sampling of a large organ and, understandably, errors of sampling can lead to a negative conclusion. This is true in cases of focal lesions, such as tumors, and in chronic liver diseases, such as PSC or PBC with wide variations of morphologic changes within the liver. Ultrasound or CT scan-guided liver biopsies provide a direct sampling of localized lesions. The type of needle used can alter the size and amount of tissue depending on the degree of fibrosis or cirrhosis present. A Tru-cut needle is more helpful in obtaining an intact, nonfragmented sample in cases of advanced cirrhosis.

In a study of hepatic pathology, histological changes of biopsy sections should be recognized and an objective morphologic diagnosis should be made prior to examining the clinical and the laboratory data. However, it is much more difficult to arrive at an etiologic diagnosis without such data. Final interpretation of liver biopsy should include a correlation of these data to provide a meaningful pathological diagnosis.

CHAPTER 144

John D. Long and Ralph A. Giannella

DIAGNOSTIC TESTS IN GASTROINTESTINAL INFECTIONS*

This chapter reviews the major tests generally used for microbiologic diagnosis in North America, provides guidelines for their use and interpretation in the evaluation of specific clinical syndromes, and discusses their limitations and cost-benefit issues. Nucleic acid hydridization and reverse transcriptase–polymerase chain reaction (RT-PCR) assays have been developed for most bacterial, protozoal, fungal, and viral pathogens. They are, in general, both sensitive and specific. These assays, however, have not yet found their way into common usage in hospital laboratories. The concept and technical aspects of these assays are discussed in Chapter 135.

MICROBIOLOGIC TECHNIQUES FOR DIAGNOSING CLASSES OF PATHOGENS

Bacteria

General Considerations Bacterial infections are most commonly diagnosed by either culture of the organisms or by the detection of specific bacterial antigens or toxins. Although microscopy or histopathological techniques may be useful in certain circumstances, several macroscopic observations increase the chances that a bacterial pathogen will be present in a body fluid. For example, the presence of grossly bloody diarrhea, especially if accompanied by fever or abdominal pain, increases the likelihood that a patient has a bacterial infection. [1] In body fluids that are normally sterile, microscopic examination often helps identify the organism. Staining of body fluids for organisms is especially valuable if patients have received antibiotics that might interfere with culture results. Stains are also helpful if a fastidious organism such as a fungus or mycobacterium is a potential etiologic agent (when culture results are likely to be either falsely negative or delayed), or when the contents of an abscess are aspirated. In contrast, microscopic examination of a body fluid that is not normally sterile, such as stool, rarely helps detect specific bacterial pathogens because of the polymicrobial composition.

Culture Bacterial culture usually involves placing an aliquot of the specimen onto solid media for stool or tissue, or into liquid media for blood or ascites. The media are incubated under conditions that favor or distinguish various pathogens. Subsequently biochemical tests and, if necessary, serotyping are performed to identify the genus and species. Bacterial cultures necessitate a minimum of overnight incubation, and for many organisms that infect the gastrointestinal (GI) tract, an additional 2 to 3 days might be required for growth and identification. Once the bacteria are identified antibiotic susceptibility can be determined, often within the next 24 hours. The most frequent bacterial test requested in GI practice is a stool culture, which in North America usually includes techniques to detect *Salmonella, Shigella,* and *Campylobacter jejuni.* [2] Greater than 95% of all clinical microbiology laboratories in the United States test for all three organisms routinely. *Escherichia coli* O157:H7, *Yersinia, Vibrio, Aeromonas* species, and *Plesiomonas shigelloides* are less regularly sought. [2] It is important for the gastroenterologist to know which pathogens will be sought routinely by the laboratory to which the specimen is sent. If clinical or epidemiologic factors suggest other pathogens, this should be communicated to the laboratory so that more specific optimal media and conditions can be employed. *Salmonella* and *Shigella* are usually detected using MacConkey *Salmonella-Shigella* agar plates or other selective media and an enrichment broth for *Salmonella.* These media are incubated aerobically and potentiate the growth of gram-negative flora while suppressing the growth of gram-positive flora. *Salmonella* and *Shigella* do not ferment lactose within 24 hours and thus do not acidify the media. An indicator dye in the agar fails to turn pink as a result and the colonies are colorless or white. Supplemental biochemical, functional, and serotyping studies are then performed to confirm the genus and assign species, a process that takes an additional 24 hours. *C jejuni* is usually detected using Campy agar plates which contain antibiotics to suppress other flora (for example, cefoperazone/vancomycin/amphotericin B). The culture process for *C jejuni* requires a microaerophilic environment of 5% oxygen. In addition the agar plates are incubated at 42°C rather than at 37°C. *E coli* 0157:H7, the most frequently isolated member of the enterohemorrhagic *E coli* (EHEC) group in the United States, can be distinguished from most other *E coli* because this serotype either slowly ferments sorbitol or does not ferment it at all. Thus *E coli* 0157:H7 are identified on sorbitol-MacConkey agar, on which they appear as colorless colonies. These colonies are then serotyped with commercially available antisera. [3] The yield of *E coli* 0157:H7 in North America equals or exceeds the yield for other classic bacterial enteric pathogens, yet in one large survey only 34% of microbiology laboratories in the U.S. test for this pathogen as part of a routine stool culture. [2] Other strains of *E coli* (enterotoxigenic, enteropathogenic, enteroinvasive, and enteroadhesive) cause acute diarrhea, but are not generally sought as the assays are only available in research laboratories. *Yersinia enterocolitica* and *Yersinia pseudotuberculosis* can be detected in stool specimens using a selective media containing cefsulodin, irgasan, and novobiocin (CIN). These agar plates need to be incubated between 25°C and 35°C. To detect *Vibrio* species, stool specimens are plated on thiosulfate-citrate-bile salt-sucrose (TCBS) agar. TCBS agar can distinguish *Vibrio cholerae* from noncholera vibrios, such as *Vibrio parahaemolyticus.* After the initial isolation on TCBS agar, biochemical and serologic tests are then performed to confirm the species and serotype. Detection methods for *Aeromonas* species and *P shigelloides* are not well established. *Clostridium difficile,* the predominant cause of antibiotic-associated pseudomembranous colitis, is recovered from stool specimens by the use of selective media such as cycloserine, cefoxitin, and fructose (CCFA) agar. Incubation is done under anaerobic conditions at 35°C and takes 48 to 72 hours. [4] Culture for *C difficile* has largely been replaced by assays to detect *C difficile* toxins in stool (see below).

Bacterial Antigens and Toxins Tests for detection of bacterial antigens and toxins provide several advantages over conventional culture techniques for certain pathogens, including increased sensitivity and much quicker time to diagnosis since most can be performed directly on stool specimens obviating the need for culture. These techniques are mainly applied to detecting infections with *E coli* O157:H7 and *C difficile.* [5], [6], [7], [8], [9], [10], [11], [12] and [13] Specific techniques employed include direct immunofluorescence, latex agglutination, enzyme immunoassays, and cytotoxicity assays. Immunofluorescence techniques involve application of labeled antibodies specific for cell wall products to prepared stool samples and identification of the organism using a fluorescent microscope. Two techniques, the latex agglutination test (LAT) and enzyme immunoassay (EIA), use latex strips or microtiter wells, respectively, which are coated with either monoclonal or polyclonal antibodies against the organism's cell wall antigens or toxins. Processed stool samples are then applied to the strips or wells. In LAT, a positive test results if agglutination of the bacteria is noted. In EIA the wells are incubated for 2 to 3 hours with antibodies conjugated with an enzyme (usually either horseradish peroxidase or alkaline phosphatase). Subsequently a substrate and a chromogen are added and if the antigen or toxin is present, a color change will result. The color change can be detected either visually or with a spectrophotometer. Cytotoxicity assays involve addition of processed stool samples to microtiter wells containing monolayers of mammalian cell lines such as MRC-5 (lung fibroblasts). These monolayers often require incubation for 24 to 48 hours to demonstrate the cytopathic effect, which is usually cell rounding. The assay is considered positive if the cytopathic effect is neutralized by antitoxin. The most common method for diagnosing *E coli* O157:H7 infection is the growth of sorbitol-negative colonies on sorbitol-MacConkey agar. *E coli* O157:H7 can also be identified by a direct immunofluorescence in less than 2 hours with 100% sensitivity and 99.7% specificity. [5] However this test is limited by its inability to detect non-O157:H7 strains that produce the Shigalike toxins Stx1 and Stx2, which are the primary mediators of disease associated with this infection. Various EIAs which rapidly detect these toxins are commercially available and have sensitivities from 82.4% to 100% and specificities of 99.7% to 100%. [6], [7] and [8] The gold standard in the U.S. for diagnosing *C difficile* has become the cytotoxicity assay which identifies toxin B and carries a sensitivity of 67% to 99%. [14] Early studies using an LAT to detect toxin A revealed sensitivities of 48% to 67% and specificities of 96% to 97%. [9], [12] Subsequently the specificity of the LAT was found to be as low as 70% to 80%. Commercially available EIAs to detect toxin A require 2 to 3 hours to complete and carry sensitivities of 64% to 99% and specificities of 93% to 100%. [9], [10], [11], [12] and [13] Unfortunately due to the low sensitivities of some of these assays, the ability to detect *C difficile* infection may be compromised if only one assay is used. [14] A negative EIA should not deter the clinician from making a

diagnosis of *C difficile* colitis and treating the patient in whom the clinical likelihood is very high.
Histopathology Histological examination of colonic biopsy specimens usually will not provide a specific bacterial diagnosis. However, histological features may be helpful in distinguishing an acute self-limited (i.e., infectious-type) colitis from a chronic colitis such as inflammatory bowel disease. In acute self-limited colitis crypt architecture is usually normal, and lamina propria inflammation is predominantly superficial and acute (polymorphonuclear cells) (Fig. 144-1). In contrast, inflammatory bowel disease, especially ulcerative colitis, is characterized by distorted crypt architecture, even early in the course of disease, and a lamina propria that contains acute and chronic (lymphocytes and plasma cells) inflammatory cells [15] (Fig. 144-2). Basilar plasmacytosis and lymphoid hyperplasia and aggregates are other histological features that are more frequent in inflammatory bowel disease and less common in acute self-limited colitis. Epithelial granulomas usually indicate Crohn's disease but can also be present in other less common conditions.

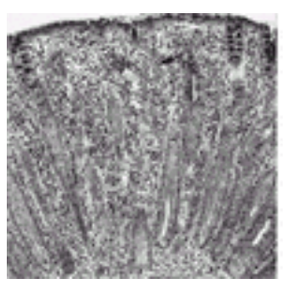

FIGURE 144-1. Biopsy specimen of colorectal mucosa from a patient with acute, self-limited, infectious-type colitis caused by *Campylobacter jejuni.* Notice the preserved crypt architecture, acute lamina propria inflammation, and cryptitis. (From Tarr PI, Surawicz CM, Clausen CR. Microbiologic studies. In: Yamada T, Alpers DH, Laine L, Owyang C, Powell DW, eds. Textbook of gastroenterology, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 1999.)

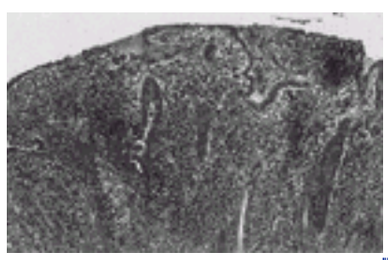

FIGURE 144-2. Biopsy specimen of colorectal mucosa from a patient with ulcerative colitis. Notice the distorted crypt architecture, chronic lamina propria inflammation, and basilar plasmacytosis. These histological features are typical of inflammatory bowel disease and rare in acute self-limited colitis. (From Tarr PI, Surawicz CM, Clausen CR. Microbiologic studies. In: Yamada T, Alpers DH, Laine L, Owyang C, Powell DW, eds. Textbook of gastroenterology, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 1999.)

Infections with *E coli* O157:H7 and *C difficile* may demonstrate certain histological features that support the diagnosis. For example, colitis from *E coli* O157:H7, which is often right-sided, may mimic ischemia clinically and demonstrate superficial necrosis histologically. [3] Colitis associated with *C difficile* is commonly associated with pseudomembranes which can be visualized on endoscopy but also demonstrated on biopsy by the presence of a layer of fibrin, neutrophils, and cellular debris emanating or erupting from the mucosa. Pseudomembranes may be present even in milder cases in which the mucosa is uninflamed. [4]

Protozoan and Parasites

General Considerations Modern air travel enables patients to acquire exotic infections that might never be considered as causative agents in the patient's home community. In this section the term *parasite* is used to include protozoan. Laboratory identification of parasites from stool specimens depends on observer competence and experience, which may be quite variable in different laboratories. Furthermore, the finding of a parasite or protozoan in a stool sample does not incriminate it as a cause of the patient's symptoms. Although parasitic infections are common, the range of diagnostic tests is limited and consists of examination of body fluids and tissues for ova, parasites, and parasitic antigens, and blood for serologic tests. Parasites are in general not identifiable by culture techniques.
Body Fluids Various stages of the life cycles of parasites can be detected by directly examining wet mounts or stains of fresh stool. A complete evaluation of stool for ova and parasites (O & P) should include an examination of both fresh and fixed specimens. Trophozoites are more likely to be detected in diarrheal or semisolid stools, whereas cysts may be detected in solid stools. If a stool specimen cannot be examined and processed immediately after collection, appropriate fixatives should be used including 10% formalin, polyvinyl alcohol, or merthiolate-iodine-formaldehyde. [16] Barium or bismuth may interfere with visualization by such methods and thus should not be administered to the patient for at least one week before examination. *Giardia lamblia* is most commonly diagnosed by the identification of cysts or, less frequently, trophozoites in fecal specimens that are stained with trichrome or iron hematoxylin. [17] Stool samples should be concentrated by formalin-ethyl acetate or zinc sulfate methods. The cysts are oval in shape and in general 11 to 15 μm in size. If motile trophozoites are detected by a direct examination of fresh stool using a wet mount, this may correlate better with symptomatic giardiasis. At best these methods, which depend largely on observer experience, are only 60% to 70% sensitive in confirming a diagnosis of giardiasis. [17] In patients with chronic diarrhea due to giardiasis, the results of stool examinations may be repeatedly negative despite high suspicion of this parasite. In such cases it may be necessary to sample the lumenal contents of the small bowel, obtained by either the string test or duodenal aspiration. For the string test, the patient swallows a capsule on the end of a string which moves to the jejunum where the trophozoites attach. After a minimum of 4 hours, the string is withdrawn and inspected for trophozoites. [17] Duodenal aspiration can also be accomplished during an upper endoscopy. Direct examination of unstained stool is not useful for the identification of some protozoa such as *Cryptosporidium, Isospora, Cyclospora,* and microsporidia, since these organisms are too small to be noted. The gastroenterologist should be aware of the practice of the laboratory when ordering a routine O & P examination, as many laboratories do not routinely perform the special staining techniques needed to detect these pathogens. *Cryptosporidium, Isospora,* and *Cyclospora* can be readily identified by a modified acid-fast stain. [18] The oocysts of *Cryptosporidium* are 2 to 6 μm in size, *Cyclospora* 8 to 10 μm, and *Isospora* 20 to 30 μm. Microsporidia spores can be identified in fecal specimens but they are hard to differentiate from bacteria and debris. Microsporidia spores can be identified using a modified trichrome stain. [19] *Entamoeba histolytica* can be diagnosed in fecal specimens by the identification of trophozoites using wet mounts or the trichrome stain. However traditional wet mount and stains are at best 60% sensitive for identifying *E histolytica,* mainly because this organism is identical in appearance to *Entamoeba dispar,* a nonpathogenic commensal protozoan. [20] Hematophagous amoebas (i.e., contain ingested red blood cells) provide better but not definitive proof of *E histolytica* infestation.
Parasite Antigens Some intestinal parasitic infections may escape detection despite multiple direct examinations of stool. To avoid the need to perform endoscopy for diagnosis in these patients, rapid antigen detection tests have been developed which can directly detect the parasite or parasite-specific molecules in the stool. Many antigen detection tests have been developed to diagnose *Giardia lamblia* and *Cryptosporidium parvum.* [21], [22], [23], [24], [25], [26], [27], [28], [29], [30] and [31] Direct immunofluorescence tests of fecal specimens have more than 99% sensitivity and 100% specificity in identifying *G lamblia* and more than 93% sensitivity and 100% specificity in identifying *C parvum*. [23], [24], [25], [26] and [27], [30] There are several commercially available EIAs that are useful for the diagnosis of *G lamblia* infection. All are directed at detecting the presence of a *Giardia*-specific antigen (GSA) that is present on both cysts and trophozoites. [17] These assays have more than 90% sensitivity and more than 96% specificity in identifying *G lamblia*. [21], [22], [23] and [24], [27], [28] Similarly, there are also several EIAs that can be used to diagnose infection with *C parvum;* these are directed at detecting the presence of a *Cryptosporidium*-specific antigen (CSA) that is present on oocysts. [31] These assays have more than 83% sensitivity and more than 96% specificity in identifying *C parvum*. [27], [28], [29], [30] and [31] As noted, distinguishing *E histolytica* from *E dispar* is difficult using conventional O & P examination of stool specimens. Only 10% of people with amebiasis suffer from symptomatic, invasive disease, whereas 90% are asymptomatic cyst passers. [20] Therefore, it is important to know whether the amoeba on a conventional O & P examination is truly *E histolytica.* One rapid EIA is available that can distinguish *E histolytica* from *E dispar* with a 95% sensitivity and 93% specificity. [32] Polymerase chain reaction (PCR) techniques, however, are the most sensitive ways to distinguish these two amoeba. [33]
Serology The local availability of parasite serologic tests varies, although most tests can be performed at the Center for Disease Control in Atlanta or in private reference parasitology laboratories. However, in many situations physicians may not be able to wait for the result of a serologic study before initiating medical or surgical therapy. Also, the clinician must determine the likelihood that a positive result explains the symptoms being evaluated. For example, the finding of antibodies to *E histolytica* in a patient with colitis or a liver abscess is helpful in confirming the presence of invasive amebiasis, [20] while the finding of antibodies to *Echinococcus* in a patient with a liver cyst might help avoid needle aspiration, which is contraindicated and could lead to anaphylaxis. [34] In contrast, the finding of antibodies to *E*

histolytica in an asymptomatic person or in a patient who has lived for many years in the tropics may not be as helpful. Negative results for parasite serologic study can be helpful in excluding *E histolytica* or *Echinococcus* in the patient with a liver abscess or cyst. Several EIAs are available for the detection of serum antibodies to *Strongyloides stercoralis.* Sensitivities vary from 80% to 90% and specificities from 90% to 100%. [35]

Histopathology Mucosal biopsy may aid in the diagnosis of parasitic infections when the stool examination or serology is negative. Parasites that may be detected by small intestinal biopsy include *G lamblia, C parvum, Isospora belli,* microsporidia, and *S stercoralis.* Parasites that can be detected by colonic biopsy include *E histolytica, S stercoralis,* and *Schistosoma* species. *G lamblia* trophozoites, which are pear-shaped, can be present on the lumenal surface of the small intestine (Fig. 144-3). *G lamblia* does not invade the mucosa and does not usually cause inflammatory or structural changes. However, in individuals who are immunodeficient, small bowel mucosa may show flattening of villi and chronic lamina propria inflammation. *Cryptosporidium* oocysts are also only present on the lumenal surface of enterocytes and on stained specimens appear as round, blue dots. [18] *C parvum* may be associated with blunting of the villi and increased eosinophilia of the lamina propria, especially in cases of massive infection. The oocysts of *I belli,* which are flask-shaped, can only be detected within the enterocytes (as inclusions). [18] Giemsa stains help identify these oocysts. Finally, microsporidia can be detected in biopsy specimens of the small bowel using routine light microscopy, although these are best detected on electron microscopy. [18] Microsporidia can be detected as inclusions at the apical surface of enterocytes.

FIGURE 144-3. Biopsy specimen of duodenal mucosa from a patient with giardiasis. Notice the trophozoites of *Giardia lamblia* lining the lumenal surface of the enterocytes. E histolytica can be detected on mucosal biopsy specimens of the colon. The cecum, ascending colon, and rectosigmoid are most commonly involved. [36] The organisms are usually found in the superficial areas of ulcerated mucosa, such as in the surface exudate, but can also be found in the mucosa and submucosa (Fig. 144-4). The trophozoites are usually large in size (10–30 µm) and have foamy cytoplasm with small, round nuclei. They are best detected through biopsy of the shallow, flask-shaped ulcers caused by amebiasis. In general these ulcers occur over lymphoid follicles and are associated with minimal inflammatory reaction.

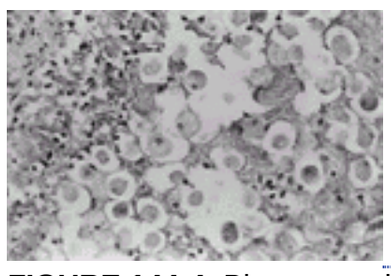

FIGURE 144-4. Biopsy specimen of colorectal mucosa from a patient with amebic colitis. Notice the abundant trophozoites of *Entamoeba histolytica* in the surface mucus. (H & E stain; original magnification ×400). (Courtesy of Amy Noffsinger, M.D., Department of Pathology and Laboratory Medicine, University of Cincinnati College of Medicine).

Both schistosomiasis and strongyloidiasis can be diagnosed on colonic biopsy. *Schistosoma* ova can be detected and can produce foreign body granulomas. *S stercoralis* causes chronic inflammation and both the adult worms and oocysts can be often be detected in the mucosa. [37]

Mycobacteria

Only 20% of cases of *Mycobacterium tuberculosis* involving the GI tract are associated with active pulmonary tuberculosis. [38] In contrast, over 75% of patients with disseminated mycobacterium avium complex (MAC) will have GI or hepatic involvement. [39] *M tuberculosis* involves the jejunum, ileum, or cecum in more than 75% of cases, whereas MAC involves primarily the duodenum. [38], [40]

Smear and Culture *M tuberculosis* is rarely diagnosed without smear or cultures of mucosal biopsy specimens. [41] The highest yield for such an evaluation is obtained by colonoscopy, since the cecum and terminal ileum are commonly involved. Smears are usually examined by use of an acid-fast stain (e.g., Ziehl-Neelsen) but in general are very insensitive. Cultures of mucosal biopsy specimens using Lowenstein media are more sensitive but take 4 to 6 weeks for results. In the patient with human immunodeficiency virus (HIV) with fever and chronic nonbloody diarrhea, disseminated MAC is most readily diagnosed by blood or bone marrow culture. [38] A positive result may avoid an invasive GI evaluation. In some cases, however, stool, or endoscopic investigations may be required. Smears and mycobacterial culture of stool specimens have a moderate (approximately 70%) yield for MAC.

Histopathology The classic histological features of GI *M tuberculosis* infection include epithelioid granulomas with Langhans giant cells. [38] Central caseation is also a helpful sign, but is more often absent on biopsy because it is more likely found in surrounding lymph nodes (which are not sampled in a biopsy). These histological signs are present in less than 50% of definitive cases of *M tuberculosis* diagnosed by other means (e.g., culture). MAC infection is most apparent in biopsy specimens obtained from the duodenum. The typical features include the presence of multiple foamy macrophages located in the intestinal villi, an appearance similar to that of Whipple disease. [40] In MAC infection, granulomas are rarely observed.

Fungi

Fungal infections should be considered in the differential diagnosis of esophagitis, hepatic masses, and rarely diarrheal syndromes. [42], [43] and [44] In particular infection with a fungus should always be considered in immunosuppressed individuals. The identification of a commensal fungus, (e.g., *Candida*) from a fluid or tissue that is not normally sterile, in the absence of gross or histological evidence of abnormality, should be interpreted cautiously. In contrast, the isolation of a fungus from a fluid or tissue that is normally sterile, such as blood, should always be taken seriously. Viral infections such as herpes simplex virus (HSV) and cytomegalovirus (CMV) can coexist with a fungus, thus the presence of a mucosal fungal infection should not stop the search for additional viral pathogens. Because fungal infections may require prolonged therapy with toxic agents, every effort should be made to establish the specific diagnosis.

Smear and Culture A smear of the characteristic exudates of mucosal fungal infections, the most common being *Candida albicans,* are obtained usually by endoscopic brushing. Stains such as Gram stain, potassium hydroxide, and periodic acid-Schiff (PAS) are used to identify the fungus. Fungal cultures are obtained by placing the appropriate specimen on growth media. The rapidity with which positive cultures are reported usually depends on the size of the inoculum and the inherent growth characteristics of the specific fungus.

Histopathology *Candida esophagitis* is the most frequent fungal infection of the GI tract encountered in immunocompromised patients. In esophageal mucosal biopsies, pseudohyphae can be seen on routine light microscopy of hematoxylin and eosin (H & E) stained sections [42] (Fig. 144-5). Silver or PAS stains can improve detection in certain situations. The finding of a granuloma on histological examination suggests the presence of a fungal infection such as histoplasmosis and blastomycosis. Additionally in histoplasmosis, the lamina propria may be filled with macrophages containing the organism in the cytoplasm. [45] With appropriate staining, a specific identification based upon the morphology of the fungus can be made.

Viruses

General Considerations A number of modalities are available for diagnosis of viral infections of the GI and hepatobiliary systems. These include viral growth in cell culture, detection of viral antigens in serum or stool, serology, electron microscopic imaging of the virus particle, nucleic acid hybridization technology, or demonstration of characteristic histological features or specific antigens in biopsy specimens.
Cultures Viral cultures of body fluids are only variably helpful in diagnosing GI infections. Virus isolation from stool, which is not normally sterile, is not useful in diagnosing acute enteric infection. The isolation of viruses from fluids and tissues that are normally sterile is more useful. For example, the recovery of CMV from blood or urine might suggest systemic CMV infection that can be associated with GI and hepatic manifestations. Viral cultures are more commonly obtained on biopsy and brushing specimens of mucosal ulcers in immunocompromised patients. The specimen should be placed in sterile viral transport medium which contains both antibacterial and antifungal agents that inhibit the growth of contaminants. Media that are supplied frozen should be kept frozen until immediately before use, but some commercially available viral transport media do not require frozen storage. A conventional viral culture entails inoculation of tissue culture cells. [46] This technique frequently uses a monolayer of cells in a shell (centrifuge) vial. Viral cultures are usually incubated for several weeks after inoculation before issuing a final negative result. HSV, adenovirus, and enteroviruses usually grow within 7 to 10 days of inoculation, while CMV usually grows within 10 to 21 days. One technique that has been developed to shorten the time to diagnosis is the application of specific monoclonal antibodies directed against viral antigens present in the inoculated tissue culture cells. This process may provide a presumptive diagnosis within 48 hours, well before any typical cytopathic effects are seen. [46]

Serology

Determining the presence and the class (i.e., immunoglobulin M or G) of antibodies directed against specific pathogens can be used to characterize whether the infection is acute versus persistent or resolved. In addition, the level of antibodies may be quantified by serial dilution or by enzyme immunoassay. [47] A significant (usually fourfold) rise in antibody levels against a specific virus, as determined by using paired acute and convalescent specimens, is presumptive evidence of acute systemic infection. The absence of antibodies to CMV viral antigens is highly predictive of the absence of mucosal disease as long as the infection has been present long enough to elicit an antibody response and the patient is able to mount an antibody response. Likewise the appearance of antibodies to HSV or CMV antigens in a previously seronegative, recently transfused person should be interpreted cautiously since these antibodies could have been obtained passively from a seropositive donor.

To properly interpret the presence or absence of antibodies to specific viruses, several qualifying circumstances must be considered. A false-positive result may result from a previous infection that has resolved and is thus no longer germane to the patient's symptoms. Other causes of false-positives include a cross-reactive antibody to a different pathogen or the polyclonal activation of the patient's B cells. A false-negative result may be caused by the fact that specific antibodies were either never produced or have not yet been formed.

Imaging by Electron Microscopy Electron microscopy is not commonly used in the clinical setting. Electron microscopic study of stool specimens can be used for diagnosing noncultivatable viruses such as the Norwalk agent or rotavirus, which have distinctive morphologic features that can be recognized. Immune electron microscopic study, which uses antibodies present in convalescent sera to enhance the morphologic features of viruses in stool obtained during the acute illness, is chiefly a research tool.
Histopathology Biopsy diagnosis of viral infection is used most frequently in evaluating esophagitis and colitis, especially in immunosuppressed adults. In immunocompetent individuals, HSV can cause esophagitis as well as a sexually transmitted, self-limited proctitis. Self-limited colitis due to CMV has also been described in immunocompetent individuals. [48] The presence of typical cytomegaloviral inclusions on routine H & E stains of mucosal biopsy specimens is considered the gold standard for diagnosing CMV infection. [49] The CMV-infected cell is large (25–35 µm) with a basophilic intranuclear inclusion surrounded by a clear halo giving rise to an "owl's eye" appearance. Intracytoplasmic inclusions are also present (Fig. 144-6). CMV typically infects endothelial cells, but glandular epithelial cells can also be infected, particularly in the stomach. The surrounding tissue may be normal or may exhibit nonspecific focal or diffuse inflammation or ulceration. Routine histological analysis for CMV, although the gold standard, is unfortunately less than 100% sensitive and in some cases the pathologist may have difficulty finding cells with typical features of CMV. Other methods that have been developed to help detect CMV in biopsy specimens include immunohistochemistry (immunoperoxidase or immunofluorescence methods), [50], [51] and [52] in situ DNA hybridization, [52], [53] and [54] and PCR. [55] All three methods are either as sensitive or more sensitive than light microscopy, with PCR being the most sensitive. [49] The only drawback of the higher sensitivity of PCR is that in patients with documented CMV mucosal lesions; 20% of biopsies taken from normal-appearing areas are positive as well. [55]

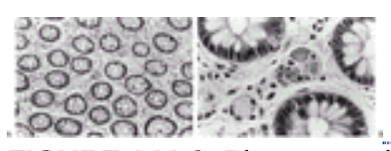

FIGURE 144-6. Biopsy specimen of colorectal mucosa from a patient with cytomegalovirus (CMV) infection. **A:** Low power (original magnification ×100) view showing scattered typical cytomegalovirus inclusions. **B:** Higher magnification (original magnification ×400) of a CMV-infected endothelial cell demonstrating the intranuclear inclusion. (H & E stains.) (Courtesy of Amy Noffsinger, M.D., Department of Pathology and Laboratory Medicine, University of Cincinnati College of Medicine.)

Light microscopy examination of H & E-stained mucosal biopsy specimens is also considered the gold standard for diagnosing HSV infection since it produces characteristic intranuclear inclusions (Fig. 144-7). The intranuclear, or Cowdry type A, inclusion is smaller than the inclusion associated with CMV infection and thus may be more difficult to detect. Other histological features that suggest HSV infection are the presence of multinucleated giant cells and cells with ground-glass nuclei. [56]

associated multinucleated giant cell. (H & E stain; original magnification ×400.) (Courtesy of Amy Noffsinger, M.D., Department of Pathology and Laboratory Medicine, University of Cincinnati College of Medicine.)

TECHNICAL ASPECTS OF SPECIMEN COLLECTION

The office and procedure suites of gastroenterologists should be equipped with the materials needed to collect and transport specimens for microbiologic testing. The most important element in specimen collection and processing is rapid transport to the laboratory. Table 144-1 summarizes the materials and other factors required for transport and processing of specimens for each of the classes of pathogens.

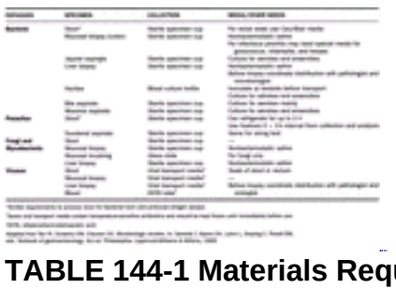

TABLE 144-1 Materials Required for Microbiologic Testing Performed By Gastroenterologists

INDICATIONS FOR MICROBIOLOGIC TESTING

Diarrhea

Acute Diarrhea Most cases of acute diarrhea in immunocompetent adults are self-limited and thus do not require investigation. However, stool cultures are obtained frequently even though their yield is notoriously low: 5.7% in combined data from 10 studies with over 90,000 stool specimens. [2], [57], [58], [59], [60], [61], [62], [63], [64] and [65] Attempts have been made to identify clinical factors that increase the yield of stool cultures. [1] Factors such as abrupt onset of diarrhea, greater than four stools per day, absence of vomiting before the onset of diarrhea, or the presence of fever, bloody diarrhea, tenesmus, abdominal pain, or raw seafood ingestion all increase the likelihood of recovering a bacterial pathogen from a stool culture. Recent American College of Gastroenterology guidelines for the evaluation and treatment of acute infectious diarrhea [1] suggest that bacterial stool culture be limited to patients with:

- severe diarrhea (>6 stools/24 hours, or >48 hours duration of illness, or diarrhea that results in clinical volume depletion)
- temperature >101.3°F
- dysentery (bloody stools)
- stools positive for occult blood, leukocytes, or lactoferrin
- immunosuppression (e.g., acquired immunodeficiency disease [AIDS], transplant, and cancer chemotherapy).

These guidelines also recognize the low yield of routine stool O & P examinations in patients with acute infectious diarrhea and suggest that indications for O & P be limited to:

- patients with acute diarrhea and recent travel to Russia, Nepal, or mountainous regions
- infants attending day care centers
- patients with AIDS or homosexual men
- those exposed to a possible community waterborne outbreak
- patients with bloody diarrhea but few or no fecal leukocytes. [1]

A spot analysis of stool samples for the presence of leukocytes has been advocated as a measure to increase the chance of isolating a bacterial pathogen. [1] Leukocytes may be detected by light microscopy using methylene blue staining. Bacterial pathogens are more likely to be isolated from samples that contain fecal leukocytes, although the absence of leukocytes does not accurately predict the absence of a bacterial pathogen. For example, in a summary of several studies that reported the prevalence of leukocytes in stool samples from patients with a documented bacterial pathogen, leukocytes were detected in 73% of samples with *Shigella,* 52% with *Salmonella,* 58% with *Campylobacter,* 54% with *E coli* O157:H7, and 42% with *C difficile*. [66] These results suggest that analysis of feces by light microscopy for the presence of leukocytes is not sensitive enough to be used as a screening test and thus certainly cannot be relied on to select patients for bacterial culture. Perhaps a more sensitive test to use for screening stool specimens for bacterial pathogens is the fecal lactoferrin assay. [66] Lactoferrin is a glycoprotein found in leukocytes and can be detected with a commercially available LAT. Two studies showed that the sensitivity of a positive lactoferrin assay in detecting *Salmonella, Shigella,* and *Campylobacter* ranged from 83% to 93%. [67], [68] Similarly one study [69] has shown that the lactoferrin assay was a more sensitive marker (75%) of *C difficile* infection compared to fecal leukocytes (40%), but this was not confirmed in a second study. [70] Two viruses are common causes of acute diarrhea, especially in the winter: rotavirus and Norwalk-like agent, in children and adults, respectively. Although EIAs are available to detect both in the stool, they are not generally used in adults as the illnesses are self-limited and no specific antiviral treatment is available. However, in pediatric practice EIAs for rotavirus are commonly used since a positive assay usually obviates the need to search for other causes.

Diarrhea in HIV-Infected Patients Although the usual bacterial pathogens such as *Salmonella, Shigella,* and *Campylobacter* are potential causes of diarrhea in HIV-infected patients, more common pathogens include protozoa (e.g., *Cryptosporidium*), viruses (e.g., CMV), and mycobacteria. [39] The likelihood of detecting an enteric pathogen in HIV-infected patients with diarrhea depends greatly on the CD4 lymphocyte count and whether endoscopy with mucosal biopsy is used in the diagnostic work-up. Guidelines published in 1996 from the American Gastroenterological Association [39] recommend the following evaluation in HIV-infected patients with chronic, nonbloody diarrhea: bacterial culture for enteric pathogens (including *Salmonella, Shigella,* and *Campylobacter*), *C difficile* toxin assay, modified acid-fast stain (to detect *Cryptosporidium* and *Isospora*), modified trichrome stain (to detect microsporidia), and blood culture for bacteria and mycobacteria (if fever is present). For patients in whom this initial evaluation fails to arrive at a diagnosis, especially in those with bloody diarrhea or CD4 counts less than 100, lower endoscopy with mucosal biopsies is recommended. In most cases a flexible sigmoidoscopy (rather than a full colonoscopy) is all that is necessary. To optimize the yield and minimize costs, colonic biopsies should be obtained from endoscopic lesions and not from normal mucosa. In addition, processing of biopsies in these patients should be limited to routine H & E staining since there is little evidence that the use of cultures or special stains increases the identification of viruses, mycobacteria, or fungi. [71] For example, one study of 121 HIV-infected patients who underwent endoscopic biopsy revealed that careful evaluation of H & E stains was 97% sensitive and 100% specific in diagnosing CMV. [71] In the same study, special stains used to identify CMV and HSV (immunoperoxidase), mycobacteria (acid-fast), and fungi (silver or PAS) did not increase the diagnostic yield over routine H & E. In a study of 290 HIV-infected patients with diarrhea who underwent colonoscopy with mucosal biopsies, the yield of culturing biopsy specimens for bacteria, mycobacteria, and fungi was found to be quite low. [72] The spectrum of causes of chronic diarrhea in HIV-infected patients has been changing over the last 5 years, and this trend may eventually impact the diagnostic approach suggested in the American Gastroenterological Association guidelines. [39] The change in spectrum is largely a result of the widespread use since 1996 of protease inhibitors and HAART (highly active antiretroviral therapy). These therapies, which significantly restore CD4 counts and lower viral load, have led to a significant reduction in the incidence of opportunistic infections. [73] For example, in a cohort of HIV-infected patients with chronic diarrhea, the prevalence of opportunistic infections fell from 53% in 1995 to 13% in 1997. [74] During this same time period the number of patients evaluated for chronic diarrhea did not change but those diagnosed with noninfectious causes increased significantly.

Nosocomial Diarrhea Diarrhea that develops in patients after 3 days of hospitalization is classified as nosocomial or hospital-acquired. Nosocomial diarrhea is rarely caused by community-acquired bacterial or parasitic pathogens. For example, 6 studies have compared the yield of bacterial stool culture obtained during the first 3 days of hospitalization (2%–12.6%) versus the yield after 3 days (0–1.5%). [2], [57], [60], [61], [63], [65] The yield in the first 3 days is 2 to 9 times higher. Similar results are obtained with the use of routine O & P examinations in patients with nosocomial diarrhea. [2], [57], [75] Despite this low yield, it has been shown that as much as 50% of all bacterial stool cultures submitted to microbiology laboratories are obtained from patients who have been hospitalized for more than 3 days, and this results in substantial costs per positive diagnosis. These issues have helped formulate the “3-day rule” which recommends that stool samples submitted for routine bacterial

culture be rejected if obtained from a patient hospitalized for more than 3 days. [66] Strict application of such criteria would result in significant reductions in costs through limiting the use of supplies and reagents and decreasing laboratory staff time. Unfortunately, a few cases of clinically important nosocomial diarrhea resulting from these bacterial pathogens could be missed. As a result, a modified 3-day rule has been advocated which allows cultures to be processed after 72 hours of admission in certain high-risk patients (age >65 with significant co-morbid illnesses, HIV infection, or neutropenia) or in cases in which a nosocomial outbreak of salmonellosis is suspected. [76] *C difficile* is the most common nosocomial infection of the GI tract and tests to detect this pathogen should be used in the evaluation of nosocomial diarrhea. Clinical factors which increase the yield of detecting *C difficile* include recent hospitalization (especially if within the last 2 weeks), antibiotic use within 30 days (particularly cephalosporins), the presence of abdominal pain or significant diarrhea, a white blood cell count more than 10,000/mm, and the presence of fecal leukocytes or lactoferrin. [70], [77], [78] Other frequent causes of diarrhea in hospitalized patients include medications, particularly elixirs that contain sorbitol, and tube feedings. In addition, antibiotics may cause diarrhea in the absence of *C difficile.*

Chronic Diarrhea Bacterial infections are rarely the cause of chronic diarrhea in immunocompetent patients. However, *Y enterocolitica, Aeromonas* species, *C difficile, Campylobacter,* and some *E coli* can cause chronic diarrhea. Thus, at least one routine stool culture should be obtained at some point during the evaluation of these patients, especially in patients with an elusive diagnosis in which an initial negative stool analysis did not include a bacterial culture. [79] In general stool should also be sent for routine O & P examination and for a *C difficile* toxin assay. [79] Some patients with chronic diarrhea may be suspected of having small intestinal bacterial overgrowth. Quantitative aerobic and anaerobic cultures of jejunal aspirates are still the most reliable methods to diagnose this syndrome. [79] Greater than 10 [6] aerobic or anaerobic organisms per mL of fluid is considered a positive culture. The most common aerobic bacteria isolated are *E coli* and *Streptococcus,* while the most common anaerobic are *Lactobacillus* and *Bacteroides.* [80] These tests are, however, cumbersome since they require intubation of the small bowel to obtain the fluid. Several noninvasive breath tests have been used in practice to detect small intestinal bacterial overgrowth, including ^{14}C (using radioactive xylose as a substrate) and hydrogen (using glucose or lactulose as a substrate) breath testing. [79] These tests are easy and safe to administer but suffer from poor sensitivity and specificity. [81] In some cases of chronic diarrhea, sampling of duodenal contents occasionally is warranted to diagnose parasitic infections such as giardiasis. The string test can be used to perform this task and can identify *G lamblia* and strongyloidiasis. Alternatively aspiration of duodenal fluid or mucosal biopsy, both accomplished using upper endoscopy, may be required to detect such infections. Other protozoa that can cause chronic diarrhea include *Cryptosporidium* and *E histolytica.*

Inflammatory Bowel Disease Bacterial enteric pathogens (*Campylobacter, Salmonella, Shigella,* EHEC, *Yersinia,* and *C difficile*), amebiasis, and CMV have all been associated with idiopathic inflammatory bowel disease (IBD). These infections may be associated with either the first attack of IBD or relapses in patients with well-established disease. [82], [83] For example, one study reported a 20% prevalence of bacterial pathogens including *C difficile* in first attacks of IBD. [82] In another study of 64 patients with IBD who suffered a relapse and in which stool cultures were obtained, 17% were found to be infected with an enteric pathogen. [83] *C difficile* and sometimes the toxin produced by this organism may be present in stools from patients with IBD, but in most cases *C difficile* does not appear to be a pathogen. However, in a patient with severe colitis or disease refractory to therapy who has cytotoxin in stools, therapy to eradicate *C difficile* should be strongly considered. Stool examination and serologic study for *E histolytica* should be done at least once in all patients with inflammatory bowel disease, particularly in those who lived or traveled in an area where amebiasis is prevalent. [84] CMV may be an important exacerbating factor in inflammatory bowel disease (particularly in patients with ulcerative colitis). Infection with CMV has been reported in patients with new-onset and flares of ulcerative colitis, [85] pouchitis, [86] and severe or refractory ulcerative or Crohn's colitis. [87] Some cases of CMV complicating ulcerative colitis involved patients who had never received steroids or other immunosuppressants. [88] Patients with both conditions often require colectomy and carry a high mortality rate. One case series found CMV on biopsy in 11% of 62 patients with severe colitis and in 37% of those refractory to steroid therapy. [87] Based on this information it seems reasonable to exclude superimposed enteric infections in patients with new-onset IBD. Furthermore, patients with IBD who develop either severe colitis refractory to medical therapy or toxic megacolon (and thus are approaching need for colectomy) might benefit from an evaluation for superimposed CMV infection since ganciclovir may be an effective therapy. [85] It remains to be determined whether it is clinically helpful and cost-effective to exclude a superimposed enteric infection in every patient with a mild-to-moderate relapse of IBD.

Infectious Esophagitis

Infectious esophagitis has been extensively reviewed in this text (Chapter 61) as well as in numerous journal articles. [42] Infectious esophagitis primarily occurs in the setting of immunosuppression, particularly in HIV-infected patients. The most frequent causes are *C albicans,* CMV, and HSV. Mixed infections can occur. Efforts should be made to establish the presence of these agents since all three are readily treatable. Since *C albicans* is by far the most common esophageal pathogen in HIV-infected patients, current guidelines recommend an empiric trial of appropriate antifungal therapy in these patients before endoscopic evaluation. [42] If therapy fails or if symptoms recur, the patient should be investigated. *C albicans* can be easily identified by mucosal brushings, which have a lower yield for identifying CMV and HSV. Biopsies of both the base and edges of an esophageal ulcer and use of H & E staining will be diagnostic of CMV and HSV. [42] Therefore it is generally not necessary to send biopsy material for fungal or viral cultures or use special techniques such as immunohistochemistry or in situ DNA hybridization in order to make the diagnosis. [71]

Cholecystitis and Cholangitis

Bile obtained from the gallbladder and the bile ducts is normally sterile in healthy individuals. [89] The prevalence of bacterial infection of bile correlates with the severity of the underlying disease. For example, patients with symptomatic cholelithiasis have a 20% prevalence while those with ascending cholangitis have over a 90% prevalence. [90] Cultures of infected bile are most often polymicrobial. The most common pathogens are *E coli, Enterococcus, Klebsiella,* and *Enterobacter,* while anaerobes are fairly uncommon. [89], [90]

Blood cultures should be obtained on febrile patients with suspected cholecystitis. Furthermore, cholecystitis or indolent ascending cholangitis should be suspected as a source of fever and bacteremia in patients without other symptoms or signs of biliary tract infection, in particular elderly patients. Samples of bile can be obtained by aspiration during procedures to decompress an obstructed biliary tree, such as percutaneous transhepatic cholangiography or endoscopic retrograde cholangiopancreatography. These specimens should be sent for aerobic culture.

Pancreatitis

Bacteria, parasites, and viruses can precipitate acute pancreatitis. [91] In order to qualify as an infectious cause of pancreatitis, patients need to have both clinical evidence of pancreatitis as well as documentation of infection by the pathogen (i.e., organism identified in the pancreatic parenchyma, duct, or juice or a fourfold-rise in serologic titers). Using these strict criteria Parenti and colleagues [91] identified 32 definite or probable cases in the literature of acute pancreatitis caused by infectious agents. The most common causes were CMV and *Ascaris lumbricoides.* The latter roundworm causes pancreatitis by direct obstruction of the common bile duct or pancreatic duct.

If the common precipitants of acute pancreatitis (e.g., alcohol, gallstones, drugs) have been excluded, it may be reasonable to consider an infectious cause although these are very uncommon. In a patient who is immunocompromised due to HIV or transplantation, CMV serology may be indicated. Likewise in a patient with risk factors for *A lumbricoides,* it would be reasonable to obtain stool for ova and parasite examination. Superimposed bacterial infection frequently complicates severe acute pancreatitis. [92]

Peritonitis

Infections of the peritoneum are almost always caused by bacteria or fungi. Spontaneous bacterial peritonitis (SBP) usually occurs in cirrhotics with preexisting ascites and complicates about 15% of such patients. [93] Over 90% of cases of SBP involve monomicrobial infections. About 70% are caused by aerobic gram-negative bacilli, the most common organism being *E coli.* Approximately 25% are caused by gram-positive organisms and only 5% are caused by anaerobes. [93] SBP is diagnosed by paracentesis and culture of the ascitic fluid. Optimal yield is obtained if the fluid is placed in a blood culture bottle at the bedside before transport to the microbiology laboratory.

For patients in which ascitic fluid culture yields a polymicrobial bacterial infection or a fungal pathogen, a perforation of a hollow abdominal organ should be suspected as spillage of both aerobic and anaerobic bacteria can occur. [94] Other indications to culture ascitic fluid for fungi include patients with peritonitis who have indwelling peritoneal dialysis catheters or patients who recently had abdominal surgery.

COST ISSUES IN MICROBIOLOGIC TESTING

The very low yield of nonselective bacterial stool culture and O & P examinations has not been subject to much scrutiny in clinical practice because these tests are easy to perform and involve little risk to the patient. The occasional positive result can lead to specific therapy and the avoidance of more expensive and risky diagnostic interventions such as endoscopy and biopsy. Despite these apparent benefits, the costs of such practices are significant with estimates of $1000 to $1300 per positive culture. The costs of performing a routine stool bacterial culture include charges for reagents, supplies, technologist time, and charges to the patient. Two surveys of microbiology laboratory practices in 668 hospitals in the United States revealed that the majority (>50%) did not have a policy that restricted the number of stool specimens that would be processed per patient. [2], [95] Furthermore, less than 25% of hospitals rejected specimens submitted after 3 days of hospitalization. Based on the fact that nearly 50% or more of stool specimens submitted to microbiology laboratories are from patients hospitalized for more than 3 days, it has been estimated that application of the “3-day rule” would save the average hospital per year $10,000 of reagent costs, over $70,000 of patient charges, and 730 hours of technologist time. [95] Extrapolation of these figures to the 6000 hospitals in the U.S. suggests that savings of $27 to $73 million a year could be achieved by implementation of such restrictions.

Another source of unnecessary costs associated with stool bacterial cultures and O & P examinations is the submission of multiple specimens from the same patient. It is not an uncommon practice to request the collection of three stool samples before the results of the first sample are known. Several studies have documented that over 90% of enteric bacterial and parasitic pathogens were detected on the first stool sample. [62] Guidelines suggest that to minimize the costs associated with multiple specimens, clinicians should submit an initial stool sample for analysis and then submit additional samples only if the first is negative. An alternative approach would be to order the initial sample, and if negative, to then send the second stool sample for the more rapid and sensitive tests such as immunofluorescence and enzyme immunoassays. For example, in a patient with chronic diarrhea with a recent history of travel to an area with a high prevalence of *G lamblia,* an initially negative routine O & P examination might be followed up with one of the EIAs that specifically detects *G lamblia* rather than another O & P analysis.

CHAPTER 145

Richard A. Kozarek

GASTROINTESTINAL DILATION AND STENT PLACEMENT

The primary goal of treatment of any stenosis is lumenal enlargement and amelioration of obstructive symptoms. Such symptoms depend on the stricture etiology and site and may include dysphagia, nausea and vomiting, abdominal pain and obstipation, or frank bowel obstruction.

Historically, the dilation of gastrointestinal (GI) strictures was limited to accessible anatomic areas, primarily the esophagus or anorectum. With the advent of endoscopically or radiographically placed polyethylene balloons, a variety of gastric, small bowel, and colonic strictures became amenable to such therapy. Likewise, prosthesis placement was initially limited to the esophagus and subsequently expanded into the pancreaticobiliary tree. Expandable metallic stent technology, however, has allowed treatment of previously inaccessible and more central stenoses.

Whereas all of the current dilating systems achieve efficacy by either stricture stretch or fracture, data are sparse regarding the mechanism of action with individual dilating systems. Nor are there good prospective data comparing endoscopically facilitated dilation with alternative treatment modalities. Finally, for central stenoses and chronic proton-pump inhibition for esophageal reflux stricture, there are few studies that compare the efficacy and side effects of various dilating systems. Similarly, despite their widespread use, there are few comparative studies randomizing expandable prostheses in the esophagus. Central placements, in turn, have been limited to small series and data comparing their placement to surgical intervention have not been published. This chapter compares the various technologies with regard to ease and site of application, patient tolerance, cost-benefit ratio, and available safety and efficacy data.

THEORETICAL CONSIDERATIONS

Dilation

The basic goals of stricture dilation include safe and efficacious lumenal enlargement plus prevention of restenosis. [1] The latter may include proton pump inhibitors after esophageal bougienage for a reflux-induced stricture, [2] placement of a prosthesis after dilation of an esophageal malignancy, or elective surgical resection, plasty, or bypass of a dilated area after dilation or stent placement for an obstructing rectosigmoid malignancy.

Although the exact mechanisms of lumenal enlargement remain uncertain, circumferential stretch and stricture split may be operative in stricture dilation. The former presupposes considerable elasticity in circumferential fibrous tissue and the latter an inherent rigidity in which dilation is effected by one or several longitudinal tears. It is unlikely that a pylorus of 3 mm diameter can be dilated to 10 or 15 mm without a significant laceration of scirrhous tissue and, potentially, of muscle. Relevant to this are the gross longitudinal tears and histological disruption of collagen and circular muscle that have been described after esophageal bougienage for fibrous stenoses and achalasia. [3] Most perforations associated with dilation, in turn, appear to be an extension of these tears.

Available dilating modalities can be divided into mercury bougies, guidewire-directed dilators, polyethylene balloons, and miscellaneous types [1] (Table 145-1, Fig. 145-1, Fig. 145-2, Fig. 145-3 and Fig. 145-4). Mercury-filled dilators, ranging in size from 3 to 20 mm (10F to 60F), can be subdivided into the original, blunt-tipped Hurst bougies and a tapered-tip variant called Maloney bougies. Originally passed without fluoroscopic control, these dilators are used infrequently by many practitioners.

Mercury Bougies
Blunt-tip (Hurst)
Tapered-tip (Maloney)
Guidewire-Directed
Metal olives (Jackson-Plummer; Eder-Puestow, including triple olive adaptation)
Hollow-core polyvinyl (Savary-Gilliard, American)
Neoplex stepped-diameter (Celeştin)
Spindle-shaped (Key-Med advanced dilator)
Polyethylene Balloons
TTS
Guidewire facilitated
CRE
Latex Balloons
Brown-McCardy
Mosher
Miscellaneous
Woven silk (Jackson, Phillips)
Graded, plastic oversheath
Tapered-tip endoscope
Balloon or tape affixed to endoscope shaft
Electronic-mechanical (Starck variant)

CRE, controlled radial expansion; TTS, through-the-scope.

TABLE 145-1 Dilators for Gastrointestinal Stenoses

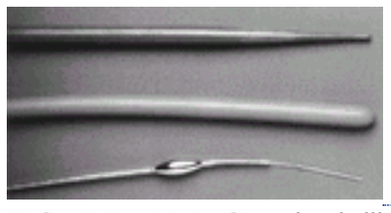

FIGURE 145-1. Standard dilating systems for esophageal bougienage: Maloney (**top**), Hurst (**middle**), Eder-Puestow (**bottom**). The latter two are obsolete but are still used occasionally.

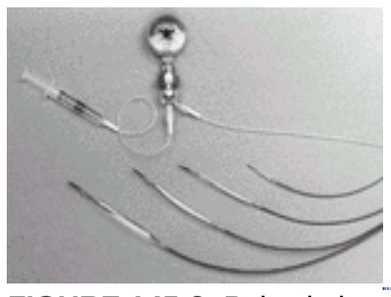

FIGURE 145-2. Polyethylene balloon dilating kit includes mercury manometer and injection syringe. Balloons are passed over an endoscopically or radiographically placed guidewire.

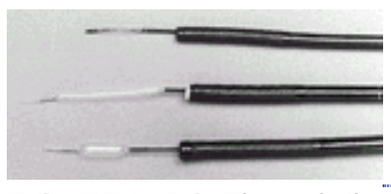

FIGURE 145-3. Through-the-scope polyethylene dilating balloons are available in various lengths and diameters. The biliary balloon (**top**) is a hybrid that passes through the scope but over a guidewire.

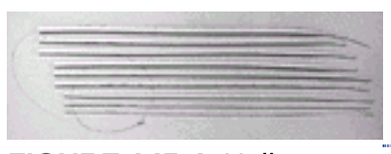

FIGURE 145-4. Hollow-core polyvinyl dilators. The Savary-Gilliard dilator is longer, more tapered, and less radiopaque.

Historically, guidewire-directed dilators have included Jackson-Plummer bougies and Eder-Puestow dilators, which include a triple olive variant in which multiple metal olives of increasing diameter are placed on the same dilating shaft. [4] Four additional wire-guided dilating systems have been marketed: the Key-Med advanced dilator, consisting of three spindle-shaped silicone bougies on stainless steel shafts; the stepped neoplex (Celestin) dilator; and two types of hollow-core polyvinyl systems, the Savary-Gilliard and the American. The Celestin dilating system consists of two tapered dilators that reach a maximum diameter of 12 and 18 mm, respectively. The Savary-Gilliard system consists of bougies ranging in size from 5 to 18 mm (15F to 54F). The American dilating system (Bard, Inc., Mentor, OH) ranges in size from 7 to 20 mm (21F to 60F). In contrast to the barium-impregnated American dilators, Savary-Gilliard dilators are longer and have a more gradually tapered tip.

Bougienage was first used by Fabricus al Acquadendente, who used a wax dilator for a food impaction. [5] The term *bougienage* is derived from the Algerian town of Bouginhay, the medieval capital of the wax candle trade. Cork and woven silk dilators have also been used, the latter since at least the 16th century, when Thomas Willis used a cork-tipped whalebone to treat a probable achalasia patient.

After wire-guided bougies, the second major advance was the development of polyethylene balloons for use in the GI tract. [6], [7] Ranging in diameter from 4 to 40 mm, [6] they allow dilation of previously inaccessible strictures in the stomach, small bowel, and colon. Dilating balloons are fixed on 5F to 7F catheter shafts that range between 100 and 200 cm in length. They can be passed over an endoscopically or radiographically placed guidewire or directly through-the-scope (TTS). A full dilation set includes balloons of variable length and diameter, 5- to 30-mL syringes, guidewires, and a manometer to delineate balloon pressure during inflation; a dilating gun to maintain pressure and stopcocks to ensure a constant pressure during inflation are optional. More recent advances in balloon technology are fabrication of low profile and high compliance balloons. The latter can withstand a dilating pressure three- to fourfold higher than previously marketed balloons and have improved results in recalcitrant strictures. A newer development is the controlled radial expansion (CRE) balloon. [8] These balloons can be passed over a guidewire and variable inflation pressure results in balloons of increasing diameter. A single CRE balloon, contingent upon the pressure used to inflate it, may increase in diameter from 6 to 8, 8 to 10, 10 to 12, 15 to 18, and 18 to 20 mm.

Stents

In contrast to dilation, prosthesis placement attempts to reestablish permanent continuity to the GI tract. The fact that such prostheses are placed primarily in the setting of malignancy suggests that the technology is imperfect: GI stents occlude, migrate, erode, and may allow reflux of potentially noxious GI contents contingent on their location. [9] Symonds is credited with the first prosthesis placement in the esophagus in 1887. Initial stents were fabricated of ivory or boxwood and held in place by a variety of external fixation devices until the development of the inverted funnel by Grootskin in the early 1900s. Since then, a variety of homemade and commercially available esophageal prostheses have been used, the latter usually constructed of latex or silicone molded over a stainless steel core (Table 145-2; Fig. 145-5). Inserted surgically or pushed into place using bougies, a small-caliber endoscope, or an expandable metal olive fixation device (Nottingham introducer), the design of these stents and insertion devices precluded placement across central or sharply angulated stenoses and their application was primarily limited to esophageal or gastroesophageal malignancies.

Conventional
Tygon tubing (homemade)
Silicone/latex-coated steel spiral*
Neoprene coated (Wilson-Cook, Inc.)
Expandable
Wallstent
Esophageal/colonic/enteral
Flamingo variant
Z Stent
21 mm/25 mm flanges
Gianturco-Rösch variant
Dua stent with antireflux valve
Song variant
Esophacoil
Ultraflex
Covered/uncovered

*Multiple types/manufacturers.

TABLE 145-2 Prostheses for Malignant Gastrointestinal Stenoses

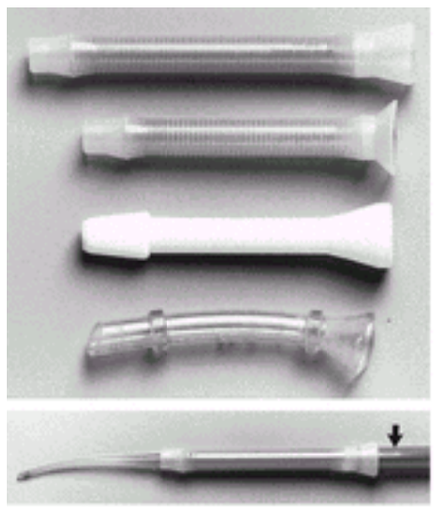

FIGURE 145-5. Conventional esophageal prostheses (**A)**. Conventional and low profile Wilson-Cook stents (**top)**, Atkinson prosthesis (**2nd from bottom**), and homemade stent fashioned from Tygon tubing. *Arrow* demonstrates pusher tube used to seat prosthesis, which is stabilized over a Savary dilator (**B**).

Currently, expandable metal prostheses have supplanted rigid stents in the esophagus and have also made gastroduodenal and colorectal stenoses amenable to prostheses [10] (Table 145-2, Fig. 145-6). Although different in expansible force and delivery systems, all of these prostheses share the feature of placement in a compressed state with subsequent spontaneous or balloon-assisted expansion. Four major types are marketed in the United States and variations of these stents are marketed around the world. The Wallstent (Microvasive, Inc., Natick, MA) was initially introduced as a two-layer stainless steel, double-dogbone prosthesis with an interposed layer of silicone. Subsequently marketed stents are uncovered or partially covered, range between 18 to 25 mm in diameter, and are constrained by an 18F delivery system. A heavily tapered version of this prosthesis (Flamingo stent) has also been marketed in Europe for esophagogastric junction tumors. [11] The Z stent (Wilson-Cook Medical, Winston-Salem, NC) is a 20-mm diameter urethane-covered prosthesis that flares to 22 to 25 mm at the ends. Ranging from 4 to 14 cm in length, the prosthesis must be backloaded into a 28F compression catheter at time of placement. [12] In contrast, the Z stent, marketed in Europe and Asia, has a different coating and delivery system and also has small barbs on the shaft to minimize migration. A variant of the Z stent (Windsock, Dua stent [Wilson-Cook, Winston-Salem, NC]) containing an antireflux valve attempts to minimize regurgitation when used for distal esophageal or cardia malignancies. [13] An additional variant, the Choo stent (Solco Intermed, Seoul, Korea) is marketed in Asia and Europe. The Ultraflex prosthesis (Microvasive, Natick, MA) consists of a 10- or 15-cm long, 18- to 25-mm diameter nitinol weave. The delivery system allows release by pulling a long suture used to constrain the stent on an insertion shaft. Finally, the Esophacoil (Medtronics, Inc., Eden Prairie, MN) consists of a spiral nitinol coil constrained on an insertion shaft by three separate trip wires.

FIGURE 145-6. Expandable prostheses (**left to right**): conventional Z stent, small intestinal mucosa covered Z stent (prototype device), Windsock Z, variably sized Esophacoil and covered Ultraflex prostheses, Flamingo, and Wallstent II.

All of these products differ not only in design and delivery system but also in physical characteristics. Although all are more malleable than conventional prostheses, Ultraflex stents and Esophacoils can often be used for angulated stenoses. Fully covered Z stents and Esophacoils can, at least in theory, be removed and may ultimately play a role in refractory benign strictures. Wallstents and Ultraflex prostheses imbed deeply into the esophageal wall and may have a role to play in patients with esophago-airway fistulae without a tumor shelf. The radial force generated by the prostheses is quite different and may help define the type of stent that is chosen (Esophacoil > Wallstent > Z stent ˜ covered Ultraflex stent). [14]

Advantages of expandable metal prostheses over their conventional counterparts in the esophagus include the ability to be inserted under combined endoscopic and fluoroscopic control and the limited need for dilation for placement. [10] The latter may decrease the risk of bleeding or perforation during insertion. Moreover their flexibility allows placement beyond acutely angulated malignancies and their ability to imbed into the esophageal wall should minimize subsequent stent migrations. Their use in central stenoses (e.g., gastric, duodenal, colorectal) offers a previously unavailable therapeutic option in patients with recurrent, metastatic, or unresectable obstructing malignancies. Examples are obstructing sigmoid cancer with widespread disease or advanced pancreatic cancer and gastric outlet obstruction. [15], [16] and [17]

What remains ill-defined, however, is the role this technology should play compared to conventional treatments such as surgery or percutaneous endoscopic gastrostomy/jejunostomy (PEG/J) placement. Moreover, where this technology fits into our therapeutic armamentarium of ablative therapies (neodymium:yttrium-aluminum garnet [Nd:YAG] laser, bipolar cautery, caustic therapy, argon plasma coagulation, photodynamic therapy) requires continued evaluation. [18]

TECHNICAL APPLICATION

Dilation

In general, radiologic- or endoscopic-directed bougienage should prove safer and more effective than blind dilation, [7], [19] particularly for sharply angulated, extremely tight, or proximal esophageal stenoses, and it should be an invariable rule with more central stenoses, including those in the stomach and colon. For dilation, these general principles must be balanced against the availability of fluoroscopy, the added cost of endoscopy or fluoroscopy, and the physician's previous experience with a particular dilating modality. Endoscopically facilitated guidewire placement and subsequent bougienage need not always require fluoroscopic control if copious guidewire has been placed into the stomach or a marked guidewire is used and attention is given to ensure that guidewire displacement does not occur with endoscope withdrawal. [1]

Of importance technically is the degree of lumenal enlargement that can be undertaken safely in a single dilating session. There remains a maxim in esophageal bougienage that one should increase a lumenal stenosis by no more than 2 mm (6F) in a single dilation session. [1] Although it is based on common sense and an attempt to avoid such complications as bleeding and perforation, this adage does not necessarily hold true for most rings or webs and some pliable, reflux-induced strictures. The degree of lumenal enlargement should be contingent not only on the stricture itself (i.e., membranous or fibrotic) but also on the degree of associated lumenal ulceration and the risks and benefits of alternative treatment modalities. These decisions cannot be made by a review of the scanty literature discussing side effects of bougienage but require a great deal of common sense on the part of the physician. [1], [19], [20]

Stent Placement

Stent placement requires stricture dilation to a size that admits a conventional prosthesis or the delivery system of an expandable stent. [9] More commonly, strictures are dilated to 30F to 36F even with small (18F) delivery systems. This precludes stent dislodgment when the delivery system is retrieved through a partially expanded prosthesis and may avoid the need for stent dilation with its potential for dislodgment. Perhaps the most important technical aspects of stent placement are adequate measurement of the stenosis with selection of a prosthesis that is 3 to 4 cm longer than the neoplasm and accurate placement. Whereas a subset of expandable prostheses can be placed either through or alongside an endoscope without x-ray control, [21] most endoscopists use concomitant fluoroscopy marking the proximal and distal stricture margins either with external markers or with injections of contrast material. The latter allows more precise prosthesis placement and may allow for repositioning of the prosthesis prior to full stent deployment.

Esophageal Strictures

Dilation Taking esophageal stenosis as the prototype, there are three basic dilation systems in widespread use: mercury bougies, guidewire-directed dilators, and polyethylene balloons. Most patients who present with dysphagia have had previous esophagoscopy, although a few with lower esophageal rings may have had barium studies alone. With rings, webs, and mild reflux stenosis, mercury bougienage after a 6-hour fast and pharyngeal anesthesia can often be done using a single 16 to 18 mm (48F to 54F) Maloney dilator. [22] Such dilators can be passed in the upright or lateral decubitus position. Although ideally done under fluoroscopic control to avoid kinking or retroflexion, many of these esophageal dilations can be performed safely without these capabilities. Long, angulated, or eccentric esophageal strictures, as well as severe (<7 mm) stenoses, are best handled with a guidewire dilating system. Patients require an initial endoscopy to define the stricture's cause and characteristics (e.g., length, diameter, pliability, eccentricity, and associated pseudodiverticula). Because a biopsy of the entire length of the stricture can be performed after dilation, I sometimes delay tissue sampling until immediately after the dilation. Use of polyvinyl dilators, which have supplanted Eder-Puestow metal olives in most centers, always requires guidewire placement. [1], [19], [23] This is usually done in conjunction with initial endoscopy, at which time a fluoroscopically monitored piano-style wire with a spring tip can be passed through the stricture and fed freely into the stomach. Alternatively, the wire can sometimes be passed radiographically without endoscopy. After baseline endoscopy and stricture sizing, a dilator approximately the size of the stricture is passed, making sure the guidewire is fixed and the head is bent forward. This is followed by one or two additional dilators, for an increment of up to 3 or 4 mm (10F to 12F), contingent on the stricture, before repeat endoscopy and stricture biopsy. Because of their gradual taper, polyvinyl dilators can pass through most stenoses with relative ease. The hesitation felt with these systems is related more to dilator friction over the guidewire than to the stricture itself. Moderate stenoses (7–13 mm) can be dilated using either mercury bougies under fluoroscopic control or polyvinyl dilators. The latter systems can be used without radiographic monitoring in some, although it is imperative that the guidewire is advanced far into the stomach and not inadvertently withdrawn at the time of endoscope removal. This is best done by feeding a marked guidewire forward simultaneously with endoscope or bougie withdrawal and having an assistant fix the wire at the level of the patient's mouth. [1] In addition, polyethylene balloons (TTS, CRE) have also been used to dilate moderate esophageal strictures. The technique is described in the section on "Nonesophageal Strictures."

Stent Placement Esophageal prosthesis placement requires adequate dilation both to allow passage of various delivery devices and to localize and measure the length of the neoplasm. [9] Necessary dilator sizes range from 48F to 51F for conventional prostheses and 24F to 36F for the expandable prostheses. Preoperative bronchoscopy may be required, particularly for bulky extrinsic neoplasms, as stent placement may be associated with airway compression and acute respiratory embarrassment. Tumor localization can be done by using external radiopaque markers taped to the patient's chest but is more commonly accomplished by injecting water or lipid-soluble contrast material into the proximal or distal tumor margins. [9] Alternatively, endoscopic clip placement can be used. Prosthesis placement requires fluoroscopic control although some of the smaller delivery systems (Ultraflex, single-braid Wallstent) allow simultaneous endoscopic visualization during delivery. [9] Stents should be 4 to 6 cm longer than the neoplasm, contingent on local anatomy (e.g., esophagogastric junction, cricopharyngeus, contralateral gastric wall; stricture angulation). Conventional prostheses are pushed into place over a guidewire using a variety of devices to stabilize the stent (e.g., small-caliber endoscope, Savary-type dilator, Nottingham expandable olive fixation shaft) and various types of pusher tubes. These devices have considerable resistance at the level of the cricopharyngeus and may require neck hyperextension for passage. Conventional stents are pushed into place followed by retrieval of the pusher tube and delivery system and an immediate repeat endoscopy to document correct prosthesis position. Expandable prostheses have variable delivery systems. [9] Z stents and Wallstents are delivered by pulling back a compression catheter. Ultraflex stents are constrained by a single long suture that can be pulled off the delivery shaft. The Esophacoil is compressed onto a delivery haft and released with three separate trip wires. [24] Although there is significant foreshortening of both Wallstents and Ultraflex prostheses, the Esophacoil foreshortens to half of its predelivery length, making proper placement crucial. Despite the plethora of prostheses now available, certain practices are followed after placement of all prostheses. The most important is the need for immediate endoscopy postinsertion to assure that the prosthesis has accomplished the treatment goal (e.g., correct location, full expansion, occlusion of tracheoesophageal fistula). Problems occur when the prosthesis is too long or short, abuts into the cricopharyngeus or contralateral gastric wall, or has inadequate radial force to open a tight neoplastic stricture. The latter may preclude retrieval of the delivery system. Airway compression and immediate migration at the time of placement are additional potential problems. Once expandable stents have fully deployed, only the coated Z stent has the potential to be repositioned. The Esophacoil and uncovered Ultraflex prostheses, in turn, can be removed, at least in theory. The endoscopist has to be prepared to deal with these problems. This requires access to balloon dilators as well as additional expandable and conventional prostheses to correct problems associated with inadequate length, acute angulation, or migration.

Nonesophageal Strictures

Dilation Most nonesophageal strictures require balloon dilation, although stenotic gastric stapling orifices and anastomotic strictures of the rectosigmoid can be enlarged with polyvinyl dilators or even electrocautery. [25], [26] and [27] Using pyloric stenosis as a representative stricture, I recommend using TTS or CRE balloons whenever possible. Advantages include direct stricture visualization, improved placement control, and immediate evaluation of the dilated stenosis. [6] The use of a TTS or CRE dilator requires endoscopic approximation of the stricture size and selection of a balloon that is 1 to 2 mm (3F to 6F) larger. Both balloon and dilator shaft should be coated with silicone, and negative pressure should be applied to the balloon using a 10- to 20-mL syringe. These measures, as well as avoiding excessive angulation of the endoscopic tip, allow dilator passage until all or part of the balloon is visualized. The balloon is centered in the stenotic pylorus under a combination of endoscopic and fluoroscopic control. The latter also helps prevent damage of the bulb apex or C loop wall related to excessive pressure of the balloon tip or extreme balloon angulation. Although air can be used for inflation, 10% to 25% contrast solution allows better visualization fluoroscopically and a more uniform balloon dilation. Obliteration of the balloon waist is required with pressures up to 12 atmospheres (atm). There is no evidence that 2 minutes of continued inflation is better than 15 seconds after the balloon waist has been effaced. [28] I usually use 30 seconds of dilation and redilate a second or third time after repositioning of the balloon. After dilation has been effected, complete evacuation of the balloon and straightening of the endoscope tip are required to allow retrieval. Additional, larger dilating balloons can then be used. However, the degree of lumenal enlargement in a single session remains a matter of common sense and is contingent on size of the initial stenosis, presence and degree of active ulceration, and patient discomfort with initial dilation. The ultimate goal is to dilate to 15 to 18 mm and follow up with complete endoscopic inspection of the pylorus and duodenum. This goal sometimes requires two or three dilating sessions separated by an interval of several days if the obstruction is acute or several weeks if it is chronic.

Stent Placement Expandable prostheses can be placed in the proximal stomach and distal colorectum using conventional delivery systems and techniques similar to those described for esophageal stenting. Duodenal, proximal jejunal, and more proximal colon strictures require either a longer insertion system or a stent mounted on a 3- to 4-mm shaft that can be placed through a large channel endoscope. [18] As of this writing, only uncovered Wallstents 18 to 24 mm in diameter and 6 to 9 cm in length are available for transendoscopic placement. These stents require balloon dilation of the malignant stenosis, delineation of the stricture length, localization with contrast injection at the tumor margins, and concomitant endoscopic and fluoroscopic control to ascertain proper placement and prosthesis expansion.

INDICATIONS

Dilation

The benefits and risks associated with lumenal dilation must be considered in relation to alternative treatment modalities (e.g., antireflux surgery or esophageal resection for a reflux stricture; vagotomy-pyloroplasty for pyloric stenosis; [29] endoscopic laser photoablation, electrocautery, or prosthesis placement [10]). Pharmacological implications of dilation also must be considered. Reflux-related esophageal strictures and many pyloric stenoses require long-term proton pump inhibition and possibly use of a prokinetic agent. Dilation of a Crohn's disease stenosis usually requires adjustment of corticosteroid dosage or initiation of immunosuppressive agents or infliximab to minimize the inflammatory response and stricture reformation. [30]

Indications for dilation are contingent on the anatomic area involved (Table 145-3). In the esophagus, symptoms are most often dysphagia and food impaction, although atypical chest pain, aspiration, and odynophagia may also be seen. [31], [32], [33] and [34] Indications for pyloric dilation are usually recurrent nausea and vomiting, weight loss, abdominal pain, and severe reflux. [35], [36] Small bowel and distal colonic stenoses may require dilation for intractable obstipation, progressive diminution in

stool size, pain, and recurrent bowel obstruction. [25], [26] and [27], [37] The causes of these and of a variety of other miscellaneous stenoses are listed in Table 145-3.

Esophagus
Ring or web
Reflux stricture
Malignancy
Miscellaneous (e.g., caustic ingestion, motility disorders)
Stomach
Pyloric stenosis
Anastomotic stricture
Gastric stapling/bypass stenosis
Miscellaneous (e.g., caustic ingestion, proximal malignancy)
Small Bowel
Duodenum (web, acid peptic stricture, anastomotic)
Ileum (Crohn's, NSAID-induced stenosis)
Colon
Anastomotic stenosis
Inflammatory stricture (IBD, diverticular, radiation-induced)
Miscellaneous
Stenotic gastrostomy, enterostomy, or colostomy stoma

IBD, inflammatory bowel disease; NSAID, nonsteroidal antiinflammatory drug.

TABLE 145-3 Indications for Gastrointestinal Dilation

Stent Placement

For the most part, prostheses should be used for obstructing or fistulizing neoplasms that are unresectable for cure or in potentially curable patients with prohibitive operative risk [9], [10] (Table 145-4). The most experience has accrued in the proximal gut for malignant dysphagia or esophago-airway fistulae, the latter a consequence of primary esophageal carcinoma, lung cancer, or mediastinal metastases. Gastric outlet obstruction in the setting of pancreatic cancer occurs in the setting of widespread disease. Traditionally treated by gastrojejunostomy or PEG/J in infirm patients, the latter might be ideal candidates for stent insertion into the C loop. [16], [38] Likewise, patients who present with malignant colon obstruction usually have far advanced disease (stage III [40%] or IV [60%]). [17] Traditionally treated with palliative resection or bypass, prosthesis placement is being evaluated both to allow adequate bowel preparation in some patients and as long-term palliation in a subset of patients with malignant ascites or liver metastases. [39]

Conventional stents
Esophagus
Malignant dysphagia (esophagus, esophagogastric junction, lung, mediastinal tumor)
Esophago-airway fistula
± Benign disease (e.g., caustic ingestion/anastomotic stricture or leak)
Expandable Prostheses
Esophagus
Malignant dysphagia
Esophago-airway fistula
Stomach/Duodenum (high surgical risk)
Malignant pyloric/C-loop obstruction
Gastric/pancreatic/biliary
Small Bowel/Colon (high surgical risk)
Obstructing/malignant stenosis
??? Benign strictures: radiation, Crohn's disease

TABLE 145-4 Indications for Prostheses

CONTRAINDICATIONS AND RISKS

Dilation

Contraindications to dilation include lack of informed consent, an acute abdomen, or a deeply ulcerated stenosis for which the risks of dilation outweigh the benefits. There may also be patient- and lesion-specific contraindications, such as coagulopathy or a colon stenosis associated with acute diverticulitis. Both the physician and the patient must be aware of alternative treatment modalities and the possible need for subsequent long-term ancillary measures such as proton pump inhibitors. Data on alternative treatment modalities are sparse but include a retrospective series on patients with pyloric stenosis treated with resective surgery, highly selective vagotomy, or vagotomy with pyloroplasty. [29] The combined morbidity was 32%, mortality was 6%, reoperation rate was approximately 10%, and the long-term symptom relief rate was not defined. Postoperative delayed gastric emptying was recorded in 25% of patients.

Risks of GI dilation include problems associated with all endoscopic procedures. The risks associated with the addition of dilation have usually been defined as an increased incidence of bleeding and perforation, [40] as well as bacteremia. [41], [42] With the exception of esophageal dilation, the incidence of these complications in various settings remains poorly defined.

Stent Placement

Prostheses are contraindicated in the good risk and potentially curable patient. [9], [18] Conventional prostheses should not be placed in the setting of a tracheoesophageal fistula unless there is an adequate shelf to seat the stent. Stents should not be used if placement of a dilator approximating the stent diameter results in significant airway compression by a bulky neoplasm. Stents may be contraindicated if placement cannot be undertaken without impingement on the cricopharyngeus muscle or anal sphincter, or if placement impacts on a contralateral lumenal wall thereby precluding adequate function. An absolute contraindication for prosthesis placement is an inability to endoscopically or radiographically define both the proximal and distal stricture margin. Nor should permanent stents be used for most benign esophageal, enteral, or colonic stenoses given long-term potential for erosion, occlusion, and migration.

Complications of prostheses are well defined in the esophagus but otherwise experience is limited. Acute procedure-related complications with conventional stents include perforation, bleeding, tracheal compression, and tube malposition. Total complications with conventional stent placement have approximated 20% with a mean procedure-related mortality of 8.6%. [9] Subacute complications include erosion with bleeding or fistula development, stent migration, food bolus impaction, and tumor overgrowth. Variable degrees of reflux are invariable if the esophagogastric junction has been stented and florid regurgitation or aspiration may be noted in patients who have delayed gastric emptying as a consequence of vagal denervation or gastric replacement by tumor.

Complications of expandable prostheses are variable and contingent on prosthesis design and endoscopist experience. Our group retrospectively reviewed 85 patients, 47 of whom had conventional and 37 a variety of expandable prostheses. [43] Insertion complications, prestent and poststent dysphagia scores, and complete tracheoesophageal fistula occlusion rates were comparable, but there was a 25% higher rate of subacute or chronic complications in patients receiving expandable prostheses. The latter included tumor ingrowth or overgrowth, migration, and aspiration pneumonia. Other studies have confirmed ingrowth through uncovered prostheses or stents that have delaminated. For instance, ingrowth occurred in 66% of 114 patients in whom an uncovered Ultraflex stent was placed. [44] Fully covered prostheses, on the other hand, appear to predispose to stent migration as noted in the U.S. Multicenter Z Stent Trial. [12]

Prior radiation and chemotherapy may predispose to significant complication, particularly with the barbed European Z stent. For instance, 23 late complications occurred in 22 (38%) of 59 patients treated with Gianturco-Rösch Z stents, including life-threatening complications in 9 (bleeding, 7; perforation, 1; tracheoesophageal fistula, 1). [46] Eight (36%) of 22 patients with prior radiation or chemotherapy had life-threatening complications as compared to only 1 (3%) of 37 without such prior therapy ($P = 0.005$). This increased risk was confirmed in a more recent publication. [47]

Metallic prostheses also have intrinsic problems. Early Wallstents delaminated, Esophacoils may deliver in a tangle, and there are multiple reports of Ultraflex fractures. [9] Moreover, the ability to place stents more proximally than with conventional prostheses [48] has been associated with complications such as cervical discitis

[49] and stent perforation into the common carotid artery. [50]

Data directly comparing expandable to conventional stent placements are sparse, although three reports [51], [52] and [53] suggest that expandable prostheses are easier to insert and potentially associated with fewer complications. Survival rates, in contrast, are not different.

ASSESSMENT OF RESULTS

Dilation

Esophagus Most data on GI dilation derive from esophageal bougienage with a combination of Eder-Puestow and mercury dilating systems. This combination, using sequential bougies over a period of days to months, is associated with 70% to 100% improvement in dysphagia in over 850 patients with benign esophageal strictures compiled from various series. [7], [22], [54] Reported complications in these patients included 16 (0.2%) perforations, 5 major bleeding episodes, 2 aspirations, and 1 death. This compares with the perforation rates of 0.4% for mercury dilators and 0.6% for metal olives reported in an American Society for Gastrointestinal Endoscopy (ASGE) survey. [7] Such perforations are usually in the cervical esophagus and relate to improper dilator introduction or in the thoracoabdominal esophagus just proximal to the stenosis related to dilator or guidewire kinking. Less frequently, the stricture itself splits, as may be seen with achalasia (1%–5% perforation rate). [1] A number of series assess balloon dilators for esophageal stenoses. In an early series, 93% of dilations of benign and malignant esophageal strictures in 88 patients were technically successful with a 3% minor complication rate and 91% symptomatic improvement over a mean of 10 months. [55] Additional series have been reported in adults and children, as have trials comparing balloon technology to Eder-Puestow or Savary dilators. [55], [56], [57] and [58] Data using the guidewire-directed dilating systems continue to accrue. In a randomized prospective trial comparing Eder-Puestow and Celestin dilators in 72 patients, there was no significant difference in long-term symptom relief, although the Celestin system was thought to be quicker and cause less pharyngeal trauma. A single perforation occurred with the Celestin system. [59] A second paper reviewed 302 dilations in 100 patients with benign esophageal strictures using this system. [60] The two reported perforations were medically managed and were thought to be related to esophageal laceration with the endoscope and not the dilator. A number of series review experiences with hollow-core polyvinyl dilating systems. [5], [57], [58], [61], [62] and [63] Dumon and colleagues [63] claimed efficacy in all 300 patients treated for benign or malignant esophageal stenosis, with only one perforation. Our group successfully dilated 432 patients with 716 courses of dilation therapy; 89% were dilated with polyvinyl dilators and only 8% required fluoroscopic monitoring. [61] Approximately 80% of the dilation sessions were undertaken with a single large dilator or employed incremental dilators more than 6F in a single session. There were no complications directly related to the bougienage. Additional large series have been published. [62]

Clinical implications. The ability to dilate a stenosis does not imply that dilation is the procedure of choice in every instance. Dilation should not be the sole treatment in individuals who require bougienage so frequently that cumulative risk and expense become prohibitive. In this setting, intralesional steroid injection might be tried or surgical resection may be more appropriate. [64] If a decision has been made that esophageal bougienage is appropriate, several considerations are involved in choosing the technique. If all types of dilators had equal efficacy and safety profiles for bougienage of routine esophageal stenoses (an unproven assumption), the physician would use the least costly system. [61] On the other hand, if inherent advantages are assumed for a particular system, there is a tendency to increase its use. The claimed advantages of balloon dilators over other systems have included ease of passage, dilation of the stricture alone, and radial as opposed to vector force applied to a stenotic wall. [1] Ideally, such balloons should be safer and more effective, claims that cannot be substantiated with available data. If fluoroscopy is used to ensure waist dilation, total costs using this technology in our institution are threefold higher than dilation with polyvinyl dilators and eightfold higher than mercury bougienage. [61] Given this and the fact that such balloons are marketed as one-time use devices, balloon technology is better limited to areas of the gut not accessible to other types of dilators. The exception to this statement is achalasia, in which polyethylene balloons have proven both effective and much easier to pass than conventional dilating systems.

Nonesophageal Strictures

Stomach. The only large series of gastric dilation is limited to polyethylene balloon dilation, and series with long-term follow-up report conflicting results. Since the initial description of successful hydrostatic dilation in a patient with pyloric stenosis and gastric outlet obstruction, [65] several series have been published using this technique. McLean and colleagues [66] radiographically dilated 94 GI strictures in 92 patients, with a mean follow-up of 389 days in 80 patients. Thirty-three of these patients had various forms of gastric stenosis. Technically, 25 of the 33 were successfully dilated, and 70% were symptom-free at 1 year. Perng and associates [35] reviewed 42 patients with benign gastric outlet obstruction. At a median follow-up of 2 years, two thirds of patients had sustained improvement and one third required surgery. The symptom-free rates at 1, 2, 3, and 4 years were 85%, 78%, 69%, and 69%, respectively, and the independent prognostic factor for failure was need for more than two courses of dilation for symptom relief. Lau and colleagues [36] reviewed 45 patients who had successful gastric outlet obstruction dilation, 4 of whom had rapid re-obstruction and were found to have malignancy. At a median follow-up of 39 months, more than 50% of patients required surgery, 18 for recurrent obstruction, 2 for interval perforations, and 1 for bleeding.

Small bowel. Because of the problems of access to the small intestine, there are few data regarding dilation of proximal small bowel strictures. [67] There are, however, multiple series using balloon technology to dilate ileal or anastomotic ileocolonic strictures in Crohn's disease. [30] Dilation of 27 anastomotic strictures in patients with Crohn's disease led to no complications, and after 7 to 38 months, 18 patients remained free of obstructive symptoms. [68] A prospective study of 55 patients with Crohn's disease with 59 ileocolonic strictures noted 90% technical success with complications in 11% (6 perforations). [37] Complete long-term symptom relief was noted in 34 (62%) patients. Corticosteroid injections into inflamed small bowel following anastomotic balloon dilation may decrease restenosis rates further. [69] As of this writing, however, results remain anecdotal and data should be placed into the perspective of surgical resection or stricturoplasty.

Colon. Most reported colonic dilations have been used for rectal or anastomotic stenoses. [25], [26] Linares and colleagues [70] dilated 33 anorectal strictures in patients with Crohn's disease with a variety of techniques; half experienced short- or long-term symptomatic relief. Pietropaolo and associates [71] dilated 42 patients with postoperative strictures with either balloons or bougies. There was no morbidity or mortality with a 2.4% failure rate. A combination of various types of dilators with endoscopic electrosection in 39 patients with benign anastomotic strictures resulted in no complications or symptoms in any patient at a mean follow-up of 25 months. [26] Finally, Virgilio and colleagues [72] used a 30- to 40-mm achalasia dilator in 18 patients with anastomotic strictures following resection for colorectal cancer. A total of 45 dilating sessions were performed in 17 of the patients. Long-term symptom relief was described in 16 patients (94%) and complications were limited to one episode of bleeding and a punctiform bowel perforation.

Clinical implications. The major question for nonesophageal stenoses is the appropriateness of stenosis dilation compared with alternative treatment modalities. Using pyloric stenosis as an example, most series are small and follow-up of dilated patients suboptimal. Nevertheless, a 60% to 65% good-to-excellent symptomatic response at 1 to 2 years has been reported, [35], [36] and this should be compared with the results of drainage or resective therapy for benign gastric outlet obstruction. [29] A cost analysis comparing pyloric balloon dilation with vagotomy and pyloroplasty at our institution [73] showed balloon dilation to be cost-effective in the short term at one tenth of the total costs for vagotomy and pyloroplasty. However, long-term acid suppression was not considered. Additional unanswered questions include the relative efficacy of balloons as opposed to polyvinyl dilators for rectosigmoid stenoses, and the rapidity with which stenoses at various sites can be safely dilated.

Stent Placement

Esophagus

Conventional. Conventional stents can be successfully placed in approximately 90% to 95% of patients with malignant esophageal obstructions, with mean patient survival of 2 to 4 months. [9] Terminal events frequently include tumor cachexia or subacute stent-related problems such as erosions into major vessels or aspiration.

Expandable prostheses. Numerous series defining long-term results of expandable stent placement for malignant dysphagia have been published. [9], [11], [52], [74], [75] As noted, these results are contingent, in part, both on stent design and initial successful palliation of dysphagia. Nevertheless, in most series, survival appears identical to that following conventional prosthesis insertion: 2 to 4 months. [9] For instance, placement of 138 Ultraflex stents in 114 patients led to improvement in dysphagia score (3.5 to 1.5), although tumor ingrowth occurred in two thirds of patients and 35 endoscopic interventions were required. [44] No significant differences in implantation success or efficacy were seen in a series using 3 types of expandable stents in 87 patients, but 22% of patients treated with Wallstents required early reintervention, compared with 37% in the Ultraflex group and 10% in the Z stent group. Subsequent reinterventions were required in 43%, 35%, and 10% in each group. [76] Comparable palliation and complication rates have been noted in studies comparing Z, Ultraflex and Flamingo prostheses. [77] Despite the invariable stent dysfunction noted in these series, expandable prostheses have also been used occasionally in benign disorders and may have a role to play for anastomotic leaks in a subset of patients with refractory benign stenoses. [78], [79]

Clinical implications. Patients with malignant dysphagia who require any form of endoscopic intervention generally have either widespread disease or an aggressive tumor biology that precludes prolonged survival. Our study comparing 85 patients in whom conventional or expandable prostheses were placed for malignant dysphagia documented comparable levels of prestent and poststent dysphagia (3[0.9]/0.4[0.9] vs. 2.7[1.1]/0.9[1.4]), fistula occlusion (13/15 vs. 13/14), and survival (87[72] vs. 90[80] days), respectively. [43] Other studies comparing conventional prostheses to Nd:YAG laser document a 2- to 4-month mean survival regardless of the treatment modality.

Nonesophageal Strictures

Stent placement. Data relating to stent placement in malignant stenoses of the small bowel and colon are limited, [15], [16], [80] and data in benign disease are almost nonexistent. Baron and colleagues [39] inserted a variety of expandable prostheses for obstructing colorectal cancer in 25 patients not thought to be operative candidates. Two thirds of these patients were adequately palliated, although there were three perforations and one procedure-related mortality. Four patients ultimately developed stent migration and one tumor ingrowth through the prosthesis. Our group placed a variety of expandable stents in nine patients with widespread obstructing malignancies. [78] Indications included afferent loop obstruction in three, colon obstruction in three, gastric outlet obstruction in two, and stenosis of an esophagojejunal interposition in one. There was a single perforation at the time of dilation prior to stent insertion. Additional problems included migration in one case and food bolus occlusion in one patient. Three additional patients developed tumor overgrowth or ingrowth through the stent that was treated with laser. Median survival approximated 9 months.

Clinical implications. The ability to insert an expandable prosthesis into a malignant stenosis does not imply that it should be done. Particularly disturbing are claims that this is first-line treatment for obstructing colorectal cancers in lieu of surgery or as a means to facilitate bowel preparation. Although this is theoretically attractive, as virtually all patients with obstructing colorectal cancer have stage III or IV disease, there are few data to support such claims. [10] It is hoped that prospective, randomized trials answer such questions in the future. Likewise, what role, if any, expandable stents should play in patients with benign central stenoses remains to be defined. Although potentially useful in a handful of high-risk patients who have pernicious stenoses (e.g., anastomotic, radiation), experience with stent-related problems in the esophagus in patients with limited survival suggests that use in individuals with the potential for several-year survival may prove to be ill-advised unless the stent is removable and placed for several weeks or months at most.

FUTURE APPLICATIONS

The future of GI dilation is contingent upon further experience with the newer dilating systems such as CRE balloons in comparison to polyvinyl dilators. Both expanded experience and controlled clinical trials should allow improved definition of the indications, benefits, per procedure costs, and risks for individual dilating systems and for specific stenotic lesions.

Additional technologic combinations using dilators and various thermal modalities for malignant stenoses are likely to become available. Just as bipolar tumor probes have conjoined Eder-Puestow dilators with multipolar electrocautery to treat concentric esophageal or rectal neoplasms, similar electrodes have been implanted on balloons or polyvinyl dilators. A new approach is to take a quartz laser fiber and surround the tip with a balloon. The balloon keeps the fiber tip in the center of the lumen. These catheters may ultimately allow treatment of nonresectable biliary, gastroesophageal, or rectal neoplasms by transmission of laser energy. Photodynamic therapy, in turn, may play an increasing role in the treatment of malignant stenoses and argon plasma coagulation may be used in lieu of Nd:YAG laser to open a lesion or facilitate stent placement.

The future of GI dilation may also include the development of dilators that can detect a fall in wall tension or resistance within a tissue during dilation. This fall in tension may predict that the dilation is adequate and that further lumenal enlargement may be unnecessary and hazardous. Devices such as these should improve safety.

Finally, as previously noted, dilation will be increasingly used in conjunction with expandable stent technology, potentially even in the setting of benign stenoses. These expandable stents, undergoing refinement both in the endoprostheses themselves and in their delivery systems, hold at least the potential of prolonged stricture patency, which would preclude the need for repeated dilation sessions. At a minimum, prostheses will be fashioned from newer materials, and prototypes testing both plastic and thermocoupled metals have been described. [81], [82]

CHAPTER 146

Jeffrey L. Ponsky and Brian J. Dunkin

PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

The percutaneous endoscopic gastrostomy (PEG) was introduced in 1980 as an alternative to operative gastrostomy for those patients requiring long-term intubation of the stomach. [1] It was devised as a safe and effective nonoperative means of providing long-term enteral nutrition. The method has become widely practiced, with about 150,000 PEGs being placed in patients in the United States annually.

The concept of a surgically created fistula between the stomach and abdominal wall was first conceived by Egeberg in 1837 and attempted by Sellidot in 1849. A variety of surgical approaches were developed, culminating in the more popular Janeway and Stamm methods. [2] Both were effective in creating a gastrocutaneous fistula, but use of these techniques was somewhat limited because the patients were frequently poor surgical candidates and these procedures required a laparotomy, often with general anesthesia.

Thus, delivery of enteral nutrition was most often by means of nasoenteric tubes. This was effective but associated with numerous frustrations and complications. These tubes were frequently large in caliber and constructed of stiff rubber or plastic, making them uncomfortable. Frequent plugging of the tubes necessitated replacement, and it was not unusual for them to become dislodged, accounting for up to 60% of tube removals. [3], [4] Esophagitis also developed from irritation of the esophageal mucosa by the tube, and gastroesophageal reflux was common because the tube rendered the esophagogastric junction incompetent. [5], [6] This reflux frequently led to the development of aspiration pneumonia. Long-term use of nasoenteric tubes also caused parotitis and erosion of the nasal cartilage.

In 1980, the technique of PEG was introduced. This method allowed the formation of a tube gastrostomy without laparotomy or general anesthesia. Safety of the procedure was ensured by endoscopic visualization of the tube insertion, and placement directly into the stomach reduced the risk for complications encountered with the nasoenteric tube. The original method described by Ponsky and Gauderer has been called the *pull technique*. [7] Two modifications of the original method have been introduced and have gained some popularity. These are referred to as the *push* or *Sacks-Vine technique* and the *introducer* or *Russell technique*. [8], [9] All of these methods have been shown to be safe and effective.

Complications of percutaneous gastrostomy, although not frequent, are known to occur and are well documented. Careful attention to patient selection and the details of the method may help to reduce the incidence of undesirable outcomes. The increasing ease by which enteral access is established with percutaneous gastrostomy has led to tremendous growth in the application and use of this procedure. Moral and ethical dilemmas arise as the technique is applied to an increasingly debilitated population of patients. Further study of the technique and its long-term outcome has provided answers to some of these problems.

METHODS

Patient Preparation

Proper preparation can help avoid complications. The patient should not be fed for 8 hours before the procedure. If an antibiotic with good gram-positive coverage is not already being administered, then a single intravenous dose should be given. The most common organisms cultured from PEG site infections are *Staphylococcus aureus* and ß-hemolytic streptococci. Cefazolin is very good at covering these and other commonly encountered organisms. [10] The patient should be positioned supine with the head elevated to reduce the risk for aspiration. Because it can be difficult to intubate the esophagus in this position, it is sometimes preferable to start the endoscopy in the left lateral decubitus position and then reposition the patient supine. Suction should be available to manage oral-pharyngeal secretions, and the patient should be maintained on supplemental oxygen. In addition, blood pressure and pulse oximetry should be monitored by a nurse in attendance throughout the procedure.

The Pull (Ponsky-Gauderer) Technique

Once positioned, the patient is given intravenous sedation, and the abdomen is washed and draped in a sterile fashion. The room lights are turned down as the gastroscope is passed into the stomach. Transillumination of the abdominal wall by the light of the scope is an indication that intervening structures have been displaced and that the stomach lies in contact with the abdominal wall. The site selected for placement of the gastrostomy should be one at which transillumination is well seen. Finger pressure by the assistant at this point produces a clear indentation of the gastric wall as seen by the endoscopist (Fig. 146-1). This indentation should be covered by an open polypectomy snare passed through the endoscope. To enhance the safety and accuracy of PEG placement, the use of the “safe tract” technique described by Foutch has been very useful. [29] Once the best site of finger indentation or transillumination is selected, the syringe with local anesthetic is advanced only a small distance beneath the skin. Suction is applied to the syringe barrel as it is advanced more deeply. The appearance of air in the syringe barrel and the visualization of the needle tip in the stomach by the endoscopist should occur simultaneously. Should air appear in the syringe barrel before the needle tip appears in the stomach, an alternative site should be selected because this usually indicates that an intervening air-containing viscus, such as colon or small bowel, has been punctured.

FIGURE 146-1. The endoscopist observes a distinct indentation of the gastric wall as the assistant applies finger pressure to the abdominal wall at the proposed site of puncture.

Local anesthetic is injected into the abdominal wall at the proposed area of puncture, and a 1-cm incision is made in the skin. An intravenous cannula is thrust through the incision and into the gastric lumen. If the polypectomy snare is correctly positioned, the thrusting needle will enter the center of its loop. If not, the snare is quickly looped around the cannula and tightened near the point where the cannula exits the gastric mucosa (Fig. 146-2). A long, stout suture or wire is passed through the needle into the gastric lumen, and the snare is moved from around the cannula to tighten around the suture itself (Fig. 146-3). The suture is pulled with the endoscope from the stomach and out of the mouth. The drainage end of the gastrostomy tube is affixed to the suture at the patient's mouth (Fig. 146-4). The tube is well lubricated, and pull is begun on the abdominal end of the long suture so that the gastrostomy tube moves down the esophagus and exits the abdominal wall (Fig. 146-5). The gastroscope is reinserted to check the position of the head of the tube, and care is taken to avoid excessive tension on the head of the catheter. The endoscope is removed, and an outer bolster is applied, which holds the gastric and abdominal walls in close contact.

FIGURE 146-2. The snare is looped around the cannula and tightened near the point where the cannula exits the gastric mucosa.

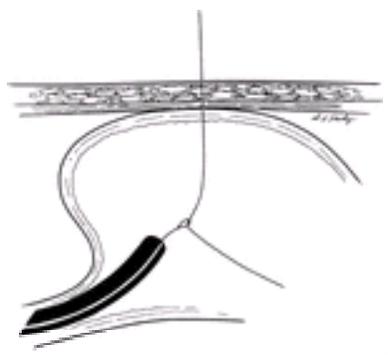

FIGURE 146-3. The snare is tightened around the suture and pulled out of the patient's mouth using the gastroscope.

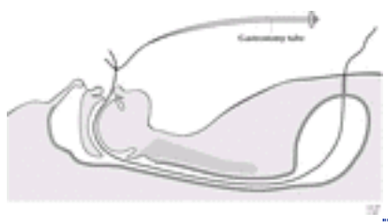

FIGURE 146-4. The gastrostomy tube is affixed to the suture at the patient's mouth.

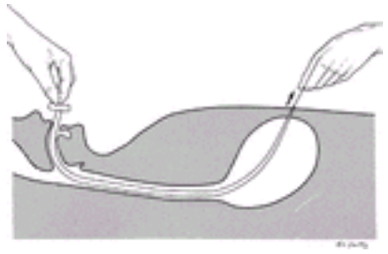

FIGURE 146-5. The assistant pulls on the abdominal end of the suture, and the gastrostomy tube proceeds down through the esophagus and stomach to exit the abdominal wall.

The Push (Sacks-Vine) Technique

The push method differs little from the pull technique. The patient is repared, the puncture performed, and a guidewire grasped and pulled from the patient's mouth in the same manner (Fig. 146-6). In this procedure, however, a special gastrostomy tube with a long tapered dilator end is pushed over the guidewire. Both ends of the wire must be held under tension as the tube is pushed down the esophagus and exits the abdominal wall (Fig. 146-7). Once the tube emerges from the abdominal wall, it may be grasped and pulled the rest of the way into its final position. The gastroscope is reinserted to ensure that the head of the catheter lies in contact with the gastric mucosa. An outer crossbar or faceplate is added to fix the abdominal and gastric walls together.

FIGURE 146-6. As in the pull technique, the cannula is inserted into the stomach, a guidewire is passed through it, and the wire is grasped and pulled out of the mouth using the gastroscope.

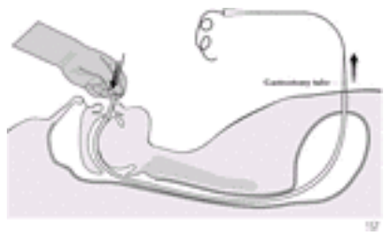

FIGURE 146-7. Both ends of the wire are held under tension while the gastrostomy tube is pushed down the esophagus and out the abdominal wall. Once the tube emerges from the abdominal wall, it is grasped and guided into position.

The Introducer (Russell) Technique

The percutaneous method for insertion of a central venous catheter as described by Seldinger has been adapted to the performance of gastrostomy placement in the introducer method. Developed by Russell and colleagues, [9] this method allows percutaneous placement of a gastrostomy tube without passing the tube through the oropharynx and with only a single insertion of the endoscope. The gastroscope is passed into the stomach, and the room lights are dimmed. Transillumination of the abdominal wall and finger pressure at the point of best transillumination are used to identify the proper site for puncture. Once the site for insertion has been established, the skin is anesthetized, and a small incision is made. A needle is introduced into the gastric lumen, and a guidewire is passed through the needle. The needle is removed, and an introducer with an outer, peel-away sheath is passed over the guidewire into the stomach (Fig. 146-8). The wire and introducer are removed, leaving only the sheath in the stomach. A balloon catheter is introduced through the sheath and inflated (Fig. 146-9). The sheath is removed, and the balloon of the catheter is pulled up to the gastric mucosa. Either the catheter is sutured to the skin, or an outer faceplate is applied to hold the gastric and abdominal walls in approximation.

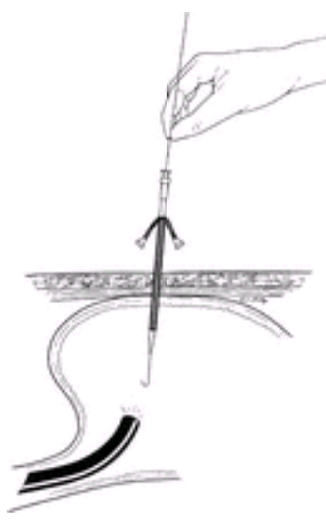

FIGURE 146-8. The introducer and its outer sheath are passed over the guidewire into the gastric lumen.

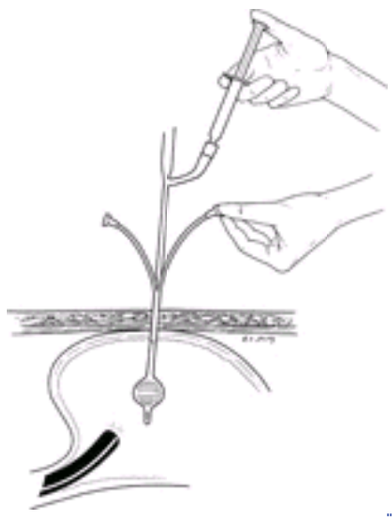

FIGURE 146-9. The introducer and guidewire are removed, and the balloon catheter is inserted through the sheath. The balloon is inflated, and the sheath is peeled away.

Comparison of Methods

All of these techniques for the performance of percutaneous gastrostomy have been widely used and found effective. Each provides benefits that should be considered in choosing a method for a particular patient. [11]

The pull technique provides a great deal of control for the physician. The puncturing needle is stabilized with the surrounding snare, ensuring that loss of air from the gastric lumen does not result in loss of the puncturing needle. The gastrostomy tube is pulled down the esophagus and out of the abdominal wall in a direction that apposes the gastric and abdominal walls. This should minimize leakage around the puncture site. The soft button of the pull PEG trailing free behind the tube may be more deformable than that of the push PEG, thus allowing it to traverse a narrowed esophagus more readily. The push method adds the stability of a guidewire to act as a trolley on which the tube can ride as it passes through the alimentary tract. Both of these methods have the potential of introducing oral bacteria or tumor cells from a lesion in the oropharynx or esophagus into the tissues of the abdominal wall. Thus, infection and metastasis of carcinoma are potential complications with

these techniques. Both require a second passage of the endoscope to ensure correct positioning of the catheter head against the gastric wall.

The introducer method enjoys the advantage of a direct puncture insertion of the tube. This avoids the potential risk for infection from oral flora and possibly reduces the risk for cancer seeding to the abdominal wall. The method permits insertion of a gastrostomy in patients with narrow lesions of the esophagus without the fear of disrupting such lesions while the catheter is positioned.

In the introducer technique, the endoscope serves only an observatory function. However, the forces of insertion with the introducer method push the stomach away from the abdominal wall and may lead to the creation of a submucosal tunnel in the stomach without puncture of the mucosa. Loss of control of the punctured stomach and leakage of gastric contents are also more likely to occur. Finally, the tubes used for this procedure are of small diameter and suffer from premature extrusion secondary to deflation of the balloon catheter.

In practice, each of these methods has been demonstrated to be effective and to have a low rate of complications. Experienced endoscopists are familiar with all of these techniques and select the one with which they are most comfortable and that best suits the needs of the patient.

Radiologically Placed Gastrostomy Gastrostomy tubes may be placed under radiologic guidance. A number of studies have examined these methods and found that they compare favorably with endoscopically guided insertion. [12] The best indications for radiologically guided PEG include esophageal stenosis due to malignant or benign stricture and the inability to place an endoscopically guided PEG owing to the inability to accurately localize a safe puncture site. Although this method of insertion is effective, the tubes used for the gastrostomy are frequently of small caliber and prone to clogging. Tube replacement may also be more involved after radiologic insertion.

INDICATIONS

The PEG was first conceived as a means of providing long-term enteral nutrition to those patients who are unable to ingest food by mouth but have a functioning gastrointestinal tract. Nutritional support should be initiated in all patients anticipated to be without nutrient intake for 2 or more weeks. If the patient has a functional gastrointestinal tract and is expected to require enteric feeding for less than 30 days, then a nasogastric or nasoenteric tube should be used. If it is anticipated that enteric feeds will be required for more than 30 days, however, then a tube gastrostomy or enterostomy should be considered. Such patients may have severe neurologic or developmental disorders, obstruction of the oropharynx from trauma or tumor, or a critical illness requiring prolonged endotracheal intubation.

As the safety and efficacy of the PEG has been demonstrated, the population of patients benefiting from it has expanded. PEGs have been placed in burn patients (even through burned skin) to facilitate enteric feeding of high caloric density formulas. [13] They also have been placed in patients about to receive neoadjuvant therapy for esophageal cancer [14] and head and neck carcinoma. [15], [16] Victims of severe maxillofacial injury have benefited from PEG placement as well. [17]

Non–alimentation-related applications also have been described. These include decompression of the stomach for gastric atony, uncorrectable obstruction, carcinomatosis, and gas bloat following Nissen fundoplication. [18], [19] and [20] The method also has been used for the administration of unpalatable medications to children [21] and the refeeding of bile to patients with external biliary fistula. [22] Finally, multiple PEGs have been placed in patients with paraesophageal gastric herniation and gastric volvulus as a method of gastropexy. [23]

CONTRAINDICATIONS

The contraindications to PEG placement can be grouped into three categories: absolute, relative, and potential. The absolute contraindications to PEG placement include uncorrectable coagulopathy, correctable intestinal obstruction, peritonitis, peritoneal dialysis, gastric varices, absence of a stomach, or any process that precludes endoscopic access to the stomach.

Relative contraindications are those situations traditionally considered absolutely contraindicated but that more recently have been successfully addressed using ultrasound imaging, better medical preparation of the patient, or the addition of a minor surgical procedure. The first of these is massive ascites. Patients with massive ascites are at major risk for complication from PEG placement. Successful placements have been described, however, using preprocedure treatment with beta-blockade, diuresis, nitrate administration, and paracentesis. [24], [25] The second relative contraindication to PEG placement is the inability to transilluminate the abdominal wall, usually because of morbid obesity or the presence of an intervening structure between the stomach and the abdominal wall. Endoscopic and transabdominal ultrasound have been used to ensure that no intervening structures are present and to guide the passage of a spinal needle through a thick abdominal wall. [26] Alternatively, a cut-down through the skin and subcutaneous tissue under local anesthesia has been used in an obese patient so that fascia could be visualized and a PEG safely placed. [27] Without these additional maneuvers, however, the inability to transilluminate the abdominal wall is a contraindication to PEG placement.

Finally, there are those situations where PEG placement is not contraindicated but should be performed with caution because there is a significant potential for a complication to occur. These include prior surgery, distended loops of small bowel, presence of a ventriculoperitoneal shunt, or severe cardiac disease. Previous abdominal surgery is not a contraindication to PEG placement if there is meticulous adherence to the details of the procedure, including transillumination of the abdominal wall. [28] A safe tract should be identified in these patients by looking for the aspiration of air from only the stomach during passage of the angiocatheter. [29] These same principles apply when treating a patient who has distended loops of small bowel. The presence of a ventriculoperitoneal shunt is not a contraindication to PEG placement as long as care is taken to avoid the catheter. [30] A preprocedure abdominal radiograph can be helpful. Severe underlying heart disease increases the risk for major complication in PEG placement, possibly related to the use of intravenous sedation. [31] Cappell and Iacovone [32] have shown, however, that a PEG can be safely placed within 1 month after myocardial infarction if it is considered essential and the patient is otherwise stable.

COMPLICATIONS

Large cumulative retrospective studies have reported that 10% to 16% of both adult and pediatric patients have at least one complication after PEG placement. [33] The overall mortality rate is 1%, with a major complication rate of 3% and a minor complication rate of 13%. [34] Wound infections account for up to 30% of all minor complications. These are caused by multiple organisms, but most commonly by *S aureus* and ß-hemolytic streptococci. Jain and colleagues [34a] have shown that a single prophylactic dose of cefazolin covers 72% of the organisms encountered in PEG infections and will reduce the rate of infection after PEG placement from 28.6% to 7.4%. In contrast, cefoxitin is only effective against 33% of the organisms encountered. Infection usually becomes evident as erythema around the gastrostomy tube site several days after the procedure, with local tenderness and slight edema of the skin. The patient often demonstrates a low-grade fever and leukocytosis. Early recognition and incision and drainage of the area under local anesthesia most often resolve the problem. Failure to identify and treat this problem at an early stage can result in necrotizing infections of the abdominal wall and death. Necrosis of the tissue of the abdominal wall that is interposed between the head of the tube and the outer bolster may play a major role in the occurrence of infection at a PEG site. Excessive tension applied to the bolster acts as a tourniquet, producing ischemia of the underlying tissue. Loose contact is all that is required between the outer bolster and skin. If a dressing is required, it should be placed over the bolster, not under it, for the same reason. It is a good idea to begin systemic antibiotics for all infections around the tube and to continue them until the infection is resolved. Also, an adequate skin incision in the abdominal wall allows room around the gastrostomy tube for the egress of bacteria.

Extrusion of the head of the tube from the gastric lumen into the subcutaneous tissue (the buried bumper syndrome) has been frequently encountered. This is almost certainly caused by excessive tension that has been applied to the tube. To prevent leakage of gastric contents and ensure adhesion of the stomach to the abdominal wall, the physician may pull up on the gastrostomy tube and push downward on the outer bolster. Although this fixes the stomach to the abdominal wall, it also produces ischemia of the intervening abdominal wall tissue, with subsequent necrosis. This can be avoided by ensuring that no tension is present when the head of the catheter is placed in contact with the gastric mucosa and that the outer bolster only loosely approximates the skin. Such approximation of the gastric and abdominal walls results in satisfactory adhesion without tissue necrosis.

Leakage of feedings into the peritoneal cavity may occur after percutaneous gastrostomy. This is usually the result of separation of the gastric and abdominal walls and often is due to necrosis of the abdominal wall tissue caused by excessive tension on the catheter. Patients who develop abdominal tenderness, fever, or leukocytosis should be evaluated for leakage and the resultant peritonitis. This may be done by instilling water-soluble contrast material into the gastrostomy tube under fluoroscopic guidance. Intraperitoneal extravasation indicates that something has gone awry. If the contrast study results indicate that the head of the tube remains in the stomach and that the extravasation is around the tube, the clinician may pull up on the tube, providing a bit more tension to seal the leak, and place the

tube to gravity drainage; intravenous fluids and antibiotics can be administered. If the contrast study results reveal complete separation of the gastric and abdominal walls with dislodgment of the tube from the stomach, the tube should be pulled from the abdominal wall, a nasogastric tube inserted to effect gastric drainage, and intravenous fluids and antibiotics begun. A patient whose PEG has been pulled out inadvertently less than 2 weeks from the time of insertion should be treated similarly. If at any time the patient's condition begins to deteriorate or signs of peritonitis worsen, exploratory laparotomy with operative repair should be performed.

Gastrocolic fistula has rarely been known to occur after percutaneous gastrostomy. This type of fistula may be caused by puncture of the colon at the time of gastrostomy or pinching of the colon between the gastric and abdominal walls with subsequent necrosis of the colonic wall and fistula formation. This complication usually becomes apparent after several weeks, with the development of severe diarrhea after feedings. It may be documented with an upper gastrointestinal series or barium enema. In nearly all cases, the condition may be treated by removing the gastrostomy tube. The fistula closes rapidly once the tube is removed.

Progressive enlargement of the gastrostomy stoma around the gastrostomy tube may occur in some patients. Although this, too, may be the result of excessive tension on the tube, it is also occasionally seen in patients in whom the gastrostomy tract is well established. Poor nutritional status may play a part in the development of this problem, as may excessive movement of the tube at the skin level. The temptation in addressing this problem is to remove the gastrostomy tube and replace it with a larger one that fills the hole. This solves the problem for a short time, but the tract soon enlarges again. A better solution is to remove the tube entirely and allow the tract to close. After it has closed a bit, a new, smaller tube may be inserted. Also, minimizing movement at the skin by securing the tube properly or placing it through a baby bottle nipple or a similar stabilizing device is effective.

Pneumoperitoneum is a frequent occurrence after percutaneous gastrostomy. This may be the result of air escaping around the puncturing needle. Routine radiographs of the abdomen are unwarranted. Air in the abdominal cavity has been shown to last for up to 5 weeks after PEG placement. Patients found to have pneumoperitoneum after gastrostomy must be clinically evaluated. In the absence of abdominal tenderness, leukocytosis, or fever, there is no need for further evaluation. However, the patient who demonstrates any of these should be evaluated using a water-soluble contrast study through the gastrostomy tube for signs of separation or intraperitoneal extravasation. One case was reported of tension pneumoperitoneum during PEG placement causing hemodynamic compromise, but this is exceedingly rare. [35]

Neoplastic seeding to the skin from both oropharyngeal and esophageal cancers has been reported after PEG placement. [36] If the gastrostomy is being placed for palliation, this may not be an issue. However, if placement is part of the patient's therapy, as in preparation for neoadjuvant radiation therapy for esophageal carcinoma, then this must be considered. There may be advantages to using an introducer technique in this setting, but this has not been tested.

Some clinicians question the need for repeat endoscopy once the PEG tube has been pulled (or pushed) into position. Endoscopic intubation of the esophagus can be difficult in a supine, often intubated, patient. It is important, however, to confirm the position of the PEG bumper because obstruction from malpositioned tubes at both the gastroesophageal junction and pylorus have been reported. Endoscopic examination also helps confirm proper tension between the gastric wall and the bumper and rules out any associated injury such as laceration of the esophagus from an improperly grasped wire (wire snared close to its tip). [37] Repeat passage of the endoscope can be simplified by attaching the end of the scope to the button of the PEG tube before it is pulled into the oropharynx. The button of the tube is snared on one side only with a polypectomy snare preloaded through the endoscope. With gentle pressure, the endoscope will follow the PEG tube as it is being pulled into position. Once in the esophagus, the button is released, and the endoscope is passed into the stomach under direct vision.

Good skin care is important after gastrostomy. It is common to see a foreign body reaction around the tube with some exudate or granulation tissue. This is usually easy to treat. The exudate is merely swabbed away with hydrogen peroxide. The site should be left open to the air. Granulation tissue may be cauterized with silver nitrate. Occlusive dressings should be avoided because they lead to maceration of the underlying skin.

FEEDING

Once the PEG has been placed without complication, the next issue is how to feed through it. Intermittent feeding is preferred because it is easy to administer (no pump required), well tolerated, and physiologic. The formula is allowed to flow in by gravity over a period of 30 to 60 minutes. Rapid bolus feeds should be avoided because they decrease lower esophageal sphincter pressure to incompetent levels and are associated with free gastroesophageal reflux. Patients should be placed in a semirecumbent position to reduce the risk for aspiration. Most endoscopy units start feeding 24 hours after PEG placement with the initiation of a continuous infusion of water at 50 mL/h. Once this has been tolerated for 4 hours, the infusion of a full-strength polymeric formula is begun at 50 mL/h and advanced by 25 mL/h every 12 hours as tolerated until the goal rate is reached. This method is anecdotal, however, and some clinicians have demonstrated that a continuous infusion of full-strength formula at 30 mL/h can be safely initiated only 3 hours after PEG placement. [38] The choice of formula is based on the patient's caloric needs, tolerance, and associated medical conditions. Fiber-containing formulas have not been shown to be of any advantage. Residual volumes should be checked on a regular basis until tolerance of the regimen has been demonstrated. If found to be more than 100 mL, this should prompt concern for intolerance but should not cause cessation of the tube feedings because a repeat measurement an hour later is often normal. [39] Residual volumes of more than 100 mL for successive measurements, however, should prompt cessation of feeding. Tubes smaller than 10 French in size have been shown to be unreliable for the determination of a residual volume. [40]

Aspiration is one of the most important complications associated with tube feeding. The prevalence is reported to be from 2% to 95%, depending on the definition and how it is measured. It has been shown that patients are at a higher risk for aspiration from nasogastric tube feedings in comparison with PEG feedings. [5] It is less clear if feeding into the jejunum decreases the risk for aspiration when compared with gavage feeding. Most studies addressing this issue are too small, are poorly designed, or do not document the position of the feeding tube. In general, direct jejunal feeding is not required unless a patient has a history of gastroesophageal reflux or has recurrent tube feeding aspiration through a PEG.

PERCUTANEOUS ENDOSCOPIC JEJUNOSTOMY

Percutaneous endoscopic jejunostomy is a modification of PEG intended to accomplish concomitant jejunal feeding and gastric decompression. The method is similar to that of PEG, with the gastric tube acting to anchor the apparatus and decompress the stomach while a longer enteric tube is passed through the PEG and positioned in the distal duodenum or proximal jejunum. [41] The proposed advantage of this system is to decrease the risk for aspiration, but early studies failed to demonstrate this advantage. The tips of the "jejunal" tubes used for these studies, however, were often only in the proximal duodenum. More recent studies have confirmed placement of the tube into the distal duodenum or proximal jejunum using an over-the-wire technique and have demonstrated a virtual elimination of aspiration associated with feeding. [42] The indications for percutaneous endoscopic gastrostomy or jejunostomy tube placement are tracheal aspiration, reflux esophagitis, gastroparesis, insufficient stomach from previous resection to perform PEG placement or to tolerate gavage feeding, or enteral access in patients with partially obstructing lesions from gastric or pancreatic carcinoma. Correct placement of these tubes has proved difficult. Traditionally, a suture is attached to the tip of a jejunal tube before passing it through the PEG and into the stomach. The suture is grasped with a biopsy forceps loaded through the endoscope and dragged under direct vision into the duodenum. Deep passage is often impossible, however, and the tube frequently drags back into the proximal duodenum or stomach during removal of the endoscope. A pediatric colonoscope or enteroscope may be used to ensure passage of the jejunal tube into the distal duodenum or proximal jejunum. More recently, various guidewire techniques have been described to assist in placement. Duckworth and colleagues [42, 43] described passing a guidewire through a 24-French PEG tube and grasping it with a biopsy forceps passed through the endoscope. The wire is dragged under direct vision into the distal duodenum or proximal jejunum. While still holding it with the forceps, tension is applied to the free end of the wire to straighten it. A 12-French jejunal feeding tube is then passed over the wire. The endoscope is removed by a rocking motion followed by removal of the guidewire. Tube placement is confirmed by abdominal radiograph. An initial placement success rate of 100% has been reported, but there is a 20% long-term tube failure rate owing to malpositioning or occlusion. Chaurasia and Chang [44] have described passing a pediatric bronchoscope through the PEG and into the distal duodenum to gain access to the bowel. A wire is passed through the scope and guided beyond the ligament of Treitz using fluoroscopy. The jejunal feeding tube is then passed over the wire and into position. Finally, Leichus and colleagues [45] have described passing the endoscope into the stomach and through an open polypectomy snare that has been passed into the stomach through the PEG. The tip of the endoscope is placed into the distal duodenum, and a guidewire passed through it and beyond the ligament of Treitz. The wire is kept in position while the endoscope is withdrawn, leaving the peroral wire to be grasped at the intragastric segment by the trans-PEG polypectomy snare. The snare is pulled so that the oral end of the wire is retrieved out the PEG. A jejunostomy tube is then passed over the wire and into position, confirmed by fluoroscopy.

To overcome some of the placement difficulty with percutaneous endoscopic gastrostomy and jejunostomy systems, Shike and colleagues [46] described placing a feeding tube directly into the jejunum using a similar technique to that of PEG. This was initially used only in patients with partial or total gastrectomy but has subsequently been used in patients without gastric resection. Such placement may require use of a push enteroscope or pediatric colonoscope, and fluoroscopic guidance is useful. When successful, this procedure obviates the problem of tube migration and ensures placement beyond the ligament of Treitz. It is also easier to place larger-caliber tubes that are less likely to fail from occlusion. When used in combination with a PEG, better decompression of the stomach can be obtained

because the PEG tube is not partially occluded by the percutaneous endoscopic gastrostomy and jejunostomy system. There is a greater potential for complications, however. The mobility of the jejunum and the higher likelihood for intervening structures between it and the abdominal wall make strict adherence to technique mandatory. The thin wall of the jejunum is also more likely to allow leakage of enteric contents around the tube. Finally, the direct percutaneous endoscopic jejunostomy tube can act as a “maypole” around which the small bowel can twist and obstruct.

REMOVAL AND REPLACEMENT OF PERCUTANEOUS ENDOSCOPIC GASTROSTOMIES

PEG tubes may require replacement when the tube has become frayed, obstructed, or develops a leak. Additionally, in some patients, an enlarging stoma may be the result of excessive tube motion at the skin level. In such cases, removal and replacement with a skin-level device may be advantageous. Elective tube removal should not be performed until a secure tract has formed, usually at least 10 days to 2 weeks following placement.

When PEG tubes are inadvertently removed prematurely, peritonitis is a threat. When discovered immediately, such patients can often be treated with nasogastric suction and intravenous administration of antibiotics. With close observation and steady improvement, the PEG may be repeated in about 1 week. Should the patient demonstrate signs of peritonitis or sepsis, urgent laparotomy is indicated.

Some PEG tube designs require endoscopic extraction of the intragastric portion at the time of tube replacement or removal. Designs are presently available that permit extraction by means of external traction without the need for endoscopy. [47] Although PEG tubes may be replaced with balloon-tip catheters, these tubes generally last only a short time and have been known to migrate and obstruct the pyloric channel. Use of a mushroom-tip catheter or a skin-level device is preferable. Gauderer and colleagues [48] developed the concept of a skin-level gastrostomy device. This device, with an antireflux valve, permits a cosmetic solution to gastrostomy feedings. It may be placed after removal of a previous gastrostomy tube or at the time of the creation of the initial PEG. A standard tube is often preferable to the skin-level device in patients who require custodial care because it is more easily accessed by nursing personnel.

Percutaneous gastrostomy is a simple procedure with few severe complications. Close attention to detail and rapid assessment of potential problems minimizes unsatisfactory outcomes.

CHAPTER 147

Joseph J. Y. Sung and James Y. W. Lau

ENDOSCOPIC THERAPY FOR UPPER GASTROINTESTINAL VARICEAL HEMORRHAGE

ANATOMY OF THE PORTAL VENOUS SYSTEM AND GASTROESOPHAGEAL VARICES

It is important to understand the anatomy of the portal system and the vascular system around the gastroesophageal junction to rationalize the management of variceal bleeding. The portal vein is formed behind the neck of the pancreas by the confluence of the superior mesenteric vein, which drains blood vessels perfusing the small bowel, and the splenic vein. The short gastric veins, which drain the gastric fundus, enter the spleen above the origin of the splenic vein. The left gastric vein, also called the coronary vein, enters the portal venous system within a few centimeters from the confluence through the splenic vein or the portal vein itself. The portal circulation of a normal individual is about 1 to 1.2 L/min with a low pressure of about 7 mm Hg. It constitutes two thirds of the hepatic blood flow and provides 30% to 60% of oxygen consumed by the liver. Blood vessels in the gastroesophageal region drain into the azygos vein before returning to the systemic circulation. The normal azygos venous blood flow is 150 to 200 mL/min (Fig. 147-1).

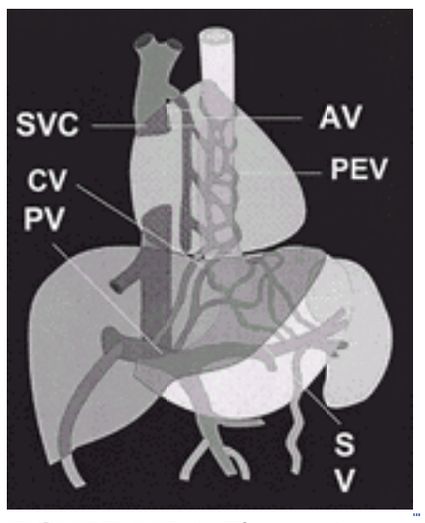

FIGURE 147-1. The anatomy of the portal venous system. AV, azygos vein; CV, coronary vein; PEV, paraesophageal vein; PV, portal vein; SV, splenic vein; SVC, superior vena cava.

Gastroesophageal varices arise from the lower esophagus and the gastric cardia. Based on radiologic imaging and corrosion casting study by Vianna and colleagues,[1] the vasculature at the esophagogastric junction can be divided into four distinct zones. The gastric zone, located just below the esophagogastric junction, is characterized by longitudinal veins draining into the short gastric and left gastric veins. The palisade zone extends 2 to 3 cm above the gastric zone and consists of uniformly distributed parallel veins running in four groups with multiple anastomoses lying in the lamina propria. Each of these groups corresponds to one esophageal mucosal fold. Blood flows in both caudad and cephalad directions in this zone depending on pressure above and below this level. The perforating zone lies above the palisade zone. It has lost the longitudinal structure but features venules penetrating through the muscle wall of the esophagus linking the submucosal vessels to the extraesophageal vessels. Above the perforating zone, the truncal zone consists of longitudinal veins and occasional perforating veins penetrating at irregular intervals.

Esophageal varices constitute a dilated venous plexus in the lamina propria of the lower esophagus. Obstruction of portal venous blood flow increases pressure in the system, which when above 12 mm Hg, causes dilation and high pressures in the periesophageal veins, rendering the valves in the perforating veins incompetent and allowing retrograde flow into the deep intrinsic veins and its tributaries. The dilated deep intrinsic veins displace the superficial venous plexus and assume a subepithelial position forming the large tortuous variceal columns in the esophageal lumen. [2] The high-pressure dilated vessels in the perforating zone force blood to flow caudally into the palisade zone where these thin parallel vessels run within the mucosal fold in a longitudinal manner. The esophageal plexus in this region is more superficial and has poor connective tissue support. The palisade zone is therefore the most common site of bleeding. Varices at the perforating and truncal zones are connected to periesophageal varices by the perforators. It has been suggested that these perforators are the cause of failed endoscopic treatment [3] and early recurrence of varices after endoscopic therapy. [4], [5] and [6]

NATURAL HISTORY OF VARICEAL BLEEDING

Thirty percent of patients with compensated cirrhosis and 60% of patients with decompensated cirrhosis have gastroesophageal varices at the time of presentation. [7], [8] Among cirrhotic patients who have no esophageal varices on diagnosis, the incidence of new varices ranges between 5% and 23% after 1 year of follow-up. [9], [10] and [11] In a recent prospective study, D'Amico and associates [12] followed 225 newly diagnosed cirrhotic patients who had no varices on first endoscopy. In the 10-year follow-up, during which patients received endoscopy every 1 to 3 years, the incidence of varices in newly diagnosed compensated cirrhosis was around 4.5% per

year, mortality rate in patients without varices at diagnosis 3% per year, and mortality rate from bleeding 0.5% per year. The risk for varices parallels the severity of liver disease as reflected by Child scoring. Platelet count also is suggested to predict development of varices. [12] Once varices have developed, they tend to increase in size. The rate of increase of variceal size from small to large is not well documented, with reported figures ranging between 5% and 31% per year. [10], [11], [12], [13] and [14] It appears that the rate of growth of varices from small to large in compensated patients is faster than the rate of de novo appearance of varices.

Among patients with cirrhosis and esophageal varices, the incidence of first variceal hemorrhage ranges from 20% to 40% within 2 years. A recent metaanalysis studying the effects of prophylactic beta-blocker treatment revealed that the mean weighted bleeding rate of the control group (without treatment) at 2 years is around 24%. [15] Interestingly, only one third of patients with esophageal varices bleed from their varices in their lifetime. [16] Thus, many patients with gastroesophageal varices may never bleed. As such, better understanding of risk factors for gastroesophageal variceal bleeding and the capability to predict which patients with varices will bleed are important in planning timely treatment.

Bleeding from gastroesophageal varices is now widely accepted as a phenomenon of “explosion”—a result of pressure inside the vascular structure. [17] Working on this theory, the risk for variceal rupture, according to LaPlace’s law, is related to the size of the varices, wall thickness, and intravariceal pressure. Several groups have confirmed that variceal size is the most important prognostic factor for variceal bleeding. [16], [18], [19] Red color signs, which include cherry-red spots and red wale markings, are also associated with a more advanced grade of varices and higher risk for hemorrhage. These signs are thought to represent focal weakness or “blowouts” in the variceal wall. Fibrin clots (“white nipple sign”) are occasionally seen over variceal columns that recently bled. [20], [21] Severity of liver disease also predicts outcome. Patients with decompensated liver disease, alcoholic hepatitis, and portal vein thrombosis fare worse than those with compensated diseases. [22], [23] The risk for bleeding from varices is correlated to the Child-Pugh score, not only because of more severe portal hypertension, but also because of other factors such as nutritional deficiency, coagulopathy, and increased fibrinolysis in advanced liver disease. [24], [25] Recently, an association between bacterial infection and failure to control bleeding has been observed. [26] Metaanalysis of prophylactic antibiotics in variceal bleeding in cirrhotic patients showed reduced morbidity and mortality. [27] A potential causal relationship between infection and bleeding has thus been put forward. [28]

A diurnal periodicity of variceal bleeding has been reported. Bleeding episodes occur more frequently in the early mornings and late evenings, [29] probably related to hyperdynamic blood flow in the portal system after a meal during these hours. [30], [31] Most variceal bleeding stops, at least temporarily, by the time the patient arrives at the hospital. Recurrent bleeding occurs in 30% to 40% of patients within the next 2 to 3 days and in up to 60% within 1 week. [32], [33] and [34] The risk for recurrent bleeding is likely related to changes in hemodynamics of the portal system, including an increase in portocollateral resistance after hypotension, increased splanchnic blood flow stimulated by blood in the gut, and an increase in portal venous pressure as a result of overzealous volume expansion during resuscitation. Bleeding-associated mortality is highest in the first 5 days after the index episode of variceal bleeding and returns to baseline levels by 3 to 4 months. [34], [35] This is the critical window for optimal treatment to improve the survival of variceal bleeders.

Several prognostic indexes have been developed to predict which patients with esophageal varices are likely to bleed. Factors incorporated include clinical and biochemical parameters, endoscopic features, and Doppler ultrasound findings. [16], [36], [37], [38] and [39] The most widely used index is the North Italian Endoscopic Club (NIEC) Index. [16] The index is based on three independent predictors of bleeding: (1) severity of liver disease (Child-Pugh class), (2) size of varices, and (3) red wale markings on the varices. Cirrhotic patients have been classified into six risk classes with a prediction rate of bleeding for each. The NIEC index has been prospectively validated in more than 1000 patients. [40], [41] and [42] The main limitation of the available prognostic indexes is that they can only identify a relatively small proportion of the patients who eventually bleed. In the NIEC index, less than 40% of the patients who eventually bled had been identified as high-risk patients. [16]

ENDOSCOPY IN VARICEAL BLEEDING

The objectives of endoscopy in gastrointestinal bleeding are to identify the source of bleeding, assess the risk for recurrent hemorrhage, and attempt to control the bleeding and prevent recurrent hemorrhage. About one third of patients with a known history of portal hypertension actually bleed from nonvariceal sources such as peptic ulcers, portal hypertensive gastropathy, and Mallory-Weiss tears. [43], [44] and [45] The use of balloon tamponade as a temporary measure without endoscopy is often futile and could be dangerous because it may aggravate an esophageal tear. The use of pharmacological methods is preferable to balloon tamponade. Somatostatin and its synthetic analogs have been shown to control bleeding from varices, providing a “dry field” for endoscopic examination. In patients with decompensated liver disease, light sedation is preferred to general anesthesia. The judicious use of endotracheal intubation is recommended during emergency endoscopy to prevent aspiration of blood. A therapeutic endoscope with a working channel of at least 3.2 mm allows for adequate suction. In the presence of a large quantity of blood and clots in the stomach obscuring the view, a large 6-mm channel endoscope can be used. In cases of blood or food material sticking to the mucosa, a water-pump system provides a forceful water jet for washing. Occasionally, an overtube in the stomach is needed for proper gastric lavage. Evacuating blood from the stomach not only allows for better vision but also helps reduce the subsequent risk for hepatic encephalopathy in cirrhotic patients with liver dysfunction.

ENDOSCOPIC THERAPIES: TECHNIQUES AND COMPLICATIONS

Endoscopic Injection Sclerotherapy

In 1939, Crafoord and Frenckner [46] pioneered endoscopic injection sclerotherapy (EST) using a rigid esophagoscope in the treatment of esophageal varices. The technique did not gain popularity until flexible endoscopy became available in the 1970s. To date, injection sclerotherapy remains the primary treatment of bleeding esophagogastric varices in many parts of the world. It is used both in the control of acute bleeding and in elective obliteration of varices. Despite its popularity, the mechanism of action of EST is not entirely clear. The hemostatic effect is unlikely to be due to acute venous thrombosis induced by sclerosant. Blood flow in varices is much faster than that in peripheral varicosities, and sclerosant injected intravariceally dissipates rapidly. [47] Furthermore, when sclerosants are injected around the varices, acute hemostasis can still be achieved at the same rate. [48] Autopsy studies indicate that venous thrombosis, mucosal ulceration, and acute inflammatory reactions can be found in the injection site as early as 2 days after sclerotherapy. A multitude of actions of EST may take effect in bringing the hemorrhage under control. [49], [50]

The technique of EST varies according to individual endoscopists. Differences include the choice of sclerosants (type, concentration, single or in combination), number of sessions, interval between sessions, site and volume of injection, and use of an overtube. Injections may be directed into the veins (intravariceal injection) or into the esophageal wall adjacent to the varices (paravariceal injection), but most endoscopists favor the former technique. When injections are made into the moving esophagus, more often than not a combination of intravariceal and paravariceal injections are given. Most endoscopists use a freehand method, injecting sclerosant into the source of bleeding or variceal column that shows a fibrin clot. Systematic injections to each variceal column hould then start from the esophagogastric junction, working upward to the midesophagus. Injections should be confined to the distal one third of the esophagus because this is the most likely area of variceal hemorrhage. Many sclerosants have been used, but there appears to be little difference in their hemostatic effects. Sclerosants are either chemical irritants such as fatty acids (e.g., sodium morrhuate, ethanolamine oleate, polidocanol) or dehydrating agents (e.g., sodium tetradecyl sulfate, ethanol, hypertonic glucose, phenol). There are few systematic comparisons between different sclerosants. The choice is largely related to personal preference and availability in different countries. For obliteration of varices, most endoscopists use 1.5% sodium tetradecyl sulfate, 5% sodium morrhuate, and 5% ethanolamine oleate. Depending on the size of the varix, 1- to 2-mL aliquots are injected into each column. A total volume of 20 ml can be injected at each session. Sodium tetradecyl may cause more severe esophageal ulceration and strictures compared with polidocanol [51] or ethanolamine oleate. [52]

Devices such as flexible overtubes and balloon catheters have been designed to provide variceal compression during EST. The Kitano tube has a tunnel running on its side for the insertion of the injection needle and a slit at the end of the injection channel. Esophageal tissue and varices invaginate through the slit into the lumen, facilitating injection. Although it confers protection against aspiration and facilitates sclerotherapy, the Kitano tube causes significant discomfort to patients and is not frequently used by experienced endoscopists. If there is no evidence of further bleeding, feeding can be resumed after several hours of observation. Recent studies support the use of prophylactic antibiotics to prevent bacteremia and associated peritonitis after EST. [26], [27] Patients may also be given sucralfate or acid-suppressive treatment after receiving EST to prevent extensive esophageal ulceration. Further injection is then continued at regular intervals until all varices are obliterated. The appropriate interval for follow-up EST after control of the initial hemorrhage remains somewhat arbitrary. Most centers adopt a weekly or biweekly treatment schedule.

Cyanoacrylate Injection

Endoscopic injection of varices with *N*-butyl-2-cyanoacrylate (Histoacryl) was first introduced in Germany. [53] The tissue adhesive coagulates almost instantaneously

when in contact with blood. To slow down the process of clotting and to allow fluoroscopic monitoring of the injection, cyanoacrylate is mixed with radiologic contrast (lipiodol) before injection. Before the injection, the working channel of the endoscope and the injector probe are flushed with 1 to 2 mL of lipiodol to prevent channel blockage. A mixture of 0.5 mL of cyanoacrylate and 0.7 mL lipiodol is injected intravariceally. The injected submucosal vessels harden, and bleeding ceases (Fig. 147-2A; see also Color Fig. 147-2A). A serpentine structure demonstrated on fluoroscopy confirms successful intravariceal injection (see Fig. 147-2B). The needle must be rinsed with distilled water before retraction. Suction should be prohibited at this time to avoid adhesive clogging the suction channel of the endoscope. A cast will slough off from the injection site within 1 to 2 weeks, leaving an ulcer. Cyanoacrylate is very effective in controlling actively spurting variceal hemorrhage. Nonrandomized studies have shown that it is superior to other sclerosants in acute hemostasis. [54], [55] In patients with hepatocellular carcinoma complicated by variceal bleeding, a single injection of cyanoacrylate has been shown to be as effective as weekly injection of sodium tetradecyl sulfate. [56] Cyanoacrylate also offers the best results in the treatment of gastric varices. [57] Serious complications, including thromboembolism of the pulmonary, coronary, and cerebral vessels, organ infarction, [58] and multiple septic emboli, [59] have been reported.

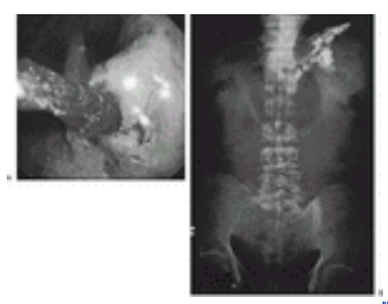

FIGURE 147-2. (See also Color Figure 147-2A.) Cyanoacrylate injection for gastric varices. **A:** The injected cyanoacrylate stops bleeding from a fundal varix instanteously. **B:** Vascular structure demonstrated on fluoroscopy confirming success of variceal obliteration.

Endoscopic Variceal Ligation

The concept of endoscopic variceal ligation (EVL) was derived from band ligation for hemorrhoids. The basic principle of variceal banding involves placement of elastic O-ring ligatures, causing strangulation of the varix. Stiegmann and Goff [60], [61] first introduced a ligation device for esophageal varices in 1986. The assembly consists of a friction-fit adaptor onto the end of the scope, an inner ligation cylinder with an elastic O-ring, and a trip wire. The varix is sucked into the inner cylinder. The trip wire is pulled to retract the inner cylinder and release the O-ring. In the treatment of actively bleeding varices, the bleeding point can be aspirated directly into the cylinder and a band applied. Varices with stigmata of hemorrhage, such as a fibrin clot, can be treated similarly. Variceal columns are banded at their most distal portions, usually just caudal to or at the esophagogastric junction. Because only a single band could be placed with the original ligation device, an overtube across the cricopharyngeus sphincter was required to facilitate multiple passages of the endoscope and its attached banding device. However, the overtube can be a cause of serious morbidity. Pinching injury of esophageal wall in the gap between the overtube and endoscope, causing esophageal laceration and perforation, has been described. The original design of the banding device also created a tunnel view and limited thorough examination. A number of modifications have since been made. Multi-fire band-ligating devices are now available, obviating the need for an overtube. The cylinder is now made of transparent plastic to improve field of vision. These multi-fire banding devices have largely replaced the single-fire banding device. They shorten the duration of each treatment session and reduce patient discomfort. [62], [63]

However, EVL still has its limitations. As varices become smaller and scarring of the esophageal wall starts to develop after a few sessions of EVL, further banding becomes difficult. In some cases, EVL alone fails to eradicate all residual varices without use of EST. The other potential problem with EVL is early recurrence of varices. Many studies have witnessed early recurrence of esophageal varices within 6 to 12 months after obliteration. [64], [65] and [66] EVL obliterates varices by pinching on the mucosa and submucosa of the esophageal wall. The periesophageal and paraesophageal varices and the perforating veins, which are the determinant factor for recurrence, are not occluded by EVL. [3], [4], [5] and [6]

Complications of Endoscopic Therapy

Both EST and EVL are associated with certain procedure-related complications (Table 147-1). Almost all patients experience some minor complications, such as chest pain, temporary dysphagia, and low-grade fever, after receiving EST. These adverse events, likely related to chemical irritation producing spasm and ulceration of the esophagus, are usually transient and self-limiting. The incidences of these complications are related to the nature, concentration, and volume of sclerosant injected. More serious complications (e.g., recurrent bleeding from esophageal ulcer, esophageal perforation, and mediastinitis) develop in up to 20% of patients after EST. Aspiration pneumonia is not uncommon in agitated patients with active bleeding. Bacteremia and bacterial peritonitis are increasingly recognized as frequent adverse events of EST. [67], [68] Severe esophageal ulcerations may heal with extensive fibrosis and stricture of esophagus requiring esophageal dilation. Rarely, portal vein thrombosis, brain abscess, spinal cord paralysis, and pericarditis have been reported. Acid-suppressing agents and sucralfate have been used to minimize the effect of acid reflux and to accelerate ulcer healing. [69], [70] Prophylactic antibiotics have been shown to reduce bacteremia and bacterial peritonitis. [26], [27], [71], [72] Judicious use of an overtube should be considered in struggling patients with active bleeding.

TABLE 147-1 Complications of Endoscopic Therapies for Variceal Hemorrhage

Compared with EST, EVL has been associated with fewer complications. This is related to the fact that EVL produces only mechanical strangulation of varices without much tissue inflammation and injury. Small ulcers are produced after the O-ring and the strangulated varix slough off from the esophageal wall. The ulcers are usually superficial and almost never produce stricture of esophagus. Complications associated with chemical irritation, such as fever, mediastinitis, and pleural effusion, are rare. The only serious complication associated with EVL is related to the use of an overtube: esophageal laceration, perforation, and pinching injury of the esophagus. As multiple banding devices are replacing single-band ligators, serious esophageal injury inflicted by overtube will become of historical interest.

Detachable Mini-Snare

The detachable snare employs the same concept as the original banding device. It was initially designed for endoscopic resection of elevated mucosal lesions to minimize the risk for bleeding. [73] The snare has a maximum diameter of 4 cm when fully opened. Yoshida and colleagues [74] used the detachable snare for the ligation of gastric varices and reported excellent results. Despite that, detachable snare ligation of gastric varices has not been very popular. Gastric varices are usually quite large, and positioning of the snare around the gastric varices is often difficult. With modification of the detachable mini-snare, it has recently been used for the treatment of esophageal varices. [75] This method of variceal ligation has the advantages of obviating the use of overtube, producing a clear endoscopic image, and offering an unlimited number of ligations. A transparent ligation chamber with a rim on the inside is fitted onto the tip of an endoscope. The detachable mini-snare, which is an oval-shaped nylon ring with a maximum diameter of 11 mm, is inserted into the working channel of the endoscope until it opens at the rim of the ligation chamber. The endoscope is positioned to obtain an en face view of a variceal column. The varix is then sucked into the ligation chamber, and the mini-snare is maneuvered to surround the varix. Ligation of the varices is performed by sliding the stopper forward. When the loop is tightened around the base of the varix, suction can be released and the mini-snare detached from the snare. The ligated portion of the varix appears as a “polyp” with a short string attached to the base (Fig.

147-3). Additional ligations are carried out by reloading the mini-snare with the endoscope remaining in the esophagus. A recent prospective randomized study showed that mini-snares performed comparably to a multi-fire variceal ligator. [76]

FIGURE 147-3. Schematic diagram on the mechanism of deployment of detachable mini-snare for the ligation of esophageal varices. **A:** An endoscope inside the esophagus loaded with the detachable mini-loop. **B:** An esophageal varix is sucked into the ligation chamber and the position of the mini-loop adjusted to surround the varix. **C:** The mini-loop is tightened by sliding the stopper forward. **D:** The mini-loop is detached from the snare when the loop is tightened. (From Sung JY, Chung SC. The use of a detectable mini-loop for the treatment of esophageal varices. Gastrointest Endosc 1998;47:178.)

Thrombin, Hemoclips, and Argon Plasma Coagulation

Both human and bovine thrombins have been used in the control of variceal hemorrhage. The injection of bovine thrombin (single intravariceal injection of 1000 U/mL) resulted in cessation of bleeding in 11 patients in a single series. [77] It has been proposed that thrombin is equally effective in controlling esophageal as well as gastric varices. The major advantage of using thrombin as a thrombotic agent to obliterate varices is that it appears to produce few complications in the absence of mucosal inflammation. Allergic reaction and infection transmission from bovine thrombin has always been a concern. Data from randomized study to confirm its efficacy is, so far, lacking.

Poly *N*-acetyl glucosamine, derived from marine microalgae, has been tested in the treatment of varices. [78] In a canine model study, it has been shown that intravariceal injection of 2.5% to 3.5% poly *N*-acetyl glucosamine has the ability to eradicate esophageal varices and achieve complete hemostasis in a single session. Further studies will be required before this gel can be considered in clinical practice.

Hemoclips were originally designed to control arterial bleeding at the base of peptic ulcers. In a Japanese study, hemoclips were used in the treatment of esophageal varices in 12 children. [79] Multiple hemoclips were applied from the lesser curve of the stomach to the lower esophageal. Although the authors claimed a 100% success rate, there is no further report to confirm efficacy.

Recently, argon plasma coagulation has been used to induce superficial burns and fibrosis on the esophageal mucosa after eradication of varices. [80] A circumferential burn at the lower esophagus is made to induce fibrosis in the submucosa to prevent recurrence of varices. Although the procedure appears safe in patients after all varices are obliterated, the long-term effect of argon plasma coagulation remains to be confirmed.

ENDOSCOPIC TREATMENT OF ACUTE VARICEAL HEMORRHAGE

In patients with acute variceal bleeding, the goals of treatment are to restore hemodynamic stability, stop hemorrhage, prevent complications, including early rebleeding, and decrease mortality. Many modalities of treating variceal bleeding have been devised, including pharmacological therapy, endoscopic treatment, surgical devascularization or bypass, and radiologic shunting.

Endoscopic Injection Sclerotherapy versus Sham or Balloon Tamponade

Although EST has been used as the standard treatment for decades, few data compare this treatment with sham to support its efficacy. The best evidence for the value of EST comes only recently from the Veterans Affairs Cooperative Variceal Sclerotherapy Group. [81] In this study, EST stopped hemorrhage from actively bleeding esophageal varices more effectively than sham EST with medical therapy (91% versus 60%) and significantly improved survival (75% versus 51%). EST was compared with medical treatment with or without balloon tamponade in four trials. Barsoum [82] randomized 100 patients and found a favorable effect of EST superior to balloon tamponade in reducing both in-hospital rebleeding and death. In the Copenhagen Esophageal Varices Sclerotherapy Project, 187 patients were randomized, and the authors reported no significant difference in the initial control of hemorrhage. [83] Rebleeding within the first 40 days was similar in either group. After 40 days, a significant reduction in rebleeding associated with EST was noted (15% versus 31%); thus, the beneficial effect of EST was seen in the long-term after eradication of varices. Paquet and Feussner [84] and Moreto and associates [85] recruited smaller numbers of patients and reported improvement in control of bleeding with EST. In summary, EST is superior to balloon tamponade in the acute control of bleeding and in the prevention of recurrent hemorrhage from esophageal varices.

Endoscopic Injection Sclerotherapy versus Vasoactive Agents

Two major classes of drugs used in the control of acute variceal hemorrhage are vasopressin and its analogs and somatostatin and its analogs. EST was compared with vasopressin in five studies, terlipressin in one study, somatostatin in four studies, and octreotide in three studies (Table 147-2). Soderlund and Ihre [86] randomized 107 unselected patients to receive either EST or vasopressin infusion supplemented by balloon tamponade. Initial control and hospital mortality were similar in both groups. With long-term follow-up, EST led to variceal eradication and less rebleeding. Larson and colleagues [87] randomized 82 patients to EST or conventional treatment, including balloon tamponade and vasopressin, and demonstrated that EST was clearly beneficial in reducing rebleeding episodes. Westaby and associates [88] compared EST with vasopressin plus nitroglycerin and reported a better control of active bleeding and fewer deaths due to variceal bleeding in the EST group. El-Zayadi and coauthors [89] and Alexandrino and colleagues [90] confirmed comparable efficacy of vasopressin and EST. The use of vasopressin is hampered by its frequent side effects due to nonselective vasoconstriction. The risk is highest among patients with cardiac ischemia and peripheral vascular diseases.

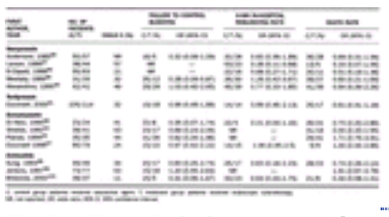

TABLE 147-2 Comparative Trials of Sclerotherapy with Vasoactive Agents in the Acute Control of Variceal Hemorrhage

In a single comparison study between terlipressin and EST, both treatments were found to have similar efficacy. [91] Side effects developed in 20% of patients receiving terlipressin and 30% of patients receiving EST, which gives the vasoactive agent a marginal superiority in safety profile over endoscopic treatment.

Unlike vasopressin, somatostatin and its analogs have selective vasoconstrictive activity in the splanchnic circulation, [92], [93] with a lower risk of systemic side effects. Four trials compared somatostatin [94], [95], [96] and [97] and three compared octreotide against endoscopic sclerotherapy in the treatment of acute bleeding esophageal varices. [98], [99] and [100] All studies showed similar rates of initial control of bleeding, recurrent bleeding, and death. In a recent metaanalysis combining data collected from 13 randomized trials, octreotide has been shown to improve control of esophageal variceal hemorrhage compared with all alternative therapies combined. Its

effect is comparable to immediate EST with fewer major complications than vasopressin or terlipressin. [101]

Endoscopic Injection Sclerotherapy versus Endoscopic Variceal Ligation

Since its development by Stiegmann and Goff in the late 1980s, more than 10 studies have compared EVL with EST. [64], [65] and [66], [102], [103], [104], [105], [106], [107], [108] and [109] (Table 147-3). Most studies reported that EVL is a safer and quicker technique with fewer episodes of rebleeding and complications. The early metaanalysis by Laine and Cook [110] demonstrated reduction in rebleeding rate (odds ratio [OR], 0.52; 95% confidence interval [95% CI], 0.37 to 0.74), overall mortality (OR, 0.67; 95% CI, 0.46 to 0.98) and mortality caused by rebleeding (OR, 0.49; 95% CI, 0.24 to 0.996) after EVL as compared with EST. The number of EVL sessions required to achieve variceal obliteration was also lower. The frequency of esophageal strictures was less with ligation. Following this metaanalysis, at least six more studies were published demonstrating the superiority of EVL over EST. Although attractive because of a faster eradication rate and fewer complications, EVL is associated with a higher variceal recurrence. The difference in variceal recurrence can be explained by the fact that the ulcers caused by banding are usually superficial and induce very limited scarring. Because the high portal pressure is not affected by endoscopic treatment and the perforating veins are not obliterated by EVL, the residual esophageal varices dilate over a period of weeks or months. In almost all studies comparing the long-term effects of EST and EVL, recurrence of esophageal varices was found more frequently in the EVL-treated patients (30% to 48%) compared with the EST-treated patients (8% to 30%). On the contrary, rebleeding from esophageal varices was significantly higher among those treated by EST than by EVL (37% versus 8%). The overall survival rates are similar in both treatment modalities and are determined by the hepatic function reserve rather than by the method of endoscopic hemostasis. A comparison between EST and EVL is summarized in Table 147-4. With the exception of the study by Gimson and colleagues, [103] EST produced a higher complication rate than EVL. In summary, EVL is at least as effective as EST in the control of acute variceal hemorrhage and has the clear advantage of producing fewer complications. Although EVL treatment is associated with more variceal recurrence, rebleeding from varices is paradoxically less common.

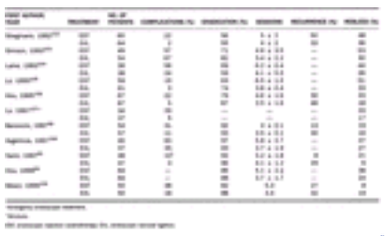

TABLE 147-3 Randomized Comparative Trials of Injection Sclerotherapy and Variceal Ligation

	SCLEROTHERAPY	VARICEAL LIGATION
Technique	Variable	Standardized
Control of active bleeding	>90%	>90%
Sessions required for obliteration	More	Less
Complications	Common	Uncommon
Recurrence of varices	Less common	Common
Effects on survival	No effect	May improve survival
Use in primary prophylaxis	Not recommended	Comparable to beta-blocker
Cost	Inexpensive	Expensive

TABLE 147-4 Comparison between Endoscopic Sclerotherapy and Endoscopic Variceal Ligation

Endoscopic Therapy plus Vasoactive Agents versus Endoscopic Therapy Alone

Because both endoscopic therapy and vasoactive drugs are effective in the acute control or prevention of recurrent bleeding in esophageal varices, it would be logical to combine modalities. Seven studies combined EST with vasoactive agents; somatostatin in two studies, [111], [112] octreotide in three studies, [113], [114] and [115] terlipressin in one study, [116] and vapreotide in one study. [117] In most studies, combination therapy of EST and vasoactive agents was shown to be more effective than EST alone.

Optimally, vasoactive drugs are given as early as possible in patients with suspected esophageal variceal bleeding. Terlipressin plus nitroglycerin started by the emergency medical team at the patient's home before arrival at the hospital significantly improved control of variceal hemorrhage. [116] Avgerinos and colleagues [111] (the ABOVE trial) and Cales and associates [117] commenced somatostatin and vapreotide, respectively, soon after hospitalization before endoscopy. In the ABOVE trial, active bleeding was seen less frequently in patients assigned to somatostatin. [111] EST was technically easier after bleeding was temporarily controlled with pharmacological therapy. Endoscopic treatment failure was less likely in the somatostatin group. Similar findings were noted in the study using vapreotide. As in the ABOVE Study, fewer patients had active bleeding during endoscopy if they had received prior vapreotide. [117] The lowering of portal venous pressure by early administration of vasoactive drugs facilitates subsequent endoscopic control of hemorrhage. In all three studies, there was significant improvement in the initial control of bleeding with combined pharmacological and endoscopic therapy. Mortality due to bleeding in the first 2 weeks was reduced with terlipressin given before endoscopic treatment. Despite the popularity of EVL, there are few studies in the literature combining EVL and vasoactive agents. Sung and coauthors [118] found that EVL plus octreotide led to significantly less rebleeding (9% versus 38%), as well as less balloon tamponade and endoscopic retreatment, than EVL alone. No effect on mortality was seen. Combination of somatostatin or its analog with either EST or EVL appears to offer the best treatment for control of acute hemorrhage and prevention of early rebleeding.

Combined Endoscopic Therapy versus Endoscopic Injection Sclerotherapy or Endoscopic Variceal Ligation Alone

EVL eradicates varices faster than EST and is associated with fewer side effects. EVL, however, has its disadvantages. After a few sessions of EVL, ligation of small residual varices becomes difficult owing to underlying fibrosis. Early recurrence of varices is often seen with EVL owing to persistence of perforating veins and paraesophageal collaterals. EVL has been combined with EST in an effort to include merits of both modalities and minimize complications. There are two approaches: a synchronous approach using both EVL and EST in the same session, or a metachronous approach using EVL to ligate varices initially, followed by EST for the small residual varices. The methodology for synchronous treatment varies: some endoscopists inject into a varix ligated at both its proximal and distal ends (sandwich technique), whereas others inject into the adjacent mucosa or ligate an injected varix. The following section summarizes randomized studies comparing combined EVL and EST to either EVL or EST alone.

Synchronous Approach Seven randomized trials compared combined therapy administered in the same session against monotherapy (five against EVL and two against EST). [119], [120], [121], [122], [123], [124] and [125] In an earlier trial, Laine and coauthors [119] observed a higher complication rate with the use of synchronous EVL and EST when compared with EVL alone (29% versus 10%), and more sessions of combined treatment were required to eradicate varices. There was little difference in the rates of eradication, mortality, and rebleeding. Saeed and associates [120] reported similar findings but observed a higher mortality rate with combined treatment. Umehara and colleagues [121] observed a significantly higher recurrence rate with EVL alone at 3 years when compared with combined EVL and EST (72% versus 21%) without a significant difference in rebleeding. On the contrary, Al Traif and colleagues [122] reported that EVL alone produces fewer recurrences of varices than combined therapy. Among the five trials comparing synchronous EVL and EST to EVL alone, all except that of Al Traif and colleagues reported a higher rate of complications associated with combined treatment (29% to 68% versus 10% to 38%). Synchronous EVL and EST took longer to eradicate varices, with equivocal benefit in reducing long-term recurrence and associated rebleeding. In the two trials comparing synchronous EVL and EST to EST alone, the rate of complications associated with EST alone was substantial (as high as 91% in one trial), suggesting that combined EVL and EST improved safety by limiting the volume of injected sclerosant. [124], [125]

Metachronous Approach Five randomized studies compared sequential EVL and EST to either EVL or EST alone. [126], [127], [128], [129] and [130] Bhargava and Pokharna [126] reported higher eradication (87% versus 24%) and lower rebleeding (19% versus 22%) with combination therapy, although the number of sessions required and the overall complication rate were higher when compared to EVL alone. Lo and colleagues [127] reported similar treatment sessions and eradication rate with EVL and EST versus EVL. The mortality rates (2.7% versus 8.6%), rebleeding rates (8% versus 31%), and variceal recurrence rates (14% versus 43%) were, however, lower with

combined treatment. In a similar study from Taiwan, Cheng and colleagues [128] noted that recurrence of varices was more common in patients receiving EVL alone. Garg and associates [129] found a higher complication rate with EST alone than with EVL and EST. Masumoto and co-workers [130] assigned patients to sequential EVL and EST (n = 21), EVL alone (n = 20), or EST alone (n = 18). Recurrence of varices was highest among those who received EVL alone (40%), and the use of EST alone was again associated with a high rate of complications (50%). In summary, synchronous EVL and EST cannot be recommended when compared with EVL alone. There may, however, be a role in the sequential use of EVL to reduce the size of varices followed by low-dose sclerotherapy for small residual varices in reducing long-term variceal recurrence and possibly rebleeding.

Endoscopic Therapy versus Surgery

Surgical treatments for variceal bleeding include direct esophageal devascularization of the lower esophagus plus the proximal stomach and a variety of surgical shunts. Simple surgical devascularization (i.e., surgical ligation of varices) with esophageal transection is an effective means of controlling acute bleeding, but long-term recurrence of varices and bleeding is common. Shunt operation can be classified as total, partial, or selective. Total shunts (side-to-side or end-to-side) divert all portal blood flow into the inferior vena cava, causing effective control in most cases of variceal bleeding but also severe hepatic encephalopathy in a significant proportion of patients. To reduce the incidence of this fatal complication of nonselected shunt, Sarfeh and associates [131] described an interposition side-to-side H-graft between the portal vein and the cava using an 8-mm graft. By maintaining partial hepatic perfusion, the incidence of encephalopathy was reduced. Its role in the prevention of recurrent esophageal bleeding has not been fully evaluated. Selective shunting refers to a shunt that selectively decompresses variceal flow while preserving portal blood flow. Distal splenorenal shunt (DSRS) anastomoses the splenic vein to the distal left renal vein, allowing the short gastric veins to drain into the systemic circulation. [132] It was designed as a selective shunt to avoid the high rate of encephalopathy seen with total shunts. However, with time, this shunt tends to reconnect with the portal vein through pancreatic branches of the splenic vein. They progressively enlarge and serve as outflow collateral for the portomesenteric system. DSRS then loses its selective quality and becomes a partial or even a total shunt. [133] A total disconnection of splenic vein from pancreas and division of splenocolic ligament (splenopancreatic disconnection) has been advocated as an adjunct at initial surgery. Because of differences in study designs, trials comparing shunt surgery to endoscopic therapy (mostly EST) must be analyzed separately in terms of short-term effects and long-term results.

In emergency control of variceal hemorrhage, EST has been compared with esophageal transections in four trials. [134], [135], [136] and [137] (Table 147-5). Except for the subgroup analysis from the study by Teres and colleagues, [136] all studies showed that surgery produced less rebleeding. However, high-risk patients treated by either EST or surgery had the same mortality rate of close to 50%. Rebleeding after esophageal transection and devascularization occurs in 31% in 4 years. It has been concluded that esophageal transection confers no benefit in long-term management of esophageal varices. Triger and associates [138] compared esophageal transection to EST in the long-term management of esophageal varices after initial stabilization with EST. Mortality and recurrence of varices with esophageal transection were no better than EST, indicating no long-term benefit of surgery over endoscopic therapy.

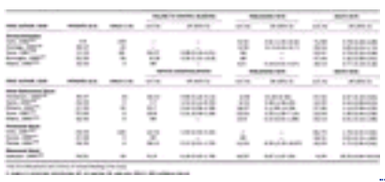

TABLE 147-5 Comparative Trials of Surgery and Endoscopic Sclerotherapy in the Control of Variceal Hemorrhage

For subsequent prevention of recurrent bleeding after the acute episode, long-term EST has been compared with DSRS in five studies. [139], [140], [141], [142] and [143] In a metaanalysis of four of these trials, the pooled relative risk for rebleeding was significantly reduced by DSRS (0.16; 95% CI, 0.10 to 0.27). [144] The overall risk for death following DSRS was not significantly decreased (0.78; 95% CI, 0.47-1.29); the relative risk for chronic encephalopathy was 1.86 (95% CI, 0.90 to 0.86). [144] Nonselective portacaval shunt was evaluated against EST in three trials [145], [146] and [147] and mesocaval shunt in one trial. [148] There is considerable heterogeneity between these studies, making comparisons difficult. In the overall group, shunt surgery was associated with significantly lower rebleeding rate. The incidence of hepatic encephalopathy after shunt surgery was significantly higher than that of sclerotherapy. Mortality rates were comparable.

Endoscopic Therapy versus Transjugular Intrahepatic Portosystemic Shunt

Transjugular intrahepatic portosystemic shunt (TIPSS) is a radiologic intrahepatic portacaval shunt. It has been compared with endoscopic therapy as a modality in the secondary prophylaxis of variceal bleeding in 11 trials involving 811 patients (Table 147-6). Endoscopic treatment in these trials are: sclerotherapy alone in five studies, [149], [150], [151], [152] and [153] EVL alone in three studies, [154], [155] and [156] and EST or EVL plus propranolol in three studies. [157], [158] and [159] In a metaanalysis pooling data from the above studies, variceal rebleeding was significantly more frequent with endoscopic therapy (47%) than with TIPSS (19%) (OR, 3.8; 95% CI, 2.8 to 5.2). [160] Despite high success in controlling hemorrhage, TIPSS has failed to demonstrate improvement in mortality (OR, 0.97; 95% CI, 0.71 to 1.34). One of the major problems with TIPSS is, as in all portosystemic shunts, the development of encephalopathy. Hepatic encephalopathy was much more frequent after TIPSS (34%) than after endoscopic therapy (19%) (OR, 0.43; 95% CI, 0.30 to 0.60). Currently, TIPSS cannot be recommended as a routine form of secondary prophylaxis. On the other hand, TIPSS is highly efficacious as a rescue procedure after failed endoscopic therapy. Therefore, TIPSS should be reserved for the subset of patients who continue to bleed or develop recurrent bleeding after endoscopic therapy. [161], [162] and [163]

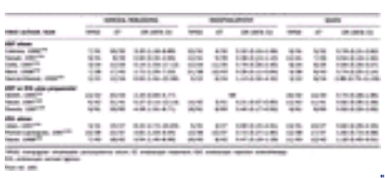

TABLE 147-6 Comparative Trials of TIPSS with Endoscopic Therapy in the Secondary Prophylaxis of Variceal Hemorrhage

Summary on Treatment of Acute Variceal Hemorrhage

Based on existing evidence, a clinical algorithm is presented in Figure 147-4. During initial resuscitation with fluid and blood replacement, cirrhotic patients with upper gastrointestinal bleeding should be given intravenous injection or infusion of a vasoactive agent: terlipressin, somatostatin, or octreotide. Emergency endoscopy should be done if the patient is hemodynamically unstable. After endoscopic confirmation of the source of bleeding, banding ligation, injection sclerotherapy, or both should be offered immediately. Vasoactive agents should be continued for 5 days to prevent early rebleeding, and prophylactic antibiotics against infectious complications should be given. When initial hemostasis is achieved, the patient can be scheduled for an endoscopic obliteration program with weekly or biweekly banding or sclerotherapy until all varices are obliterated. Patients who fail to respond to endoscopic therapy or suffer from recurrent bleeding during the acute phase should be offered balloon tamponade before a second session of therapeutic endoscopy. Vasoactive therapy should be continued. In patients who continue to bleed from their varices despite nonoperative means, the choice between TIPSS or surgical shunts is less well defined. Rosemurgy and associates [164] randomly assigned such patients to receive either TIPSS or surgical shunts using a small-diameter prosthetic H-graft (35 in each group). The use of TIPSS was associated with more frequent shunt failure and total occlusions, resulting in more rebleeding and death. In low-risk patients with compensated liver function unlikely to require liver replacement in due course, surgical shunts in the form of selective shunt (e.g., DSRS) should probably be offered. TIPSS is reserved for patients with limited hepatic reserve as a bridging procedure while awaiting liver transplantation.

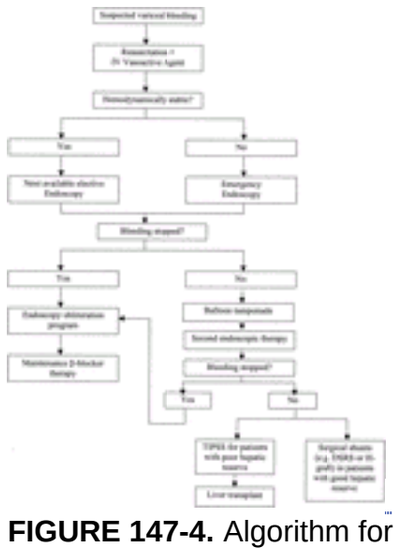

FIGURE 147-4. Algorithm for management of acute bleeding from esophageal varices.

PROPHYLACTIC TREATMENT OF ESOPHAGEAL VARICES

Beta-blockers reduce the risk for the first variceal hemorrhage, especially in patients with large esophageal varices. The protective effects of beta-blockers may be enhanced when co-prescribed with nitrates. However, only one third of patients respond to beta-blockers, and they are not tolerated by all patients. Controversy exists regarding the role of endoscopic treatment as primary prophylaxis.

Endoscopic Injection Sclerotherapy as Primary Prophylaxis to Prevent Variceal Hemorrhage

Prophylactic EST was used in the 1980s to prevent variceal bleeding. Discrepant results were found for the bleeding and mortality rates. Three of the four initial controlled trials reported that prophylactic EST significantly reduces the risk for first variceal bleeding and improved survival. [165], [166] and [167] However, in subsequent trials, prophylactic EST did not show a survival benefit. Sclerotherapy may even provoke bleeding that is difficult to control. Indeed, in two American studies, the mortality rate was higher in the EST group than in the control group. [168], [169] However, these studies were heavily criticized for patient selection. A metaanalysis revealed marked heterogeneity among these trials and showed that EST significantly reduced the risk for a first episode of bleeding, whereas the mortality rate was higher in those who received EST in certain studies. [170]

Endoscopic Variceal Ligation as Primary Prophylaxis to Prevent Variceal Hemorrhage

Although EST may produce more harm than good in patients with cirrhosis, EVL is associated with fewer procedure-related complications. Three trials [171], [172] and [173] compared EVL to no treatment in the prevention of the first bleeding, and two compared EVL to propranolol therapy [174], [175] (Table 147-7). These studies showed a significant decrease in the risk for bleeding, and the mortality rate was also significantly reduced in two studies. Sarin and colleagues [175] showed reduced bleeding with EVL as compared with propranolol (15% versus 43%). [175] The overall mortality rate related to variceal bleeding, however, was identical. It has been pointed out that the rebleeding rate of the propranolol-treated group was unusually high. [176] Beta-blockers should remain the first choice for prophylaxis, with EVL reserved for patients with contraindications or intolerance to these drugs. In a recently published metaanalysis based on four trials and 283 patients, EVL reduced the risk for variceal bleeding by 64% (relative risk [RR], 0.36; 95% CI, 0.26 to 0.50) and mortality by 45% (RR, 0.55; 95% CI, 0.43 to 0.71). [177] When compared with beta-blocker, EVL reduced the risk for variceal bleeding by 52% (RR, 0.48; 95% CI, 0.24 to 0.96) but failed to reduce mortality (RR, 0.95; 95% CI, 0.56 to 1.62).

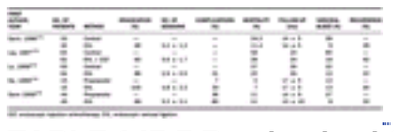

TABLE 147-7 Randomized Comparative Trials of Band Ligation or a Combination of Band Ligation and Injection Sclerotherapy for the Primary Prophylaxis of Variceal Bleeding

Summary on Primary Prophylaxis of Variceal Bleeding

All patients with a confirmed diagnosis of portal hypertension with or without cirrhosis should receive screening for varices by upper endoscopy. Based on natural history studies, [11], [12] patients with no varices need to have follow-up endoscopy every 3 to 4 years. Patients with esophageal varices should be assessed by a predictive scoring system, such as the NIEC score. Low-risk patients should be reexamined yearly for progression of esophageal varices. Moderate- to high-risk patients (e.g., NIEC score higher than 30) should be offered prophylactic therapy. Beta-blockers are recommended as the first-line prophylaxis. Patients with contraindications or intolerance to beta-blockers can be offered prophylactic banding ligation (Fig. 147-5).

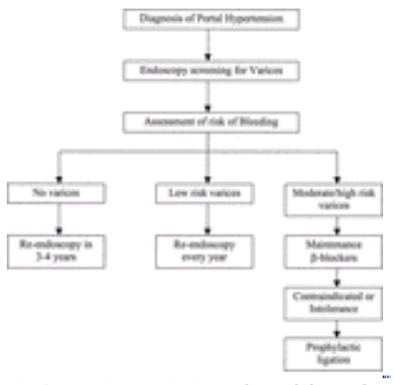

FIGURE 147-5. Algorithm for primary prophylaxis of variceal bleeding.

GASTRIC VARICES

Compared with esophageal varices, the natural history and optimal treatment of gastric varices are much less well defined. Gastric varices can occur in patients with portal hypertension or occlusion of splenic vein (primary), or after endoscopic treatment of esophageal varices, which produces back pressure on vessels in the gastric zone (secondary). Sarin and colleagues [178] prospectively studied 586 patients with portal hypertension. At first endoscopy, gastric varices were found in 20% of patients, and they developed in 9% of patients within 2 years after eradication of esophageal varices. Gastric varices tend to bleed less frequently than esophageal varices, but bleeding tends to be more severe. Mortality in those who bleed from gastric varices is substantial.

Gastric varices can be categorized into two groups according to their locations in the stomach and relationship with esophageal varices: gastroesophageal varices (GOV), found associated with esophageal varices; and isolated gastric varices (IGV), found independent of esophageal varices. Each of the subtypes can be further classified into type 1 and 2 based on their locations in the stomach (Fig. 147-6). Type 1 GOV are continuous, with esophageal varices extending 2 to 5 cm beyond the gastroesophageal junction along the lesser curvature of the stomach, whereas type 2 GOV extend into the fundus of the stomach. Type 1 IGV are isolated fundal gastric varices, and type 2 IGV are isolated "ectopic" varices occurring in the distal portion of stomach, including the duodenum.

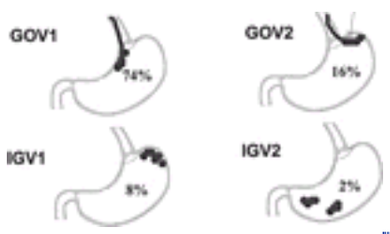

FIGURE 147-6. Classification of gastric varices and their relative frequencies. (Adapted from ref. [178].)

Sarin's classification of gastric varices has prognostic implications and may be helpful in management planning. [178] Type 1 GOV are the commonest type, accounting for 75% of cases. Their rate of bleeding was only 11.8%. Their treatment is identical to that of esophageal varices, and they are usually responsive to endoscopic therapy. Type 2 GOV tend to bleed more frequently (55%). Type 1 IGV have the highest rate of bleeding at 78% and carry substantial mortality. Sclerotherapy has been described in the treatment of bleeding gastric varices as an overall group, with initial control in about 80% of patients. [179] The reported rate of initial control of bleeding in type 1 IGV, however, was much lower. Active bleeding was arrested in only 26% of patients with IGV in one reported series. [180] In addition, rebleeding after endoscopic sclerotherapy for bleeding gastric varices is common, especially in type 1 IGV. EVL is less effective in bleeding gastric varices. Deployment of bands can be difficult with the endoscope in a retroflexed position. Band retention rate is low, leading to frequent early rebleeding.

Histoacryl injection may produce better results. [181] In a nonrandomized series, Oho and colleagues [54] compared injections using cyanoacrylate to ethanolamine in 53 patients. [54] Their study showed that the rate of initial control of bleeding is significantly higher in patients treated with cyanoacrylate (93% versus 67%). The in-hospital mortality rate was significantly higher in the ethanolamine-treated group (67% versus 38%). [54] In a recent randomized study comparing EVL with cyanoacrylate injection in 60 patients, cyanoacrylate injection had better initial hemostasis, less recurrent bleeding, fewer transfusions, and lower mortality. [182]

In general, the low rate of hemostasis and high rate of recurrent bleeding in IGV with endoscopic treatment would imply that alternate therapies such as surgery or TIPSS are sometimes indicated. The management of gastric varices requires further study.

ENDOSCOPIC ULTRASONOGRAPHY IN VARICEAL HEMORRHAGE

Endoscopic ultrasonography (EUS) has been applied in patients with variceal hemorrhage since 1990. [183] Using EUS, a large part of the portal venous system can be visualized, including the portal vein, splenic vein, superior mesenteric vein, and azygos vein. However, when used in detecting esophageal varices, EUS was found to be inferior to conventional upper endoscopy and gave little additional information. [184], [185] This was mainly due to the large-bore echoendoscope of the first generation, and the use of a water-filled balloon, which compresses variceal columns in the esophageal lumen. With improvement in technology, and the development of catheter probes using higher ultrasound frequency, [186], [187] EUS can detect vascular channels both inside and outside the esophageal lumen. EUS can map vessels in the connective tissue layer just outside the esophageal wall (periesophageal varices), collateral veins in the mediastinum running longitudinally alone with the esophagus (paraesophageal varices), and the perforators that connect the submucosal and peripheral vascular channels [188], [189] (Fig. 147-7). Paraesophageal varices and perforating veins are reported in about 80% of patients with esophageal varices, and their presence has been associated with poor response to endoscopic therapy and early recurrence of varices. [3], [4] and [5], [190], [191], [192] and [193] It has been suggested that patients undergoing EVL are more likely to have multiple paraesophageal varices of considerable size compared with those who received EST. [192] EUS-guided sclerotherapy using color Doppler has been attempted to improve results of EST. [194] It has also been suggested that after endoscopic therapy has achieved obliteration of submucosal varices, EUS examination of the lower esophagus is warranted to identify those who have perforating veins and periesophageal or paraesophageal varices. Small-volume injections of sclerosants may be given to seal these perforators to prevent early recurrence of varices and rebleeding. The development of color Doppler EUS has also permitted study of blood flow hemodynamics in the portal venous system. Cirrhotic patients have been found to have enlarged azygos veins and thoracic ducts. [195] Azygos vein blood flow has been found to be reduced after intravenous infusion of vasoactive agents [195] and after endoscopic therapy. [196] Recently, the measurement of azygos vein blood flow using EUS has been validated by thermodilution method. [197] The use of azygos blood flow measurement in the clinical management of variceal hemorrhage remains to be defined.

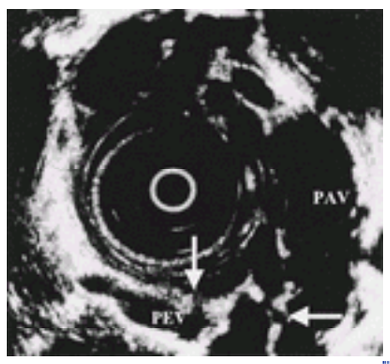

FIGURE 147-7. Periesophageal varices (PEV) and paraesophageal varices (PAV) together with perforators (*arrow*) as seen with endoscopic ultrasonography.

Unlike esophageal varices, EUS has been found to be very useful in detecting gastric varices because it can easily distinguish vascular structure from other submucosal lesions in the gastric fundus. [183], [184] EUS also is a useful tool in monitoring the effects of injection sclerotherapy because it confirms obliteration of vascular channels in the submucosa of the stomach. Cyanoacrylate injection monitored by EUS is reported to reduce recurrence of gastric varices. [198]

CHAPTER 148

David J. Bjorkman

ENDOSCOPIC DIAGNOSIS AND TREATMENT OF NONVARICEAL UPPER GASTROINTESTINAL HEMORRHAGE

Upper gastrointestinal (GI) bleeding is a common clinical disorder. It is responsible for more than 250,000 to 300,000 hospital admissions and $2.5 billion in costs in the United States each year. [1] The most common cause of nonvariceal upper GI bleeding is peptic ulcer disease, but other disorders may have an identical presentation. [1] GI endoscopy remains both the diagnostic and therapeutic procedure of choice for upper GI bleeding. Despite progressive advances in the diagnosis, the mortality rate from acute upper GI bleeding remains 5% to 15%. [2], [3] Recent data demonstrate an age-related mortality rate that ranges from 4% in young patients to 9% in elderly patients. [4] It is possible that part of the failure to see a significant reduction in overall mortality is that patients presenting with upper GI bleeding today are often older and have significant co-morbid illnesses that affects the outcome of the bleeding episode. [2]

INITIAL EVALUATION AND PREPARATION FOR ENDOSCOPY

The initial evaluation of patients with acute GI bleeding should focus on the hemodynamic status. Hemoglobin concentration and hematocrit are unreliable markers of acute blood loss. Intravenous access and vigorous volume replacement should be immediately initiated in all patients with hemodynamically significant GI bleeding. [5] This requires large-bore vascular access, preferably in at least two sites, or through a central line. Immediate infusion of isotonic electrolyte solutions should be given until vital signs become stable. The use of blood products should be determined by the patient's clinical condition and the rapidity of blood loss. [6] Other diagnostic and treatment decisions should not take precedence over volume resuscitation.

ASSESSING THE LOCATION OF BLEEDING

Endoscopy is the optimal method for establishing the location of bleeding. A history of hematemesis with frank blood or coffee ground–like material is sufficient to confirm the level of bleeding to be above the ligament of Treitz. A prior history of bleeding ulcers, nonsteroidal antiinflammatory drug use, or variceal bleeding is suggestive but is not sufficient to establish the presence of an upper GI bleeding source. A history of melena is also suggestive of upper GI bleeding, but melena can occur with slow bleeding from the small bowel or, rarely, the proximal colon. Hematochezia is more suggestive of a bleeding site in the lower GI tract but may also result from vigorous upper GI bleeding in 10% of cases.

Nasogastric aspiration is 80% sensitive for an actively bleeding upper GI source when it produces fresh or altered blood. False-negative aspirates occur when the tube is improperly positioned or when the reflux of blood from a duodenal source is prevented by pylorospasm or obstruction. [7] When vigorous bleeding is identified, gastric lavage using a large-bore orogastric tube is often needed to clear the stomach of blood and clots before endoscopic evaluation and treatment. [8]

ROLE OF ENDOSCOPY IN DIAGNOSIS

After the patient has become hemodynamically stable, endoscopy is the diagnostic procedure of choice in the setting of upper GI bleeding. The contraindications to endoscopy are listed in Table 148-1. Absolute contraindications include refusal of the procedure by the patient, a situation in which the risks of the procedure outweigh the potential benefits of the procedure (such as shock), and a situation in which the procedure will not alter the outcome or care of the patient. [9] The relative contraindications can often be overcome by appropriate patient preparation. For example, airway protection may be achieved by endotracheal intubation before endoscopy, and coagulation disorders may be mitigated by the infusion of blood products.

Absolute contraindications
Refusal of informed consent
The risks of the procedure outweigh the potential benefits
Endoscopic information or therapy will not alter the outcome or care
Relative contraindications
Suspected gastroduodenal perforation
Hemodynamic instability
Combative, uncooperative patient
Severe coagulopathy
Unprotected airway

TABLE 148-1 Contraindications to Upper Gastrointestinal Endoscopy

Endoscopy has a sensitivity of 92% when the entire stomach and proximal duodenum can be carefully visualized and has a specificity that approaches 100%. [10] By comparison, barium radiography has a sensitivity of only 54%. Visualization of the bleeding lesion may be aided by local application of 3% hydrogen peroxide through the endoscope. [11], [12] The ability to perform biopsies to diagnose malignancy and the presence of *Helicobacter pylori* infection is not available with barium studies. Most importantly, barium radiography interferes with subsequent endoscopy, angiography, or surgery. As a result, barium radiography should be avoided in the setting of acute upper GI bleeding.

Not only will a careful endoscopic examination identify the source of upper GI bleeding, but also it can provide predictive information about the prognosis (probability of rebleeding, morbidity, and mortality) for the patient. Clinical prognostic factors include older age, shock, volume of bleeding (as determined by hemodynamic parameters and the volume of fluids needed to restore blood pressure and pulse to normal), need for transfusion, onset of bleeding in the hospital, and co-morbid conditions. [13], [14] Since the advent of endoscopy, however, it has been demonstrated that the endoscopic appearance of bleeding ulcers more accurately predicts the risk for rebleeding-associated morbidity and mortality. Shortly after the availability of endoscopy, Forrest and colleagues [15] recognized specific endoscopic findings that were associated with an increased risk for rebleeding. The endoscopic findings that correlate with the risk for rebleeding (in order of risk for rebleeding and increased mortality) are ulcers with a clean base; the presence of flat, pigmented, spots in the base; an adherent clot resistant to vigorous flushing; a nonbleeding visible vessel; and active bleeding (either oozing or vigorous bleeding) (Fig. 148-1, Color Fig. 148-1). This classification has been repeatedly shown to predict accurately the rate of rebleeding, morbidity, and mortality in multiple studies. [1], [16] A review of the data from various studies by Laine and Peterson [1] is presented in

Table 148-2, demonstrating that patients with high-risk stigmata for hemorrhage (active bleeding or a nonbleeding visible vessel) have a high rebleeding rate that is associated with correspondingly high morbidity and mortality rates. Patients without high-risk stigmata (those with a clean ulcer base or flat, pigmented, spots) have an extremely low rate of rebleeding and a negligible mortality rate. [1] In a large study in the United Kingdom, Rockall and colleagues [17] combined the previously noted clinical predictors with the endoscopic appearance of lesions into a scoring system to predict the outcome of acute upper GI bleeding (Table 148-3). This validated scoring system demonstrates the utility of endoscopy in predicting the outcome of acute upper GI bleeding. Patients with a score of 2 or less have a risk for rebleeding of less than 5% and virtually no mortality. [17] The addition of endoscopic findings to the other clinical criteria dramatically increased the accuracy of prognosis prediction based on clinical factors alone. In another study, Jaramillo and colleagues [18] evaluated 1567 consecutive patients with acute upper GI bleeding using multivariate analysis. None of the patients had endoscopic therapy. The rebleeding rate was 20%. The factor that best predicted the risk for rebleeding was the presence of endoscopic high-risk stigmata (odds ratio [OR], 3.1; $P < 0.001$).

ENDOSCOPIC FINDING	RISK FOR REBLEEDING (%)	MORTALITY (%)
Active bleeding	55	11
Visible vessel	43	11
Adherent clot	22	7
Flat spot	10	3
Clean base	5	2

Adapted from ref. 1.

TABLE 148-2 Association of Endoscopic Findings with Risk for Rebleeding and Mortality in Patients with Bleeding Ulcers

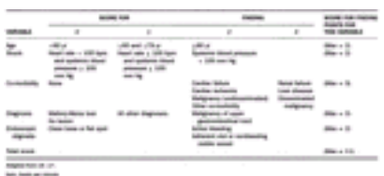

TABLE 148-3 Rockall Classification of Risk in Acute Upper Gastrointestinal Bleeding

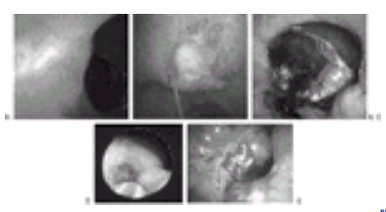

FIGURE 148-1. (See Color Fig. 148-1.) Endoscopic photos of stigmata of recent hemorrhage. **A:** Clean base. Duodenal ulcer with a clean base. No evidence of protruding or pigmented areas is present. The rebleeding rate in this lesion is near zero. **B:** Flat spot. Pyloric channel ulcer with a flat, black spot in the center. The risk for rebleeding in this lesion is less than 10%. **C:** Adherent clot. Duodenal ulcer with a large adherent clot in the base that could not be removed with vigorous irrigation. The nature of the lesion beneath the clot is unknown. The risk for rebleeding in this lesion is intermediate (up to 25%). **D:** Nonbleeding visible vessel. A prominent protruding visible vessel with a bipolar probe in the foreground. This lesion has a high risk for recurrent bleeding (40% to 50%) without endoscopic therapy. **E:** Active bleeding. A duodenal ulcer with blood vigorously flowing. This is the lesion with the highest risk for continued or recurrent bleeding (approaching 60%). Endoscopic hemostasis can control active bleeding in most patients and can reduce the risk for rebleeding.

Other endoscopic findings have been suggested to increase the risk for recurrent bleeding. These include the size and location of the ulcer. [19], [20] Both of these findings relate to the proximity of the base of the ulcer to a major artery or arteriole. Lesions in the posterior duodenal bulb may penetrate into the gastroduodenal artery. Likewise, lesions high on the lesser curvature of the stomach may involve the left gastric artery. Doppler ultrasound probes have been used in an attempt to identify large vessels in or near ulcers to predict the risk for rebleeding. These attempts have met with moderate success in targeting endoscopic therapy but have limited sensitivity and specificity. [21], [22] The technology has not been widely accepted.

Diagnostic Role of Urgent Endoscopy (Endoscopic Triage)

Although it may seem intuitively obvious that endoscopy would improve patient outcomes, randomized trials have indicated that *diagnostic* endoscopy alone does not improve mortality, rebleeding rates, the need for surgery, or hospital stay. [23], [24] and [25] Most patients (75% to 80%) with bleeding ulcers stop bleeding spontaneously, limiting the impact of early endoscopy for diagnosis. [16], [18], [25] Based on these data, patients are often initially admitted to the hospital for volume resuscitation and observation, then undergo diagnostic endoscopy electively. Because urgent endoscopy improves morbidity and mortality only in the subset of patients with persistent or recurrent bleeding, both the National Institutes of Health and the American Society for Gastrointestinal Endoscopy have recommended that endoscopy be urgently performed in the subset of patients for whom endoscopic therapy is anticipated. [26], [27]

Recent data have raised the possibility of endoscopically identifying patients with acute upper GI bleeding who are at low risk for rebleeding and require limited medical care. Laine and colleagues [28] demonstrated that patients with clean ulcer bases or Mallory-Weiss esophageal tears had only a 2% risk for rebleeding and could be safely fed and immediately discharged from the hospital. Rockall and colleagues [29] applied the previously mentioned scoring system to 2531 consecutive patients seen with acute upper GI bleeding in the United Kingdom. They identified 29.4% of the patients who had a score of 2 or less and a negligible risk for rebleeding or morbidity. Based on these data, the authors suggested that a large number of patients without clinical risks or endoscopic stigmata for rebleeding could be safely managed without hospital admission. They stated, "… hospital admission has usually been regarded as obligatory until the risk of further haemorrhage has receded. This policy means that some patients at low risk stay in hospital for longer than is necessary especially when diagnostic endoscopy is delayed." [17] Kodali and colleagues [30] demonstrated that 21% of patients with bleeding from peptic ulcer disease had a clean ulcer base at endoscopy. These patients had a 3% risk for rebleeding. These authors concluded that this group of patients could be safely managed as outpatients.

Two trials have retrospectively reviewed hospitalizations for upper GI bleeding, and then developed criteria for same-day discharge (endoscopic triage) that were prospectively applied with success. [31], [32] In a single-center study, Lee and associates [33] demonstrated a decrease in costs of care associated with decreased resource use in patients undergoing endoscopic triage for nonvariceal upper GI bleeding, with no increase in morbidity. Another similar-sized prospective multicenter study, however, demonstrated no difference in the length of stay or clinical outcomes of patients undergoing urgent (preadmission) endoscopy or elective endoscopy after admission. [34] The major difference between these studies was the number of patients discharged from the emergency department. In the first study, 46% of the patients randomized to receive urgent endoscopy were discharged from the emergency room by the endoscopist, whereas in the second study, the decision regarding admission was left to the attending physician (not the endoscopist), and only 4 of 47 eligible patients avoided hospitalization. These studies demonstrate the difference between efficacy and clinical effectiveness. In a situation in which the endoscopic findings drive subsequent clinical care, endoscopic triage can significantly decrease hospitalization and costs of care for patients at low risk for rebleeding. If the endoscopic findings do not affect subsequent care, then the information will not affect resource use.

Additional data regarding the effectiveness of endoscopic triage are provided by two studies by Hay and colleagues. [35], [36] In the first study, the authors developed a treatment guideline for upper GI bleeding retrospectively, demonstrating the potential for substantial cost savings using endoscopy and three other factors as predictors of low risk and possible discharge. [35] In the second study, they used an alternating time approach to evaluate implementation of the guideline. [36] During the intervention periods, they aggressively modified physician behavior in the emergency department, promoting the previously developed clinical guideline that included

preadmission endoscopy and discharge of patients at low risk for rebleeding. During the control periods, Hay and colleagues allowed the physicians to make the admission decisions. Compliance with the guideline was 70% during the period of aggressive promotion and only 30% during the other periods. Aggressive implementation of the guideline resulted in substantially decreased hospitalization and costs without compromising patient care or satisfaction. The cost savings were lost during the control periods.

It appears that urgent endoscopy can substantially reduce the costs of care for upper GI bleeding by identifying a group of patients who can be safely treated as outpatients only if the endoscopic findings, in conjunction with other clinical information, can alter the subsequent care of the patient.

ENDOSCOPIC THERAPY FOR BLEEDING PEPTIC ULCERS

As previously noted, about 20% of patients with nonvariceal upper GI bleeding have persistent or recurrent bleeding. There is compelling evidence that endoscopic therapy reduces both the morbidity and mortality in these patients. [26], [27] All available endoscopic techniques appear to have similar results, but they vary in their approach to sealing the bleeding vessel and maintaining hemostasis. The major methods may be divided into thermal coagulation, injection therapy, and mechanical compression.

Thermal Coagulation

Thermal therapy of bleeding peptic ulcer disease is based on the understanding that the ulcer erodes into a submucosal vessel. Therapeutic interventions using heat have the goal of coagulating or sealing this vessel to stop active bleeding and prevent rebleeding. [8]

Tissue has a characteristic response to thermal energy. When heated to 50° to 60°C, intracellular proteins become denatured, destroying the tissue and forming a white coagulum. This also produces a surrounding area with a zone of sublethal damage manifest by erythema and edema. [37] When heated to 100°C, the water in cells is vaporized, resulting in cavitations and tissue ablation. The goal of endoscopic therapy is to coagulate the bleeding lesion and create a ring of edema that reduces blood flow and promotes hemostasis without causing tissue vaporization or cavitation that may exacerbate the bleeding. There are multiple methods of delivering different types of energy capable of raising tissue temperature, including light energy (lasers), electrical energy (monopolar or bipolar [multipolar] electrocoagulation), and direct application of a heated surface.

Laser Therapy Laser therapy was the first endoscopic method of hemostasis extensively evaluated. Although different lasers produce wavelengths of light with specific effects on tissue, the most commonly used laser is the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser. The light from this laser (1060-nm wavelength) can be delivered through a flexible quartz fiber that is introduced through the working channel of a standard endoscope (Fig. 148-2). As the light strikes the tissue, it is converted to thermal energy, creating the heat necessary for coagulation. Tissue contact is avoided while coagulating a ring of tissue surrounding the bleeding site. Other lasers (argon, KTP) commonly used in endoscopic therapy produce light of a shorter wavelength with more limited tissue penetration. As a result, they are less effective in the setting of acute upper GI bleeding. The Nd:YAG laser has been shown to stop bleeding lesions in the stomach and duodenum in more than 90% of cases and to reduce rebleeding to less than 20%. [38]

FIGURE 148-2. Laser fiber. A quartz laser fiber with covering plastic sheath. Fibers may also have a sheath that provides coaxial gas flow. The quartz fiber conducts the laser light but is flexible enough to be passed through an endoscope channel. Similar fibers are used for argon, Nd:YAG, and KTP lasers.

Disadvantages of laser therapy include variable control of the depth and type of tissue injury, with the potential for overheating, vaporization, and charring of tissue that exacerbates the bleeding. There is a small risk for perforation (less than 2%) when used in the stomach. When coaxial gas is used around the quartz fiber, abdominal distention can result. The equipment necessary for laser therapy is expensive and requires special expertise for its use and maintenance. Most lasers are not portable and require special safety precautions and training. Because of these logistic issues and the availability of equally effective alternatives, lasers are now rarely used in the setting of acute upper GI bleeding.

Electrocoagulation Electrocoagulation uses an electrical current passed through tissue to generate thermal energy to coagulate the target tissue. The earliest use of electricity used an electrified endoscopic biopsy forceps touched to the tissue. In this case, the electrical current flowed from the tip of the forceps through the patient to an electrical pad placed on the hip or thigh. In this method, the degree of tissue injury depends on electrical current density at the site of contact with the forceps and local tissue factors that are poorly controlled. The result is an unpredictable depth of injury. For this reason, monopolar electrocoagulation is usually avoided in the treatment of acute upper GI bleeding. [26] To avoid the problems associated with monopolar electrical current, endoscopic probes have been developed that have both the positive and negative electrical poles at the end of a catheter (Fig. 148-3). An electrical circuit is completed between a positive and negative electrode (bipolar electrocoagulation). To allow tangential application, probes have been designed with multiple pairs of positive and negative electrodes on the tip (often referred to as *multipolar electrocoagulation*) or alternating positive and negative electrodes circling the end of the probe. The result is limited delivery of electrical current within the diameter of the probe, using the electrical resistance of the tissue to heat only that area where the probe is placed. The depth and degree of tissue injury are well controlled. The probe also allows for direct pressure to be applied to the bleeding lesion to seal the vessel (coaptive coagulation). [39]

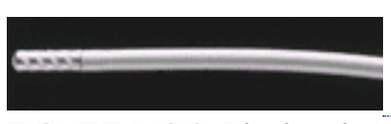

FIGURE 148-3. Bipolar electrocoagulation catheter. Electrodes circle the end of the catheter, and a central channel provides vigorous water irrigation. Some electrodes have a retractable central injection needle to allow combined electrocoagulation and injection therapy.

Multipolar electrocoagulation was evaluated by Laine [40] in a randomized prospective trial of patients with acute upper GI bleeding. Hemostasis was achieved in 90% of the patients treated with the multipolar probe, compared with 13% treated with medical therapy. [40] There was also a significant reduction in transfusion requirement, hospital stay, morbidity, and costs for the patients receiving endoscopic therapy. In a similar trial limited to patients with nonbleeding visible vessels, the rebleeding rate was reduced by more than 50% in the treatment group (18% compared with 41%). [41] There was a similar improvement in transfusion requirements, hospital stay, need for surgery, and cost in the treatment group. Multiple other trials have demonstrated similar results when using bipolar or multipolar electrocoagulation. [42], [43]

Heater Probe Direct application of thermal energy can be applied to bleeding lesions using a heater probe. This device uses a catheter with a heating element at the tip that can be passed through the endoscope channel (Fig. 148-4). The heating element delivers a prespecified amount of energy by adjusting the time of the energy burst. The tissue effect is limited to the area in contact with the probe. As with the bipolar electrode, pressure can be applied directly to the bleeding site, allowing coaptive coagulation of bleeding essels.

FIGURE 148-4. Heater probe. A flexible catheter tipped with a heating element that is placed directly on the tissue for coagulation. No electrical current passes through the patient. Vigorous water irrigation is possible through the central channel of the catheter.

The efficacy of this method is very similar to that of the bipolar probe. Initial randomized trials demonstrated that hemostasis could be achieved in actively bleeding lesions in 78% of patients, compared with none in a sham treatment group. [44] In a study limited to patients with nonbleeding visible vessels, there was, again, a greater than 50% reduction in the rebleeding rate (10% compared with 26%) in the treatment group. [45] As with bipolar electrocoagulation, multiple other studies have confirmed the ability of heater probe therapy to control active bleeding and reduce the risk for rebleeding from high-risk lesions. [8]

Argon Plasma Coagulation A more recently developed method of endoscopic hemostasis is the argon plasma coagulation (APC) device. This device uses a flow of ionized argon gas to conduct electricity from the power generator to the tissue (Fig. 148-5). It is a type of monopolar electrocautery and should not be confused with

the argon laser. Few controlled studies have evaluated the efficacy of this method of hemostasis. The distribution of tissue injury depends on the flow of the gas and density of the electrical current at the tissue surface. One small study of 41 patients found no significant difference in results comparing APC with heater probe therapy in acute upper GI bleeding. [46] This methodology, however, has not undergone the rigorous evaluation of other thermal hemostasis methods. [47], [48]

FIGURE 148-5. Argon plasma coagulation catheter. This hollow catheter produces a flow of electrically charged argon gas when activated. The catheter should not come in contact with the tissue. It allows rapid electrocoagulation of larger areas of tissue, or areas that are difficult to reach with a contact probe.

Technique of Thermal Therapy The technical approach to thermal treatment of bleeding lesions is different in contact methods (bipolar electrocoagulation, heater probe) and noncontact methods (laser, APC). Sapphire tips can also be attached to laser fibers, creating a light-heated tip for contact therapy. Bleeding in peptic ulcer disease occurs when the ulcer erodes into a vessel. Either the vessel wall or the clot in the vessel can be identified endoscopically as a "visible vessel" (Fig. 148-6, Color Fig. 148-6). In the noncontact method, the vessel feeding the bleeding site is cauterized below the surface by treating circumferentially around the clot or point of bleeding (Fig. 148-7). This has the advantage of not disrupting any clot that may have formed in the lesion, but it does not seal the vessel with coaptive coagulation. Contact probes, on the other hand, are used to apply direct pressure to the bleeding site, using the water-jet capability of the probes to clear away surrounding blood and debris. Multiple bursts of energy are applied to the lesion until hemostasis or adequate coagulation has been achieved (Fig. 148-8). Larger probes are more effective, as are longer pulses of lower energy. [49] The design of the contact probes also allows for tangential treatment of lesions that are in difficult locations. The disadvantage of contact probes is tissue adherence to the probe. When the probe is moved, the clot and coagulated tissue can be dislodged, leading to more vigorous bleeding that rarely requires surgical intervention. Vigorous bleeding was precipitated in 18% of patients treated with contact probe therapy in one randomized trial. [42]

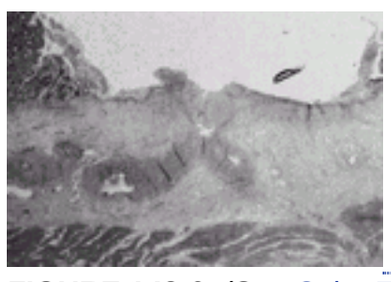

FIGURE 148-6. (See Color Fig. 148-6.) Visible vessel. This classic image demonstrates the histology of a bleeding vessel in the base of an ulcer. The submucosal vessel is seen extending to the ulcer surface, with a thrombus present in the "hole" in the arterial wall. (Courtesy of C. Paul Swain, M.D.)

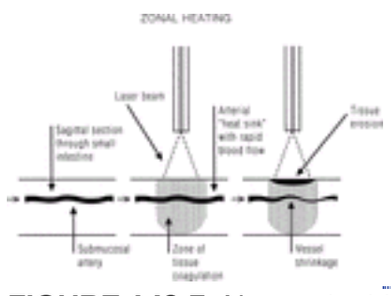

FIGURE 148-7. Noncontact therapy diagram. Coagulation of tissue with noncontact methods, such as laser therapy or argon plasma coagulation. The area surrounding the bleeding site is treated with the aim of coagulating the submucosal vessel. Even when the vessel is not coagulated, the resulting circumferential edema results in enough tamponade to control bleeding.

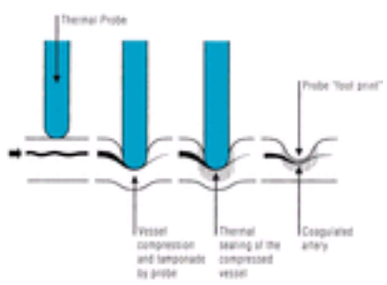

FIGURE 148-8. Contact therapy diagram. Treatment with contact probes focuses on coaptive coagulation of the bleeding site. Considerable pressure is applied with the probe to tamponade the bleeding vessel. Multiple bursts of energy are then delivered to coagulate the lesion and seal the bleeding vessel. Care must be taken to avoid dislodging coagulated tissue, which can adhere to the catheter tip. (From Johnston JH, Jensen DM, Auth D. Experimental comparison of endoscopic yttrium-aluminum-garnet laser, electrosurgery, and heater probe for canine gut arterial coagulation. Importance of compression and avoidance of erosion. Gastroenterology. 1987;92:1101.)

The approach to patients with adherent clots in the base of ulcers remains controversial. Adherent clots are those that cannot be dislodged by prolonged application of a vigorous water jet. Unless the clot is removed, the nature of the underlying lesion cannot be determined. Laine and colleagues [50] evaluated 46 patients with adherent clots. All received a directed water-jet wash for 5 minutes to try to dislodge the clot. After this time, 57% of the patients still had clots obscuring the bleeding site, 15% had active bleeding, and 13% had nonbleeding visible vessels. The remainder had clean ulcer bases or flat spots. Endoscopic therapy was applied to the high-risk lesions uncovered by the removal of the clot, but not in patients with clots that remained. This approach resulted in an excellent outcome. Only one patient (who had an actively spurting vessel) rebled, and there were no deaths. An alternative approach of cold snare guillotine removal of the clot and treatment of underlying lesions has been advocated by Jensen and colleagues. [51] In a pilot study, 11 patients with adherent clots were randomized to either medical therapy or snare removal of the clot with endoscopic therapy as appropriate. Rebleeding occurred in 40% of the patients treated medically and in none of the patients in whom the clot was removed. When clot removal is contemplated, it should be done only if the endoscopist is prepared to deal with any underlying lesion, including vigorous bleeding. Freeman [16] has advocated injection therapy of the base of the clot before attempted mechanical removal to reduce the risk for vigorous bleeding. It appears that the clinical outcome of patients with adherent clots found at endoscopy depends on the lesion under the clot and the stability of the hemostatic plug formed by the clot. Preliminary reports have suggested that the rebleeding rate in patients with nonbleeding adherent clots can be reduced from between 25% and 30% to between 0% and 5% with clot removal and endoscopic therapy of the underlying lesion. [52], [53] The removal of such clots should be determined by the patient's condition and the availability of appropriate therapy in the event that clot removal precipitates vigorous bleeding.

Injection Therapy

The least expensive method of endoscopic therapy for upper GI bleeding is the use of a simple needle catheter to inject the bleeding site with a compound selected to achieve and maintain hemostasis. There are different classes of materials used for injection therapy, including hemostatic agents, sclerosants, and thrombogenic agents.

The most commonly used material is diluted epinephrine, usually in the readily available 1:10,000 dilution. This is injected submucosally around the bleeding site in

aliquots of 1 to 2 mL to a total volume of 5 to 10 mL. On occasion, larger volumes may be required to achieve the desired tamponade effect. Hemostasis is postulated to occur as a result of a combined effect of vasoconstriction from the epinephrine and tamponade of the bleeding vessel by the volume effect of the injection. [54], [55] The efficacy of this method was demonstrated by Chung and colleagues [56]: 68 patients with actively bleeding ulcers were randomized to receive either injection therapy with 1:10,000 epinephrine or medical therapy. Initial hemostasis was achieved in all patients in the injection therapy group. There were fewer patients who required surgery (5 versus 14), fewer blood transfusions, and a shorter hospital stay in the epinephrine-treated group. These findings were validated in a larger prospective trial of 98 patients with acute upper GI bleeding. Subjects were randomized to receive either 1:10,000 epinephrine injected in 1- to 2-mL aliquots around the lesion and 1 to 2 mL of ethanolamine into the bleeding site, or medical therapy alone. The rebleeding rate was 17% in the injected group and 47% in the control group (*P* = 0.011). There was also reduced mortality, need for surgery, transfusion requirement, and the length of hospital stay in the endoscopic treatment group. [57]

Other agents have also been used for subcutaneous injection to tamponade bleeding upper GI lesions. These include normal saline, 3% saline, distilled water, and 50% glucose in water. These solutions have an effect not significantly different than that of 1:10,000 epinephrine. [58], [59]

Sclerosing agents include absolute ethanol, polidocanol, ethanolamine, and sodium tetradecyl sulfate. An important difference between these compounds and those that act by local tamponade is that the sclerosants cause tissue desiccation or destruction. As a result, much smaller volumes must be used (e.g., for absolute alcohol, 0.1 to 0.2 mL/injection with total volume of less than 2 mL). [56] Even with these volumes, there is a risk for extending tissue destruction and complications. [60], [61]

Initial trials demonstrated that ethanol injection could control active upper GI bleeding, [62] reduce the rate of rebleeding, and improve clinical outcomes [63] to a degree similar to that seen with epinephrine injection. Other sclerosants have mainly been used in conjunction with epinephrine injection. Studies have suggested that the combination of a sclerosant with epinephrine has no better outcome than epinephrine alone. [64], [65] and [66] One study randomized 64 patients with bleeding ulcers to receive epinephrine injection alone or epinephrine injection followed by alcohol injection. [67] The volumes of epinephrine used were similar in both groups. Initial therapy failed in one patient treated with epinephrine alone and in none who received dual-injection therapy. The rebleeding rate was lower when alcohol injection was added to epinephrine injection (16% versus 36%), but this was not statistically significant.

Thrombin acts to convert fibrinogen to fibrin, thus stabilizing the clot in a bleeding vessel. In a large European trial, [68] fibrinogen and thrombin were combined to form a fibrin-glue ubstance that was compared with polidocanol. There was no significant difference between the groups after a single injection, but there was a statistically significant improvement in the fibrin-glue group after repeated endoscopy with multiple injections. The need for multiple endoscopic sessions to achieve this result limits its utility in clinical practice. The one advantage of fibrinogen or thrombin glue may be the ability to achieve an effect similar to that of sclerosants without causing tissue damage. Thrombin alone has also been investigated but has not been widely adopted.

As the practice of endoscopic therapy progresses, it has become clear that the combination of injection therapy and thermal therapy can be very useful. In the setting of an actively bleeding lesion, initial therapy with injected 1:10,000 epinephrine or other agent around the bleeding site to tamponade the lesion helps slow the rate of bleeding and clears the field, facilitating subsequent thermal coagulation. [54] It has also been suggested that this injection pretreatment creates a cushion of fluid that reduces the complication of a transmural thermal injury. Chung and colleagues [55] performed a prospective trial of 270 patients randomized to epinephrine injection alone or epinephrine followed by heater-probe treatment. In actively bleeding lesions, there was a significant advantage in the group treated by both injection and thermal therapy, with a reduction in both rebleeding and the need for surgery. [69] In the same study, there was a statistically nonsignificant trend toward better outcomes (rebleeding and the need for surgery) in the group that received dual therapy compared with injection therapy alone. The failure of the difference in the rebleeding and surgery rates to achieve statistical significance was likely due to a beta error resulting from the small number of patients in the trial.

In summary, epinephrine injection given to slow or control active bleeding should be followed by a second treatment modality. The optimal role of epinephrine may be as an initial therapy, in preparation for thermal modalities or sclerosants to achieve more effective long-term hemostasis. On the other hand, as compared with a thermal method alone, injection of epinephrine plus a thermal method appears to have no significant advantage in terms of rebleeding.

Hemostatic Clips

The use of hemostatic clips was first reported in 1975 by Hayashi and colleagues. [70] The technique was based on the use of clips to seal specific vessels in both surgery and radiology (Fig. 148-9). As the logistics of clip placement were improved, the use of clips was shown to be effective in the treatment of active bleeding in uncontrolled studies. [71], [72] Binmoeller and colleagues [72] treated 88 patients with either active bleeding (n = 78) or nonbleeding visible vessel (n = 10) with endoscopic clips. Initial hemostasis was achieved in all patients with an average of three clips. With a mean follow-up of longer than 1 year, only 5 patients rebled, all of whom were successfully retreated with clips. In randomized studies comparing the use of clips to injection therapy, thermal therapy, and injection therapy plus clips, there was no significant difference in the outcomes among the three approaches. [73], [74] One study compared the use of endoscopic clips to heater probe in ulcers with major stigmata of hemorrhage. The rebleeding rate was significantly lower in the patients treated with clips (1.8% versus 21%). [75] The study has been criticized, however, because the rebleeding rate in the heater-probe group is at the high end of that reported in other studies, and the rebleeding rate in the clip-treated group is remarkably low. [76] Nonetheless, the same study noted that logistic issues prevent adequate treatment of lesions that are in specific locations (lesser curve of the stomach, posterior gastric wall), where it is difficult to achieve an en face endoscopic approach for clip placement. Rare complications have also been reported with clip placement. [77]

FIGURE 148-9. Hemostatic clip. A hemostatic clip with its delivery catheter is shown. The clip can be rotated to achieve optimal position, then closed and released from the delivery device. Multiple clips are often required to achieve the appropriate hemostatic effect.

Summary of the Efficacy of Endoscopic Therapy

It is clear that the application of endoscopic therapy to bleeding from peptic ulcer disease is a successful means of treating active bleeding and reducing the risk for recurrent bleeding. Two large metaanalyses combining studies of endoscopic hemostasis in acute upper GI bleeding demonstrate the efficacy of thermal therapies and injection techniques. [43], [78] Very similar outcomes are achieved regardless of the treatment method used (laser, bipolar, heater probe, or injection). [78] In one analysis, thermal endoscopic therapy reduced the rate of rebleeding (OR, 0.38), surgery (OR, 0.36), and mortality (OR, 0.55). The overall complication rate requiring surgery or causing perforation of therapy was less than 1% for each method. Subgroup analysis showed no significant differences in the outcomes among the various thermal methods of therapy. The benefit of therapy was limited, however, to patients with endoscopic stigmata suggesting a high risk for rebleeding (visible vessels, active bleeding), but was not seen in patients with low-risk stigmata (clean ulcer base, flat pigmented spots, adherent clots). This confirms the importance of endoscopic criteria in the selection of patients for therapy. As mentioned previously, rebleeding occurs in only 20% to 25% of patients. Those with a low risk for rebleeding do not require endoscopic therapy. In the subset of patients with a high risk for rebleeding, however, endoscopic therapy improves clinical outcomes.

NONULCER UPPER GASTROINTESTINAL BLEEDING

Upper GI bleeding may also occur from non–peptic ulcer sources. The most common of these is a tear at the gastroesophageal junction, called a Mallory-Weiss tear, which accounts for 5% to 14% of upper GI bleeding. [79], [80] Bleeding usually stops spontaneously, but when persistent bleeding is found, this lesion should be treated in a similar manner as bleeding from peptic ulcers. Patients who have self-limited bleeding have a good prognosis. [27], [81] Active bleeding responds to the same methods outlined for peptic ulcers, including thermal therapy, injection therapy, and endoscopic clips. [79], [82] Another method of hemostasis reported for therapy of a bleeding Mallory-Weiss tear is band ligation. [83], [84]

Dieulafoy lesion is an aberrant submucosal artery that erodes into the lumen of the stomach and often presents as intermittent massive upper GI bleeding. [85] Although

more common in the cardia, these lesions can occur anywhere in the stomach and have also been reported throughout the GI tract. The overall prevalence of Dieulafoy lesion in upper GI bleeding is probably less than 5%. [80] Because these lesions are not accompanied by ulceration, they are often difficult to identify unless seen while actively bleeding. The infrequent nature of Dieulafoy lesion has prevented randomized trials on different types of endoscopic therapy. Combining uncontrolled experience, it appears that endoscopic therapy is effective for initial hemostasis in 96% of patients and achieves permanent hemostasis in 85% to 90%. [85], [86] As with Mallory-Weiss tears, ligation of the lesion with either a rubber band [87] or endoscopically placed loop, [88] has been reported to be successful.

P>Malignant and benign tumors are rare (less than 1%) causes of acute upper GI bleeding. [88] They more commonly present with other symptoms and chronic low-grade blood loss. When the cause of acute bleeding, they may respond to endoscopic therapy as outlined for peptic ulcer disease. [7], [88]

Another rare cause of acute upper GI bleeding is a vascular ectasia. These lesions may occur as part of the hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu) syndrome or sporadically. [89] The sporadic lesions are a common cause of lower GI bleeding but rarely present with hematemesis. These lesions also respond to standard thermal or injection therapy. [89], [90] An uncommon cause of acute upper GI bleeding is a diffuse antral form of vascular ectasia, often called a “watermelon stomach” or gastric antral vascular ectasia. [91] As with other vascular ectasias, chronic blood loss is a more common presentation of this lesion. Endoscopic laser therapy has been demonstrated to control acute bleeding and decrease transfusion requirements. [92] Other thermal methods have also been demonstrated to be effective. Contact methods (bipolar electrocoagulation, heater probe) may require more time to perform than noncontact methods (laser, APC). [93], [94], [95] and [96]

Bleeding from diffuse gastric erosions, as seen in critically ill patients, does not respond to endoscopic therapy and should be avoided by primary medical prevention. [94], [95], [96], [97] and [98]

REPEAT ENDOSCOPIC THERAPY

Some investigators have advocated routine second-look endoscopy in the setting of acute upper GI bleeding to assess the efficacy of the first therapy and retreat lesions that have persistent stigmata for rebleeding. [99] Multiple studies have randomized patients to receive second-look endoscopy or standard care. [100], [101], [102] and [103] Most have found a statistically significant difference in clinical outcomes of rebleeding or the need for surgery. [99], [100] and [101] Smaller studies have suggested a possible small difference in rebleeding rates. [102], [103] The number of additional endoscopic procedures, with the associated costs and risks, needed to prevent one episode of rebleeding appears to make this approach clinically inappropriate in most cases. [102]

It is clear that not all initial attempts at endoscopic therapy are equal. Patient condition, the presence of blood or clots in the stomach or duodenum, and other logistic factors can affect the efficacy of the treatment. The endoscopist often has a perception of how adequate the initial therapy was. In cases in which the therapy was thought to be suboptimal, a second procedure timed to provide optimal therapy may be appropriate. Routine second-look endoscopy for all patients, however, requires further evaluation before the benefits (e.g., fewer surgeries or deaths) can be demonstrated to outweigh the costs and risks to the patient.

On the other hand, it is clear that repeated endoscopic therapy is indicated in the setting of rebleeding. Lau and colleagues [104] randomized 92 patients who had recurrent bleeding after endoscopic thermal therapy to either endoscopic retreatment or surgery. The second endoscopic therapy session produced sustained hemostasis in 35 (73%) of the 48 patients randomized to endoscopy. Thirteen patients went to surgery, 11 of whom had a failure of the second endoscopic therapy and 2 of whom had a perforation resulting from the repeat endoscopy. Thirty-day mortality rates were similar in the two groups, but complications were less in the endoscopy group, of whom 7 patients (6 of whom ultimately went to surgery) had complications, compared with 16 of 44 patients in the surgery group. The authors concluded that a second attempt at endoscopic therapy can avoid surgery, with its associated complications, in many patients and does not increase mortality.

In most cases of rebleeding after endoscopic therapy, a second attempt at endoscopic therapy is indicated before resorting to surgical therapy. [105] Thermal therapy in this situation may be associated with a higher rate of perforation.

MEDICAL TREATMENT TO PREVENT REBLEEDING

The prevention of recurrent bleeding after endoscopic therapy has been the source of considerable controversy. It is clear that the ulcerogenic conditions that led to peptic ulcer bleeding should be ameliorated. In most cases, this means the discontinuation of nonsteroidal antiinflammatory drugs and treating *H pylori* infection. [106] There are no data, however, indicating that this improves the short-term (72-hour) outcome of the acute bleeding episode.

Normal hemostatic mechanisms are inhibited in the low pH of the stomach. Increasing the pH can improve coagulation and platelet aggregation. [107] In an attempt to increase gastric pH, intravenous histamine H_2 receptor antagonists have been routinely used in the setting of acute upper GI bleeding. Unfortunately, they have not been demonstrated to be better than placebo in reducing the rate of recurrent bleeding. [108] This is probably because of a decrease in the acid reduction effect of these agents over time. [109]

Despite the failure of histamine H_2 receptor antagonists, it is clear that profound acid suppression can reduce the rebleeding rate of peptic ulcers with high-risk stigmata. Khuroo and colleagues [110] randomized 220 patients to receive either oral omeprazole (40 mg twice daily for 5 days) or placebo. No endoscopic therapy was provided. Rebleeding occurred in 12 of 110 patients in the omeprazole group and in 40 of 110 patients in the placebo group ($p < 0.001$). Subgroup analysis showed the benefit of omeprazole to be limited to those patients with nonbleeding visible vessels. In a prospective study of patients with either active bleeding or nonbleeding visible vessels (high-risk stigmata), Lau and colleagues [111] randomized patients to either intravenous omeprazole (8 mg/hour for 72 hours) or placebo. All patients received endoscopic therapy before randomization. Rebleeding occurred within 72 hours in 5 of the patients receiving omeprazole and in 24 of the patients receiving placebo ($p < 0.001$). This difference persisted through the 30-day follow-up. Based on these data, it is clear that profound acid suppression using a proton pump inhibitor is an appropriate adjunct to endoscopic therapy of acute upper GI bleeding. High-dose constant proton pump inhibitor infusion is indicated as an adjunct to endoscopic therapy in patients with clinically significant bleeding and high-risk endoscopic stigmata.

Somatostatin, or its analog, octreotide, is standard therapy for bleeding esophageal varices. It has been suggested that the reduction in splanchnic blood flow caused by these agents could also control acute upper GI bleeding from other causes. In a metaanalysis, Imperiale and Birgisson [112] demonstrated a modest advantage of somatostatin or octreotide over histamine H_2 receptor antagonists in the prevention of recurrent bleeding from peptic ulcer disease. The authors suggested a possible role for these agents in patients awaiting endoscopy or when endoscopy is not available. It should be noted, however, that there was significant heterogeneity in the results of the metaanalysis, suggesting that combining the studies may not be appropriate. Limiting the analysis to rigorously done prospective double-blinded trials eliminated the heterogeneity but also suggested that there was no significant impact of somatostatin or octreotide on the outcome of the bleeding episode.

SUMMARY

Acute upper GI bleeding is a major medical problem in terms of both the burden of disease and the mortality of an individual episode. Endoscopy is the gold standard for diagnosis of the cause of bleeding and provides important prognostic information on the risk for continued or recurrent bleeding. Early endoscopy may also identify a group of patients at very low risk for rebleeding who can be treated safely as outpatients. Endoscopic therapy is effective in controlling active bleeding, reducing the risk for recurrent bleeding, and decreasing morbidity and mortality from bleeding peptic ulcers. It has a similar efficacy in bleeding from most nonulcer lesions in the upper GI tract. Endoscopic diagnosis and therapy is the standard of care for acute upper GI bleeding.

CHAPTER 149

Douglas K. Rex and Emad Y. Rahmani

ENDOSCOPIC THERAPY FOR POLYPS AND TUMORS

The development of endoscopic methods for resection of polyps and tumors in the gastrointestinal tract has been an important advance and a useful complement to traditional surgical therapy. Endoscopic resection allows treatment without general anesthesia, provides shorter recovery time than open surgical resection, reduces costs by moving patients out of operating rooms and eliminating or reducing the need for hospitalization, and reduces the risk for resection relative to surgery. Palliative endoscopic therapy of advanced cancers similarly reduces costs and risks compared with surgical treatment. This chapter reviews methods of endoscopic therapy of polyps and tumors, the principles and goals of endoscopic therapy, selection of candidates for endoscopic treatment, and, finally, data from clinical trials on endoscopic treatment of specific lesions in the esophagus, stomach, duodenum, and colon. Endoscopic therapy for tumors in the pancreas and biliary tree is covered in Chapter 141.

METHODS OF ENDOSCOPIC THERAPY

Resection

Resection is the optimal method of endoscopic treatment of polyps and tumors because it provides the potential for curative removal. An immediate requirement for curative endoscopic resection is that a lesion can be reached with endoscopy and properly positioned in the endoscopic visual field to be treated in its entirety. Furthermore, it must be of a shape and sufficiently small size that endoscopic resection can be accomplished in a time frame that is practical and with a low to minimal risk for perforation. Given these features, curative endoscopic resection should be generally possible for disease confined to the mucosa and sometimes possible for mucosal disease extending into the submucosa or originating from and confined to the submucosa (Fig. 149-1). Disease extending into the muscularis propria or originating from it is usually not amenable to curative resection.

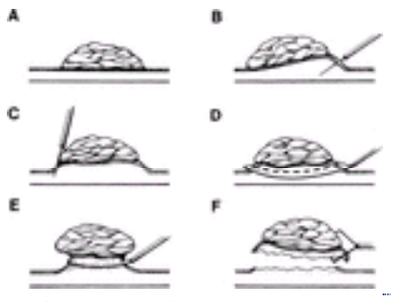

FIGURE 149-1. Mucosectomy technique. **A:** Sessile lesion limited to the mucosa. **B,C:** Physiologic saline is injected into the submucosa, creating a cushion effect. **D,E:** The lesion is resected using a loop snare. **F:** The entire specimen is retrieved.

A successful endoscopic resection is one resulting in complete removal of a polyp or tumor and retrieval of the pathological specimen without subsequent recurrence or complication. There are several general methods of endoscopic resection.

Cold Resection Cold resection refers to removal of polypoid tumors without electrocautery and can be performed with either biopsy forceps or polypectomy snares. Cold forceps removal is most readily applied to polyps of less than 4 mm in size, for which two to four bites is generally sufficient for apparent complete removal. Polyps of 1 to 2 mm generally appear to be completely removed in a single bite, although residual tissue may be left. [1] Minor immediate bleeding is very common and should not be treated with electrocautery. Delayed bleeding is rare because there is no cautery burn (delayed bleeding is associated with erosion of a cautery burn into a submucosal vessel). Cold snare resection has been applied to colon polyps of less than 7 mm in size. The polypectomy snare is placed around the base of a polyp, which is then guillotined by mechanical closure of the snare. Small amounts of immediate bleeding are typical. Like cold forceps resection, the major advantage appears to be a reduction in the risk for delayed hemorrhage. [2], [3] and [4] There may also be a reduction in the risk for perforation, although with small polyps, the risk for perforation is very low regardless of method. Safety of the technique for polyps larger than 7 mm has not been established. Initial evaluation suggests that cold snare resection is more effective than either hot or cold forceps at eliminating small polyps.([3])

Electrosurgical Resection

Diathermic snare. Endoscopic electrosurgical resection is typically accomplished using monopolar snares. A wire loop is placed around the base of a lesion with application of electrocautery followed by mechanical transection. The principal effect of electrocautery is tissue heating. Power sources for electrosurgery generate currents of typically more than 1,000,000 cycles per second (10 Hz). At these very high frequencies, the current alternates before sufficient time has transpired to depolarize muscle or nerve cells; thus, no muscle contraction occurs, and there is no danger to cardiac muscle. The current excites the molecules in the tissue, increasing their kinetic energy and raising tissue temperature. Electrosurgical resection typically produces temperatures of 45° to 100°C, with the degree of heating related to the high electrical resistance of the tissue. To obtain effective heating, the current must be concentrated through the smallest amount of tissue possible. This principle is referred to as *current density*. Current density is thus highly dependent on the tightness of closure of the diathermic snare. In fact, generated heat increases as the square of the current density. On the other hand, heat is directly proportional to the power setting and the length of time of power application. Thus, current density (snare closure) is the dominant determinant of heating. Heating results in tissue coagulation. Coagulation necrosis is visible endoscopically as tissue whitening and reflects denaturation of proteins and cell death. A second effect of heating is desiccation and resultant shrinkage. Desiccation facilitates subsequent mechanical tissue transection. Shrinkage results in blood vessel constriction and thrombosis and thus prevents hemorrhage. Properly applied, the controlled tissue injury results in easy mechanical transection, sealing of blood vessels in the base of the lesion, and an increased probability of complete excision by destruction of any abnormal cells in the lesion base. Concurrently, the injury should be sufficiently controlled that the depth of coagulation does not extend through the muscularis propria and the lateral spread of the burn is not unnecessarily beyond the borders of the lesion. After electrosurgical resection, there is typically an erythematous rim of tissue at the margin of the white coagulum in the lesion base. This reflects edema and vasodilation from radiant thermal injury, and subsequently, this tissue sloughs. Electrocautery power sources offer options of pure coagulation current, pure cutting current, or a mixture (blend). Coagulating current consists of intermittent high-voltage pulses. High voltage allows current passage through desiccated tissue, producing a wide coagulation zone. Cutting occurs primarily by mechanical

closure through the soft coagulum. Cutting current is low voltage but continuous flow. The low voltage prevents current passage through desiccated tissue, so that the heating effect remains local. Similar settings of cutting and coagulation on many power sources are such that cutting is more powerful. Thus, high power and localized heating results in vaporization of tissue near the wire loop, which in turn creates the cutting effect. The overall incidence of bleeding with cutting and coagulation current is similar, but cutting current is associated with more immediate bleeding and coagulation current with a tendency toward delayed bleeding. [5],[6] Monopolar electrocautery currents travel from the device tip to a grounding pad placed on the skin. These pads should not be placed near electrically sensitive devices such as pacemakers. Monopolar electrocautery should not be used at all in patients with defibrillating pacemakers. Electrocautery snares are available in multiple sizes (e.g., jumbo, large, standard, diminutive, micro) and shapes (e.g., oval, crescent, hexagonal). Availability of larger snares is essential for large lesions, but small snares are easier to place around small lesions. Choice of shape is made by personal preference. One rationale for shapes other than oval is that oval snares may not maintain an open oval with repeated use. This factor has become irrelevant with the progressive move toward nonreusable snares. Barbs or spikes on snares may prevent slippage during mucosectomy. Bipolar snares should limit the depth of coagulum and are theoretically safer than monopolar snares. However, they are inefficient for removal of larger polyps [7] and have no proven advantage.

Hot Biopsy Forceps Hot biopsy forceps can be used to remove polyps 5 mm or smaller in size. Proper placement involves grasping the polyp tip with the forceps and stretching or “tenting” the polyp to produce a stalk, then applying electrocautery. Endoscopically, the coagulum is seen to fan out from the forceps tip. When the coagulum appears to have destroyed the entire polyp, the forceps are withdrawn. The tip of the polyp is preserved in the forceps for histological assessment. Hot forceps are generally the easiest instrument with which to grasp a small polyp but the most difficult for controlling the coagulum. Thus, if too much tissue is grasped, if tension is greater on one side of the polyp, or if current is applied too long, the coagulum can spread easily into normal tissue. This can result in a larger, deeper ulcer than desired with a risk for delayed bleeding or perforation. Bipolar forceps provide the advantages of monopolar forceps with a potentially decreased risk for a deep burn, although greater safety remains unproven. Hot forceps are available in small (2.3 mm) and larger (3.2 mm) diameters. The small forceps are preferable because it is easier to grasp only the polyp tip. Anecdotal reports of serious delayed hemorrhage abound, but a risk for hemorrhage with monopolar hot forceps of 0.41% in a retrospective series [8] is similar to that reported with diathermic snares. For colon polyps, the risk for complications with hot forceps is five times greater with right than left colon polyps. [9] Some experts have nearly abandoned hot forceps for colon polyps in favor of diminutive snares, especially in the right colon. [10] These small snares can be readily placed around most small polyps.

Mucosectomy *Mucosectomy* refers to removal of sessile or flat neoplasms confined to the mucosa or penetrating but not fixing the submucosa. The method was initially referred to as *strip biopsy*. In Japan, the technique has been used to remove barely elevated, flat, or even “depressed” neoplasms. In the West, the principal application has been resection of large sessile colon polyps (saline-assisted polypectomy). Mucosectomy begins with injection of the submucosal space under the lesion with a cushion of normal saline. [11] A variceal injection catheter is generally used. Hypertonic saline is preferred by some. [12] Either solution can be supplemented with epinephrine, generally in a 1:10,000 dilution. [12] Only the submucosal space of the intestinal wall has sufficiently loose connective tissue to allow accumulation of saline. Volumes up to 10 to 50 mL may be needed to create an adequate submucosal “mound” (see Fig. 149-1). The lesions can then be removed using a diathermic snare in one or several pieces (see Fig. 149-1). Endoscopic mucosal resection with a cap (EMRC) is a variant useful in removal of flat lesions less than 20 mm in maximal diameter. [13] A variceal ligation hood is placed on the endoscope tip, and the raised lesion and surrounding normal mucosa are suctioned into the ligation hood. The lesion is then snare-resected using a crescent-shaped snare mounted on the hood (Fig. 149-2). An alternative is snare resection after placement of a ligation band over the suctioned tissue (Fig. 149-3). The band effectively ensures hemostasis and falls off the tissue several days later. Another variation of this type of mucosectomy is the use of a dual-channel endoscope, with a biopsy forceps through one channel to “lift” the lesion and a snare through the other channel (Fig. 149-4).

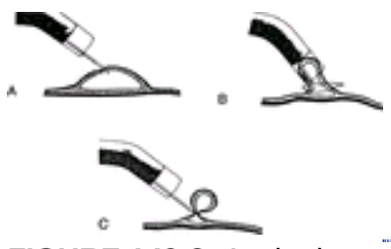

FIGURE 149-2. Aspiration mucosectomy using a snare. **A:** Physiologic saline is injected into the submucosal layers. **B:** The lesion-bearing mucosa is captured inside the cap attached to the endoscope tip under full suction. **C:** Mucosal lesion is snared tightly with the snare device passed through the biopsy channel of the endoscope.

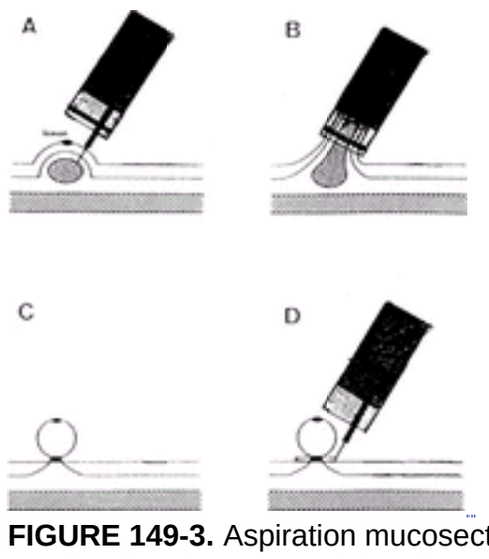

FIGURE 149-3. Aspiration mucosectomy using band ligation. **A:** Physiologic saline is injected into the submucosal layer. **B,C:** The lesion is suctioned into the cap-fitted endoscope and then ligated with a rubber band. **D:** The ligated “polypoid” lesion is snared and resected with electrocautery.

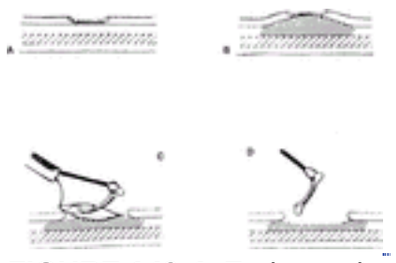

FIGURE 149-4. Endoscopic mucosectomy with the lift-and-cut technique. **A:** Flat lesion. **B:** Physiologic saline is injected into the submucosal layer. **C:** The lesion is slightly elevated using a biopsy forceps, and a snare is introduced through the second channel of the dual-channel endoscope. **D:** The lesion is resected and retrieved.

Mucosectomy has expanded the spectrum of endoscopically removable lesions. Very flat and depressed lesions cannot be removed by conventional snaring because the margin is not raised enough to enable grasping with the snare. Mucosectomy is preferred by some for sessile lesions that could be removed by conventional snaring because the saline cushion theoretically reduces the risk for a deep burn that might result in perforation, although this principle remains unproven. Mucosectomy should not be attempted for lesions that do not “raise” during submucosal injections. Failure to raise (the nonlifting sign) indicates fixation of the submucosa by tumor. [14] Such lesions should be surgically resected. However, the nonlifting sign is often present if there has been a previous attempt at removal; in this instance, it does not indicate the need for surgery. Japanese investigators have correlated the nonlifting sign with the depth of submucosal invasion in early colorectal cancer. [15]

Ablative (Destructive) Therapies

Ablation (tissue destruction) is indicated for relief of obstruction or control of bleeding when neither curative endoscopic resection nor surgical resection is feasible (Fig. 149-5). Ablation may also be considered when curative treatment is desired but endoscopic resection cannot be achieved and for any reason surgery is not selected. Ablation is generally less desirable than resection because it does not provide tissue for histological evaluation. Thus, focal cancer can go unrecognized when ablative therapy is used, but its presence might influence a decision regarding surgery. Alternatively, the risk for cancer may be so small that the cost-effectiveness of resection and submission of tissue for histological evaluation can be questioned. Such an approach has not been evaluated but may be applicable when techniques for real-time assessment of histology (e.g., high-magnification endoscopes combined with chromoscopy [16]) or light-induced fluorescence microscopy [17] are available. Ablation can be achieved by induction of coagulation necrosis (temperatures 45° to 100°C) or by vaporization (temperatures greater than 100°C).

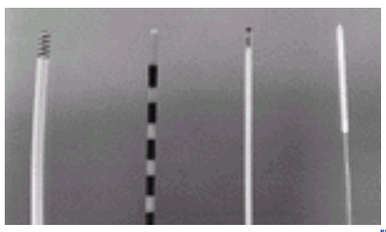

FIGURE 149-5. Probes used in mucosal ablation in the gastrointestinal tract. **A:** Bipolar probe. **B:** Argon plasma coagulation probe. **C:** Nd:YAG laser probe. **D:** Photodynamic therapy probe.

Bipolar Electrocoagulation In bipolar electrocoagulation (BEC), current flows out one electrode and back to another electrode, both of which are located in the device tip. No grounding plate is needed. During application, tissue desiccation occurs, and resistance rises, keeping the current path localized and limiting depth of injury. Bipolar probes are highly effective for endoscopic hemostasis. Relative to noncontact methods, bipolar probes are easy to use in the setting of active hemorrhage. They can be effectively applied to the surface of bleeding tumors to achieve hemostasis and have been used for eradication of residual flat neoplastic tissue that cannot be snare-resected and for ablation of very small polyps. Advantages of BEC probes are low cost of the cautery unit (although the probes are relatively expensive) and ease of application (en face or tangential). BEC probes are not useful for ablation of malignant tumors because of inadequate depth of injury and a tendency for tissue to stick to the device, requiring frequent cleaning. The principal use of this modality for tumor ablation has been the BICAP bipolar tumor probe (Circon, ACMI, Santa Barbara, CA). Superficial tissue destruction and tissue sticking have limited the usefulness of this device.
Heater Probe The heater probe uses a thermal element that heats the device tip and results in tissue coagulation. The power settings range from 5 to 30 joules, and the length of the pulse is determined by the power setting. Heat is transferred regardless of the degree of coagulation, so that the depth of injury tends to be deeper than with BEC probes. [18] The primary role of the heater probe has been in hemostasis rather than treatment of neoplasia.
Laser Laser (*l*ight *a*mplification by *s*timulated *e*mission of *r*adiation) delivered by endoscopic probes is an effective modality for relief of malignant obstruction, control of hemorrhage from tumor, and curative ablation of benign growths. The use of probe-delivered laser has declined for treatment of cancer and polyps because of purchase cost and need for repeated treatments. For malignant obstruction, stenting with self-expanding metal stents has increased in popularity relative to laser. For large benign sessile growths, mucosectomy and localized surgical resection (through transanal or laparoscopic route in the rectum and colon, respectively) have reduced the use of laser. Laser's lack of portability and depth of penetration have almost eliminated its use in hemostasis, so that endoscopic probe–delivered laser therapy has undergone a general decline. However, laser is used in the emerging field of photodynamic therapy (PDT), and, despite the previous comments, probe-delivered laser is effective and remains available in many centers. Laser depends on an active lasing medium. The medium is a material that, when illuminated, first excites electrons to higher energy states and then releases photons. Two media have been particularly useful for treatment of gastrointestinal tumors: the rare earth neodymium doped in yttrium-aluminum-garnet (Nd:YAG) and argon gas (Table 149-1). The lasing medium is housed in a nearly closed-space cylinder with mirrors at each end (Fig. 149-6). As photons are released, they are reflected and focused by the mirrors. Repeated excitation and decay of electrons in the lasing medium allows amplification of the process. An opening in one of the mirrors allows release of a monochromatic beam of photons whose wavelength is determined by the properties of the lasing medium.

LASERS	WAVELENGTH (nm)
Argon	458–514
KTP	532
Nd:YAG	1060

TABLE 149-1 Currently Available Thermal Lasers

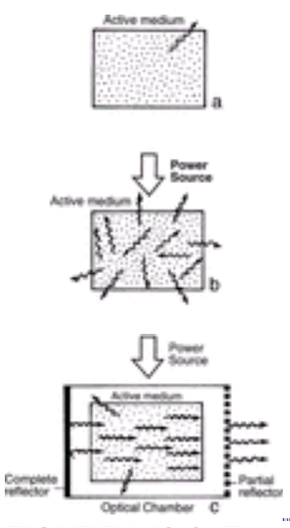

FIGURE 149-6. Essential components of lasers. **A:** Active medium of the laser in its nonactivated state. There are few, if any, excited atoms. **B:** A power source is applied to the active medium to produce a population inversion with many excited atoms. There is no directionality to the emitted photons and little amplification. **C:** The addition of an optical chamber with two reflective surfaces provides the directed output and feedback and amplification between the back reflector and the front partial reflector.

Laser effects on tissue depend on the extent of absorption of the laser beam. Absorption results in tissue excitation at a molecular level, resulting in heating and coagulation or vaporization. Absorption is a function of wavelength of the laser beam and the tissue content of water and hemoglobin, the principal absorption molecules. Scattered light may heat adjacent tissue, depending on the tissue-wavelength interaction of this tissue. If the tissue-wavelength interaction is not optimal for absorption, light is transmitted or reflected, resulting in no tissue damage. The Nd:YAG laser delivers an invisible light with wavelength in the near-infrared spectrum at 1.06 µm. The power of most clinically available units is up to 120 W. The light is pointed endoscopically at the target through a red aiming beam. The argon laser delivers a blue-green light of wavelength 0.50 µm. The depth of penetration using argon is less than BEC. [19] On the other hand, Nd:YAG penetration is five or more times greater than argon, and heating can readily reach a level (more than 100°C) allowing vaporization. [19] Thus, the Nd:YAG laser has been the most useful probe-delivered laser for treatment of gastrointestinal tumors. Tissue heating is affected by the power setting, pulse duration, and probe distance from the tumor, which determines the spot size of the beam. Continuous (nonpulsed) therapy of tumors using Nd:YAG laser leads to conduction of heat energy to surrounding tissue, increasing patient discomfort and increasing perforation risk. Pulsed therapy helps focus heating on more superficial tumor. The most commonly used laser probes are noncontact. The optimal spot size and tissue heating are achieved by a focal distance of about 10 mm. Noncontact probes generally allow the most efficient application. In very tortuous or narrow strictures, however, unintended probe contact can result in the need for repeated cleaning or even probe replacement.

Contact laser tips overcome this problem. Contact tips can be used to cut tumor tissue. [19], [20] In general, they require less power (12 to 20 W) and produce less smoke, but operators often find application less efficient than with noncontact probes.

Chemical Injection Small series have reported control of malignant obstruction and bleeding through endoscopic injection of agents that result in chemical necrosis. Relief of obstruction occurs by tissue sloughing, and hemorrhage is controlled by thrombosis, edema, and vasoconstriction. The technique is inexpensive and easily applied, and the necessary equipment and agents are widely available. Despite this, injection has not become popular, probably because of absence of an immediate tissue destructive effect that would guide and limit further therapy. Effective agents include sclerosants such as ethanol, sodium morrhuate, and polidocanol and chemotherapeutic drugs such as 5-fluorouracil.

Argon Plasma Coagulation Argon plasma coagulation (APC) is a noncontact thermal coagulation method in which current is applied by high-frequency electric current passed through argon gas. When the argon gas is passing current, an electrically insulating steam layer develops as soon as fluids in the tissue reach boiling point. This increases electrical resistance and can limit the depth of coagulation. [21] However, in experimental models, APC can readily produce transmural injury. [22] Depth of injury is a function of duration of application and secondarily of power setting. [22] In the cecum and right colon, power settings of 40 to 45 W and short bursts are most appropriate. In the rectum and stomach, settings of 60 to 75 W and more prolonged application are appropriate for benign tumor ablation. For palliation of cancers, power settings of 90 to 100 W and repeated application result in overt cavitation and marked tissue charring. APC has been used successfully in Europe and Canada for thermal hemostasis of gastrointestinal angiomata, [23] to treat gastrointestinal tumors, to treat tumor ingrowth or overgrowth, and to treat residual flat neoplasia after snare resection. [24], [25] and [26] It is effective in the treatment of radiation proctitis [27] and has been used to eradicate Barrett esophagus in combination with antisecretory therapy. [28]

Photodynamic Therapy PDT involves the use of a photosensitizer administered before photoradiation [29], [30] (Fig. 149-7). To activate the photosensitizer, photoradiation using a light of appropriate wavelength, good tissue penetration, and optimal absorption by the photosensitizer is applied using an optical fiber. The photosensitizer then destroys the dysplastic cells to which it is bound by production of cytotoxic singlet oxygen species.

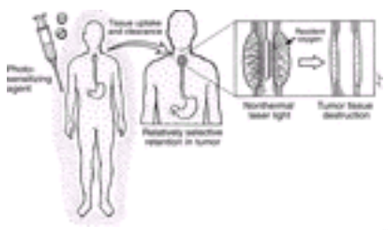

FIGURE 149-7. Method of photodynamic therapy (left to right). A light-sensitive drug is administered and accumulates selectively in the tumor. After a certain time, photoactivation of the drug by illumination with laser light initiates the photodynamic reaction, which kills the cells containing the specific drug.

Porfimer sodium (Photofrin), the only photosensitizer currently approved by the U.S. Food and Drug Administration, is indicated for palliation of patients with esophageal cancer. After an intravenous injection of porfimer sodium (2 mg/kg), clearance from a variety of tissues occurs over 40 to 72 hours, but tumors, skin, and organs of the reticuloendothelial system retain the drug longer. Illumination with 630-nm wavelength laser light initiates free radical production after porfimer sodium absorbs light to form a porphyrin-excited state. Spin transfer from porfimer sodium to molecular oxygen may then generate singlet oxygen (Fig. 149-8). Subsequent reactions can form superoxide and hydroxyl radicals, with subsequent cell death. Tumor death also occurs through ischemic necrosis secondary to vascular occlusion partly mediated by thromboxane A_2 release.

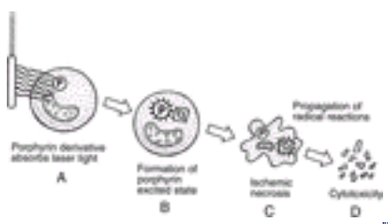

FIGURE 149-8. Photodynamic therapy: mechanism of action. Light-sensitive drug (*P*, porphyrin derivative) absorbs laser light (**A**). Energy is transferred from the excited triplet state of the sensitizer to molecular oxygen (**B**) to generate singlet oxygen (**C**), which oxidizes cell membranes; this results in ischemic necrosis and cell death (**D**).

PDT is contraindicated in pulmonary esophageal fistula and in patients with porphyria. Patients should avoid exposure of the skin and eyes to direct sunlight or bright indoor light, including unshaded light bulbs at close proximity, for 1 month or more. Some patients require a second laser light treatment 96 to 120 hours after the initial injection. PDT using 5-aminolevulinic acid (5-ALA) has been used in Canada and Europe for gastrointestinal cancers with promising results. [31], [32] It is administered orally, and the associated photosensitivity reaction is short lived and minimal. 5-ALA appears most useful for the treatment of very thin dysplastic or malignant lesions. The laser system used for PDT must be approved for delivery of a stable output (for porfimer sodium and 5-ALA at a wavelength of 630 nm). Light is delivered to the tumor by a cylindrical fiberoptic diffuser passed through the operating channel of the scope. Photoreactivation of the drug is controlled by the total light dose delivered. In the treatment of esophageal cancer, a light dose of 300 joules/cm of tumor length should be delivered. The cylindrical fiberoptic diffusers (OPTIGUIDE, Diomed, Andover, MA) are available in several lengths. The total power output at the fiber tip is set to deliver the appropriate light dose using exposure times of 12 minutes and 30 seconds. The major limitation of PDT is its cost, which is substantial both for the equipment and for the photosensitizers. New photosensitizers with more selectivity for the dysplastic and cancer cells and with fewer side effects will enhance the safety and effectiveness of the treatment.

Other Methods Palliative modalities that produce displacement (dilation and stent placement) are covered in Chapter 145.

ENDOSCOPIC TISSUE STAINING AND TATTOOING

Tissue staining and tattooing are adjuncts to the endoscopic therapy of polyps and tumors. *Tissue staining* refers to the topical application of chemical stains or pigment to alter tissue appearances in order to improve localization, characterization, or diagnosis.

Absorptive or vital stains identify specific epithelial types or cellular constituents by preferential entry. Contrast stains highlight tissue topography by entering mucosal depressions and crevices, a process called *chromoscopy*. Lugol solution is an iodine-based absorptive stain with affinity for glycogen in nonkeratinized squamous epithelium. When applied to normal esophagus, it turns a green-brown color within moments of application. Absence of staining indicates diminished or absent glycogen content, as seen in squamous cell cancer and dysplasia, [33], [34] Barrett epithelium, [35] and occasionally inflammatory esophagitis. Typically, 20 to 50 mL of a 1% to 3% Lugol solution is sprayed onto the mucosa during endoscopy.

Methylene blue enters the cytoplasm of absorptive tissues such as colonic and small bowel epithelia. Staining in the stomach and esophagus identifies intestinal metaplasia, [36], [37] whereas the absence of staining in the duodenum or colon usually indicates metaplastic, [38] neoplastic, [39] or inflammatory change. [40] After washing the mucous layer with 10% *N*-acetylcysteine or other mucolytics, a 0.05% to 1% solution of methylene blue is sprayed onto the mucosa. A few drops of methylene blue added to saline for submucosal injection during mucosectomy will sharply delineate the extent of the saline cushion as it develops and will sharply delineate the margin of flat colon polyps. Its use during colon polyp removal eliminates the need for chromoscopy to define the edges of the polyp.

Indigo carmine is a blue stain used for chromoscopy. [41], [42] It is sprayed as a 0.1% to 0.8% solution or ingested as a capsule. Chromoscopy using indigo carmine dye has been used to identify or enhance flat adenomas and can distinguish hyperplastic from neoplastic lesions, by observing the innominate grooves and pit pattern. [16], [43]

Tattooing is a means of labeling a site by intramural injection of a pigment for future identification during surgery or repeat endoscopy. India ink is particularly useful because it produces a black stain visible permanently from serosal and lumenal surfaces. [44], [45] India ink is a suspension of inert carbon particles in a variety of aqueous and nonaqueous stabilizers and diluents. Pure India ink is preferable because inclusion of other materials may evoke an immunologic response, although toxicity is exceedingly rare. A 1:10 or 1:100 ink-to-saline dilution can be autoclaved or filtered, [46] and commercial preparations ready-made for endoscopic injection are available. The tattoo is made by injections of 0.1 to 0.5 mL using a sclerotherapy needle inserted tangentially to make a submucosal bleb. Injection into four quadrants ensures easy intraoperative identification.

GOALS OF ENDOSCOPIC THERAPY

Tumors in the gastrointestinal tract can be approached with the objectives of curative resection or palliation of symptoms. These same general goals are applicable to endoscopic treatment of polyps and tumors. Palliation becomes the goal when staging of a malignant tumor shows it to be incurable or when a tumor is present that cannot be completely resected endoscopically, and when the patient is not a candidate for or is unwilling to undergo other types of therapy.

RATIONALE FOR ENDOSCOPIC THERAPY VERSUS OTHER MODALITIES

Optimal features of curative resection include a minimally invasive approach, low rate of complications, outpatient procedure (minimal need for hospitalization), limited or no need for sedation or anesthesia, minimal recovery time, recovery of the surgical specimen, and minimal need for repeated examinations or treatments. Compared with surgery, endoscopic therapy is generally superior in each regard, except the recovery of the specimen (occasional failures with endoscopic therapy) and the need for repeated examinations or treatments.

The objective of palliative therapy is usually maintenance of lumenal patency and nutrition or cessation of bleeding. The optimal features of palliative therapy are similar to those of curative resection, except that recovery of a specimen is less important. Endoscopic therapy is generally better tolerated than surgical therapy for palliation, except that it may necessitate multiple treatments.

PRECURSOR LESIONS

Most gastrointestinal malignancies arise from the mucosal lining. In some cases, a sequence of dysplasia progressing to cancer is documented. In the colon, this progression involves a benign growth (the adenomatous polyp) in nearly all cases of colorectal cancer arising in the United States and Europe. A careful endoscopic examination of the colon can identify these lesions and remove them with nearly complete protection from colorectal cancer mortality. Adenomatous polyps also arise in the stomach and duodenum. An adenoma-carcinoma sequence is less well established in these areas, particularly the stomach. Nevertheless, the association of adenomas with cancer in these sites is clear, and a general principle throughout the gastrointestinal tract is that endoscopically identifiable growths that are benign and dysplastic (adenomatous polyps) should be removed to prevent progression to cancer. Concepts regarding precursor lesions are critical to the endoscopist because endoscopy is superior to all other technologies in both their detection and removal.

A number of mucosal cancers in the gastrointestinal tract are not associated with an identifiable precursor that is appreciable by routine endoscopy. Examples include some colorectal cancers in ulcerative colitis and Crohn's colitis, and squamous cell and adenocarcinomas of the esophagus. A progressively important focus of endoscopic research is to identify dysplastic, flat mucosa and treat the area endoscopically or by surgical resection before carcinoma develops or spreads to an incurable stage. In some cases (e.g., Barrett esophagus and chronic ulcerative colitis), the area at risk is endoscopically apparent and can be subjected to systematic sampling using endoscopic biopsy forceps. Several methods are under investigation to allow sampling that is more directed to areas of possible dysplasia. One approach is to use dye spraying (chromoscopy) or staining. Areas of dysplasia can then be subjected to mucosectomy or surgical resection (stomach or esophagus), ablative therapy (esophagus), or regular intensive surveillance biopsies to rule out cancer (esophagus). Other approaches that can help direct biopsy to flat precursor lesions are high-magnification endoscopy [43] and light-induced autofluorescence. [17]

Japanese investigators have accumulated an extensive experience with chromoscopy, sometimes in combination with high-magnification endoscopy, to enhance detection of small, flat dysplastic colonic lesions, often referred to as *flat adenomas* and *flat cancers*. These lesions appear endoscopically as slightly raised, flat, or even depressed lesions, sometimes with an erythematous halo. Although an exact definition is not possible, they are usually defined as being less than 1 to 1.5 cm in size, and the total histological height of the lesions should not exceed twice that of the normal mucosa. Flat adenomas are said to have an increased probability of severe dysplasia relative to their size, although Japanese pathologists have been shown to vary widely in their interpretations of severe dysplasia. [47] Similarly, it is clear that lesions determined by Japanese pathologists to be cancer lesions would be termed high-grade dysplasia in the West. [48] However, a single pathologist who reviewed the histology of flat adenomas from both Tokyo and Stockholm found that flat adenomas in Japan are more likely than those in the West to contain high-grade dysplasia or invasive cancer. [49]

The prevalence of flat adenomas and cancer is relatively low, even in Japan. [42], [50] In the West, one colonoscopist found that 12% of adenomas met histological criteria for flat adenomas, but none had severe dysplasia or cancer. [51] In an autopsy study in Vancouver, 29 flat adenomas were found, of which 41% had high-grade dysplasia. [52] Three prospective studies have evaluated patients in Britain [53], [54] or the United States [55] using Japanese colonoscopic techniques to investigate the issue of flat colonic neoplasms. This technique in essence is to scan the colonic mucosa for subtle surface irregularities or color changes and then to spray dye, usually indigo carmine, on any such abnormalities. Rembacken and associates [53] studied 1000 British patients and found four very small depressed lesions, three of which had Dukes A cancer or high-grade dysplasia. It is uncertain whether these lesions would have been detected without chromoscopy. In another study, five small flat cancers were identified in 870 British patients. [54] These new data must be viewed in light of the National Polyp Study, in which conventional colonoscopy and resection of all polypoid lesions was essentially completely effective in preventing colorectal cancer mortality. [56] However, in the National Polyp Study, as well as in other large postpolypectomy studies, colonoscopy is not fully protective against development of incident cancers. [56] It is possible that failure to detect flat and depressed neoplasms accounts for some incident cancers after apparent clearing colonoscopy. [57]

PATIENT SELECTION FOR ENDOSCOPIC TREATMENT

When considering an attempt at curative endoscopic resection, the endoscopist first considers the likelihood that a lesion is malignant. Irregular surface contour, large size, ulceration, and firmness of the lesion with probing are all indications of malignancy. Careful staging is indicated before any attempt at resection of a lesion with these features because surgical resection offers the best chance for cure of intestinal cancers. In uncertain cases, submucosal injection of saline may be helpful because fixation of the submucosa by tumor will prevent elevation of the lesion, and endoscopic resection can be aborted. Injections should not be made directly through lesions that appear possibly malignant. In general, lesions involving the mucosa are resectable for cure by endoscopic methods, as are some lesions extending into the submucosa or involving only the submucosa (e.g., carcinoids). In the esophagus, which lacks a serosa, even superficial cancers are at times associated with lymph node metastasis. Factors such as surgical candidacy and the feasibility of endoscopic removal (size of the lesion) can influence the decision of an endoscopic attempt versus surgery. Similarly, transanal surgical resection of a rectal lesion may at times be preferable for a large benign rectal growth because the distal rectum is easily accessible to transanal surgery, and endoscopic resection or ablation, although feasible, might require many sessions. Lesions extending into the muscularis propria are seldom treated in a curative fashion by endoscopy.

At times, the need for surgical treatment is not evident until after endoscopic resection with curative intent. This need is best established for malignant pedunculated colon polyps, in which the presence of cancer at the histological resection line of an endoscopically removed polyp, poorly differentiated cancer, or vascular (lymphatic) invasion are predictors of metastasis and serve as a general guide indicating the need for segmental colon resection. In some centers, any cancer in a sessile colon polyp is an indication for surgical resection in a good surgical candidate.

Staging should generally be accomplished by computed tomography (CT) scan and endoscopic ultrasound (EUS). EUS is more accurate for T and N staging, and CT scan is more accurate for distant metastases. Patients with unresectable disease may be candidates for endoscopic palliation of symptoms, provided they have reasonable life expectancy (perhaps greater than 1 month).

FAILURE OF ENDOSCOPIC THERAPY

Curative endoscopic resection fails when a lesion is too large for removal, when a lesion recurs despite attempts at resection, when complications occur, when a lesion contains invasive cancer requiring resection, when a patient is lost to follow-up before completion of endoscopic resection, or when metastasis occurs after what was thought to be complete endoscopic removal. The likelihood of endoscopic failure should be carefully considered in cases in which both endoscopic and surgical resections are reasonable alternatives. Conversely, the patient is poorly served when surgery is performed unnecessarily to remove a section of the intestinal tract containing an endoscopically removable lesion.

ESOPHAGEAL LESIONS

For patients with localized esophageal cancer, surgical resection with or without preoperative chemoradiation is the preferred approach. Many patients with esophageal cancer are elderly and may not be good operative candidates even if staging demonstrates localized disease. Patients with T1 or T2 disease (TNM staging system) who are not surgical candidates or who refuse surgery may undergo an attempt at curative therapy by endoscopic methods such as PDT, [58] mucosectomy, [59] or both. Patients whose disease is not resectable for cure and those who are not operative candidates should be offered palliative therapy if their life expectancy is greater than 1 month. Because tumor stage and operative candidacy guide therapy, accurate staging is critical. Local staging and involvement of lymph nodes is determined by EUS, which is generally indicated when CT fails to demonstrate distant metastases. Palliation is directed toward maintenance of lumenal patency so that swallowing can continue. Palliative therapy does not generally lead to substantial prolongation of survival. Modalities for the palliation of esophageal cancer include surgery, radiotherapy, chemotherapy, and endoscopic therapy. Endoscopic palliative treatments include dilation, thermal modalities (Nd:YAG laser, BEC, argon coagulation), nonthermal ablation using PDT, endoscopic endoprosthesis, and intratumor chemical injections.

Screening programs for squamous cell carcinoma have used Lugol iodine solution to identify early cancers and flat precancerous lesions. Endoscopic mucosal resection with a cap-fitted endoscope has been performed after submucosal injection with saline and epinephrine solution. [59]

Endoscopically delivered Nd:YAG laser therapy may be used as primary palliation of dysphagia or to establish patency and improve nutritional status before initiating radiation or chemotherapy (Table 149-2). Favorable factors for successful laser therapy include exophytic tumor, tumor location in a straight segment of the middle or distal esophagus, and tumor less than 5 cm in length. Patients with noncircumferential tumors may be treated more effectively with Nd:YAG laser than with stent placement. Patients with tumors in the cervical esophagus or with submucosal tumors are poor candidates for laser therapy. A major disadvantage of Nd:YAG laser therapy is the need for repeated treatments at 4- to 8-week intervals. [60], [61], [62], [63], [64], [65], [66] and [67] Retrograde application is preferred, [66] and power settings of 90 to 100 W are commonly used.

TUMOR CHARACTERISTICS	STENT	LASER	BIPOLAR	PDT
Circumferential cancer	Yes	Yes	Yes	Yes
Noncircumferential cancer	Maybe	Yes	No	Yes
Exophytic	Yes	Yes	Yes	Yes
Intramural	Yes	No	Yes	Maybe
Cervical esophagus	No	Maybe	Yes	Yes
Gastroesophageal junction tumor	Maybe	Maybe	Yes	Yes
Angulated stricture	Yes	Maybe	No	Yes
Tracheoesophageal fistula	Yes	No	No	No
Recurrence after radiation	Maybe	Maybe	Maybe	Yes

PDT, photodynamic therapy

TABLE 149-2 Selection of Palliative Procedures for Esophageal Cancer

Contact probes [19] produce less smoke than noncontact methods and eliminate the concern about fiber tip damage during the procedure, although in a randomized comparison, the two fiber types had equal performance. [20] Nd:YAG laser produced fewer complications than plastic stents in the treatment of esophageal cancer, [68], [69] but the need for repeated treatments has led to replacement of Nd:YAG by self-expanding metal stents.

The bipolar tumor probe is now used infrequently for palliation of esophageal malignancy. [70], [71] and [72] The principal advantages are the relatively low cost and widespread availability of the power unit. After sufficient dilation, the probe is passed to the distal end of the tumor. [70] Probes with electrodes oriented circumferentially are used most frequently. Partly circumferential probes are available for treatment of partly circumferential tumors and must be maintained in correct radial orientation by endoscopic observation.

APC has been used in palliative tumor ablation, in stent overgrowth and ingrowth, and for treatment of tumors after laser therapy. [24], [73], [74] Sessler and associates [25] used APC in eight patients with T1 tumors of the esophagus who were not candidates for surgical resection. Follow-up for 9.45 ± 2.8 months showed no tumor in seven of eight patients. In another study, APC was used as an adjunct to PDT in 11 patients with high-grade dysplasia and Barrett esophagus. Short-term follow-up revealed effective eradication. [73]

A prospective 12-year follow-up study of PDT for esophageal malignancy revealed that PDT caused minimal complications and no procedure-related deaths. The length of palliation for patients having noncurative treatment was equal to or better than that reported historically for most other treatment regimens. For patients with Barrett esophagus and severe dysplasia or T1 carcinoma who are high surgical risks, it can be considered an alternative treatment. [75] Overholt and Panjehpour [76] treated 100 patients with Barrett esophagus and dysplasia (13 with early superficial cancer) with PDT. Patients were maintained on long-term acid-suppressive therapy. Follow-up endoscopy demonstrated ablation of the superficial cancer in 10 of 13 malignancies, [66] elimination of dysplasia in 78 of 100 patients, reduction of the extent of Barrett esophagus in all patients, and eradication of Barrett esophagus in 43 patients. Laukka and Wang [77] used low-dose PDT (1.5 mg/kg) in patients with Barrett esophagus and revealed a mean reduction of 2.4 ± 0.9 cm in the length of columnar epithelium. PDT was also effective in treating tumor ingrowth and overgrowth of an esophageal stent. [78], [79] A multicenter randomized trial comparing PDT and thermal ablation with Nd:YAG laser for palliation of esophageal cancer revealed that both methods are equally effective for palliation of dysphagia and objective tumor response rate. However, PDT was easier to use and was associated with fewer acute perforations than Nd:YAG laser therapy. [30]

Endoscopic mucosal resection (EMR) of high-grade dysplasia and superficial esophageal cancer has emerged as a potential alternative treatment. Endoscopic treatment can be considered for esophageal cancer if it is at an early stage, is intramucosal or microinvasive (involving only the most superficial aspect of the submucosal), and has no lymph node involvement by endoscopic ultrasound. The tumor should generally be less than 2 cm in diameter, and the patient should be a suboptimal candidate for surgery. [80], [81], [82], [83] and [84] Yoshida and colleagues [83] observed a 12.9% rate of immediate complications, of which mediastinal emphysema (usually asymptomatic) and bleeding were the most common. They also observed a 7% of late complications that were mainly stenoses. Inoue [82] had two severe complications (one perforation and one stenosis resistant to dilation) in a series of 142 patients.

GASTRIC LESIONS

Gastric polyps are usually adenomas or hyperplastic polyps. Adenomas are markers of an increased risk for adenocarcinoma, but an adenoma-carcinoma sequence is not fully established in the stomach. Adenomas are predominantly solitary and antral in location. Their size appears to be of great importance in predicting malignant potential. In polyps larger than 2 cm, there was a 24% incidence of malignancy; whereas in the polyps smaller than 2 cm, there was only a 4% incidence. [85] Carcinoma arising in adenomas is usually of the intestinal, well-differentiated type. [86] Hyperplastic polyps are more common than adenomas, are randomly distributed throughout the stomach, and typically are less than 2 cm in diameter. Endoscopically, these lesions may have surface inflammatory erosion and exudate. Giant gastric hyperplastic polyps occasionally undergo malignant transformation. [87] Fundic gland polyps were unrecognized in early series and often called “hyperplastic.” They now account for up to 50% of gastric epithelial polyps. Fundic gland polyps occur within the body or the fundus and are multiple. There is no association between fundic gland polyps and atrophic gastritis or adenocarcinoma. [88] Because biopsy specimens obtained by forceps have been shown to be unreliable in determining the type of polyp present, [89] gastric polyps larger than 1 cm should be removed endoscopically if feasible. [90], [91]

Gastric polyps smaller than 5 mm can be removed using biopsy forceps. Gastric polyps larger than 5 mm should be removed by snare excision. When the resected specimen shows carcinoma invading the polyp base or if poorly differentiated carcinoma is present, surgical resection should be considered. Cancer developed in 1.3% of 1177 patients after resection of gastric adenomas, and yearly follow-up was recommended. [92]

The technique of gastric polypectomy is similar to that for colonic polypectomy (see later). Intravenous glucagon may reduce peristalsis. Bleeding is more common after gastric polypectomy [89], [91], [93] than after colonic polypectomy, but the risk for perforation is very low. Polyps should be retrieved in a manner providing airway protection. An overtube or a Roth retrieval net should be considered for polyps that cannot be suctioned through the endoscope. Acid-suppressive therapy may help heal the cautery ulcer produced by polypectomy.

Endoscopic resection of gastric submucosal lesions may be performed using strip biopsy, [94] aspiration mucosectomy, [95] or endoscopic mucosal resection with a cap-fitted endoscope. [59] Aspiration mucosectomy produces larger specimens that contain a greater depth of submucosa compared with strip biopsy. [95]

Early gastric cancer is defined as carcinoma limited to the gastric mucosa or submucosa regardless of lymph node involvement. [96], [97] and [98] In Japan, mass screening programs and the availability of widespread endoscopy methods have increased the fraction of gastric cancer diagnosed at the early stage from 5% to more than 30% in 15 years. [98] Unfortunately, early gastric cancer is diagnosed in the United States in only 3% to 6% of the cases. [99] Several large series described EMR for gastric superficial carcinoma. [100], [101], [102] and [103] Depending on the technique and the characteristics of the lesion, the complete resection rate ranges between 43% and 100%. In one series, complete resection was achieved in 43% of cases, which increased to 87% when it was combined with laser ablation.

A band ligation device can be used to convert flat neoplasms to polypoid lesions. [104], [105] The resulting polypoid lesion is resected below the elastic ring using conventional polypectomy snare technique. Other successful treatments for early gastric cancer include PDT [106], [107] and intratumor injection of OK-432, a drug produced by treating the Su strain of *Streptococcus pyogenes* with penicillin. [108] Thus, endoscopic "curative" therapy for early gastric cancer is feasible in patients who are poor candidates for surgery. EUS staging should precede any attempt at endoscopic resection.

Nd:YAG laser has been useful as a palliative treatment of advanced gastric cancer in patients who are poor surgical candidates. A mean of three treatment sessions of about 6000 W/second per session was required to establish a lumenal opening, and 73% of patients could eat all foods. [109]

DUODENAL LESIONS

Adenomas are the most common duodenal neoplasms. Large, villous adenomas have an increased risk for containing adenocarcinoma, [110] and resection is generally indicated. [93], [111] Endoscopic resection of lesions on the medial wall of the duodenum is facilitated by use of a duodenoscope (side-viewing endoscope). Periampullary lesions should be staged by EUS before resection. [112] Endoscopic therapy of periampullary tumors may be accompanied by pancreatitis or bleeding. Snare polypectomy, [112] strip biopsy, [113] EMR, [114] Nd:YAG laser, [115], [116] and PDT with 5-ALA [31] or Photofrin [117] have all been used to resect or ablate duodenal adenomas or early cancer.

COLORECTAL POLYPS AND TUMORS

The goal of endoscopic treatment of benign colorectal neoplasms is curative resection. The evidence to support the effectiveness of colonoscopy and polypectomy in the prevention of colorectal cancer incidence and mortality includes three adenoma cohort studies [56], [118], [119] with reductions in incidence compared with reference populations, a small randomized controlled clinical trial, [120] a case-control study, [121] case-control studies of sigmoidoscopy and polypectomy, [122], [123] and a randomized controlled trial in which fecal occult blood testing reduced the incidence of colorectal cancer by identifying large polyps that were then removed by colonoscopic polypectomy. [124]

The standard therapy of colorectal cancer is surgical. However, the mean age of colorectal cancer diagnosis is 70 years, and incidence continues to rise with age. [125] If operative risk is substantial owing to age or co-morbid illness, endoscopic therapy may be preferable. Many patients with metastatic disease benefit from operative resection or diversion to avoid colonic obstruction. However, patients with widely metastatic disease and short life expectancy may opt for endoscopic palliation, as may those who are unwilling to have a stoma.

Pedunculated Polyps

Pedunculated (stalked) polyps are more common in the left colon than the right. They may be positioned in the sigmoid colon in areas of marked angulation. Repositioning the patient may improve exposure of the polyp head and stalk. A skilled endoscopist should be able to remove essentially all pedunculated colon polyps. Ensnaring a very large polyp is often facilitated by the use of an extra-large (jumbo) snare. The closed snare should be positioned near the polyp head or at least two thirds of the distance from the base of the stalk to the polyp head. This leaves residual stalk that can be snared if there is immediate bleeding. On the other hand, some have argued that if the polyp looks as though it may be malignant, it is preferable to close on the base of the stalk [126] in order to improve the chance of a clear resection margin. If the tip of the polyp head touches the contralateral colon wall, current may pass through that wall and produce a burn (Fig. 149-9). Gentle movement of the snare during application of cautery will dissipate this burn on the contralateral wall and eliminate the risk for perforation. Most experts hold the colonoscope shaft in position with their right hand during application of cautery, or pin the scope against the bed with their hip to prevent scope movement if manipulation of the snare during cautery is needed. An assistant generally closes the snare. If, before passing the snare down the instrument, a mark is placed on the snare handle at the point of closure where the snare tip just enters the plastic sheath, then the distance from the mark to the closing portion of the snare provides an estimate of the amount of tissue in the snare. If this distance is excessive (more than 1 to 1.5 cm), then careful inspection or remanipulation of the snare is prudent to ensure that no portion of the normal wall or the polyp head is in the snare.

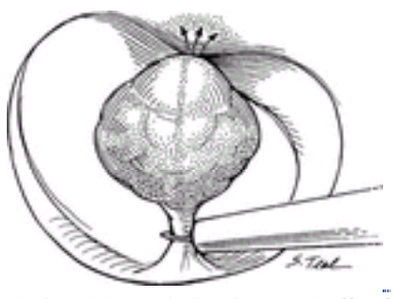

FIGURE 149-9. Current dissipation through the contralateral colonic wall. The electrosurgical snare is around the stalk of a pedunculated polyp. The polyp head is in contact with the contralateral wall. Leaking current during cautery may cause thermal injury to the contralateral wall (*arrows*). Significant injury is easily averted by moving the polyp head during application of electrocautery whenever the polyp head touches the contralateral wall.

The risk for perforation with pedunculated polyps is exceedingly low, so that application of current can usually be liberal and mechanical closure slow. A white coagulum should be endoscopically visible adjacent to the snare before mechanical closure begins. Current should be applied continuously because intermittent application allows cooling of the snare and may seal it to the tissue ("stuck snare").

The most common complication of endoscopic transection of pedunculated polyps is bleeding, which can be either immediate or delayed. Some experts preinject the stalk with epinephrine and saline. However, the risk for immediate bleeding overall is low, particularly if coagulation current is used. Thus, the use of an injection catheter and epinephrine routinely for colon polyps is not cost-effective. A time-honored approach to immediate hemorrhage is to regrasp the stalk with the snare and hold the stalk for 10 to 15 minutes. No additional cautery is applied, yet this method is consistently effective. Alternatively, epinephrine can be injected into the stalk if immediate bleeding occurs, followed by bipolar coagulation of the transection site on the stalk. A recent innovation, proved effective in a randomized trial, [127] that appears to prevent both immediate and delayed bleeding is a detachable snare, which is placed on the polyp stalk before transection (Fig. 149-10). The snare subsequently sloughs up to 1 week later. The detachable snare can also be placed on the stalk after transection. Attempted application to semi-pedunculated polyps before or after transection is often unsuccessful. An alternative is to place a metal clip across the base of the stalk.

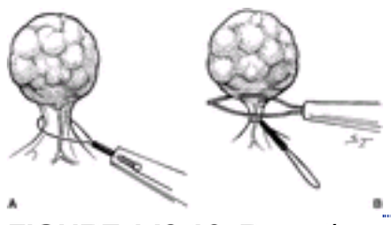

FIGURE 149-10. Resection of a pedunculated polyp with a detachable snare. **A:** The loop of a detachable snare is placed around the stalk of the polyp, tightened, and then detached from the handle. **B:** A cautery snare is placed above the loop and transects the stalk by electrocoagulation.

More than 95% of colon polyps can be successfully retrieved. Small pedunculated polyps can be suctioned through the colonoscope into a trap. If the polyp is not visible in the trap after suctioning, it is usually impacted in the umbilical cord of the instrument. Water can be suctioned from a syringe inserted into the suction or biopsy inlet of the instrument through the umbilical cord to flush the polyp into the trap. Larger pedunculated polyps are most easily retrieved by gently regrasping the transected polyp head. If 2 to 3 cm of the snare is left outside the colonoscope tip, then examination can continue while the polyp is being delivered. If additional small polyps are encountered, the large polyp is dropped in the lumen, the small polyps are removed and suctioned, the large polyp is regrasped, and the examination then continues. Combined cautery and retrieval snares have been recently described. [128]

Large pedunculated colon lesions with overlying normal mucosa are usually lipomas. The diagnosis is confirmed by the “cushion” or “pillow” sign of easy deformability with probing; by the yellow hue, which is sometimes present; and if necessary, by EUS. These tumors are usually asymptomatic but can produce intussusception. Endoscopic snare resection is often unsuccessful. Fat has low water content and resists the desiccation necessary for easy mechanical transection.

Endoscopic resection of a malignant pedunculated polyp is considered curative if (1) the cancer is well or moderately differentiated, (2) there is no vascular (lymphatic) invasion, and (3) the margin is clear. If these criteria are met, surgical resection is not advised. If the criteria are not met, the risk for metastasis is increased, with the extent of increase depending on the number and severity of the changes. [129], [130] and [131] If the estimated risk of operation is lower than the risk for metastasis, then surgical resection should be considered.

Diminutive Polyps

Polyps less than or equal to 5 mm in size are diminutive. Most of these polyps in the proximal colon are adenomas, and most in the rectosigmoid are hyperplastic. The concept of “clearing” colonoscopy includes removal of these polyps, although they rarely contain cancer. In some instances, they are so frequent in the rectosigmoid that only representative biopsy sampling is feasible. In these instances, biopsies generally demonstrate hyperplastic polyps. Whether it is cost-effective to remove diminutive polyps and send them for histology has not been evaluated.

Cold biopsy, cold snaring, hot forceps biopsy, and snare cautery are all acceptable approaches to diminutive polyps. Diminutive snares are almost as easy to use as forceps, [2] although flat 1- to 2-mm polyps can still reliably be grasped only with forceps. Snare cautery is the most reliable of the four methods for completely removing small polyps. Hot forceps are five times more likely to produce a complication in the right colon as in the left [9] (Fig. 149-11). Cold methods appear to be the safest. [4]

FIGURE 149-11. Hot biopsy forceps. **A:** Diminutive polyp. **B:** The forceps grasps the polyp (or even just the polyp tip), and the polyp is pulled way from the bowel wall as cautery is applied. Failure to “tent” the polyp by pulling it away from the wall may allow the burn to penetrate the wall deeply. **C:** Other errors with hot forceps include grasping too much tissue (i.e., including normal tissue) or tenting the polyp too much in one direction, which may cause the cautery burn to spread selectively down one side of the polyp.

Sessile Polyps

Sessile polyps larger than 5 mm are typically removed by snare cautery. Lesions smaller than 1.5 cm should be removed in a single piece if possible. Larger polyps may require removal in pieces. [132], [133] The snared polyp or portion of polyp is tented into the lumen to create an artificial stalk. In the right colon, lumenal deflation will thicken the wall before application of cautery.

Large sessile polyps that demonstrate surface irregularity or ulceration are usually malignant; biopsy should generally be performed to rule out cancer before attempting endoscopic resection. The rationale for biopsy is that sessile malignant lesions are a general indication for surgical resection. However, some experts consider endoscopic resection to be definitive therapy for sessile malignant polyps if they exhibit favorable histological criteria. [4] In this case, a sessile polyp with some malignant features could be resected endoscopically if it could be lifted on a submucosal saline mound, indicating that no submucosal fixation is present. In general, lesions covering more than one third of the colon circumference or having a longitudinal extent of more than two haustral folds should be considered for surgical resection as primary therapy. However, in the right colon and rectum where the lumenal diameter is relatively large, much larger sessile lesions may be amenable to endoscopic resection.

Submucosal saline injection should be considered for large or flat sessile polyps. Injection begins at the proximal edge or, for smaller polyps, is made directly into the polyp center. Only injection into the submucosa will raise a mound. Injection has not been associated with a risk for tumor seeding or peritonitis, although clearly, the needle may pass through the colon wall. During injection polypectomy, the snare may close over the saline mound without grasping tissue. This effect can be countered by barbed snares (Olympus Corp, Lake Success, NY) or needle-tipped snares (Wilson-Cook, Winston-Salem, NC) that hold the snare in place. Alternatively, a circumferential incision cut with electrocautery in the saline mound but outside the polyp forms a groove that seats the snare in position around the polyp. [134]

In some cases, sessile adenomas are so flat (so little elevated aspect) that the lesions are unsnarable even after submucosal injection. Potentially effective treatments in this instance include ablative therapy (see later) and EMRC. EMRC has the advantage of retrieving a histological specimen. In the colon, EMRC use is best confined to the thicker-walled left colon and rectum. EMRC is performed only after submucosal saline injection, and volumes of at least 30 to 40 mL are anecdotally important to reduce the risk for perforation associated with aspiration of deep wall layers into the cap. In our experience with an American population, EMRC is needed much less frequently in the colon than the stomach and especially toward the esophagus.

Visualization of the margin of very flat polyps can be facilitated by dye spraying with methylene blue, indigo carmine, or cresol violet, or by addition of small amounts of methylene blue to the saline before injection (see earlier). Sections that are flat and that cannot be removed by saline injection can be destroyed using Nd:YAG laser, BEC, or APC. The latter two techniques are preferred because they have a lower chance of perforation.

Endoscopic localization for possible subsequent surgery is not reliable unless the ileocecal valve is in view or the polyp is in the rectum or distal sigmoid. Between these sites, large polyps should be marked by tattooing with India ink.

If a sessile polyp is removed in piecemeal fashion and the fragments are too large to be retrieved by suctioning, retrieval can be facilitated by the Roth retrieval basket. This device consists of a net on a large snare, which is repeatedly opened and closed on the fragments until all are trapped in the net.

Histological criteria to assess the need for surgical resection are less clearly applicable to sessile malignant polyps. In a review of nine studies reporting the frequency of cancer at surgery or during follow-up after endoscopic resection of a sessile malignant adenoma, polyps with favorable histology had a 4.1% incidence of residual cancer, compared with 20.6% in polyps with unfavorable histology. [135] In another study, the incidence of metastasis from sessile malignant polyps was 15%. [136] Thus,

operative resection should be considered in any sessile malignant polyp because the risk for metastasis is several times that of pedunculated polyps with similar histological criteria.

Endoscopic resection of sessile polyps carries a risk for perforation, postpolypectomy syndrome, and immediate and delayed bleeding. Perforation should be managed operatively in most cases, particularly if it is recognized within the first few hours after resection. Perforations presenting later with well-localized peritoneal signs can sometimes be managed nonoperatively. [137] Postpolypectomy syndrome is the result of a serosal (transmural) burn without free perforation. Patients present with localized pain and tenderness, fever, and elevated white blood cell count, but no free air on abdominal radiographs. In some instances, a water-soluble contrast enema or CT scan may be necessary to rule out perforation. Treatment is bowel rest, antibiotics, and careful observation. Immediate bleeding is best managed by injection of epinephrine (1:10,000 in normal saline) into the polypectomy base or simply spraying the solution onto the polyp base. This can be followed by BEC or heater-probe treatment of the bleeding site. Monopolar cautery should not be reapplied. Most delayed bleeding stops spontaneously. If delayed bleeding remains active, repeat colonoscopy with epinephrine injection and bipolar cautery or heater probe treatment of the base is effective. [138] Application of metal clips is an inexpensive and effective alternative for both immediate and delayed bleeding from sessile polypectomy sites.

Recurrence rates of large sessile adenomas after endoscopic piecemeal polypectomy vary from 16.5% to 50%. [131], [139] Nearly one half of recurrences occur after one negative follow-up examination, and recurrences may develop more than 1 year after the initial resection. [139] It should be recalled that most current guidelines for postpolypectomy surveillance [140], [141] are derived primarily from the National Polyp Study. [142] However, sessile adenomas greater than or equal to 3 cm in size were excluded from the National Polyp Study, [142] and thus the conclusions derived from that study do not apply to these large polyps. Most recurrences can be successfully treated by additional endoscopic therapy. [139] Repeat examinations at 3- to 6-month intervals are indicated after piecemeal resection of large sessile adenomas. [139] After complete resection appears verified, another examination at 1 year is prudent. [139]

Several groups have reported experience with Nd:YAG laser ablation of large rectal polyps. [143], [144] and [145] A disadvantage is that tissue is obliterated and not available for histological evaluation, so that late presentation of metastatic cancer is possible. The overall success rate depends on the polyp size, with success rates as low as 56% for lesions occupying two thirds of the circumference, [145] and as many as 10 treatment sessions required. Complications include bleeding, rectal stenosis, and fever. Perforation is rare owing to the retroperitoneal location of much of the rectum. Snare cautery debridement before Nd:YAG laser therapy is superior to Nd:YAG therapy alone. [146], [147] Transanal or transsacral resection should also be considered, although recurrence rates of 6% to 42% and complications in 13% follow the transanal approach, and the transsacral approach is followed by fistula formation in up to 21% of patients. [148], [149] and [150]

PDT was reported to eradicate sessile villous adenomas in the rectosigmoid that had failed to respond to Nd:YAG laser. [151] PDT has been reported to debulk large sessile rectal adenomas before Nd:YAG therapy. [152] Debulking by snare excision, however, is the preferred approach. [146], [147]

When lesions compatible with flat adenomas or cancers are identified, mucosectomy is the preferred approach because it allows clarification that the submucosa is not fixed and gives an ideal histological specimen for ascertainment of tumor-free margins. [153], [154], [155] and [156]

Endoscopic Treatment of Colorectal Cancers

The treatment of choice for cure or palliation of colorectal cancer is surgical resection. Less than 5% of patients are not candidates for surgery because of widely metastatic disease, inability to tolerate surgery, or unwillingness to undergo surgery or ostomy. In these instances, management depends on local expertise. However, Nd:YAG laser, PDT, and placement of a colonic stent may all be considerations, depending on symptoms. The Nd:YAG laser is effective for relief of bleeding, obstruction, or both. [157], [158], [159], [160], [161], [162], [163] and [164] In rare instances in which surgery cannot be performed, Nd:YAG laser can be used to treat T1 or T2 lesions staged as N0, M0 with curative intent. [162], [163] and [164]

PDT was used for 21 patients with inoperable or recurrent colorectal cancer, and 16 had evidence of necrosis, 15 had increased lumenal diameter, and 10 had relief of obstructive symptoms. [165] However, the ease with which colonic stents can be placed and the need for repeated treatments with ablative therapies has made stent placement the treatment of choice for palliation of obstructing colorectal cancer.

EVALUATION OF GASTROINTESTINAL MOTILITY: METHODOLOGIC CONSIDERATIONS

Abnormalities of gastrointestinal (GI) motor function contribute directly or indirectly to a number of common clinical problems. Advances in monitoring techniques allow relatively noninvasive recording of GI motility under physiologic conditions. This chapter emphasizes the developments in the application of esophageal manometry, electrogastrography (EGG), gastroduodenal manometry, electronic barostat, and anorectal manometry to evaluate GI motility.

ESOPHAGEAL MANOMETRY AND 24-HOUR pH MONITORING

Esophageal manometry and 24-hour pH testing are accepted clinical and investigative tools for the study of esophageal dysfunction. [1],[2] These procedures are most frequently performed in evaluating patients with dysphagia who have no evidence of mechanical obstruction and in patients with suspected noncardiac chest pain or gastroesophageal reflux. Generalized motor disorders of the GI tract, such as scleroderma and chronic intestinal pseudoobstruction, can affect the esophagus. Confirmation of the diagnosis frequently can be made by esophageal manometry.

Technical Aspects of Esophageal Manometry

Equipment Esophageal motility testing requires intubation of the esophagus with a recording catheter, which is connected to a physiograph. The clinician must choose between two major systems of recording catheters available: water perfused or solid state. The standard system in most esophageal motility laboratories uses a water-perfused catheter system connected indirectly to a physiograph through a series of transducers. [3],[4] Pressure is recorded at predetermined recording orifices; the signal from each orifice is changed into electrical current at external transducers and retransformed into a pen deflection at the physiograph. The major advantages of this system are the initial comparatively low cost, rapid repair of malfunctioning external transducers, and extensive experience with the system. The major disadvantage of the water-perfused system is variability in recording accuracy when measuring transient high-pressure events such as upper esophageal sphincter (UES) pressure and pharyngeal UES coordination. This disadvantage can be overcome by using low-compliance microcapillary tubing and perfusing with a low-friction pneumohydraulic pump, which allows recording of all intraesophageal events at acceptable perfusion rates. [5] Other disadvantages are the constant need for recalibration and the possible need for a separate pH recording system. The second system is a solid-state recording catheter with multiple, small-diameter intralumenal transducers that directly interface with the physiograph. The major advantages of the solid-state system are ease of use, minimal need for calibration, accuracy of recording, and the capability of performing simultaneous motility and pH recordings. Major disadvantages of the intralumenal transducer system are the high initial cost and the potential downtime for the system if one or more transducers are damaged. The major cause of transducer breakdown is transducer membrane breakdown with acid exposure. Another disadvantage is the fixed nature of the transducer position; solid-state recorders can be made to order, albeit at greater expense. Both systems can measure intraesophageal events with acceptable precision. Recent technical advances permit continuous monitoring of lower esophageal sphincter (LES) pressure. This led to examination of the relationship between acid reflux and transient spontaneous relaxation of the LES. The systems described previously cannot adequately measure LES pressure or relaxation continuously because of movement of this sphincter during respiration. To circumvent this problem, Dent [6] developed a 6-cm sleeve catheter to straddle the LES throughout its entire range of motion. This device monitors the maximal pressure sensed at any point on the sleeve. Although manometric sleeve catheters are available commercially, they are used predominantly in the research laboratory. The choice of the physiograph to record pressure events is also important because this represents the major cost in any manometric system. The physiograph should satisfy the following requirements: at least four separate pressure-recording channels, including an extra channel for swallow sensor or event marker; variable paper speeds from 1 to 10 mm/second; full-scale recording for pressures between 0 and 400 mm Hg; and a recording channel for pH testing.

Recording Procedure Before attempting intubation, all of the necessary accessories must be on hand. Nasal topical anesthesia should be used: topical cocaine and viscous lidocaine are the most common agents used. Tissue paper, an emesis container, and a 30-mL water cup should be available. Reassuring the patient and explaining the procedure step by step are prerequisites to obtaining consistently good recordings. Short-term oral intubation studies using a manometric catheter passed through a mouthpiece can be used in place of nasal studies and may be more comfortable for the patient. [7]

Lower Esophageal Sphincter Measurements After GI intubation, all recording sites should be positioned in the stomach. This can be confirmed by observation of a positive deflection during abdominal breathing or compression. LES pressure usually is measured first. Two techniques are used. The first is the rapid pull-through technique. [8] The catheter is withdrawn at a rate of 1 cm/second while the patient suspends respiration until the distal three recording sites give LES pressure readings. The three distal sites are again placed in the stomach, and the cycle is repeated two more times. Mean and peak pressures are recorded from these nine measurements as that pressure above intragastric pressure. The second approach is the station pull-through technique. This method involves withdrawing the catheter in 0.5- to 1-cm increments and leaving it in each position for a few seconds. LES pressure and relaxation can be measured by this technique. Values from rapid pull-through LES pressure are usually 2 to 3 cm higher than those obtained with the station pull-through technique. [9] Relaxation of the LES requires that a distal recorder be stationed in the LES and a more proximal recording orifice be stationed in the lower esophagus to measure completeness of relaxation and coordination of relaxation with esophageal peristalsis. Relaxation should be complete, with a drop in intragastric pressure, and coordinated for more than 90% of wet swallows.

Esophageal Body Measurements After LES manometry is completed, all recording sites are withdrawn into the esophagus. The most distal recording site is placed 2 cm above the upper border of the LES. Because recording sites are separated by 5 cm and three sites are usually used, the distal 15 cm of the esophagus can be recorded. This segment represents the smooth muscle portion of the esophagus. Water is given with each swallow because esophageal body pressure is most reliably recorded after a bolus. [10] A total of 10 wet swallows is used to measure distal esophageal, or smooth muscle, body pressure. The striated muscle portion and the junction of the striated and the smooth muscles can be measured by sequentially withdrawing the catheter in 3-cm intervals and recording 5 wet swallows and again withdrawing the catheter 3 cm and repeating 5 wet swallows. Measurements of the esophageal body contractions include amplitude of contraction, duration of contraction, and percentage of abnormal contractions. Esophageal peristalsis is then observed. Simultaneous contractions (contractions in multiple segments at the

same time), spontaneous activity (pressure waves in the esophagus without swallowing), or repetitive contractions (three peaks) are considered abnormal. Failure of peristalsis increases somewhat with age but usually occurs in less than 15% of all wet swallows.

Upper Esophageal Sphincter Measurements UES pressure and ability to relax are measured. Techniques for the UES are the same as those for the LES. Recording speed may have to be increased from the usual 2.5 mm/second to 5 to 10 mm/second to record UES relaxation adequately. If a question of incomplete relaxation is present, different recording sites placed in the UES may demonstrate more complete relaxation. Because measurement of the UES may require withdrawing the catheter almost completely, only two recording orifices should be used to measure UES pressure, and more swallows should be performed to give a reliable pressure measurement. Continuous monitoring of the UES has been reported. [11] UES pressure values recorded with this technique tend to be lower than the values obtained with the method described previously. Special circumstances, such as a suspicion of striated muscle disorders of the upper esophagus (e.g., dermatomyositis), may require more attention to the proximal esophagus, but most of the clinician's time is spent recording from the distal esophageal segment. At the completion of the standard manometric examination, provocative tests, such as bethanechol, edrophonium, or balloon distention, can be performed to induce chest pain in patients sent for the evaluation of noncardiac chest pain. The mechanism by which provocative agents induce chest pain is unknown, and the use of provocative agents is experimental. [12]

Technical Aspects of pH Studies

Standard Tests After standard manometry is completed, pH studies are obtained. The first test is acid clearance. A 15-mL bolus of 0.1 normal hydrochloric acid is injected into the esophagus 5 cm above the LES. The patient is asked to dry-swallow every 30 seconds until the pH is restored to the baseline level. This requires at least 15 dry swallows. Poor acid clearance is seen predominantly in conditions that disrupt peristalsis (e.g., achalasia, diffuse esophageal spasm, and scleroderma) or in disorders affecting salivation (e.g., scleroderma and the sicca syndrome) because these conditions can disturb bolus movement or esophageal acid neutralization. The Bernstein examination allows the clinician to determine whether acid in the esophagus induces chest pain or discomfort. Infusions of 0.1 normal hydrochloric acid or saline should be given in a blinded manner by using a three-way stopcock connected to both reservoirs that are located behind the patient. Saline infused at a rate of 120 drops/minute for 5 minutes should be the initial perfusate. Acid infusions at the same rate should then be started, and saline should be stopped. Acid infusion should continue until symptoms begin or until 30 minutes have elapsed. If acid, but not saline, produces chest pain or heartburn, gastroesophageal reflux is likely. If both acid and saline or saline alone induces pain, the patient may have a hypersensitive esophagus. If neither produces pain, acid reflux is not the source of chest pain. Saline washout, to evaluate pain relief after acid-induced pain, is no longer considered essential to the diagnosis of acid-induced chest pain. Simultaneous recording of esophageal body pressures may show dysmotility as a mechanism for acid-induced chest pain. To determine whether gastroesophageal reflux is present, standard acid reflux testing is performed. The pH probe is placed 5 cm above the LES, and the patient is placed in the supine, right-sided, left-sided, and prone positions. In each of these positions, the patient is asked to perform the Valsalva maneuver and to move into the knee-chest position. Both maneuvers increase intra-abdominal pressure and increase the possibility of overcoming a weak sphincter. These maneuvers are repeated in the basal state and after loading the stomach with 300 mL of 0.1 normal (N) hydrochloric acid. Reflux of acid, seen as a decrease in pH to less than 4.0, in any position in the basal state, or in two positions after acid loading, is considered pathological reflux. [13] Sensitivity of this examination in patients with chronic reflux symptoms approaches 90%. After esophageal manometry and pH testing are completed, the patient should be observed for 30 minutes. Heartburn usually responds to antacids. More serious complications such as bleeding or perforation are extremely rare.

Ambulatory 24-Hour pH Testing, Esophageal Topographic Analysis, and Esophageal Impedance Recording Ambulatory outpatient evaluation under true-life conditions gives a better determination of whether acid in the esophagus is associated with symptoms. [14] Six monitoring systems are available in the United States. [15] All have demonstrated reasonable durability, and the life expectancy of each recording catheter is five to eight examinations. [15] Glass or antimony electrodes are frequently used. Reference electrodes must be attached to the patient with a conducting jelly for proper measurements. Newer recording catheters contain the reference electrode, eliminating the errors often seen with dislodgment of the reference electrode. The pH electrode is placed 5 cm above the upper border of the LES. Until recently, localization of the LES required manometric testing before pH recording. Using a standard electrode to measure the step-up in esophageal pH while the recording catheter crosses the LES allows placement accuracy of within 1 to 2 cm, when compared with positioning guided by manometry. This pH recording technique may be an acceptable alternative to standard manometric placement for 24-hour pH recording in patients who cannot tolerate esophageal manometrics or in an office practice in which manometric equipment is too costly for routine use. The ideal duration of recording has not been established. To differentiate patients with reflux from normal subjects, recording times of 12 and 24 hours have been more successful than shorter recording periods of only 3 hours postprandially. [16], [17] An ambulatory pH profile is best interpreted by calculating the total time that the pH is less than 4.0 and the number of episodes lasting longer than 5 minutes; this method yields the best positive-negative predictive value. [16], [18] Symptom correlation with pH decreases is also crucial in defining acid reflux as a cause for chest pain. [17] Correlation is rarely 100%, and multiple indexes have been used. Association of chest pain with pH less than 4.0 in 75% or more of painful episodes is considered strong evidence for acid-induced chest pain. Esophageal topographic analysis and esophageal impedance are two new technologies that have increased our understanding of esophageal and gastroesophageal reflux, respectively. [17], [19], [20] By using multiple, closely spaced, and circumferentially placed intralumenal sensors, esophageal topographic methods allow us to examine both the spatial and temporal relationships of esophageal peristalsis simultaneously. This technique allows the generation of three-dimensional maps of esophageal peristalsis beginning in the pharynx and ending in the gastric fundus (Fig. 150-1). Esophageal peristalsis has been demonstrated by topographic methods to be composed of four separate esophageal segments with demonstrable segmental abnormalities in motility and different responses to pharmacological interventions. [17] The research potential of topography is substantial, although application to clinical practice is unproven.

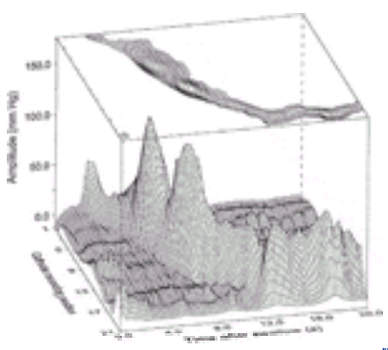

FIGURE 150-1. Three-dimensional topographic plots. The peristaltic wave proceeds from the upper through the lower esophageal sphincter shown in the foreground. Spatial distribution amplitude and duration are easily evaluated by multiple catheter recording sites separated by 1 cm over a 20-cm catheter length. The top of the figure has a contour plot to demonstrate three-dimensional amplitude data. Increasing amplitudes are represented by increasing concentric rings.

Concepts of gastroesophageal reflux and the antireflux barrier have been limited to measurement of acid and bile reflux and the measurement by manometry of common cavity phenomenon. [19], [20] Liquid reflux of gastric contents and gas reflux without change in pH could barely be detected. Using impedance measurement of bolus movement, gas or liquid reflux can be detected as a rise or drop in impedance, respectively. Initial studies have shown that reflux patients and controls do not differ in the total rate of reflux episodes but that acid reflux is higher in patients with reflux disease. Mixed reflux of both liquid and gas was seen in reflux patients and control subjects but pure liquid reflux and prolonged reflux were more common in reflux patients. One third of all reflux episodes are nonacidic. This technique will allow better definition of patterns of reflux in patients with esophagitis, patients with nonerosive reflux disease, and patients who fail proton pump inhibitor therapy despite good acid control. [20]

Indications, Contraindications, and Clinical Applications

Indications for esophageal manometry and pH monitoring are presented in Table 150-1. The primary indication is to evaluate esophageal dysfunction when anatomic causes (e.g., esophagitis, tumors, strictures, rings, webs, diverticula) are not present.

Indications for Esophageal Manometry
Patients with oropharyngeal dysphagia and normal anatomic studies
Cricopharyngeal achalasia (poor UES relaxation)
Pharyngeo–UES dyscoordination
Low-amplitude pharyngeal contractions
Early or later pharyngeal contraction
Early upper esophageal body contraction
Patients with esophageal dysphagia and normal anatomic studies
Primary esophageal body dysmotility
Achalasia
Diffuse esophageal spasm
Nutcracker esophagus
Hypertensive lower esophageal sphincter
Nonspecific esophageal dysmotility
Secondary esophageal body dysmotility
Collagen vascular diseases
Amyloidosis
Secondary achalasia
Chronic intestinal pseudoobstruction
Laser treatment for esophageal cancer
Sclerotherapy
Hypothyroidism
Patients with noncardiac chest pain
Primary esophageal body dysmotility
Indications for 24-hour pH Monitoring
Patients with noncardiac chest pain
Refractory acid reflux symptoms: evaluate treatment efficacy
Preoperative and postoperative evaluation for antireflux surgery
Patient with atypical presentations of acid reflux (ENT, pulmonary)

ENT, ear-nose-throat; UES, upper esophageal sphincter.

TABLE 150-1 Indications for Esophageal Manometry and 24-Hour pH Monitoring

Esophageal manometry is mandatory in patients with suspected achalasia, particularly in patients before pneumatic dilation or cardiomyotomy. Manometry has had less utility in patients with presumed diffuse esophageal spasm. Classic findings of esophageal spasm are not frequently seen in patients with esophageal chest pain.[10],[21],[22] Usually, esophageal manometry is performed to help exclude an esophageal source for chest pain. Motility disorders, other than diffuse esophageal spasm, that can cause chest pain and dysphagia include nutcracker esophagus and hypertensive LES. Although specific manometric criteria exist for each of these diagnoses, the physiologic basis for the symptoms in patients having these manometric findings remains to be elucidated. Position statements and a technical review for the clinical use of manometry have been published.[22]

Twenty-four-hour pH monitoring of the distal esophagus has helped to establish that excessive acid exposure is associated with chest pain. Young patients with no history of dysphagia or weight loss do not need pH testing to evaluate typical pyrosis or regurgitation. Twenty-four-hour pH testing is indicated in patients presenting with typical reflux symptoms who do not respond to treatment. Patients presenting with cervical dysphagia, cough, recurrent sore throat, or aspiration with a normal result from pulmonary and otorhinolaryngology evaluation also constitute a patient group in whom pH monitoring may define the cause for the symptoms.[22] Before antireflux surgery, all patients should undergo pH monitoring of the distal esophagus. This establishes the occurrence of acid reflux and whether the presence of acid in the distal esophagus is the source for symptoms because up to 10% of patients presenting for antireflux surgery do not have acid reflux.[23] In addition, this permits objective evaluation of the surgeon's ability to prevent acid reflux in the early and the late postoperative period. A technical review on the use of esophageal pH recording has been published recently.[23]

The use of esophageal function testing in patients with generalized GI motility disorders such as scleroderma and chronic intestinal pseudoobstruction is in its infancy. Testing should be confined to three groups of patients. The first group includes patients for whom the results of esophageal function testing will help the clinician in making a treatment decision. Although manometric findings are not highly specific for scleroderma, they are reasonably sensitive and occasionally can be helpful in supporting the diagnosis. Esophageal manometry and 24-hour pH monitoring also can be useful in evaluating patients in whom a therapeutic change will be forthcoming, depending on the findings. Examples include 24-hour pH monitoring in patients with scleroderma and recalcitrant esophagitis or patients with chronic idiopathic intestinal pseudoobstruction and dysphagia in whom pneumatic dilation is a treatment option. The last group includes patients in whom documentation of how the disease affects esophageal function may improve the physician's understanding of the mechanisms underlying symptoms and general knowledge of the disease process. These patients are the least likely to be candidates for monitoring and should be monitored only at established research motility laboratories.

Major contraindications for esophageal manometry are few and involve esophageal obstruction or large diverticula because of the risk for perforation. Barium study or endoscopy is prerequisite to manometric studies. The major reason for not performing esophageal manometry is if the information will not affect management. Esophageal manometry and pH testing are not required in all patients with typical reflux symptoms or noncardiac chest pain. A treatment course, coupled with careful exclusion of chest wall pain or panic attacks, should be attempted before manometry is performed. About 20% to 40% of patients referred with dysphagia or chest pain require manometric evaluations.[12]

GASTRODUODENAL MANOMETRY

Gastroduodenal manometry provides information regarding normal and abnormal contraction patterns in this region. The technique is helpful in diagnosing motility disturbances by localizing and characterizing abnormal motor patterns.

Gastroduodenal Motility in the Fasting and Fed States

Gastroduodenal manometry is used to assess the presence of interdigestive migratory motor complex (IMMC) activity in the fasting state and the occurrence of a typical fed pattern postprandially. In the fasting state, the stomach and small intestine demonstrate a cyclic, periodic contractile pattern referred to as the IMMC.[24] The IMMC is typically divided into four phases:

Phase 1: a period of quiescence
Phase 2: irregular motor activity
Phase 3: a brief period of regular contractions
Phase 4: a brief period of irregular activity, which is occasionally noticed before the quiescence of phase 1.

Figure 150-2A depicts examples of normal fasting intralumenal pressure patterns. Normal phase 2 activity is demonstrated, culminating in a phase 3 complex in the antrum and duodenum. Phase 3 contractions occur at a rate of 3 per minute in the antrum; they occur more rapidly, 11 to 12 per minute, in the duodenum. Occasionally, phase 3 activity begins in the proximal duodenum and not in the stomach, although this usually is preceded by strong antral phase 2 activity.

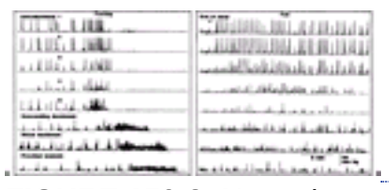

FIGURE 150-2. Normal gastrointestinal motility. **A:** Normal fasting interdigestive migrating motor complex (IMMC). Notice phase 2 activity in the antrum and duodenum culminating in phase 3 (IMMC) activity in the antrum, the pressure activity gradually propagating into the duodenum, and the gradual change in configuration of the waves while they move through the antroduodenal junction. **B:** Normal fed activity. Notice irregular but persistent phasic pressure activity in the distal antrum and proximal small bowel. (From ref. [36].)

After ingestion of nutrients, IMMC activity is inhibited and replaced by a fed pattern, the characteristics of which vary.[25] For example, liquid nutrients decrease the amplitude of contractions in the antrum and generate irregular motor activity in the small intestine, whereas ingestion of solid food produces high-amplitude contractions in the distal antrum and a motor pattern similar to that generated by liquid nutrients in the small intestine. Figure 150-2B shows the irregular but persistent phase 2 activity characteristically observed postprandially in the distal antrum and proximal small intestine. Repetitive pressure activity with an amplitude of more than 50 mm Hg is usually noticed in the antrum at a rate of 3 per minute, and persistent, irregular activity is noticed in the duodenum.

Technical Aspects

Gastroduodenal manometry requires upper GI intubation with a specially adapted polyvinyl catheter on which miniature pressure transducers are mounted; alternatively, manometric perfusion catheters are assembled together as a multilumen tube. The monitoring probe is guided into the proximal jejunum under fluoroscopic guidance. Manometric devices using miniature transducers or the pneumohydraulic perfusion system provide similar information on GI motor activity. Both techniques measure changes in intralumenal pressure, which is an indirect assessment of smooth muscle contractions. Occasionally, the recording probe must be positioned in the duodenum with an endoscope and manually advanced into the proximal jejunum.

Assessing gastroduodenal motility requires the capability to monitor pressure changes from 6 to 12 recording sites, including the antrum, pylorus, duodenum, and proximal jejunum. Manometric sites should be spaced 1 cm apart across the gastroduodenal junction and at 10-cm intervals in the small intestine. A commonly used arrangement involves positioning five closely spaced recording sites to monitor antral, pyloric, and proximal duodenal motility, whereas three sites are spaced more widely for assessment of distal duodenal and proximal jejunal motility. The manometric recording system includes a polygraph with sufficient channels to monitor each recording site. The pressure transducers must be calibrated at the beginning and end of each study. Recent studies suggest that 24-hour antroduodenal motility can be recorded reliably and reproducibly in the ambulatory setting using solid-state catheters. [26]

Indications and Contraindications

Mild to moderate GI symptoms are of limited value for predicting the outcome of manometric studies because patients with normal manometry results may report symptoms similar to those whose studies yield abnormal results. [27] The presence of GI symptoms and evidence of collagen-vascular, metabolic, urologic, neurologic, and psychiatric disorders increase the likelihood of abnormal manometric findings. [27] Gastroduodenal manometry is indicated in a patient with suggestive symptoms after mechanical obstruction has been ruled out with endoscopy or radiologic studies; appropriate consultations and workups have been performed to evaluate possible endocrine-metabolic, neurologic, and psychiatric disorders; and documentation of delayed gastric emptying or impaired small intestinal transit is available. Gastroduodenal manometry can be helpful in making the diagnosis of a motility disorder by demonstrating an abnormality in motor activity and localizing the involved region. In addition, the technique can be useful in monitoring the patient's course and response to therapy. These results rarely indicate the need for additional procedures, such as laparotomy, to rule out undetected anatomic abnormalities, or biopsy, to obtain a full-thickness intestinal specimen to rule out an infiltrative or degenerative process.

Contraindications to gastroduodenal manometry include anatomic abnormalities such as a diverticulum or fistula, respiratory diseases or a hypersensitive gag reflex that may lead to poor tolerance of the procedure, and prior GI surgeries, such as a Billroth II antrostomy, that can be difficult to evaluate because of manometric tube placement issues.

Data Interpretation

The typical recording session lasts about 5 hours. Three hours are devoted to recording motor activity in the fasted state, followed by ingestion of a standard meal and 2 hours of postprandial recording. Long-term (6 to 24 hours) records of small bowel motility, including evaluation during sleep, may enhance diagnostic accuracy. [28] The motility pattern normally observed during the fasting state, the IMMC, is often examined for the following: the mean cycle duration or period of time between phase 3 complexes; the duration of each phase and the amplitude and propagation velocity of phase 3 complexes in different regions of the stomach and small intestine; and the rate of contractions during phase 3 activity. [29], [30] Useful qualitative information is derived from inspection of the tracing to determine whether phase 3 activity is present; whether phase 3 activity originates from the gastric pacemaker or an ectopic site; whether the time intervals for the phases of the IMMC are appropriate; and whether the complex propagates in a normal (aboral) or abnormal (retrograde) manner.

The pressure activity pattern observed in the fed state is determined by the solid versus liquid composition of the meal and its nutrient content. Therefore, the meal must be standardized to exclude meal composition as a variable between studies. Usually, inhibition of IMMC activity occurs postprandially, replaced by phasic pressure waves in the antrum and irregular, phasic contractions in the small intestine. Pressure activity is often quantified in the form of a motility index, which reflects the amplitude and frequency of contractions for a defined period.

Interpretation of gastroduodenal manometric tracings is complicated by the intrinsic variability of the fasting and fed motor patterns. A number of IMMC parameters, including the duration of its constituent phases, the velocity of propagation of the phase 3 activity, and the duration of inhibition by food, demonstrate variability among patients as well as within the same individual when evaluated serially. [31], [32] A number of motor patterns, such as the presence of jejunal-clustered contractions, which have been proposed as a characteristic feature of the irritable bowel syndrome, apparently can be influenced by emotional and physical stress, including the anxiety associated with having the examination. [31], [33], [34] Abnormalities that have been reported in the fasting and fed motility patterns are summarized in Table 150-2.

Abnormalities Observed During the Fasting State
Bursts of phasic activity having an abnormal duration (>2 min), amplitude (>20 mm Hg), and frequency (10-12/min), which are nonpropagating and distinct from phase 3 activity
Sustained (>30 min) poorly coordinated phasic activity, isolated to one or more segments of the intestine
Low-amplitude contractions but otherwise normal
Absent, incomplete, or retrograde propagation of phase 3 complexes covering a distance of at least 30 cm
Prolonged (>3 min) increase in basal tone (>30 mm Hg) during phase 3 activity
Abnormalities Observed During the Fed State
Persistence of a fasting-like pattern after ingestion of a meal
Low-amplitude pressure waves in the antrum and small intestine
Bursts of phasic contractions that fail to propagate
Premature return of IMMC activity within 90 min after ingestion
Broad-based contractions occurring in the presence of increased tone, sometimes termed *minute clusters*

IMMC, interdigestive migratory motor complex.
Adapted from ref. [8].

TABLE 150-2 Abnormalities Reported in the Fasting and Fed Motility Patterns on Gastroduodenal Manometry

Clinical Situations that Affect Gastroduodenal Motility

GI manometry can be useful to distinguish motility patterns that are typically observed with intestinal myopathy versus enteric or extrinsic neuropathy. Diseases associated with an intestinal myopathy often demonstrate normal motor patterns but with abnormally low pressures. In contrast, diseases that affect the enteric or extrinsic neural pathways can demonstrate abnormalities in the configuration and propagation of the IMMC or failure to convert from the fasting to fed motor pattern postprandially.

Manometry often reveals a localized region of infrequent, weak contractions, particularly in the postprandial state in the presence of a relatively normal fasting motility pattern (Fig. 150-3). This pattern can be contrasted with the patient who also presents with a pseudoobstruction-like picture but whose disease affects the intrinsic or extrinsic neural pathways that regulate GI motility. [35] In this situation, abnormalities of fasting and postcibal motility are observed. In the fasting state, abnormalities in the configuration and propagation of phase 3 complexes are seen (Fig. 150-4).

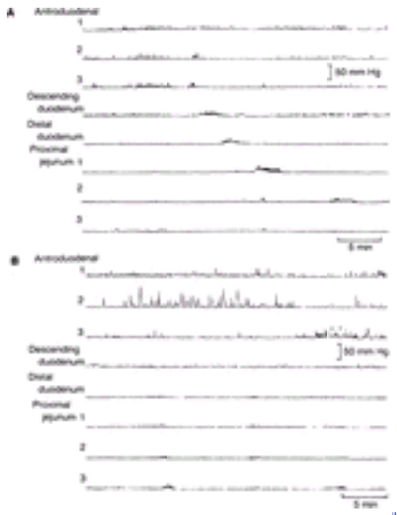

FIGURE 150-3. Myogenic chronic intestinal pseudoobstruction in a 71-year-old man with recurrent episodes of vomiting, abdominal pain, and constipation for 1 year. Radiologic examination revealed markedly dilated intestinal loops without mechanical obstruction. Full-thickness specimens taken from the terminal ileum and sigmoid colon at exploratory laparotomy showed smooth muscle degeneration with replacement of muscle fibers by fibrous tissue. **A:** Fasting tracing shows low-amplitude but normal propagation of migrating motor complex and virtual absence of activity in the most distal jejunal port. **B:** In the fed phase, antropyloric activity is mostly preserved, with waves of normal amplitude and frequency. In contrast, there is virtual absence of phasic pressure activity in the intestine. (From ref. [36].)

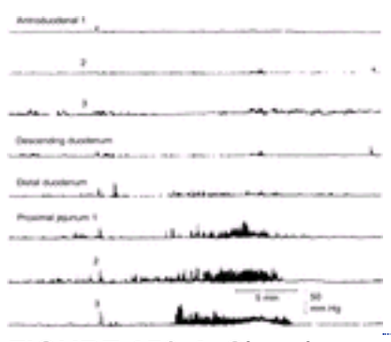

FIGURE 150-4. Chronic sensory and autonomic neuropathy with gut dysmotility in a 34-year-old woman with weakness in the extremities, speech impairment, and dysphasia for 10 years. At the time of study, she had episodes of diarrhea, abdominal pain, and labile blood pressure with hypertensive crises followed by hypotension. There was evidence of autonomic dysfunction with sympathetic and parasympathetic involvement, and a peripheral sensory neuropathy involved upper and lower extremities. Fasting tracing reveals simultaneous bursts of phase 3–like activity in the proximal small bowel. (From ref. [36].)

Gastroduodenal manometry is typically performed on patients who present with evidence of gastroparesis. During the fasting state, phase 3 activity may be absent in the antrum, but the most common abnormality is postcibal antral hypomotility: antral phasic pressure waves occur less frequently and with less force (i.e., decreased amplitude). This motility disorder often is associated with delayed gastric emptying of solid food. [36], [37] Antral hypomotility is observed in a wide range of clinical situations: diabetes mellitus, generally type 1 with evidence of autonomic neuropathy [38], [39]; use of adrenergic and dopaminergic agents [40], [41] or cholinergic agonists [42]; occasionally after surgical procedures, including fundoplication, [43] vagotomy alone or with pyloroplasty, [44], [45] and cardiomyotomy for achalasia [46]; and idiopathic gastroparesis. [47], [48]

Localized, uncoordinated bursts of tonic and phasic activities can occur in the small intestine that blur the distinction between fasting and fed motility patterns. Diseases that can present in this manner include early scleroderma [49], [50]; diabetes mellitus [38], [39]; amyloidosis [51], [52]; visceral autonomic neuropathies and degenerative conditions involving the autonomic system, such as idiopathic orthostatic hypotension, Shy-Drager syndrome, and pandysautonomias [53], [54]; chronic idiopathic constipation, that is, colonic inertia [55]; lesions involving the central nervous system, especially the brain stem [56], [57]; and neurodegenerative disorders involving the spinal cord, such as syringomyelia. [58] Patients with intestinal dysmotility may have normal gastric manometric patterns but demonstrate delayed gastric emptying, supporting the view that these two tests can be complementary.

After partial gastrectomy and gastroenteric anastomosis, occasional patients experience a profound motility disturbance involving fasting and fed activities. [59] Although no pathognomonic findings are seen on manometry, typically localized areas of intense activity alternate with regions of quiescence. In patients treated for postoperative gastric stasis with the Roux-en-Y procedure, the Roux limb may contribute to delayed emptying in some, perhaps because of loss of electrical synchrony in the implanted jejunal efferent limb. [60] In addition, patients with postcholecystectomy sphincter of Oddi dysfunction can demonstrate abnormalities in phases 2 and 3 of the IMMC. [61]

Patients with radiation enteritis can exhibit abnormal gastroduodenal manometric findings, especially localized, poorly coordinated, either high- or low-amplitude pressure activity. Antral hypomotility can be observed and, in the presence of uncoordinated small intestinal activity, may be associated with intractable vomiting. [62], [63] A number of infectious processes can present with pseudoobstruction-like symptoms and signs thought to be due in part to disturbances of motility. These disorders may affect intrinsic or autonomic neural pathways and include infectious mononucleosis, [64] herpes varicella-zoster virus, [65] botulism B, [66] secondary bacterial overgrowth in the small intestine, [67] and Guillain-Barré syndrome. [68]

Malignancies involving the posterior abdominal wall may interfere with the autonomic neural pathways to the GI tract, producing a chronic ileus. Extra-abdominal malignancies such as oat cell carcinoma of the lung can be associated with a paraneoplastic syndrome, which produces a clinical and manometric picture consistent with intestinal pseudoobstruction. [69], [70]

Metabolic abnormalities associated with disturbances of motility include hyperthyroidism and hypothyroidism and hyperparathyroidism and hypoparathyroidism. Some reports suggest that rapid gastric emptying and rapid intestinal transit occur in hyperthyroidism. [71], [72] Patients with hypothyroidism are at risk for pseudoobstruction, paralytic ileus, and megacolon. [73], [74] Patients afflicted with hyperparathyroidism frequently report symptoms of abdominal pain, nausea, vomiting, gastroesophageal reflux, and constipation possibly related to defective neurotransmission. [75], [76] Hypoparathyroidism can be associated with intestinal pseudoobstruction and regional areas of tetany. [77] Patients with malnutrition and anorexia nervosa frequently have delayed gastric emptying, especially of solid meals. [78] The etiology of the disorder is not known, but disturbances of autonomic function have been reported. [79] Patients who have experienced hypoxia and reperfusion can demonstrate abnormal motility patterns. [80] When evaluating patients with suspected colonic inertia, it is important to consider the possibility of a more generalized panenteric motility disorder. [81] Clinical situations associated with abnormalities of GI manometry are summarized in Table 150-3.

Disorders Presenting with Symptoms and Signs of Gastroparesis and Absent Phase 3 Activity or Postcibal Antral Hypomotility on Manometry
Diabetes mellitus, type I with autonomic neuropathy
Drugs: adrenergic agonists, cholinergic antagonists, and opiate agonists
Postoperatively: fundoplication, vagotomy ± pyloroplasty, and cardiomyotomy for achalasia
Idiopathic
Disturbances of Intestinal Motility Presenting Clinically as Chronic Intestinal Pseudoobstruction
Manometry reveals localized region of infrequent, weak contractions, particularly in the postcibal state in the presence of relatively normal fasting motility pattern
Myotonic dystrophia
Late progressive systemic sclerosis
Manometry reveals abnormalities in both fasting and postcibal motility; in the fasting state, abnormalities in the configuration and propagation of phase 3 complexes are observed, whereas in the small intestine, localized, poorly coordinated bursts of tonic and phasic activities are seen
Early scleroderma
Diabetes mellitus
Amyloidosis
Visceral autonomic neuropathies, degenerative conditions involving the autonomic nervous system, and lesions involving the central nervous system

TABLE 150-3 Clinical Situations Associated with Abnormalities on Gastroduodenal Manometry

ELECTROGASTROGRAPHY

Electrophysiologic Basis of Gastric Motility

Electrogastrography (EGG) measures gastric electrical activity noninvasively. The development of a gastric contraction requires that electrical events occur at the membrane of smooth muscle cells. The electrophysiologic properties of gastric smooth muscle cells vary, depending on the region of the stomach. Myoelectrical activity in the proximal one third of the stomach is characterized by a steady, nonfluctuating transmembrane potential associated with slow contractions occurring every 1 to 3 minutes. The electrical changes observed in this region are small in magnitude and usually not seen during EGG. The distal two thirds of the stomach and small intestine demonstrate slow, phasic changes in membrane potential. This cyclic change in electrical potential has been called by various names, including basal electrical rhythm (BER), slow waves, pacesetter potential, and control potential.

The BER appears to originate from the longitudinal muscle layer or nonneural boundary cells between the longitudinal and circular layers. [82], [83] An important feature of the BER is that it represents cyclic depolarization of the smooth muscle cells in the absence of associated peristaltic contractions. Rapid depolarization of the smooth muscle membrane is necessary for a contraction to occur. This event is referred to as an action potential or *electrical response activity* (ERA). Peristaltic contractions in the gastric body and proximal antrum are associated with an increase in the amplitude and duration of the depolarization plateau above the threshold for smooth muscle contraction. In the distal antrum and small intestine, contractions are associated with electrical spikes or action potentials superimposed on the depolarization plateau.

The maximal frequency that GI smooth muscle can contract is established by the frequency of the BER in that region. In the stomach, the frequency of the BER is established by a pacemaker site located in the proximal body along the greater curvature. [84] In humans, the BER propagates longitudinally and circumferentially from this site at a frequency of about 3 cycles per minute. In the duodenum, the frequency increases to 11 to 12 cycles per minute, which is established by a different pacemaker. Passage of the BER between the stomach and duodenum is prevented by the pylorus, which acts as a functional barrier. Propagation of the BER occurs myogenically by way of gap junctions between adjacent smooth muscle cells. Occurrence of peristaltic contractions is influenced by several factors, including the presence of a fed or fasted state, the neurotransmitter and hormonal milieu, and, most likely, the presence of local regulatory, or paracrine, substances. The presence of these regulatory substances appears to influence the sensitivity of smooth muscle cells to contract by decreasing or increasing the occurrence of plateau potentials. The force of contraction is determined by the amplitude and duration of the plateau potential.

Technical Aspects

Serosal, mucosal, and cutaneous EGGs have been used to record electrical activity of the stomach. This chapter emphasizes cutaneous EGG because it is noninvasive. Serosal recordings require a laparotomy for surgical placement of the recording electrodes. Mucosal recordings require intubation and attachment of the recording electrode to the gastric lining by suction or by using magnetic force to hold the electrode in position. [85], [86] Mucosal recordings reflect the true extracellular gastric electrical activity better than cutaneous recordings and appear to be less susceptible to interference from extragastric electrical signals from duodenal, colonic, cardiac, and respiratory sources. [83] Proper positioning of the recording electrodes is confirmed fluoroscopically. Optimally, at least three internal electrodes should be used, which permits assessment of the direction of electrical propagation: antegrade versus retrograde conduction. Respiratory movements are recorded concurrently with a pneumobelt transducer.

Cutaneous recording requires the placement of electrodes across the anterior abdominal wall, along the antral axis, which represents the imaginary line along the proximal to distal portion of the stomach. Monopolar recording devices (those with one active and one ground electrode) and bipolar recording devices (those with two active and one ground electrode) have been used. The quality of recordings obtained with the bipolar configuration appears to be better because of the advantageous signal-to-noise ratio it provides. [85] The electrical activity detected by the electrodes reflects potential differences over large areas of the stomach and, therefore, the summation of electric potentials generated by many gastric smooth muscle cells. [87] The signal represents the BER in the noncontracting stomach and the ERA in the contracting stomach. It correlates well with the frequency but not the amplitude of serosal recordings.

The signals monitored during cutaneous EGG usually require filtering to decrease undesired signals from other sites, such as the duodenum, colon, heart, or lungs. [88], [89] However, filtering can result in the loss of useful data. In addition, cutaneous monitoring may increase the likelihood of missing focal gastric electrical disturbances because they are hidden by the signal from the normally depolarizing gastric smooth muscle cells.

The normal gastric electrical signal in humans occurs at a frequency of about 3 to 4 cycles per minute. This is equivalent to 0.05 Hz. The typical EGG filter partially eliminates signals having frequencies of more than 0.2 Hz (12 cycles per minute) and less than 0.03 Hz (1.8 cycles per minute). In addition to filtering, the EGG signal is amplified and recorded along with other signals, such as manometric data, on a polygraph. [90], [91] Contemporary recording systems include an analog-to-digital converter, which allows electronic storage of data.

Mucosal and cutaneous recordings can be analyzed visually for information regarding frequency, amplitude, and configuration of waveforms. However, computer-based analytic techniques have become the norm because they analyze large amounts of data and generate useful information from recordings unsuitable for visual interpretation. Most methods used to analyze EGG signals employ some form of spectral analysis incorporating one of several available mathematical models such as the fast Fourier transformation, which transforms the signal from the time domain to a frequency spectrum. [92], [93]

A power spectrum of the recorded signals is then obtained (Fig. 150-5). The fundamental frequency, 3 cycles per minute or 0.05 Hz in humans, is represented with greater power because this frequency contributes a greater portion of the recorded signal frequencies. Other electrical frequencies originating from the duodenal, colonic, respiratory, or cardiac sources may be represented, but at a lower power. One drawback is loss of the ability to determine when specific events occurred during the recording period. For example, it is typically necessary to record data for several minutes to compute the transform, which generates the frequencies present during the recording interval and, therefore, hinders correlation of the EGG data with manometric data and the patient's symptoms. This limitation has been partially alleviated by the development of running spectral analysis. [94] Using this approach, the power spectra of brief overlapping stretches of the EGG signal are computed and presented as a function of time. Although easy to perform, this approach is susceptible to problems associated with inaccurate or erratic spectral estimates because of the recording time required to generate an accurate fast Fourier transformation. Dysrhythmias of brief duration will not be detected reliably using this approach. This issue is addressed in part by adaptive spectral analysis that improves the detection of short-duration dysrhythmias using adaptive autoregressive moving-average modeling. [95] Thus, the reduction of artifact in the EGG signal is an ongoing technical challenge. Discussion of these issues and recommendations regarding possible corrective measures have been published. [96], [97]

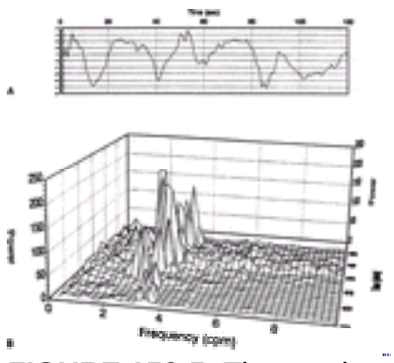

FIGURE 150-5. The results of an electrogastrographic study of a healthy volunteer. **A:** The raw slow-wave signal after ingestion of a 500-kcal mixed solid-liquid meal. The signal appears as a regular sinusoidal wave with a period of about 20 seconds. The raw signal can be analyzed by power spectral analysis to determine the dominant slow-wave frequency at any given time during the recording. **B:** The pseudo–three-dimensional plot from the power spectral analysis. With fasting, the slow wave was regular at 3 cpm, but of low intensity. With meal ingestion, at 15 minutes, there was a transient decrease in slow-wave frequency and a prolonged increase in signal amplitude at 3 cpm. (Courtesy of William L. Hasler, M.D., Ann Arbor, MI.)

Indications and Contraindications

The indication for performing EGG is similar to that for gastroduodenal manometry, namely, a patient who presents with a history of unexplained nausea, vomiting, and evidence of impaired gastric emptying. EGG is usually performed after documentation of abnormal gastric emptying or in conjunction with gastroduodenal manometry. EGG complements gastroduodenal manometry and gastric emptying studies by providing additional information that may reveal the basis for disturbed gastric motility.

Interpreting the Electrogastrogram

The normal gastric electrical signal is established by the gastric pacemaker at a frequency of 3-4 cycles per minute. The characteristic shape of the electrical waveform detected during EGG varies, depending on the location of the electrode: internal (mucosal or serosal) versus external (cutaneous) electrogastrogram. Abnormalities include both increased rates (tachygastria) and decreased rates (bradygastria) of electrical pacemaker activity. Tachygastria, defined as more than 4 cycles per minute, and bradygastria, defined as less than 2 cycles per minute, should be present for at least 1 minute. [98] Other electrical abnormalities include the presence of a dysrhythmia associated with an irregular resting membrane potential and abnormal wave configuration and a mixed or so-called tachybradyarrhythmia. [98] Tachygastria frequently develops at an ectopic site in the distal antrum and propagates in a retrograde manner. [99] Gastric contractions are often absent in the presence of tachygastria because of deformed BER, resulting in the failure of the plateau potential to reach threshold potential. [91], [100] In contrast, bradygastria arises in the corpus and antrum and propagates aborally. [101]

Clinical Situations that Affect the Electrogastrogram

The amplitude of slow-wave activity detected by cutaneous EGG increases during gastric contractions in the fasting and fed states. The EGG amplitude, but not the frequency, correlates significantly with gastric emptying. [102] Tachygastria and other dysrhythmias have been reported in unexplained nausea, bloating, and vomiting [99], [103] (Fig. 150-6); symptomatic ulcer [104]; nonulcer dyspepsia and delayed gastric emptying in children [105]; nausea during pregnancy [106] (Fig. 150-7); diabetes with chronic nausea, vomiting, and delayed gastric emptying in the fasting state [93]; chronic renal failure [107]; chronic intestinal pseudoobstruction [108]; Parkinson's disease [109]; systemic sclerosis [110]; and end-stage liver disease [111] and in normal subjects in whom motion sickness is induced experimentally. [112], [113] It is noteworthy that the EGG correlated poorly with nuclear scintigraphic gastric emptying studies in children with symptoms suggestive of gastric motility disorders. [114]

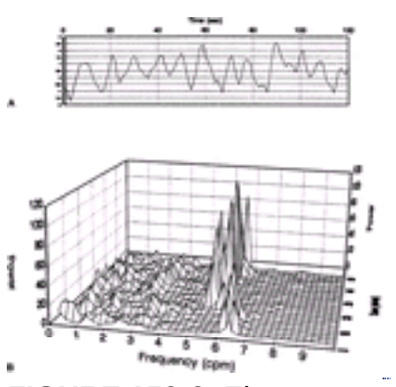

FIGURE 150-6. Electrogastrography (EGG) was used to evaluate a 28-year-old woman with persistent nausea, bloating, and fullness who had previously undergone a solid-phase gastric emptying scan, which yielded normal results. **A:** A low-amplitude raw EGG signal after ingestion of a 250-kcal liquid meal with a period of about 10 seconds. The raw EGG signal was evaluated with power spectral analysis. **B:** The pseudo–three-dimensional plot demonstrates the presence of a dominant slow-wave frequency that is higher (5 to 6 cpm) than in the healthy volunteer (see Fig. 150-5). This patient showed evidence of tachygastria, which was associated with antral hypomotility on a simultaneously performed manometric study. (Courtesy of William L. Hasler, M.D., Ann Arbor, MI.)

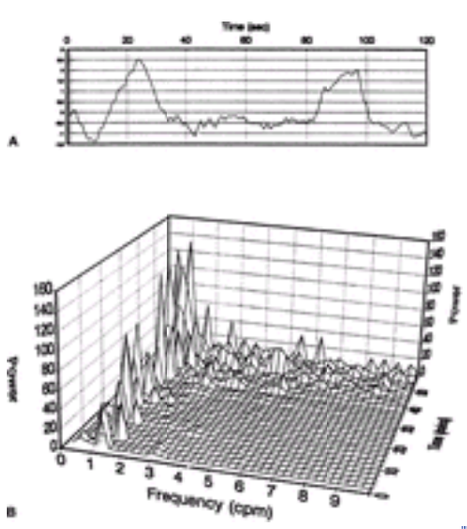

FIGURE 150-7. Women with nausea in the first trimester of pregnancy can exhibit marked slow-wave disturbances. Electrogastrography was performed on a 22-year-old woman in the 11th week of pregnancy. **A:** Large but infrequent slow waves are seen on the raw tracing. **B:** Pseudo–three-dimensional plotting of the power spectral analysis demonstrates that the bulk of the slow-wave signal is in the frequency range from 0.75 to 2 cpm. This pregnant patient exhibited bradygastria in association with her first-trimester nausea. (Courtesy of William L. Hasler, M.D., Ann Arbor, MI.)

In summary, EGG can be a useful diagnostic tool in the evaluation of patients with unexplained nausea, vomiting, and delayed gastric emptying. The EGG should be considered in individuals with delayed gastric emptying after metabolic and structural abnormalities have been ruled out. EGG can provide information regarding whether a gastric dysrhythmia presenting in the form of tachygastria, bradygastria, or a combined tachybradyarrhythmia is the cause of the motility disturbance. This information is not readily derived from manometry. The technique also may prove to be useful for following a patient's course and response to therapy. Technical advances will allow routine 24-hour ambulatory EGG in the future. [115]

ELECTRONIC BAROSTAT AND ITS APPLICATION IN EVALUATING GASTROINTESTINAL SENSORY AND MOTOR FUNCTION

Technical Aspects

The barostat is a research tool used by investigators interested in identifying the pathways underlying the physiology and pathophysiology of GI neuromuscular function. It has been used extensively to evaluate tone in the digestive tract and visceral sensitivity. The objective of barostat studies is to isolate a segment of the gut without interfering with its function and to follow the movements of the wall. [116] The barostat was designed to maintain constant pressure within an air-filled bag positioned in the lumen of the target organ. The barostat aspirates air to maintain a constant intrabag pressure during contraction and injects air during relaxation. The volume of air entering or leaving the bag is an indirect measurement of changes in the tone of the organ. Circumferential wall tension is defined by the Laplace law as the radius of the distended viscus multiplied by the transmural pressure. The transmural pressure is the difference between pressure within the distending bag and the pressure in the chest or abdomen outside the viscus.

The probe consists of a bag or a balloon connected by a catheter to the barostat. Latex balloons have been used widely and are characterized by a rapid increase in internal pressure for small-volume changes. When the pressure increases above the elastance threshold, the balloon becomes plastic and may accommodate large volumes with little increase in pressure. By contrast, polyethylene bags display an infinite compliance at low pressure or volume ranges, so that they may accommodate large volumes without an increase in pressure until the volume of air injected into the bag is equal to the volume of the bag itself. Further increases in volume will be associated with a rapid increase in internal pressure.

In distention studies, the function of the probe is to apply pressure on the wall of the gut in such a way that the pressure stimulus is equally distributed around the circumference of the organ over the whole segment to be distended. The probe should not interfere with the measurement of volumes needed to reach a given pressure. Many investigators use a bag instead of a balloon. The primary advantage of a latex balloon is its compact size, making it is easier to pass through the mouth or anus. The subject's position is important because the weight of adipose tissue overlying the organ and the tone of the abdominal wall directly influence barostat recordings. [117]

Investigators agree on some elements in distention study design: First, measurements of balloon pressure are less susceptible to intersubject and interlaboratory variability than measurements of balloon volume because the pressure scale compensates for differences in bag shape, smooth muscle compliance, and contractile activity. Second, both the pressure and volume that produce a sensation should be used to define sensory thresholds. Finally, the threshold for sensation tends to be higher when using a rapid inflation protocol compared with slow inflation. Additional information regarding distention protocols is available in a comprehensive review. [118]

When designing protocols to evaluate sensory thresholds, the investigator should be aware of the distinction between perceptual sensitivity and response bias. *Perceptual sensitivity* refers to the ability to detect distention, whereas *response bias* refers to the subjective aspects of reporting behavior—for example, the intensity of pain. Most protocols are designed to minimize response bias. Within practical limits, multiple distentions at each pressure or volume yield more reliable estimates of perceptual sensitivity.

Subjects should be asked to rate the intensity and unpleasantness of the sensations produced by distention separately and on scales, rather than simply indicating the presence or absence of the sensation because the latter is less sensitive. The rating scale should be an equal-interval or ratio scale, although many investigators use ordinal scales or visual analog scales. [119], [120]

Before barostat study, the investigator should be aware of potential anatomic abnormalities in subjects, such as diverticulosis or prior surgical procedures, that could complicate intubation. Patients who are gravely ill or experiencing persistent nausea, vomiting, or diarrhea are not likely to tolerate the technique.

Clinical Applications and Caveats

The electronic barostat has been used to measure changes in visceral tone in several regions of the GI tract. The technique has proved useful in several areas: (1) assessing sensory thresholds and reflex behavior in the GI tract, [121], [122] and [123] (2) establishing the role of altered visceral perception in functional bowel disorders, [124], [125], [126] and [127] and, (3) evaluating new therapeutic modalities. [128], [129] and [130]

When designing a protocol, the investigator should always be conscious of the likelihood of intraindividual and interindividual variability. Some authorities believe that phasic distentions are reproducible when repeated twice on the same day or even at 2-week intervals. [131] Others suggest that significant variation exists between results obtained in the same subject on different days. [128] These different opinions have resulted in the recommendation to include a baseline distention test before each attempt to evaluate the response to a therapeutic intervention or placebo. This allows the investigator to compare the response to distention during the therapeutic intervention (e.g., active drug or placebo) with the baseline distention performed on the same day. The differences between intervention and baseline distentions can be compared across sessions. Interindividual variability in sensory thresholds accounts for most of the large overlap between healthy controls and patients with functional bowel disorders when evaluating sensory thresholds.

The barostat also has been used to study gut reflex behavior, such as the gastrocolonic reflex and peristaltic reflex. [108] The ability of the barostat to record both increases and decreases in visceral tone reliably lends itself to the examination of the peristaltic reflex (e.g., ascending contraction and descending relaxation).

ANORECTAL MANOMETRY

Anorectal manometry is used in the clinical assessment of patients in whom a problem with defecation is suspected. The technique is particularly helpful in evaluating the most distal components of the anorectal sphincter mechanism: the internal and external sphincter muscles and the neural regulation of these muscles. [132], [133] and [134]

Technical Aspects

Direct pressure-sensitive microtransducers and perfused probes have been used to record anal sphincter pressure. The former eliminates the need for a fluid perfusion system by positioning the sensor device at the point at which pressure is to be monitored. Potential drawbacks include the relatively high cost and susceptibility of the solid-state microtransducer system to malfunction. The latter approach relies on the perfusion of a noncompressible fluid, such as water, at a constant rate through low-compliance catheters. Change in pressure is monitored as change in the resistance to flow that the sphincter offers to the constant flow.

Several technical issues must be kept in mind when performing anorectal manometry, particularly with the perfused catheter system. These include the potential for inducing recording artifacts because of probe rigidity, probe diameter, and the infusion rate. For example, a rigid probe is easier to position but can deform the anal canal and thereby produce an artifact. The diameter of the probe introduces some distortion of the anal canal by its very placement; therefore, it is advisable to use the smallest probe diameter (4 to 8 mm) that allows adequate contact with the opposing surfaces of the canal. From a practical standpoint, this is not an important issue unless dealing with a patient who has a markedly patulous sphincter. In this situation, it may be necessary to use a larger-diameter probe of 10 to 20 mm. Infusion rates usually are 0.3 to 1 mL/minute per channel. During a routine study taking 15 to 45 minutes, considerable fluid accumulation can occur within the rectum when using a multilumen probe with 3 to 12 channels per probe. This can alter the reproducibility of the results during the recording period.

The pressure profile of the anal sphincter is obtained using a station pull-out or continuous pull-out technique. The station pull-out approach involves positioning the probe several centimeters above the anal verge and measuring the pressure at various intervals, usually 1 cm, while removing the probe. Because moving the probe

induces changes in sphincter pressure, a stabilization period of 30 seconds is observed before recording the pressure at each interval. The advantage of this approach is the accuracy of the pressure recordings at each interval. This is potentially offset by the absence of the entire pressure profile, and failure to identify accurately the point of maximal squeeze pressure. With the continuous pull-out technique, the probe is positioned above the canal and subsequently pulled through the sphincter at a constant rate, producing a continuous pressure profile along the longitudinal axis of the anal canal. To help avoid recording artifacts, a mechanical pulling device must be used to ensure consistency and reproducibility. The probe should be rendered as frictionless as possible with the liberal use of lubricant.

An important modification of these recording techniques involves positioning and distention of a balloon within the rectum to examine the rectal-anal inhibitory reflex.[108] This is often referred to as *balloon reflex manometry*. Distention of the rectum by stool, or artificially with a balloon, should evoke relaxation of the internal anal sphincter. The balloon catheter assembly is positioned 10 to 15 cm above the anal verge and distended to a volume greater than 60 mL to initiate the inhibitory reflex. Either two small balloons or the perfused catheter system are positioned in the anal canal to monitor the internal and external sphincter response to distention of the rectal balloon. Relaxation should be observed only at the level of the internal sphincter. A typical perfusion apparatus used to perform balloon reflex manometry is shown in Figure 150-8. Normal proximal sphincter response to increased rectal pressure during balloon distention is depicted in Figure 150-9.

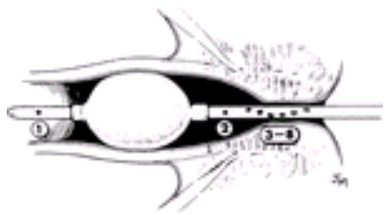

FIGURE 150-8. Perfused multilumen probe for balloon reflex manometric study. The balloon, positioned 10 to 15 cm above the anal verge, is capable of distending through at least 60 mL. Orifices 1 and 2 record intralumenal rectal pressure. Orifices 3 through 8 are located within the sphincter at 0.5-cm intervals. (From Coller JA. Clinical application of anorectal manometry. Gastroenterol Clin North Am 1987;16:27.)

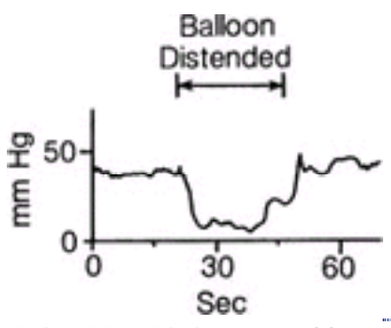

FIGURE 150-9. Normal internal anal sphincter relaxation response to balloon distention in the rectum. The balloon was located 15 cm above the anal verge and distended to 60 mL for the time shown. (Courtesy of Jeffrey L. Barnett, M.D., Ann Arbor, MI.)

Indications and Contraindications

Most patients complain of constipation or incontinence. A number of problems can be assessed adequately on the basis of clinical history, physical examination, and routine laboratory tests. Examples include irritable bowel syndrome, maldigestion, and thyroid dysfunction. A specific example involving the anal sphincter mechanism in which anorectal manometry would not be indicated is the presence of an acute anal fissure. This condition is associated with a deviation from the normal mean resting anal sphincter pressure,[135] but performance of manometry would not contribute any useful information beyond that obtained from the physical examination. Use of the examiner's finger as a pressure probe is highly inaccurate compared with objective measurements of sphincter function.[136]

When constipation is associated with the perception of increased pelvic or rectal pressure, incomplete evacuation, or difficulty initiating defecation, there is an increased likelihood that anorectal manometry may be a useful diagnostic aid. On the other hand, if resting sphincter tone appears normal or elevated in the presence of incontinence, balloon reflex manometry is indicated to evaluate the possibility of decreased threshold or increased sensitivity to rectal distention.

Data Interpretation

Manometric studies of the anal canal are typically plotted on an X-Y recorder, which presents a visual comparison of the various channels relative to one another. Unfortunately, subsequent quantitative analysis is often manually performed, which is laborious and time-consuming. However, software has been developed that uses an analog-to-digital converter to process and store data and to facilitate subsequent analysis of the pressure recordings. A typical microcomputer-generated tracing of the resting longitudinal anorectal sphincter pressure profile is depicted in Figure 150-10. The proximal end of the sphincter is that point at which the pressure is clearly above the intralumenal rectal pressure. This occurs when the perfusion orifices are withdrawn from the intralumenal rectum into the anal sphincter musculature. The normal sphincter length varies from 2.5 to 5 cm. A high-pressure zone is observed while the perfusion apparatus passes the distal portion of the internal sphincter muscle. The high-pressure zone is defined as that portion of the sphincter that demonstrates pressures greater than one half the maximal pressure. The point of maximal pressure is located in the distal portion of the high-pressure zone, about 1 to 1.5 cm from the distal end of the sphincter musculature. The normal average maximal resting pressure in the adult ranges from 65 to 85 mm Hg above rectal intralumenal pressure when measured with a perfused multichannel probe using the continuous pull-out technique. Usually, a modest lowering of the resting pressure occurs with aging.[137]

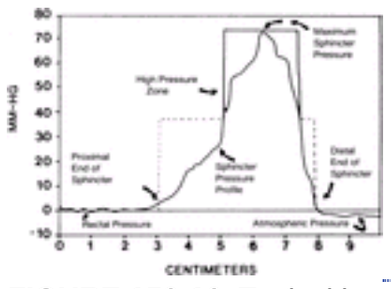

FIGURE 150-10. Typical longitudinal pressure profile of the resting anorectal sphincter. Pressures have been equated to a rectal pressure of zero. The pressures from an eight-channel multilumen probe during continuous resting pull-out have been averaged at each point along the sphincter by microcomputer. (From Coller JA. Clinical application of anorectal manometry. Gastroenterol Clin North Am 1987;16:20.)

Recent studies evaluating the longitudinal pressure profile of the anal canal with multichannel, radially positioned probes reveal evidence for radial pressure asymmetry. In the proximal sphincter, the posterior quadrant exhibits pressure predominance, whereas in the distal sphincter, the anterior quadrant demonstrates predominance.[138] Therefore, the longitudinal pressure profile reveals that the resting sphincter is a somewhat distorted cylinder with a gentle gradient of pressure, which shifts from posterior to anterior with movement from the rostral to the caudal end of the sphincter.

In addition to the resting sphincter pressure profile, patients undergoing anorectal manometry often have the maximal voluntary squeeze pressure evaluated. This test

is thought to reflect the contribution of the striated external sphincter. A voluntary squeeze should produce an increase of 50% to 100% over the average maximal resting pressure. Absolute normal values or ranges for voluntary squeeze pressure have not been agreed on in the literature, although women tend to have lower values than men. [137] The point of maximal pressure is located in the distal portion of the sphincter, similar to the status at rest. When evaluating external sphincter function with the voluntary squeeze maneuver, several technical issues should be kept in mind. The examiner must clearly tell the patient what is required to perform a voluntary squeeze. This is best achieved by placing a finger into the anal canal and instructing the patient regarding the appropriate voluntary squeeze effort. The squeezing effort results in movement of the anal canal because of the involvement of pelvic musculature; therefore, the probe should move freely with the sphincter to maintain the same position within the canal, which allows accurate comparison of resting and voluntary squeeze pressure at the same point. The external sphincter can sustain a voluntary squeeze for about 1 minute, after which fatigue occurs; therefore, the probe should be withdrawn within 30 to 40 seconds to obtain an accurate indication of the longitudinal pressure profile during voluntary squeeze.

Clinical Applications

Anorectal manometry is useful in the initial evaluation of patients with constipation and in the person with incontinence. The technique also may be useful to monitor progression of a disorder that affects anal sphincter function or the response to therapeutic interventions, such as biofeedback in the appropriate patient with incontinence.

Constipation When anorectal manometry reveals a normal or high average maximal resting pressure, the examiner should proceed with balloon reflex manometry to evaluate whether the internal sphincter relaxes in response to rectal distention. If rectal distention fails to initiate relaxation of the internal sphincter, the diagnosis of Hirschsprung disease should be considered [139] (Fig. 150-11). If the inhibitory reflex is present but demonstrates a high threshold for initiation, a problem with rectal compliance or afferent (sensory) pathways may be present. This pattern is observed in some patients with acquired megacolon or spinal cord injuries. [140] If the patient shows a deficient increase in voluntary squeeze pressure, abnormalities of sacral root innervation to the external sphincter should be considered. [141], [142]

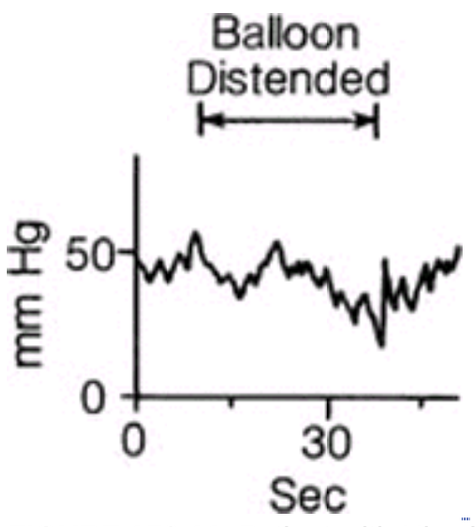

FIGURE 150-11. Patient with Hirschsprung disease. Tracing depicts failure of normal internal anal sphincter relaxation in response to rectal balloon distention. The balloon is positioned 15 cm above the anal verge and distended to 60 mL for the time shown. (Courtesy of Jeffrey L. Barnett, M.D., Ann Arbor, MI.)

Some patients with constipation demonstrate a low-average maximal resting pressure and normal rectal distention-mediated inhibition of the internal sphincter. In this scenario, the examiner should consider other anatomic abnormalities in the anorectal mechanism, such as accentuated puborectalis angulation or internal rectal prolapse, to explain the defecation problem. In addition, the constipated patient with low resting sphincter pressure deserves special mention because of the problems these patients face if an inappropriate sphincterotomy is performed. This procedure could potentially leave the patient with persistent constipation and iatrogenic loss of anal sphincter control.

Incontinence Assessment of resting and sphincter pressures, voluntary squeeze response, and balloon reflex manometry can be used to identify the location of abnormalities in anorectal function associated with incontinence. These findings can be helpful in directing therapy. For example, when the incontinent patient exhibits normal or elevated resting sphincter pressures, balloon reflex testing should be performed to rule out decreased threshold or increased sensitivity to rectal distention. Demonstration of these abnormalities suggests that a problem in rectal compliance underlies the incontinence. The typical patient with incontinence related to anorectal dysfunction and no history of trauma has low resting anal sphincter pressures. The voluntary squeeze response can help localize a problem in anal sphincter control to the internal or external sphincter. If a normal increase in tone is noticed with voluntary squeeze, this suggests that the problem resides in the internal sphincter, which can occur after hemorrhoid surgery or with diseases that affect the autonomic nervous system or smooth muscle cell function, such as diabetes mellitus and progressive systemic sclerosis. [143], [144] If a diminished or absent response to voluntary squeeze is observed, dysfunction of the external sphincter should be considered. This can be seen in patients with a neuropathy secondary to long-standing defecatory straining, sacral nerve impairment, and disorders affecting striated muscle. [145], [146] In patients with idiopathic fecal incontinence, documentation of increased pudenal nerve terminal motor latency is supportive that a neuropathy is present. However, a normal pudenal nerve terminal motor latency does not necessarily correlate with abnormalities in maximum squeeze pressure because this measurement does not exclude weakness of the pelvic floor. [147] Patients who receive radiation therapy for localized carcinoma of the prostate can demonstrate chronic heightened rectal sensitivity for at least 1 year after completion of therapy. [148], [149]

FUTURE APPLICATIONS

Novel technologies to evaluate GI neuromuscular function are being evaluated on a continuing basis. Manometry and barostat studies are invasive, technically challenging, and costly, which reduces their widespread clinical utility. Novel approaches to study gastric motility include magnetic resonance imaging (MRI), single photon emission computed tomography (SPECT), ultrasonography, tensostat, water and nutrient drink test, paracetamol absorption test, and ^{13}C-octanoic acid breath test. [150] Each of these tests has strengths and limitations. For example, the water and nutrient test has been proposed as a noninvasive alternative to sensory (satiety) testing with an intragastric balloon. The tensostat measures gastric wall tension that correlates with the perception of gastric distention. The paracetamol absorption test, ^{13}C breath tests, ultrasound, and MRI have been used to assess gastric emptying. MRI requires expensive equipment and ultrasound advanced training to perform and interpret the results. SPECT has been employed to assess gastric accommodation to a meal. This technology requires intravenous injection of 99mTc-pertechnetate and specialized imaging and analysis capability. Each of these technologies requires validation of their utility in the research and clinical settings.

CHAPTER 151

William D. Chey and William Y. Chey

EVALUATION OF SECRETION AND ABSORPTION FUNCTIONS OF THE GASTROINTESTINAL TRACT

This chapter reviews the available gastric secretory function tests, pancreatic exocrine function tests, and breath tests for carbohydrate malabsorption or bacterial overgrowth. No attempt is made to review the physiology of gastric secretory and pancreatic exocrine function; instead, for detailed discussions of these topics, see Chapter 13 and Chapter 15.

TESTS OF GASTRIC SECRETORY FUNCTION

The clinical applications of gastric acid analysis and prolonged intragastric pH monitoring are limited. However, these tests remain critical for better understanding the effects of various disease states and pharmaceuticals on gastric secretory function. Gastric acid analysis and prolonged intragastric pH monitoring have played a pivotal role in our understanding of the link between *Helicobacter pylori* infection and changes in acid secretion documented in patients with peptic ulcer disease decades ago.[1] As the *H pylori* story has taught us, groundbreaking discoveries of the future will require an ongoing reevaluation of our understanding of gastric secretory function. As such, the methodology, strengths, and weaknesses of gastric acid analysis and prolonged intragastric pH monitoring continue to be worthy of the gastroenterologist's understanding.

Gastric Acid Analysis

Indications Traditionally, physicians have used gastric acid analysis to answer the following questions: (1) Does the stomach produce acid? (2) If so, what is the basal or unstimulated gastric acid secretion? (3) How much acid is secreted in response to physiologic or pharmacological stimulants? (4) Is the vagal innervation to the stomach intact?[2] In the past, gastric acid analysis served as an important tool in the evaluation of patients with a large number of disorders affecting the stomach. With the development of more effective diagnostic and therapeutic modalities for acid peptic disorders, however, the importance of tests to measure gastric acid secretion has decreased substantially. Gastric acid analysis remains the gold standard to evaluate gastric secretory function and is useful to today's gastroenterologist or gastrointestinal surgeon in several clinical situations (Table 151-1). Gastric acid analysis can be helpful in the evaluation of patients who develop recurrent ulcers after surgery for peptic ulcer disease. In this setting, gastric acid secretion can be quantified and hypersecretion excluded. In addition, the completeness of vagotomy can be determined by sham feeding that evaluates the vagally mediated cephalic phase of acid secretion. In the age of *H pylori* and proton pump inhibitors, however, the role of gastric analysis in the patient with postoperative ulcer recurrence will have to be redefined. With more effective medical therapies, fewer patients have chronic or recurrent peptic ulcer disease. Thus, fewer patients require operative intervention for this indication. In addition, most of the classic literature addressing postoperative ulcer recurrence was performed before the acceptance of *H pylori* as one of the major pathogenic factors in the development of peptic ulcer disease.[3] It is possible that *H pylori* eradication may alter postoperative gastric acid secretion or decrease the likelihood of peptic ulceration after surgery. As such, in the age of *H pylori,* it is unclear whether gastric acid analysis will retain the same importance in postoperative patients with ulcer recurrence.

I. Assess the patient with ulcer recurrence after surgery for peptic ulcer disease
a. Exclude acid hypersecretion
b. Assess the completeness of vagotomy (sham feeding)
II. Evaluate an elevated fasting plasma gastrin level
a. Assess physiologic response (atrophic gastritis)
b. Assess pathological response (gastrinoma, ulcerogenic tumor syndrome with nongastrin secretagogue)
III. Assess the adequacy of proton pump inhibitor therapy in patients with diseases of gastric acid hypersecretion

TABLE 151-1 Indications for Gastric Acid Analysis

Gastric analysis can help determine whether an elevated circulating gastrin level is physiologic (achlorhydria) or pathological (acid hypersecretory states). Gastric analysis can establish that hypergastrinemia is an appropriate consequence of the inability to produce acid, as seen in the setting of atrophy, pernicious anemia, or malignancy involving the body of the stomach.[4],[5] On the other hand, hypergastrinemia can be seen in diseases of excessive acid secretion such as Zollinger-Ellison syndrome.[6] The development of secretin stimulation testing and accurate imaging modalities, such as high-resolution computed tomography (CT), endoscopic ultrasound (EUS), and somatostatin receptor scintigraphy, has relegated gastric acid analysis to an adjunctive role in the diagnosis of this disease.[7],[8] Gastric analysis remains critical to the evaluation of the unusual patient with acid hypersecretion attributable to the ulcerogenic tumor syndrome, in which circulating gastrin levels are typically normal.[9],[10] Gastric analysis can be useful in determining the adequacy of acid suppressive therapy after the diagnosis of gastrinoma or the ulcerogenic tumor syndrome has been established. Gastric acid analysis remains an important means of better understanding the effect of various disease states and pharmaceuticals on gastric secretory function. For example, it has long been known that patients with duodenal ulcer have higher levels of basal acid secretion than controls.[11],[12] Studies using gastric acid analysis have shown that this abnormality is related to *H pylori* infection and that eradication of this infection leads to normalization of basal acid output (BAO). On the other hand, pentagastrin stimulated maximal acid output (MAO) in patients with duodenal ulcer remains elevated even after successful *H pylori* eradication. This suggests the presence of parietal cell hypersensitivity to gastrin or an increase in parietal cell mass that persists after eradication of *H pylori* infection.[1] As opposed to patients with duodenal ulcer, healthy volunteers with *H pylori* infection can have normal, enhanced, or diminished acid secretion.[13],[14] Investigators have also recently used gastric analysis to prove that proton pump inhibitors and histamine H_2 receptor antagonists more effectively suppress gastric acid secretion in individuals with *H pylori* infection than in noninfected individuals.[15],[16] It is now clear that gastric analysis does not accurately differentiate between functional versus ulcer-related dyspepsia because the overlap in acid secretion between the two groups is substantial[11],[12] (Fig. 151-1). There are a number of situations in which the role of gastric analysis has not been clearly defined. For example, the utility of gastric acid analysis in patients with peptic ulcer disease, but no evidence of *H pylori* infection or history of nonsteroidal antiinflammatory drug use, has yet to be determined. Preliminary data suggest that acid secretion may be abnormal in such patients.[17] Other patient populations in whom gastric acid analysis might be useful include those with a nonhealing ulcer despite appropriate acid-suppressive therapy and those with ulcer recurrence despite successful *H pylori* eradication.

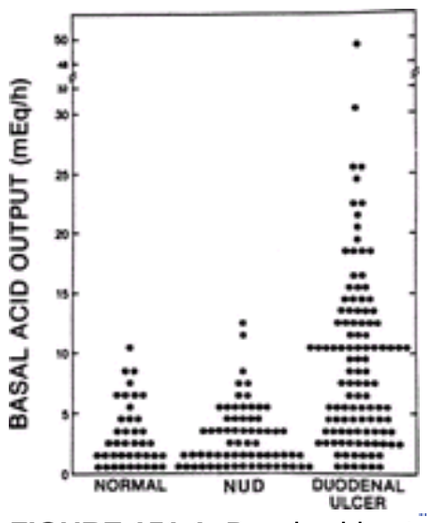

FIGURE 151-1. Basal acid output (BAO) in 40 healthy controls, 66 patients with nonulcer dyspepsia (*NUD*), and 114 patients with duodenal ulcer. There was no difference in mean BAO between normals (3.2 ± 2.7 mEq/h) and patients with NUD (2.9 ± 2.7 mEq/h). However, the mean BAO was significantly higher in patients with duodenal ulcer (9.1 ± 7.6 mEq/h) than in either normals or patients with NUD. (From ref. [11].)

Methodology The most widely practiced means of measuring acid secretion is the aspiration method in which gastric contents are withdrawn through a nasogastric tube at timed intervals under different test conditions. The hydrogen ion concentration in these samples can then be determined providing a quantitative assessment of basal (BAO) and stimulated (MAO, modified sham feeding) acid secretion. A point worthy of consideration is the reliability of gastric acid analysis. A great deal of variability in test results has been observed in studies of healthy individuals. Both BAO and MAO tend to be higher in males than females. Patients with duodenal ulcer tend to have greater acid secretion than healthy individuals [1], [11], [12] (see Fig. 151-1). Because of considerable overlap between populations, however, gastric analysis does not reliably discriminate between those with peptic ulcer disease and healthy volunteers. Even when Zollinger-Ellison syndrome is suspected, gastric analysis is not always a reliable single diagnostic test because of the overlap in results yielded by patients and controls. [4] Aside from the considerable interindividual variability, there is also intraindividual variability when gastric acid analysis is performed on different days. [18] Reproducibility of this test is dependent on several factors, including day-to-day variations in BAO, day-to-day variations in responsiveness of acid output to various secretagogues, and the completeness of gastric contents recovery. A review article reported a relatively poor coefficient of variation for intraindividual BAO data. [18] This is likely related to the multiple factors (time of day, mental state, duodenal losses of gastric contents, neutralization of acid with swallowed saliva, and neurohormonal effectors of acid secretion) that influence acid secretion and its measurement in the basal state. [19] In contrast to basal acid secretion, acid secretion stimulated by histamine or pentagastrin is much more reproducible from day to day. [18] The recovery of gastric contents can be facilitated by proper tube placement and patient position. The aspiration tube should be of sufficient caliber to allow recovery of the gastric contents but not so large as to be intolerable to the patient. In general, tubes in the range of 14 to 18 French fulfill these requirements. Testing should be performed in the seated position. The tip of the tube should be placed into the most dependent portion of the stomach, and proper placement should be confirmed with fluoroscopy. Even when test conditions are optimized, recovery of the gastric contents is often not complete. [20] The recovery of gastric contents during aspiration can be quantified by the infusion of a nonabsorbable marker such as polyethylene glycol or radiolabeled chromic chloride ($^{51}CrCl_3$). [2], [20] Although this is the ideal means of performing gastric acid analysis, the infusion and measurement of a nonabsorbable marker, particularly one that is radioactive, makes the procedure much more cumbersome and costly to perform. For this reason, most centers, including our center, perform gastric acid analysis without the infusion of a nonabsorbable marker.

Basal acid output. On the evening before undergoing gastric acid analysis, the patient should take a clear liquid dinner and consume nothing by mouth after midnight. Unless the purpose of the study is to assess the effect of a medication on acid secretion, dosing of agents that affect acid secretion should be modified before the test. Histamine H_2 receptor antagonists, antihistamines, anticholinergics, and cholinergic agonists should be discontinued at least 24 hours before gastric acid analysis. Proton pump inhibitors inactivate the hydrogen-potassium ATPase found on the parietal cell. [21] As such, proton pump inhibitors have prolonged effects on acid secretion [22] and should be withheld for at least 7 days before testing. For patients who suffer with recurrent symptoms once their proton pump inhibitor has been discontinued, a histamine H_2 receptor antagonist may be used until 24 hours before gastric acid analysis. On the day of gastric acid analysis, the patient is intubated, and tube placement is confirmed as described earlier. The study starts with a 30-minute washout period during which all gastric contents are aspirated and discarded. After this washout period, samples are collected at 15-minute intervals. Sample volume is recorded, and an aliquot is used to determine the titratable acidity. Titratable acidity (millimoles [mmol] per liter) is determined by adding a base, such as NaOH, to an aliquot of gastric juice until the pH reaches 7.0. Values are then corrected for the size of the total timed sample. The following equations can be used to determine the titratable acidity:

$$(\text{mL base to titrate to pH 7.0}) \times [\text{concentration of the base}] = \text{millimoles } H^+ \text{ per aliquot}$$

$$\frac{\text{volume of sample}}{\text{volume of aliquot}} \times \text{millimoles } H^+ \text{ per aliquot} = \text{millimoles } H^+ \text{ per sample}$$

BAO (millimoles H^+ per hour) is the sum of the acid output from the four 15-minute collections done in the unstimulated state. In healthy unoperated volunteers, BAO should be less than 15 mmol H^+ per hour. A BAO of greater than 5 mmol H^+ per hour is considered abnormal for a patient who has previously undergone partial gastrectomy or vagotomy. [4] In humans, BAO should be about 10% of the maximal secretory capacity of the stomach. [18]

Maximal and peak acid output. MAO and peak acid output (PAO) indirectly assess functional parietal cell mass through the measurement of acid secretion after the administration of maximally effective doses of agents that directly stimulate the parietal cell. [23], [24] Such stimulants of acid secretion include pentagastrin, histamine, and histamine analogs such as 3-ß-aminoethylpyrazole. Pentagastrin is the most widely used agonist and is usually administered subcutaneously (6 µg/kg). Pentagastrin can also be given intramuscularly (6 µg/kg) or intravenously (1 to 6 µg/kg/h). After pentagastrin administration, gastric juice is collected every 15 minutes for 1 to 1.5 hours. The titratable acidity (millimoles H^+ per sample) is then determined for each of the four to six samples obtained after pentagastrin administration. MAO represents the greatest sum of the titratable acid from four consecutive samples (millimoles H^+ per hour). PAO is the sum of the two highest acid outputs multiplied by two to yield results in millimoles H^+ per hour. MAO and PAO measurements vary widely in healthy subjects, ranging from 0 to 80 mmol H^+ per hour. MAO is influenced by a number of variables, including sex, age, and lean body mass. [25] MAO decreases by about 50% after truncal or proximal gastric vagotomy. [26], [27] In conjunction with the BAO, MAO measurement can suggest the presence of the ulcerogenic tumor syndrome, including gastrinoma. Because the presence of an elevated plasma gastrin concentration stimulates gastric acid output by parietal cells in the basal state, patients with gastrinoma typically have a BAO-to-MAO ratio of greater than 0.6. [4] Another approach to the study of gastric secretory function is to administer gastrin-releasing peptide (GRP) rather than pentagastrin or histamine. [1] GRP leads to the release of gastrin from the antral G cell and thereby indirectly stimulates gastric acid secretion by the parietal cell. [28], [29] In addition, GRP influences the release of counterregulatory hormones, such as cholecystokinin (CCK), secretin, gastric inhibitory peptide, vasoactive intestinal peptide, neurotensin, enteroglucagon, and somatostatin. [30], [31] and [32] Therefore, unlike pentagastrin or histamine, which assess only the parietal cell response to direct stimulation, GRP theoretically evaluates the sum of both stimulatory and inhibitory pathways responsible for the control of acid secretion. Investigators have used this approach to demonstrate abnormalities in the inhibitory control of acid secretion in patients with *H pylori* infection and duodenal ulcer. [1] At the current time, GRP is an interesting clinical investigative tool but cannot be considered part of routine gastric acid analysis.

Testing of vagally stimulated acid secretion. Since the turn of the 20th century, it has been known that the thought, sight, smell, and taste of food stimulate gastric acid secretion. Food-induced stimulation of the senses leads to activation of cerebral cortical sites, resulting in increased gastric acid secretion. The cephalic phase of gastric acid secretion is dependent on an intact vagus nerve and is cholinergically mediated. [18] In the past, vagally mediated acid secretion was assessed after insulin-induced hypoglycemia (Hollander test). [33] The absence of an increase in acid secretion with hypoglycemia suggested the presence of vagotomy. Unfortunately, this test was associated with a number of severe adverse reactions, including myocardial infarction, seizures, and, on rare occasions, death. [34], [35] For this reason, the Hollander test has been replaced by the sham feeding test. Most commonly, the sham feeding test is used to determine the completeness of vagotomy in patients with ulcer recurrence after surgery for peptic ulcer disease. [36] In humans, acid output in response to sham feeding is 50% to 65% of secretagogue-induced acid output. [18] In addition, some investigators have used this technique to assess the patency of vagal autonomic innervation to the stomach in the patients with diabetes mellitus. [37] During sham feeding, patients are allowed to see, smell, taste, and chew an appetizing meal. Food is then expectorated by the patient, thus avoiding the gastric phase of acid secretion. Gastric juice is collected through a nasogastric tube, and the titratable acidity is calculated as described previously. Feldman and colleagues [37] have shown that a sham acid output (SAO)-to-PAO ratio of less than 0.1 is abnormal in healthy volunteers. Therefore, an SAO-to-PAO ratio of more than 0.1 in a patient who has previously undergone peptic ulcer surgery suggests the presence of intact vagal innervation to the stomach. [36]

Ambulatory Intragastric pH Monitoring

Indications The role of ambulatory intragastric pH monitoring in clinical practice is limited. Like gastric acid analysis, however, the prolonged measurement of intragastric pH is an important clinical research tool. Prolonged intragastric pH monitoring has gained popularity as an investigative tool because it is better tolerated by patients, is less cumbersome to perform, and arguably gives more physiologic information than traditional gastric analysis. This technique has most often been used to evaluate the effects of duodenogastric reflux [38], [39] and drugs that suppress acid secretion (e.g., histamine H_2 receptor antagonists and proton pump inhibitors) on intragastric pH. [40], [41] Intragastric pH monitoring can also help to establish a link between pH events and gastrointestinal symptoms. [41] Recently, differences between patients with duodenal ulcer associated with *H pylori* infection and controls were demonstrated using ambulatory intragastric pH monitoring. [42], [43] Intragastric pH monitoring has also been used to identify differences in the effectiveness of proton pump inhibitor therapy between those infected and those not infected with *H pylori*. [44], [45] It is important to understand the differences in information yielded by gastric acid analysis and intragastric pH monitoring. Although gastric acid analysis provides a quantitative measure of gastric secretory function, intragastric pH monitoring yields only qualitative information. As has already been discussed, gastric acid analysis quantitates basal and maximal acid secretion in response to the administration of a specific secretagogue. On the other hand, intragastric pH monitoring allows only the determination of pH, albeit in a more physiologic setting than gastric acid analysis. How well results obtained with prolonged intragastric measurement correlate with traditional gastric acid analysis remains controversial. Several studies have eported a good correlation between data obtained from the two techniques. [40], [46] However, studies have questioned the validity of drawing conclusions regarding overall intragastric pH solely on the basis of measurements obtained with a single electrode. [39], [47], [48] and [49] Simultaneous recordings from the body and antrum have demonstrated significant differences in pH both in the interdigestive and postprandial periods. [39], [47], [48] and [49] In general, H^+ concentration is higher when measured by intragastric pH monitoring compared with gastric acid analysis. [48] The precise reasons for these differences are not clear, but biophysical phenomena, including environmental carbon dioxide (CO_2) concentration, temperature, and technical problems, such as electrode instability, artifact, or interference, may play a role. [48], [50]

Methodology There are a variety of ways to measure intragastric pH. The most widely employed method has been to place a catheter containing a single electrode transnasally into the body of the stomach. [51], [52] As mentioned previously, recent literature has questioned the practice of extrapolating data from a single electrode to the stomach as a whole. Obtaining pH measurements from more than one part of the stomach appears to yield more complete information. Whether this more complete information has practical relevance to the clinician or investigator remains to be determined. Proper placement should be confirmed fluoroscopically. Both antimony and glass pH electrodes have been used and appear to give equivalent results. [53] The catheter is connected to any of a number of commercially available computerized modules that can digitally record changes in intragastric pH. Careful attention should be paid to proper calibration of the pH monitoring equipment before each study. The probes used for intragastric pH monitoring reportedly become less accurate with repeated use. [50] Data are often expressed as the percentage of time above or below a certain pH. This means of data presentation is simple and easy to understand. However, differences in gastric secretory function are more difficult to appreciate using this means of data presentation because pH is the inverse log of H^+ concentration. As such, it is more precise to express data from intragastric pH monitoring as H^+ concentration. [48], [54]

TESTS OF PANCREATIC EXOCRINE FUNCTION

Traditionally, it has proved challenging to identify patients with mild to moderate chronic pancreatitis. The use of endoscopic retrograde pancreatography (ERP), CT, transcutaneous ultrasonography, and, more recently, EUS has facilitated the diagnosis of chronic pancreatic diseases. Unfortunately, despite evaluation with structural studies, a definitive diagnosis will not be apparent in a subset of patients with chronic pancreatitis. In addition, structural studies cannot quantitatively assess the degree of exocrine dysfunction. Although local expertise and availability influence the choice of diagnostic studies, functional testing can uncover previously unidentified abnormalities or complement information yielded by structural studies.

Tests of pancreatic exocrine function can be divided into four categories: (1) tests that quantitate pancreatic secretion through gastroduodenal intubation; (2) studies that assess exocrine function indirectly using an orally administered test substrate; (3) tests that rely on the measurement of fat or pancreatic enzyme activity in feces; and (4) a miscellaneous group of tests, including the measurement of serum pancreatic enzyme activity, plasma pancreatic polypeptide response to ingestion of a meal, and changes in plasma amino acid concentration after stimulation of the pancreas (Table 151-2).

Tests Requiring Gastroduodenal Intubation
Direct tests
Secretin test
Secretin-cholecystokinin (CCK) or CCK-8 test
CCK-8 or cerulein test
Indirect tests
Lundh test
Tubeless Pancreatic Function Tests
Oral tests
N-benzoyl-L-tyrosyl-paraamino benzoic acid (NBT-PABA) test
Fluorescein dilaurate (pancreolauryl) test
Dual-labeled Schilling test
Breath tests
Triolein and mixed triglyceride breath test
Histamine H_2 and [^{13}C]-labeled starch breath tests
Fecal tests
Fecal fat determination
Chymotrypsin
Lipase
Elastase
Miscellaneous tests
Serum trypsin-like immunoreactivity
Plasma pancreatic polypeptide test
Plasma amino acid consumption test

TABLE 151-2 Pancreatic Function Tests

Tests Requiring Gastroduodenal Intubation

These tests rely on the collection of pancreatic juice from the duodenum before and after the administration of secretagogues including secretin or CCK or its analogs (e.g., CCK-8, pancreozymin, cerulein). Tests that measure pancreatic secretion from duodenal contents provide an accurate, sensitive (67% to 90%), and specific (80% to 90%) means of assessing pancreatic exocrine function. [55], [56], [57], [58] and [59] These tests may be more sensitive in detecting pancreatic dysfunction than traditional imaging techniques including ERP [60] but are probably not as sensitive as EUS. [61] Although these tests are clearly superior to the so-called tubeless pancreatic function tests, they are labor intensive, expensive, and require specially trained personnel. As such, they are performed almost exclusively in large referral centers and research laboratories.

Secretin and Cholecystokinin Tests The secretin test was developed in the early part of the 20th century [55], [56] to measure exocrine pancreatic secretion in response to the intravenous injection of purified porcine secretin. The aspirate volume as well as the concentration of bicarbonate and pancreatic amylase [56], [57] are measured before and after the administration of secretin. To minimize contamination of the duodenal aspirate by gastric juice, a double-lumen tube should be used. With fluoroscopic guidance, gastric aspiration ports are positioned in the antrum and body while duodenal aspiration ports lie in the first, second, and third portion of the duodenum (Fig. 151-2). Gastric juice and duodenal contents are separately collected by continuous suction. Gastric contents are discarded while duodenal contents are retained for analysis.

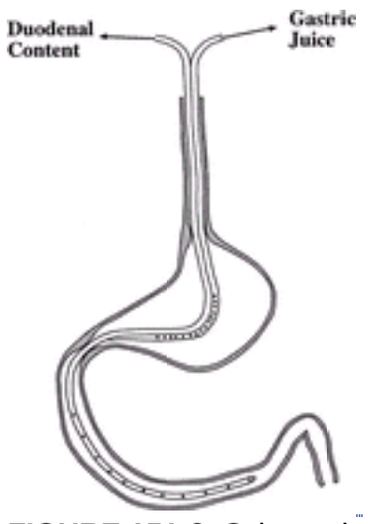

FIGURE 151-2. Schematic representation of the set-up for pancreatic function tests requiring gastroduodenal intubation. A double-lumen tube is placed into the stomach and duodenum with the assistance of fluoroscopy. Gastric and duodenal contents are then simultaneously aspirated during the basal state and after intravenous administration of pancreatic secretagogues, including secretin, cholecystokinin-8, or cerulein alone or in combination. Gastric contents are discarded, whereas duodenal contents are stored for subsequent analysis as described in the text.

Gastric aspiration is important because contamination of duodenal contents with gastric acid produces falsely low bicarbonate concentration and inaccurate volume measurements. Moreover, acid stimulates the release of secretin from the duodenal mucosa, which can affect test results. The pH of uncontaminated duodenal fluid should be greater than 7.5. In clinical conditions associated with gastric acid hypersecretion such as Zollinger-Ellison syndrome, the collection of uncontaminated duodenal fluid is virtually impossible. Once the tube is in place, duodenal fluid is collected every 15 minutes for 1 hour. Secretin in a dose of one clinical unit per kilogram of weight is administered as a bolus intravenous injection, and duodenal fluid is collected for an additional 1 to 1.5 hours. Except in patients with gallbladder dysfunction and those who have previously undergone cholecystectomy, the duodenal aspirate should lose its bile-stained appearance, becoming clear and colorless, after secretin injection. [59] Normal values for duodenal fluid after secretin injection are provided in Table 151-3. In patients with chronic pancreatitis, one of the four following patterns can be seen: (1) low maximum concentration of bicarbonate only; (2) low enzyme output only; (3) low bicarbonate concentration and low enzyme output; and (4) abnormally low volume, bicarbonate concentration, and amylase output. It is difficult to judge the significance of an isolated abnormality in duodenal juice volume because the adequacy of aspiration is often unclear. To avoid this technical error, a nonabsorbable marker can be infused into the proximal duodenum during the course of the study. Quantification of the marker in the samples collected allows determination of the completeness of duodenal aspiration. [62] When low volume is truly the only abnormality found, the clinician should consider the possibility of cancer in the head of the pancreas. When abnormalities in volume, bicarbonate concentration, and amylase output are all present, patients virtually always exhibit signs of advanced pancreatic disease, such as extensive calcification, steatorrhea, or pancreatic endocrine dysfunction. [63] The secretin test is sensitive enough to detect the presence of mild to moderate chronic pancreatitis. In such patients, low bicarbonate concentration may be the only abnormality. At the time of this writing, secretin is not commercially available in the United States. Recombinant human secretin is under review by the U.S. Food and Drug Administration. It is hoped that this agent will become available in the near future.

1. Secretin test* (mean ± 2 SD)	
Volume: 107–223 (mL/h)	
Bicarbonate concentration: 92–124 (mEq/L)	
Bicarbonate output: 14–21 (mmol/h)	
Amylase output: 174–1270 (U/h)	
2. Secretin + CCK (lower limits of normal)†	
Volume: 151 (mL/h)	
Bicarbonate concentration: 70 (mmol/L)	
Bicarbonate output: 11.3 (mmol/h)	
Amylase output: 131 (units during 30 min of CCK)	
3. CCK test‡ (range in 16 control subjects)	
Trypsin output: 25–54 (Ku/h)	
Lipase output: 77–322 (Ku/h)	
4. Lundh test§ (mean ± 2SD)	
Mean tryptic activity: 7–38 (IU/L)

CCK, cholecystokinin; Ku, kilounits; SD, standard deviation

TABLE 151-3 Normal Ranges for Results of Pancreatic Function Tests Requiring Gastroduodenal Intubation

Using the basic technique described previously, testing can be modified by adding the intravenous injection of CCK [58], [59] or its analogs. [64] However, there is no convincing evidence to suggest that the additional administration of CCK improves the sensitivity or specificity of the secretin test. Alternatively, some investigators have used CCK alone to stimulate pancreatic enzyme output. [65] Whenever CCK is used, measurements of trypsin and lipase output are performed. Normal values for the secretin and CCK tests are given in Table 151-3.

Lundh Test The Lundh test determines the pancreatic enzyme concentration of the duodenal contents in response to a test meal. After fluoroscopically guided placement of a catheter into the duodenum, the test subject ingests a standardized 300-mL meal composed of dried milk, vegetable oil, and dextrose. [66] Duodenal contents are aspirated at set intervals for measurement of pancreatic enzyme concentration. When chymotrypsin is measured, a concentration below 12.6 IU suggests the presence of pancreatic exocrine insufficiency. Because this test relies on secretin and CCK-stimulated pancreatic secretion and these hormones are released mainly from the duodenal mucosa, it is necessary for patients to have gastroduodenal continuity and normal duodenal mucosa. [67], [68] Although this test is simpler and less expensive than the secretin test, it allows determination of enzyme concentration only. The sensitivity of this test ranges from 66% to 94%. [69], [70] The secretin or CCK tests appear to be more sensitive than the Lundh test, particularly in patients without steatorrhea. [71], [72]

Tests that Do Not Require Gastroduodenal Intubation

Like studies that identify structural pancreatic disease, all of the tubeless pancreatic function tests are reasonably sensitive and specific in patients with severe pancreatic exocrine dysfunction. Unfortunately, the tubeless tests have yielded only marginal sensitivity and specificity in patients in whom an accurate test is most needed: those with mild to moderate exocrine dysfunction. Furthermore, recent data suggest that combining tubeless tests does little to improve their accuracy in patients with mild to moderate disease. [73] Because of their inadequacies, these tests have not gained wide acceptance in clinical practice. General information regarding the oral, fecal, and miscellaneous pancreatic function tests is provided in Table 151-4.

	WHAT IS MEASURED	SOURCE
Oral Tests		
NBT-PABA test	PABA	Urine, serum
Pancreolauryl test	Fluorescein	Urine, serum
Dual-labeled Schilling test	[^{58}Co]/[^{57}Co]	Urine
Breath tests		
Triolein	[^{14}C]O_2	Breath
Mixed triglyceride breath test	[^{13}C]O_2	Breath
[^{13}C]-labeled starch breath tests	[^{13}C]O_2 or H_2	Breath
Fecal Tests		
Fecal fat determination	Fat	Feces
Chymotrypsin	Chymotrypsin	Feces
Lipase	Lipase	Feces
Elastase	Elastase	Feces
Miscellaneous Tests		
Serum trypsin-like immunoreactivity	Trypsin-like activity	Serum
Plasma pancreatic polypeptide test	Pancreatic polypeptide	Plasma
Plasma amino acid consumption test	Amino acid levels	Plasma

Note: All of the tubeless tests are substantially better able to identify patients with severe pancreatic exocrine dysfunction (steatorrhea present) than those with earlier stages of disease.

TABLE 151-4 Tubeless Pancreatic Function Tests

Oral Pancreatic Function Tests

N-Benzoyl-L-tyrosyl-paraamino benzoic acid test. The *N*-benzoyl-L-tyrosyl-paraamino benzoic acid (NBT-PABA) or bentiromide test [74], [75] is a simple and noninvasive test of pancreatic exocrine function. After oral administration, NBT-PABA, a synthetic peptide, is specifically cleaved by chymotrypsin to yield free PABA. A dose of 500 to 1000 mg appears to provide the best separation between healthy subjects and patients with chronic pancreatitis. [76], [77] The necessity of giving a test meal to stimulate pancreatic secretion with the NBT-PABA is controversial. PABA is absorbed in the small intestine, conjugated by the liver, and excreted in the urine. Thus, the quantitation of PABA and its metabolites in serum or urine provides an indirect measure of duodenal chymotrypsin activity. The reported sensitivity of the NBT-PABA test is between 37% and 90%. [77] The specificity of the test has also been variable (39% to 100%). Tests using a timed urine collection have not been as reliable as serum testing. Perhaps the most important factor influencing the sensitivity and specificity of this test has been the severity of pancreatic disease in the population studied. When data from several studies using the secretin-CCK test as a gold standard were pooled, the sensitivity of the NBT-PABA test with a 6-hour urine collection was 71% in patients with severe exocrine dysfunction but only 46% in those with mild to moderate insufficiency. [77] In addition, the measurement of PABA and other arylamines can be confounded by certain clinical conditions (gastrointestinal surgery, small bowel disease, diabetes mellitus, severe liver disease and renal insufficiency), drugs (acetaminophen, phenacetin, benzocaine, lidocaine, procaine, chloramphenicol, sulfonamides, sulfonylurea, and thiazides), and foods (prunes and cranberries). Pancreatic enzyme supplements can cause false-negative results and should be discontinued at least 5 days before the test. The specificity of the NBT-PABA test can be improved by administering a marker that allows the determination of individual variability in extrapancreatic factors such as gastric emptying and intestinal, hepatic, or renal handling of PABA. To these ends, it is possible to administer free PABA [78] on a separate day or to coadminister *p*-aminosalicylic acid, [79], [80] carbon-14 (^{14}C)-PABA, [81] or carbon-13 (^{13}C)-PABA [82] with NBT-PABA to assess better the effects of extrapancreatic factors on the test.

Urine test. If assessing urinary excretion, a 6-hour urine collection appears to yield the greatest sensitivity in patients with pancreatic exocrine dysfunction. The lower limit of normal for a 6-hour urine collection is 50% excretion of the dose administered.

Serum test. The measurement of serum PABA is simpler, more reliable, and more accurate in assessing pancreatic exocrine function than a timed urinary collection. [82], [83], [84], [85] and [86] Blood samples are obtained before and 150 minutes after NBT-PABA administration. [83] The reported cutoff value for PABA that discriminates between healthy controls and patients with chronic pancreatitis is 20 nmol/mL. Using this cutoff value, the sensitivity and specificity of this test are 70% to 90% and 87% to 95%, respectively. [83], [84] In a variation on this study that used ^{13}C-PABA as a marker, [82] both PABA and ^{13}C-PABA in blood were measured using a detailed analysis including hydrolysis, extraction, separation by high performance liquid chromatography (HPLC), and methyl ester formation of the test substances before chromatography and mass spectrometry. The modified protocol appeared to discriminate better between healthy volunteers and patients with pancreatic insufficiency.

Fluorescein dilaurate test (pancreolauryl test). The fluorescein dilaurate test [83], [87] is similar in principal to the NBT-PABA test. Fluorescein dilaurate, a synthetic, relatively water-insoluble ester, is given orally with a standardized breakfast. Fluorescein dilaurate is specifically hydrolyzed by pancreatic arylesterases to lauric acid and water-soluble, free fluorescein. Fluorescein is readily absorbed by the small intestine, conjugated in the liver, and excreted in the urine. Urine or serum measurements of fluorescein can be performed. The pancreolauryl test performs in a manner similar to the NBT-PABA test, with a sensitivity of 55% to 100% and a specificity of 46% to 97%. [77] Like the NBT-PABA test, the pancreolauryl test is more sensitive in patients with severe pancreatic exocrine insufficiency than mild to moderate disease. The accuracy of the test can be negatively influenced by previous gastrointestinal surgery, small bowel mucosal diseases (e.g., celiac disease, Crohn's disease), severe liver disease, or bacterial overgrowth. Pancreatic enzyme supplements should be discontinued at least 5 days before the study.

Urine test. Urinary fluorescein is measured spectrophotometrically in 10-hour collections on two separate days. The recovery of fluorescein on the test day (T) is expressed as a percentage of the recovery of free fluorescein during a control study (C): [T/C × 100]. A T/C ratio of less than 20 is considered abnormal, whereas results between 20% and 30% fall into the equivocal range. [83], [87]

Serum test. A modified serum test [88] consisting of a standard breakfast with two capsules of 0.5 mmol fluorescein dilaurate was studied in a large number of patients with chronic pancreatitis confirmed by endoscopic retrograde cholangiopancreatography. [89] Patients received simultaneous intravenous infusions of metoclopramide (10 mg) and secretin (1 clinical unit/kg). Their modified protocol achieved a more rapid peak in serum fluorescein concentration after the test meal and improved the sensitivity of the test in patients with moderate chronic pancreatitis. A value below 2.5 µg/mL was thought to represent the optimum cutoff value for this test. In this large group of patients with varying degrees of pancreatic disease, the modified test yielded a sensitivity of 82% and specificity of 91% for chronic pancreatitis. In those with mild to moderate chronic pancreatitis, the test had a sensitivity of 70%. Another recent study confirmed the value of secretin administration before the test meal. [90]

Dual-labeled schilling test. Cobalamin (vitamin B_{12}) malabsorption occurs in a subset of patients with exocrine pancreatic insufficiency. R protein is a nonintrinsic factor cobalamin-binding protein present in the saliva, gastric juice, and other body fluids. Brugge and colleagues [91] reported a modified dual-labeled Schilling test that indirectly evaluates pancreatic exocrine function. The basis of the test is that duodenal pancreatic enzymes digest the cobalamin–R protein complex, allowing cobalamin to bind intrinsic factor (IF). The cobalamin-IF complex is then absorbed in the ileum. As such, patients with exocrine dysfunction absorb cobalamin bound to IF normally but are unable to absorb cobalamin bound to R protein. After the oral ingestion of a test solution containing human IF[^{57}Co]cobalamin (0.2 nmol), hog R protein [^{58}Co]cobalamin (0.2 nmol), free human IF (0.4 nmol), and cobinamide (200 nmol), an intramuscular injection of cobalamin is administered. Urine is then collected for 24 hours, and [^{58}Co] and [^{57}Co] are measured. The ratio of [^{58}Co] to [^{57}Co] is calculated. Chen and associates [92] have reported that an excretion ratio for [^{58}Co]/[^{57}Co] of less than 0.68 was abnormal. Among 26 patients who underwent ERP, 0 of 9 patients with a normal pancreatogram, 4 of 9 patients with mild to moderate ductal changes on pancreatogram, and 7 of 8 patients with advanced ductal abnormalities on pancreatogram showed a positive value lower than the ratio of 0.68. In 28 patients who underwent CCK-secretin or cerulein-secretin testing, 2 of 13 with a normal test, 6 of 9 with mild exocrine dysfunction, and 5 of 6 with definitive exocrine dysfunction had an abnormal dual-labeled Schilling test. The [^{58}Co]/[^{57}Co] ratio significantly correlated ($r = 0.73$) with the maximal bicarbonate concentration as determined by CCK-secretin testing. The authors suggested that the dual-labeled Schilling test may be useful for identifying patients with relatively mild disease as well as those with more severe exocrine dysfunction.

Breath tests. Various breath tests using labeled carbon in a fatty acid of triglyceride have been developed to assess intralumenal digestion of fat by pancreatic lipase activity. [77]

Triolein breath test. Triglycerides such as triolein can be labeled with [^{14}C] fatty acids. After oral administration, triglycerides undergo digestion by pancreatic enzymes in the small intestine. Free fatty acids are absorbed by the intestinal mucosa and hepatically metabolized to yield [^{14}C]O_2, which is subsequently exhaled in the breath. Patients with severe pancreatic dysfunction exhale low to nonexistent levels of [^{14}C]O_2 after the ingestion of labeled triolein. Because only those with pancreatic dysfunction severe enough to cause fat maldigestion are identified and steatorrhea occurs only when lipase output is less than 10% of normal, [65] the triolein breath test is relatively insensitive in the setting of mild to moderate disease. For this test truly to reflect pancreatic function, nonpancreatic factors involving gastric emptying, gastroduodenal anatomy, intestinal absorption, hepatic metabolism, and pulmonary function must be intact. Disease states affecting any of these functions can lead to misleading results. In an attempt to improve specificity, some have suggested repeating the test after the oral administration of pancreatic enzyme supplements. Those with pancreatic exocrine insufficiency should experience an improvement in test results with exogenous pancreatic enzyme supplementation, whereas those with nonpancreatic causes would not be expected to improve. [93] Although this modification likely does improve specificity, it does not improve sensitivity of this test.

Mixed triglycerides breath test. Vantrappen and colleagues [94] recently described the mixed triglycerides breath test that uses 1,3-distearyl,2[carboxyl- ^{13}C] octanoyl glycerol as a substrate. In the presence of pancreatic lipase, the two stearyl groups are cleaved from the glyceryl group. [^{13}C]octanoyl monoglyceride and [^{13}C]octanoate, a medium-chain fatty acid, are absorbed and rapidly metabolized to [^{13}C]O_2. Breath [^{13}C]O_2 production correlates well with lipase output as measured by duodenal intubation with CCK administration. The reported sensitivity of 89% and pecificity of 81% for the mixed triglyceride breath test are comparable to other noninvasive studies, such as the pancreolauryl test. The authors claimed that this test is much more sensitive in detecting impaired pancreatic exocrine

function than fecal fat determination. [94] Indeed, the test detected most of the patients with chronic pancreatitis based on decreased pancreatic lipase output by invasive testing but no steatorrhea. It appears that the mixed triglyceride breath test is a promising noninvasive method to assess duodenal pancreatic lipase activity. This method may also provide a useful means of monitoring the efficacy of pancreatic enzyme replacement therapy. A breath test using ^{13}C-cholesteryl octanoate as a substrate has been reported. [95] Like the triolein breath test, nonpancreatic factors, including previous gastroduodenal surgery and significant intestinal, hepatic, metabolic, or pulmonary disease, can affect test results.

Starch breath test. The excretion of [^{13}C]O_2 in the breath after the oral administration of [^{13}C]-labeled rice starch (amylase dependent) or [^{13}C]-labeled glucose (amylase independent) has been measured in patients with chronic pancreatitis. [96] One study reported that breath [^{13}C]O_2 excretion after starch was significantly less than after glucose in both healthy volunteers and patients with chronic pancreatitis. However, [^{13}C]O_2 excretion after rice starch was significantly less in patients with chronic pancreatitis than in healthy volunteers. Unfortunately, the sensitivity of this test was less than 50%. Others have reported improved sensitivity (50% to 71%) with test modifications, including the administration of 100 mg of rice starch and the measurement of breath hydrogen excretion rather than [^{13}C]O_2. [97], [98] As is the case with tubeless pancreatic function testing in general, the starch breath test has poor sensitivity in patients with mild to moderate pancreatic exocrine dysfunction. False-positive breath hydrogen measurements can occur in the setting of small bowel bacterial overgrowth. Theoretically, bacterial overgrowth of the stomach, as seen in patients with gastroparesis and in those taking medications such as proton pump inhibitors, could also cause false-positive results.

Fecal Fat and Enzyme Tests

Quantitative stool collection with fecal fat determination is the gold standard for the detection of steatorrhea. For this study, patients should be instructed to ingest a diet containing 100 g of fat per day starting at least 3 days before the 48- to 72-hour stool collection. Fecal fat excretion of more than 7 g per 24 hours is abnormal. [2] If a patient is ingesting a proper diet, qualitative analysis of random stool samples with Sudan staining also sensitively and specifically detects steatorrhea. Unfortunately, less than 10% of normal lipase output must be present before fat maldigestion from pancreatic disease can be detected. [65] In addition, many other gastrointestinal diseases (e.g., Crohn's disease, celiac disease, Whipple disease) can cause steatorrhea. Consequently, the detection of steatorrhea by stool testing is neither sensitive nor specific for pancreatic disease. The specificity of fecal fat testing can be improved by performing a two-stage procedure in which a repeat collection is done in conjunction with oral pancreatic enzyme replacement. A decrease in fecal fat excretion after enzyme replacement supports the presence of pancreatic exocrine dysfunction.

Fecal pancreatic enzyme determination has been used to identify patients noninvasively who have severe chronic pancreatitis. The enzymes most commonly measured for this purpose include chymotrypsin and elastase.

Chymotrypsin Fecal chymotrypsin determination has been used for many years to identify patients with chronic pancreatic disease. The test is typically performed on random stool samples, although prolonged collection may enhance accuracy. It is convenient because fecal chymotrypsin remains stable at room temperature for days, [77] and it is easy to perform now that rapid colorimetric techniques are available. [99] Fecal chymotrypsin determination has a sensitivity of 45% to 100% and a specificity of 49% to 90%. [77], [99], [100], [101], [102] and [103] Measurement of fecal chymotrypsin can be confounded by binding to insoluble debris in the intestine. [104] Other factors, including Billroth II gastrojejunostomy, severe hepatic disease, and gastrointestinal diseases that cause diarrhea or malabsorption can affect the accuracy of this test. [77] Pancreatic enzyme supplementation can cause falsely normal results and should be discontinued 5 days before stool collection (Fig. 151-3). As is the case with other forms of noninvasive pancreatic function testing, fecal chymotrypsin measurement is better able to identify those with advanced disease as defined by invasive testing. [105]

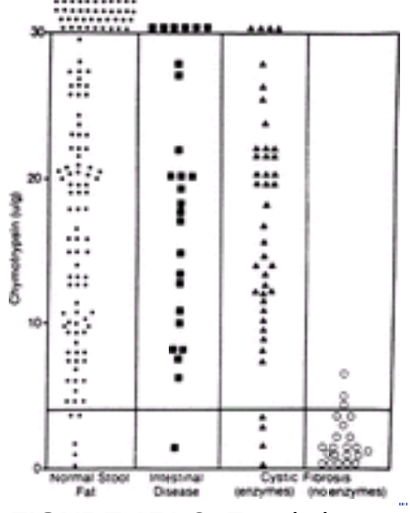

FIGURE 151-3. Fecal chymotrypsin activity in patients with normal stool fat excretion (127 cases), patients with steatorrhea due to intestinal disease (26 cases), patients with pancreatic insufficiency and steatorrhea due to cystic fibrosis but receiving pancreatic enzyme therapy (42 cases), and similar patients before enzyme replacement therapy (22 cases). (From ref. [101].)

The noninvasive nature, relatively low cost, and ease of performing and repeating fecal chymotrypsin determination are attractive features of this test. However, the marginal performance characteristics limit the usefulness of this test as a screening tool for chronic pancreatitis.

Elastase Human pancreatic elastase 1, a member of the acidic elastase family, was detected by Sziegoleit [106] as a new endoprotease and sterol-binding protein present in both human pancreatic secretion and feces. Elastase is measured with a new sandwich-type enzyme immunoassay. [107] Unlike chymotrypsin, quantitative studies using immunoelectrophoresis have shown that fecal elastase levels remain unaffected during intestinal transit. In fact, concentrations of elastase were found to be five to six times greater in stool than in pancreatic juice. [107], [108] Elastase has been found to be stable in stool samples for up to a week at room temperature. [109] Immunoreactive elastase cannot be detected in either porcine or bovine pancreatic enzyme preparations. Consequently, in contrast to fecal chymotrypsin determination, elastase measurement is not affected by oral pancreatic enzyme replacement therapy (Fig. 151-4). In addition, this test is not affected by previous gastrointestinal surgery, gastric dysmotility, or mucosal disease of the small intestine. [110]

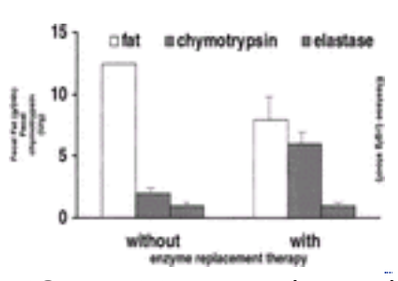

FIGURE 151-4. Fecal excretion of chymotrypsin (mean ± SD), fat, and immunoreactive elastase during a 24-hour collection period in 12 patients with cystic fibrosis and steatorrhea with and without enzyme replacement therapy. Fecal elastase content, unlike fecal fat and chymotrypsin content, was not influenced by pancreatic enzyme therapy. (From ref. [111].)

When patients with an abnormal secretin-pancreozymin test were divided into groups based on the presence or absence of steatorrhea, abnormal fecal elastase levels were found in 96% of patients with severe exocrine pancreatic insufficiency and steatorrhea and in 88% of those with pancreatic dysfunction but no steatorrhea. In the same group of patients, the sensitivity of fecal chymotrypsin measurement in those with steatorrhea was 91% but was only 56% in those without steatorrhea [111] (Table 151-5). The fecal elastase test was also compared with the pancreolauryl test in patients with chronic pancreatitis confirmed by ERP and CT. [110] Fecal elastase determination was as sensitive and more specific than the pancreolauryl test in detecting chronic pancreatitis.

TABLE 151-5 Fecal Elastase 1 Compared with Secretin-Pancreozymin Test and Fecal Chymotrypsin in Pancreatic Insufficiency with and without Steatorrhea

The fecal elastase test is a simple, noninvasive, relatively inexpensive functional test for patients with suspected chronic pancreatitis. Although reasonably sensitive in patients with severe disease, this test has not been found to be sufficiently sensitive in patients with mild or even moderate disease. [112], [113]

Miscellaneous Indirect Tests of Pancreatic Function

Serum Trypsin-like Immunoreactivity and Pancreatic Isoamylase Concentration The measurement of various pancreatic factors in peripheral blood as an indirect assessment of pancreatic function is an attractive prospect. Although serum trypsin-like immunoreactivity and pancreatic isoamylase concentration have been shown to be low in patients with severe pancreatic dysfunction, the sensitivity of these tests is probably less than 50% overall. [78] There are no reliable serum markers for severe pancreatic disease.

Plasma Pancreatic Polypeptide Concentration Pancreatic polypeptide (PP) is found in both the endocrine and exocrine portions of the pancreas. In normal volunteers, plasma PP concentration rises after stimulation of the pancreas and therefore may provide an indirect measure of exocrine function. An insufficient rise in plasma PP concentration after pancreatic stimulation with CCK, secretin, bombesin, or a test meal has a sensitivity of more than 90% in patients with severe pancreatic disease and steatorrhea. [78], [114] However, the sensitivity of this test in a population with less severe disease and no steatorrhea is likely less than 50%. [115]

Plasma Amino Acid Consumption Test In response to agents such as CCK, secretin, or cerulein, plasma amino acids are taken up by the pancreas and used in protein synthesis. The premise of the amino acid consumption test (AACT) is that a patient with severe pancreatic dysfunction should not deplete the plasma amino acid pool as efficiently as an individual with a normal pancreas. [116] Amino acid concentrations in timed venous blood samples obtained before and after pancreatic stimulation are compared. A fall in amino acid concentration of less than 12% after pancreatic stimulation with CCK is considered abnormal. [117] Although some investigators have reported sensitivity of the AACT to approach 90%, [116], [117] and [118] others have not been able to confirm these results. [119] In addition, the specificity of this test has been reported to be as low as 21%. [117] Given the need for multiple timed blood samples and the marginal performance characteristics, the AACT is of little value in clinical practice.

Comparison between Pancreatic Exocrine Function and Imaging in Chronic Pancreatic Disease

Transcutaneous ultrasound and high-resolution CT are widely accessible means of evaluating the pancreatic parenchyma. CT is more accurate than transcutaneous ultrasound in detecting small cysts and parenchymal calcifications. ERP has traditionally been regarded as the gold standard method to detect morphologic changes of the pancreatic duct. Unfortunately, ERP has a number of drawbacks, including relatively high cost and the potential for significant adverse events such as pancreatitis and even death. More recently, EUS has been shown to accurately detect abnormalities of the pancreatic duct and parenchyma. [120] EUS is clearly superior to transcutaneous ultrasound and CT and at least equivalent and arguably superior to ERP in detecting chronic pancreatitis. [61], [121], [122] One potential advantage of EUS over ERP is its lack of association with postprocedural pancreatitis. For all of the diagnostic tests for chronic pancreatitis, the challenge is not in the detection of severe disease that can usually be easily established with a limited evaluation. Rather, the difficulty lies in identifying patients with earlier stages of chronic pancreatitis. Unfortunately, none of the available structural or functional tests is always diagnostic in such patients. As such, a combination of structural and functional studies is often required to achieve diagnostic certainty in patients with mild to moderate disease. Among the structural and functional tests, ERP and invasive pancreatic function testing appear to be the best able to identify those with mild to moderate chronic pancreatitis.

There are relatively few studies that directly compare the ability of structural and functional tests to detect chronic pancreatitis. [123], [124], [125], [126] and [127] The best designed studies are those that evaluate functional or structural studies against a histological gold standard. For practical reasons, few such studies have been conducted. [128], [129] and [130] When direct comparisons have been made, invasive functional testing has been found to correlate more closely with histological findings than ERP in patients with chronic pancreatitis. [129], [130]

A number of published protocols have used one or more structural studies or invasive pancreatic function testing as a gold standard, making meaningful direct comparisons difficult, if not impossible. In one study that directly compared invasive pancreatic function testing (secretin-pancreozymin test) to ERP, Lankisch and colleagues [123] found that in most patients with chronic pancreatitis, there was a good correlation between the two tests. Of 202 patients, 129 (64%) had parallel secretin-pancreozymin and ERP test results. Twenty-one percent had abnormal results on both tests, but the degree of abnormalities observed was not consistent. Fifteen percent had discordant results, with one test abnormal and one test normal. In the group with discordant results, all but one patient had an abnormal ERP but normal secretin-pancreozymin result. Others have also observed discordant ERP and invasive functional test results in 12% to 29%. [124], [125], [126] and [127] Another recent study evaluated ERP, EUS, and the secretin test in 80 consecutive patients with recurrent pancreatitis and 25 controls. [61] The secretin test agreed with EUS 100% of the time in controls and patients with severe pancreatic disease. However, agreement was only 13% in those with mild and 50% in those with moderate chronic pancreatitis by EUS. There are several possible explanations for this observation. First, prior episodes of severe acute pancreatitis may have resulted in morphologic abnormalities of the pancreatic duct without long-term consequence to pancreatic function. [131] Second, morphologic changes of the pancreatic duct without corresponding changes in exocrine function are known to occur with aging. [132] Third, there are likely situations in which ERP films are thought to demonstrate changes suggestive of mild, chronic pancreatitis when in fact they do not. Finally, it may be that ERP is more sensitive than invasive functional testing or that the invasive functional testing is falsely normal in some patients with discordant results. This possibility seems less likely based on a recent study by Lambiase and associates, [127] who reported that 8 of 52 (15%) patients had divergent functional and ERP test results. Six of 8 patients had an abnormal functional test but normal ERP. Of the 6 patients with an abnormal functional test but normal ERP, 5 were subsequently found to have chronic pancreatitis. In contrast, neither of the 2 patients with an abnormal ERP and normal functional test was later found to have chronic pancreatitis. This study would suggest that invasive functional testing is better able to detect early chronic pancreatitis than ERP.

In summary, both structural and functional studies play an important role in establishing the diagnosis of chronic pancreatitis. This is especially true in patients with earlier stages of chronic pancreatitis. The information gained from such studies can prove independently diagnostic or complementary, particularly when assessing disease severity. Given the limitations of the available tests, perhaps the future of diagnostic testing for pancreatic disease will include the marriage of structural and functional studies. Recently, *intraductal secretin testing,* which involves the collection of pure intraductal pancreatic juice during ERP, has been described. Preliminary work suggests that this test yields performance characteristics comparable to traditional secretin testing. [133], [134] Hopefully, the future will bring the development of other novel tests for the diagnosis of chronic pancreatitis.

BREATH TESTS TO EVALUATE CARBOHYDRATE MALABSORPTION AND BACTERIAL OVERGROWTH

Measurements of the respiratory excretion of labeled CO_2 after oral administration and metabolism of carbon-labeled substrates, or of H_2 after administration of carbohydrates can be used to assess fat, carbohydrate, and bile salt malabsorption or bacterial overgrowth. [135] All breath tests that rely on the measurement of labeled CO_2, both those using radioactive ^{14}C and those using the stable isotope ^{13}C, are based on the idea that either intralumenal (bacterial) or cellular (intermediary) processes convert the substrate into CO_2, which is excreted in expired air. To calculate the dilution of tracer in the total CO_2 excreted, one must assume a constant CO_2 production of 9 mmol/kg body weight or 300 mmol/m^2 body surface area. The process is complicated further by the fact that it is impractical to measure CO_2 excretion continuously, and interval samples must be taken. The stable isotope (^{13}C) tests require mass spectrometric or infrared detection techniques and are subject to variability because of the natural abundance and inconsistency of ^{13}C in the diet.

Hydrogen breath tests can be used to study carbohydrate malabsorption or bacterial metabolism because the sole source of H_2 in the mammal is bacterial fermentation. The most commonly used breath tests are described in the following paragraphs.

Hydrogen Breath Test for Carbohydrate Malabsorption

In those individuals in whom a therapeutic trial of carbohydrate-restricted free diet is inconclusive or impractical, either breath hydrogen testing or lactose tolerance

testing may be indicated. [136], [137] Because hydrogen is produced only by bacterial fermentation of carbohydrates, increased breath hydrogen excretion after a carbohydrate challenge can be used to uncover small intestine bacterial overgrowth, disaccharidase deficiency, and even excess carbohydrate wastage that might occur with motility disorders. [138] Patients with small intestine mucosal disease and pancreatic exocrine insufficiency may also have mild carbohydrate malabsorption. Bacterial overgrowth of the small bowel may cause an early peak of increased hydrogen production within 2 hours of giving a carbohydrate meal. In disaccharidase deficiency, small intestine mucosal disease, or pancreatic insufficiency, the peak in hydrogen may come later, between 3 and 6 hours after ingestion, when the carbohydrate reaches the colonic bacteria [139], [140] and [141] (Fig. 151-5). The increase in hydrogen excretion by patients with pancreatic insufficiency can be reduced by concomitant administration of pancreatic enzymes. Therefore, depending on the type of carbohydrate malabsorption sought, an oral dose of lactose (0.25 to 1.0 g/kg body weight), glucose (50 g), lactulose (10 g), fructose (1 g/kg), or rice flour (100 g) may be given after an overnight fast. To test for lactose intolerance, a lactose dose of 25 g is frequently used, although a 50-g test dose may be more sensitive and a 12.5-g dose more specific. [136], [141] The test must be standardized for each carbohydrate and dose, but generally an increase of over 20 ppm in exhaled hydrogen over baseline values within the first 2 to 8 hours of ingestion is diagnostic. It is important to realize that the breath hydrogen test measures only carbohydrate malabsorption, and about 10% of people have a gut flora incapable of producing H_2. [142] In this circumstance, the measurement of breath methane excretion can be of value. Unfortunately, there are currently no standards established for what constitutes an abnormal rise in breath methane excretion in patients with suspected carbohydrate malabsorption.

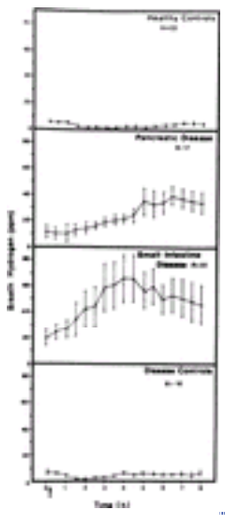

FIGURE 151-5. Breath histamine-2 (H_2) production following ingestion of 100 g of rice carbohydrate. Healthy and disease controls are compared with patients with pancreatic insufficiency and intestinal mucosal disease. The increased H_2 produced in patients with pancreatic insufficiency was corrected by addition of pancreatic extract to the rice pancake test meal. (From ref. [139].)

Hydrogen and Carbon-13 and -14 Breath Tests for Bacterial Overgrowth

The breath hydrogen test can be used to diagnose bacterial overgrowth and has a sensitivity of 62% to 90% and a specificity of 78% to 83% [143], [144] and [145] if breath H_2 increases are found within the first 2 hours of either glucose or rice flour ingestion. Because of its ready availability, glucose (50 to 75 g) is the most commonly used substrate. The combination of a high fasting breath hydrogen excretion rate and a significant increase in breath hydrogen after glucose (more than 10 to 12 ppm H_2 excretion over baseline) is present in about half of the patients with bacterial overgrowth. [146] An isolated increase in basal breath hydrogen excretion has a sensitivity for bacterial overgrowth of 4% to 29%. [147] Lactulose and rice flour have also been used as substrates for hydrogen breath testing, but sensitivity for bacterial overgrowth has been less than 50%. [148], [149] A number of factors can influence the accuracy of this test. Diseases affecting small intestinal absorption of the test substrate or with rapid intestinal transit can lead to false-positive results. In addition, bacterial overgrowth of the stomach, as can be seen in patients with gastric stasis and those taking a proton pump inhibitor, can also lead to false-positive results. Delayed gastric emptying in the absence of gastric bacterial overgrowth can cause false-negative results. About 10% of patients harbor non–H_2-producing enteric bacteria leading to false-negative results. As has already been mentioned, the measurement of breath methane excretion may be helpful in these patients, although studies to validate this suggestion have not been performed.

The ^{14}C-D-xylose breath test is said to be more specific for bacterial overgrowth, with more than 85% of patients having an increase in exhaled $^{14}CO_2$ within 60 minutes of ingesting 1 g of ^{14}C-D-xylose. [150], [151] Because most of the ^{14}C-labeled xylose is absorbed in the small intestine, less reaches the colon, where it can be metabolized to CO_2 by bacteria, confounding interpretation of the test. A version of the D-xylose breath test using the stable isotope ^{13}C has been used in children. [152] Although the test can be complicated by delayed gastric emptying, the champions of the test claim excellent specificity, sensitivity, and reproducibility for this test. Unfortunately, the available studies have typically involved small numbers of selected patients and have not universally endorsed this test. [153] A recent study in 46 consecutive patients with suspected bacterial overgrowth found the sensitivities for the ^{14}C-D-xylose and glucose hydrogen breath tests to be similar (42% versus 58%, respectively). [154]

The cholyl- ^{14}C-glycine breath test is based on the rationale that conjugated (glycine or taurine) bile acids are reabsorbed passively throughout the jejunum and actively absorbed in the terminal ileum. [155], [156] Bacterial overgrowth hydrolyzes the peptide bond, releasing the ^{14}C-labeled glycine, which is then absorbed, metabolized to $^{14}CO_2$, and exhaled in expired air. Unfortunately, the test is not specific, and it gives similar results in patients with terminal ileal disease or resection and may be misleading in severe mucosal disease.

PLAIN AND CONTRAST RADIOLOGY

ABDOMINAL PLAIN FILMS

Abdominal plain films often play an important role in the evaluation of patients with abdominal pain or distention or with clinical signs of an acute abdomen. [1] The purpose of this section is to review plain film findings such as bowel dilation, pneumoperitoneum, and pneumatosis and to discuss their significance. However, computed tomography (CT) has increasingly been recognized as a more sensitive technique than abdominal plain films for diagnosing a host of conditions in patients with acute abdominal symptoms.

Technique

In patients with acute abdominal findings, both supine and upright plain films of the abdomen should be obtained. The upright films should be centered to include the diaphragms. This permits assessment not only of free intraperitoneal air beneath the diaphragms but also of air-fluid levels within the bowel that can be detected only on horizontal beam views. If patients are too sick or debilitated to stand, left lateral decubitus views should instead be obtained to detect free air between the liver and the right lateral abdominal wall.

Abnormalities

Bowel Dilation Bowel dilation is usually caused by obstruction or ileus. The small bowel is a more common site of obstruction than the colon. Other patients may develop an adynamic ileus without evidence of mechanical obstruction. These conditions are considered separately in the following sections.
Small Bowel Obstruction Because of the great increase in abdominal surgery in recent decades, most small bowel obstructions are caused by postoperative intraperitoneal adhesions. [1] Other, less common causes include incarcerated hernias, metastases, radiation, Crohn's disease, intussusception, and gallstone ileus. In a mechanical small bowel obstruction, supine abdominal plain films usually reveal multiple loops of dilated small bowel and a paucity of colonic gas (Fig. 152-1A); multiple air-fluid levels are almost always seen on upright or decubitus films (see Fig. 152-1B). Dilated small bowel can usually be differentiated from dilated colon by its more central location in the abdomen as well as the presence of tightly spaced folds or valvulae conniventes that completely traverse the diameter of the bowel.

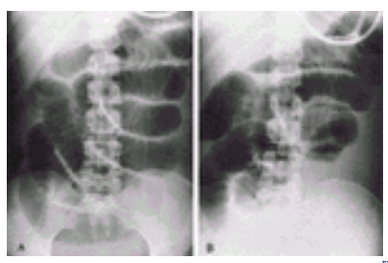

FIGURE 152-1. Small bowel obstruction due to postoperative adhesions. **A:** Supine abdominal film shows multiple loops of dilated small bowel and a paucity of colonic gas. **B:** Upright film shows multiple air-fluid levels in dilated small bowel. These findings are characteristic of small bowel obstruction. (From ref. [1].)

Although advanced small bowel obstructions are easily recognized on abdominal plain films, the diagnosis can be more difficult in patients who do not swallow a large amount of gas. In such cases, gaseous distention of bowel can be minimal or absent. Nevertheless, accumulation of fluid still occurs, and horizontal beam films may still demonstrate numerous air-fluid levels in nondilated bowel. Occasionally, a row of tiny gas bubbles or "string of pearls" may be seen on upright or decubitus films as a result of small amounts of gas trapped along the superior margin of small bowel loops almost completely filled with fluid. [2] In patients who swallow virtually no air at all, plain films may reveal a gasless abdomen with multiple fluid-filled loops of bowel appearing as tubular or sausage-shaped densities in the bowel that may be indistinguishable from true abdominal masses. [2] A simple mechanical obstruction usually does not cause bowel ischemia. However, a closed loop obstruction due to an incarcerated hernia, volvulus, or other cause may occasionally produce a strangulating obstruction with ischemia or necrosis of the involved segment of bowel. Recently, CT has been recognized as a sensitive technique for detecting strangulation of bowel in patients with closed loop obstruction. [3] It is important to recognize that advanced cecal carcinomas may obstruct the ileocecal valve, mimicking the plain film appearance of a distal small bowel obstruction. [1] More distal colonic obstructions may also be masked by an incompetent ileocecal valve that allows gas to reflux from the obstructed colon into the small bowel. A barium enema may be performed on patients with radiographic evidence of a distal small bowel obstruction to rule out an unsuspected colonic carcinoma, particularly when there is no history of prior abdominal surgery.
Colonic Obstruction In colonic obstruction, supine abdominal plain films usually reveal disproportionate colonic distention proximal to the obstructing lesion with air-fluid levels in the dilated bowel on upright films. The transition from dilated to nondilated bowel can often be recognized on the radiographs and most commonly occurs in the sigmoid colon because of an obstructing carcinoma. Primary colonic carcinoma accounts for 80% to 90% of all colonic obstructions, but diverticulitis, metastases, and volvulus are other, less common causes. [1] The most devastating complication of colonic obstruction is cecal perforation. Because of the high mortality associated with cecal perforation, colonic obstruction should be considered a surgical emergency. In general, a cecal diameter greater than 10 to 12 cm on

abdominal plain films is thought to be an indication for urgent colonic decompression because of the high risk for perforation. [4] Colonic volvulus should be distinguished from a simple colonic obstruction because it results from twisting of the colon around a fixed point on its mesentery, producing a closed loop obstruction. Most cases involve the sigmoid colon or cecum. [5] Sigmoid volvulus is an acquired condition that often occurs in elderly patients who have chronic constipation or a high-residue diet. [6] In contrast, cecal volvulus tends to occur in younger patients owing to congenital failure of retroperitoneal fixation of the cecum and ascending colon. [6] As a result, the right side of the colon has a persistent mesentery on which a volvulus can take place. In sigmoid volvulus, abdominal plain films usually reveal a massively dilated sigmoid colon that extends out of the pelvis into the upper abdomen with some degree of proximal colonic distention [1], [7] (Fig. 152-2). In contrast, cecal volvulus usually produces a massively dilated cecum that flips into the left upper quadrant with a single air-fluid level on upright or decubitus horizontal beam films. [1], [7] Because colonic volvulus is a closed loop obstruction, twisting of the mesentery may compromise the vascular supply of the bowel, leading to strangulation, infarction, and perforation of the involved loop. Early diagnosis is therefore essential, so that colonic volvulus can be treated before strangulation occurs.

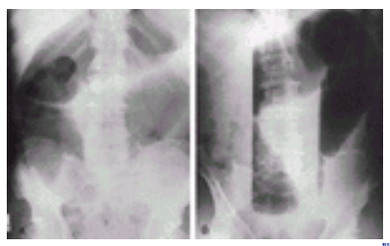

FIGURE 152-2. Sigmoid volvulus. **A:** Supine abdominal plain film shows a massively dilated sigmoid colon rising out of the pelvis into the abdomen. **B:** Right lateral decubitus film shows long air-fluid levels in both limbs of this dilated sigmoid loop. (From ref. [1].)

Because of the risk for cecal perforation in patients with colonic obstruction, a barium enema may be required as an emergent procedure to determine whether an obstruction is present and to delineate the nature and site of the obstructing lesion. Carcinoma of the colon typically manifests as an annular lesion with shelflike, overhanging borders, whereas diverticulitis produces a tapered area of narrowing with intact but distorted mucosal folds. In colonic volvulus, the barium enema reveals a typical “bird-beak” deformity at the site of the volvulus.

Adynamic Ileus In patients with an adynamic or paralytic ileus, there is interference with intestinal transport without an actual mechanical obstruction. As a result, a supine abdominal radiograph classically shows diffusely dilated small and large bowel. Although the degree of distention depends on the degree of air swallowing, horizontal beam films usually demonstrate air-fluid levels throughout the bowel. [8] For reasons that are unclear, however, abdominal plain films sometimes reveal an isolated small bowel or colonic ileus. In such cases, the findings may be indistinguishable radiographically from a mechanical small bowel or colonic obstruction. [1], [8] When the colon appears dilated, the presence of a significant amount of rectal gas on left lateral views of the rectum should favor an ileus. [9] If it is unclear whether the patient has a distal colonic obstruction or an ileus, a single-contrast barium enema should be performed to differentiate these conditions.

Pneumoperitoneum Upright chest and abdominal films and left lateral decubitus films of the abdomen are extremely sensitive for detecting free intraperitoneal air (i.e., pneumoperitoneum) and may demonstrate collections of intraperitoneal air as small as 1 mL. [10] In patients with an acute abdomen, the presence of free air almost always indicates a perforated viscus with subsequent peritonitis. The most common cause is a perforated duodenal ulcer. [1] Colonic perforation due to ischemic bowel disease, toxic megacolon, and diverticulitis is much less common but should be suspected in any patient with pneumoperitoneum and colonic distention on abdominal plain films. [11] Pneumoperitoneum can readily be documented on upright chest films or upright or left lateral decubitus films of the abdomen by the presence of free intraperitoneal air directly beneath the diaphragms (Fig. 152-3A) or between the liver and the right lateral abdominal wall. Unfortunately, some patients are too ill or debilitated to stand or lie on their side; supine abdominal radiographs may be the only films that are obtained in these patients. However, pneumoperitoneum can be recognized on supine films by the presence of air on both sides of the bowel wall (i.e., the Rigler sign) (see Fig. 152-3B), by linear or triangular collections of gas in the subhepatic space, or by air outlining the falciform ligament as a linear density in the right upper quadrant. [1], [2] In one study, one or more signs of free intraperitoneal air were present on supine films in 59% of patients with pneumoperitoneum. [12]

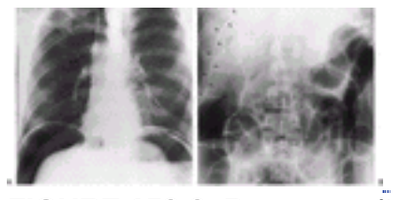

FIGURE 152-3. Pneumoperitoneum. **A:** Upright chest film shows large amounts of free intraperitoneal air beneath the diaphragm in this patient with a perforated duodenal ulcer. **B:** Supine abdominal plain film of a different patient shows an indirect sign of pneumoperitoneum with air on both sides of the bowel wall (the Rigler sign) (*arrows*) after inadvertent perforation at colonoscopy. (From ref. [1].)

Pneumatosis Intramural bowel gas or pneumatosis may be caused by ischemic or necrotic bowel but may also occur as a benign finding in asymptomatic patients. In patients with intestinal necrosis, gas may dissect into the wall of the bowel, producing mottled or linear gas shadows that have a characteristic plain film appearance [1], [13] (Fig. 152-4). CT has been recognized as a more sensitive technique than abdominal plain films for detecting pneumatosis in patients with necrotic bowel. In patients with intestinal necrosis, tiny, linear, peripherally branching gas shadows may occasionally be identified over the liver owing to gas within the portal venous system. [13] This finding usually indicates severe disease with an extremely ominous prognosis. However, portal venous gas should be distinguished radiographically from biliary gas (i.e., pneumobilia), which tends to collect centrally in the common bile duct because of the opposite direction of bile flow. Pneumobilia can result from a variety of causes, including gallstone ileus, emphysematous cholecystitis, and a surgical or spontaneous biliary-enteric fistula. [1]

FIGURE 152-4. Pneumatosis due to an infarcted left colon after surgery. Close-up view from supine abdominal plain film shows tiny, mottled, and linear collections of gas in the wall of the descending colon.

Pneumatosis can also occur as a benign condition in which multiple gas-filled cysts or blebs are present in the wall of the bowel. [1], [13] These patients are rarely ill, and the condition is usually discovered accidentally on abdominal plain films obtained for other reasons. Radiographically, these gas-filled blebs are typically recognized as cystic or grapelike collections of gas that appear quite different from the linear gas shadows associated with intestinal necrosis.

CONTRAST STUDIES

Contrast studies of the gastrointestinal tract can be performed using single- or double-contrast technique. Single-contrast studies entail filling the lumen with a relatively low-density barium suspension and evaluating for contour abnormalities or filling defects in the barium pool. In contrast, double-contrast studies use a smaller amount of high-density barium and gas to evaluate the en face appearance of the mucosal surface. As a result, double-contrast techniques have dramatically

improved the radiologist's ability to diagnose a variety of inflammatory and neoplastic diseases throughout the gastrointestinal tract. A major advantage of these techniques is their ability to demonstrate superficial mucosal abnormalities that cannot easily be recognized on conventional single-contrast examinations. In other cases, double-contrast studies may detect lesions that are missed or misinterpreted at endoscopy. Double-contrast radiography is also less expensive and less invasive than endoscopy. Thus, it is a valuable technique for evaluating patients with suspected gastrointestinal disease. All radiologists should strive for excellent double-contrast studies to maximize the information available from the procedure.

PHARYNX

Indications

With increased survival of elderly people, pharyngeal disorders have become an increasingly frequent problem in modern medical practice. About 35% of nursing home patients have some form of swallowing dysfunction. [14] Aspiration pneumonia and choking are particularly common causes of morbidity and mortality. Radiographic examination of the pharynx is now recognized as a valuable tool in the diagnostic workup of this large group of patients with pharyngeal disorders.

Contrast studies of the pharynx are most frequently performed on patients who have difficulty swallowing. However, disorders of the pharynx also may manifest as respiratory and speech problems. Laryngeal penetration or overflow aspiration may lead to recurrent pneumonia, asthma, chronic bronchitis, coughing, or choking. In other patients, soft-palate insufficiency may result in nasal regurgitation or may give the voice a nasal quality. A pharyngoesophagram may be helpful in patients who have a wide spectrum of respiratory, speech, and swallowing difficulties. Barium studies are also useful in assessing pharyngeal function and morphology in patients with a history of neuromuscular disease, stroke, pharyngeal tumor, or prior head and neck surgery or radiation.

Normal Anatomy

The pharynx is a complex muscular tube suspended superiorly from the skull base and styloid process, posteriorly from the cervical spine, and anteriorly from the mandible and hyoid bone. At least 26 muscles and six cranial nerves participate in pharyngeal function. [15], [16]

The pharynx can be arbitrarily divided into three portions: the nasopharynx, oropharynx, and hypopharynx. The soft palate separates the nasopharynx from the oropharynx, and the pharyngoepiglottic fold separates the oropharynx from the hypopharynx. The tongue forms the anterior wall of the oropharynx. The larynx, with its associated epiglottic, thyroid, cricoid, and arytenoid cartilages, forms the anterior wall of the hypopharynx. This laryngeal complex often protrudes into the lower hypopharynx as an apparent mass.

The mucosal surface of the pharynx is thrown into a series of folds by underlying lymphoid and muscular tissue. The vertical surface of the base of the tongue often has a nodular appearance as a result of the circumvallate papillae and lingual tonsil. Nodular lymphoid tissue or linear webs may also interrupt the normally smooth surface of the valleculae. Although the anterior border of the hypopharynx usually has a smooth contour, close apposition of the longitudinal muscles of the pharynx to the overlying squamous mucosa results in longitudinal striations of the lateral and posterior walls of the hypopharynx. [16] Horizontal mucosal striations are seen in the redundant mucosa overlying the arytenoid processes and cricoid cartilages. [16]

Technique

A complete radiographic examination of the pharynx includes a cine or video pharyngoesophagram to evaluate motility and a series of spot films to evaluate morphology. [17], [18] and [19] In patients with suspected foreign body, fistula, or abscess, frontal and lateral plain films of the neck should also be obtained.

The barium study is initially performed with a high-density barium suspension for optimal visualization of the pharynx. The patient is asked to swallow barium in frontal, lateral, and oblique projections. A video recording of each swallow permits a frame-by-frame or slow motion analysis of the various parameters of deglutition. Movement of the tongue, soft palate, and epiglottis, as well as of the laryngeal closure and cricopharyngeal opening, are best evaluated in the lateral projection. However, symmetry of tongue motion, pharyngeal peristalsis, and epiglottal tilt are best evaluated in the frontal projection.

After individual swallows of barium, double-contrast spot films of the pharynx are obtained in frontal and lateral projections. The spot films are obtained during suspended respiration and during a modified Valsalva maneuver or phonation to distend the pharynx optimally. [20] The frontal view is best for demonstrating the contours of the valleculae and piriform sinuses, the lateral walls of the tonsillar fossae and hypopharynx, and the superior border of the base of the tongue. The lateral view is best for demonstrating the inferior border of the base of the tongue, the soft palate, the posterior pharyngeal wall, the anterior hypopharyngeal wall, the epiglottis, and the cricopharyngeus.

After the pharyngeal examination has been completed, upright double-contrast and prone single-contrast views of the esophagus are obtained to rule out associated esophageal disease.

Abnormalities

Laryngeal Penetration and Aspiration Laryngeal penetration occurs when barium enters the laryngeal vestibule during swallowing. Penetration may be limited to the region of the subepiglottic space or may extend as far as the true vocal cords or trachea. Laryngeal penetration occurs because of poor timing of oral and pharyngeal events associated with swallowing or pharyngeal dysmotility due to neuromuscular disorders such as amyotrophic lateral sclerosis, multiple sclerosis, or cerebrovascular accidents. Inflammatory or neoplastic diseases that restrict pharyngeal motility may also cause penetration. Aspiration occurs when barium enters the laryngeal vestibule during normal breathing. Aspiration results from stasis and retention of pharyngeal contents because of tumor, diverticula, or neuromuscular disease in the pharynx. Aspiration may also be caused by gastroesophageal reflux or reflux of esophageal contents above an obstructing esophageal lesion, such as a stricture or carcinoma. Penetration is primarily associated with dysmotility, and aspiration is associated with stasis.
Cricopharyngeal Prominence The pharyngoesophageal segment, the radiographic equivalent of the manometrically defined upper esophageal sphincter (UES), is formed by the inferior portion of the cricopharyngeus and possibly the proximal cervical esophagus. [21], [22] Although the UES is tonically contracted at rest, initiation of swallowing causes the sphincter to relax ahead of the oncoming bolus. The UES also acts as part of the pharyngeal peristaltic wave, functioning in sequence with the constrictor musculature. The pharyngoesophageal segment is best evaluated on a dynamic recording of the pharynx in a lateral projection. During swallowing, a prominent cricopharyngeus appears as a smooth, 1-cm in height, barlike protrusion of the posterior pharyngeal wall into the barium column on lateral projections (Fig. 152-5). The cricopharyngeus may show delayed opening, incomplete opening, or early closure. A prominent cricopharyngeus is detected on barium studies in about 5% of asymptomatic individuals. [23], [24] However, some patients with this finding complain of dysphagia. In symptomatic patients, a prominent cricopharyngeus is often associated with pharyngeal paresis or occurs as a compensatory response to gastroesophageal reflux or esophageal obstruction.

FIGURE 152-5. Incomplete opening of cricopharyngeus, manifested by posterior indentation on pharyngoesophageal segment (*large arrow*). Notice the associated

webs anteriorly (*small arrows*) and pseudo Zenker diverticulum posteriorly (*curved arrow*) that is seen because barium is trapped above a prominent cricopharyngeus. Cricopharyngeal dysmotility is often related to underlying gastroesophageal reflux or pharyngeal paresis.

Lateral Pharyngeal Pouches and Diverticula Lateral pharyngeal pouches are transient protrusions of the lateral pharyngeal wall at sites of anatomic weakness, such as the posterior thyrohyoid membrane and tonsillar fossae after a tonsillectomy. [25] These pouches are common findings, usually occurring as normal variants in asymptomatic patients. In contrast, lateral pharyngeal diverticula are persistent protrusions from the tonsillar fossae or region of the thyrohyoid membrane. These diverticula are much less common than pharyngeal pouches, occurring primarily in individuals who have markedly elevated pharyngeal pressure, such as glassblowers and tuba players. If stasis occurs in pharyngeal pouches or diverticula, the subsequent spillage of pouch contents into the hypopharynx may result in aspiration into the larynx or tracheobronchial tree. Stasis with delayed spill into the hypopharynx may also cause mild neck discomfort or dysphagia after swallowing. Diverticula may also manifest as neck masses and occasionally may be sites of ulceration or neoplasia. Lateral pharyngeal pouches appear on frontal views as transient, hemispheric protrusions of mucosa in the upper hypopharynx above the calcified edge of the thyroid cartilage. These pouches can be recognized on lateral views as ovoid barium collections or rings anteriorly in the upper hypopharynx just below the hyoid bone. In contrast, lateral pharyngeal diverticula appear as persistent protrusions in these areas.
Zenker Diverticulum Zenker diverticulum, or posterior hypopharyngeal diverticulum, is an acquired mucosal herniation through an area of anatomic weakness in the region of the cricopharyngeus (i.e., the Killian dehiscence). This area of anatomic weakness is located between the thyropharyngeus and cricopharyngeus or between the oblique and horizontal fibers of the cricopharyngeus. [21], [22] Most patients with Zenker diverticulum have an associated hiatal hernia or gastroesophageal reflux. Rarely, these diverticula are complicated by ulceration or malignancy. During swallowing, a Zenker diverticulum appears radiographically as a posterior bulging of the distal pharyngeal lumen above an anteriorly protruding cricopharyngeal bar (Fig. 152-6A). At rest, the barium-filled diverticular sac often extends below the level of the cricopharyngeus posterior to the proximal cervical esophagus (see Fig. 152-6B).

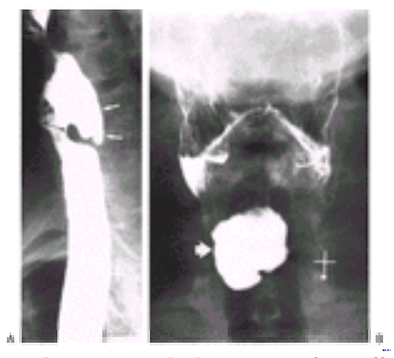

FIGURE 152-6. A: Zenker diverticulum seen as a posterior outpouching of the hypopharyngeal wall (*white arrows*) above a prominent cricopharyngeus (*black arrow*) during swallowing. **B:** A frontal view shows retention of barium in a diverticulum (*arrow*) at completion of the swallow.

Inflammatory Conditions Barium studies are of limited value in patients with viral, bacterial, or fungal infection of the pharynx. [26] Such patients usually have normal pharyngograms or nonspecific lymphoid hyperplasia of the palatine tonsil or base of the tongue. Occasionally, however, *Candida* species infection or herpes pharyngitis may manifest on double-contrast radiographs as plaques or ulcers in the pharynx, particularly in patients with acquired immunodeficiency syndrome (AIDS). Barium studies may also be helpful in a patient who has a chronic sore throat to determine whether there is underlying gastroesophageal reflux or reflux esophagitis.
Tumors Double-contrast pharyngography has an important role in the initial detection and subsequent workup of pharyngeal tumors. [27], [28] Double-contrast radiographs of the pharynx can accurately define the size, level, and extent of the lesion. The radiologic examination is particularly helpful in demonstrating regions of the pharynx (e.g., valleculae, lower hypopharynx, cricopharyngeus) that are difficult to visualize at endoscopy. It also enables detection of submucosal masses that are easily missed at endoscopy. Although its accuracy is limited in the region of the palatine tonsil, the double-contrast examination is capable of detecting more than 95% of all mucosal neoplasms in the pharynx below the level of the pharyngoepiglottic fold. [27] Squamous cell carcinoma is by far the most common malignant tumor of the pharynx. With an overall 5-year survival rate of about 20%, this tumor has a somewhat better prognosis than esophageal carcinoma. These lesions may manifest on double-contrast radiographs as an intralumenal mass, mucosal irregularity, or loss of distensibility. [29] An intralumenal mass may cause asymmetry or obliteration of the normal pharyngeal contour, barium-coated lines in unusual locations, or a superimposed radiodensity. Mucosal irregularity may manifest as an irregular, lobulated, nodular, or granular surface pattern. A loss of distensibility may be associated with fixation of pharyngeal structures by infiltrating tumor. When malignant lesions are detected in the pharynx, the esophagus should be carefully evaluated radiographically because of the increased incidence of synchronous esophageal cancers in these patients. [30]

UPPER GASTROINTESTINAL TRACT

The development of routine double-contrast techniques for examining the upper gastrointestinal tract has dramatically improved our ability to diagnose a variety of inflammatory and neoplastic diseases in the esophagus, stomach, and duodenum. Despite increasing acceptance of this technique, some investigators advocate endoscopy as the initial screening study in patients with dyspepsia or other upper gastrointestinal symptoms. Although endoscopy has been recognized as a highly accurate technique for examining the upper gastrointestinal tract, it is also an invasive technique with a small but measurable risk for gastric perforation or other complications. Furthermore, it is an expensive technique, costing three to four times more in the United States than double-contrast upper gastrointestinal examinations. Because barium studies are safer and less expensive than endoscopy, radiologic evaluation of the upper gastrointestinal tract remains a viable alternative as long as its accuracy approaches that of endoscopy for clinically significant disease. We think that a carefully performed double-contrast examination provides the best opportunity for radiology to be competitive with endoscopy as a diagnostic modality.

Technique

The routine double-contrast upper gastrointestinal examination should be performed as a biphasic study in which double-contrast and single-contrast views of the esophagus, stomach, and duodenum are obtained. [31] In the double-contrast portion of the study, a series of maneuvers is required to achieve adequate gaseous distention of the lumen while a thin layer of high-density barium is spread on the mucosa. The double-contrast examination is facilitated by the use of pharmacological agents (e.g., 0.1 mg of glucagon given intravenously) to induce gastric hypotonia. After the double-contrast portion of the study has been completed, prone or upright single-contrast views of the esophagus, stomach, and duodenum are obtained with a low-density barium suspension and various degrees of compression to supplement the double-contrast study. Because of its greater diagnostic yield, this biphasic study has been advocated as the best radiologic technique for examining the upper gastrointestinal tract.

Indications

Esophagus In patients with reflux symptoms, barium studies have traditionally been advocated to document the presence of a sliding hiatal hernia or gastroesophageal reflux, to detect complications such as strictures, and to rule out other abnormalities in the esophagus that can mimic reflux esophagitis. By permitting a more detailed assessment of the esophageal mucosa, double-contrast radiographic techniques have made it possible to detect superficial ulceration and other changes of esophagitis before the development of deep ulcers and strictures. Because modern medical care is prolonging the survival of patients who are immunosuppressed, infectious esophagitis has become an increasingly frequent problem. When infectious esophagitis is suspected on clinical grounds, double-contrast esophagography may be performed to confirm the diagnosis and differentiate the various underlying organisms. The radiologist's ability to differentiate fungal and viral esophagitis is particularly important for patients with AIDS because some gastroenterologists are reluctant to perform endoscopy on these individuals because of fear of contaminating their endoscopic instruments or exposing themselves to the human immunodeficiency virus (HIV). However, endoscopy should be performed if the radiographic findings are equivocal. Dysphagia is another important indication for performing barium studies. If the sensation of dysphagia is localized to the pharynx, a careful pharyngeal examination should be obtained. However, some lesions involving the distal esophagus or cardia may cause dysphagia referred to the upper esophagus or pharynx. Thus, the gastric cardia and esophagus should be carefully evaluated radiographically in all patients with unexplained pharyngeal dysphagia to rule out a distal lesion masquerading as a pharyngeal disorder.
Stomach and Duodenum The most common indications for performing a double-contrast examination of the stomach and duodenum include epigastric pain or discomfort, bloating, belching, early satiety, and signs or symptoms of upper gastrointestinal bleeding, such as hematemesis, melena, and guaiac-positive stool. If erosive gastritis or duodenitis, duodenal ulcers, or unequivocally benign-appearing gastric ulcers are diagnosed radiographically, the patient can be treated medically without need for endoscopic intervention. If, however, the double-contrast examination demonstrates a gastric ulcer or other lesion that is equivocal or suspicious for malignancy, endoscopy and biopsy should be performed for a more definitive diagnosis. If the double-contrast examination is normal, the decision for endoscopy

should be based on the severity of symptoms, age, and overall health of the patient.
Contraindications and Risks Because oral barium sulfate is contraindicated in patients with suspected esophageal or gastric perforation, water-soluble contrast media should be used if there are any clinical or radiographic signs of mediastinitis or peritonitis. Otherwise, the risks of the barium study are negligible. Nevertheless, a double-contrast examination may be difficult to perform on elderly or debilitated patients who cannot undergo the turning maneuvers required for this examination. These patients may be evaluated by conventional single-contrast barium studies.

Abnormalities

Gastroesophageal Reflux Disease In patients with suspected gastroesophageal reflux disease, barium studies may be performed not only to detect gastroesophageal reflux but also to look for the morphologic sequelae of reflux, including reflux esophagitis, peptic strictures, and Barrett esophagus. Conventional single-contrast esophagography has been considered an unreliable technique for diagnosing reflux esophagitis, with an overall sensitivity of only 50% to 75% reported in the literature. However, the use of double-contrast esophagography has increased the radiographic sensitivity to almost 90%. [32] In relatively mild reflux esophagitis, mucosal edema and inflammation may manifest on double-contrast radiographs as a granular or finely nodular mucosa. [32] Other patients may have shallow ulcers and erosions appearing as one or more tiny collections of barium in the distal esophagus near the gastroesophageal junction (Fig. 152-7). In more severe disease, the esophagus may have a grossly irregular contour, with serrated margins and decreased distensibility due to extensive ulceration, edema, and spasm. Scarring from reflux esophagitis may lead to the development of reflux-induced or peptic strictures, most commonly seen as tapered areas of concentric narrowing in the distal esophagus above a hiatal hernia.

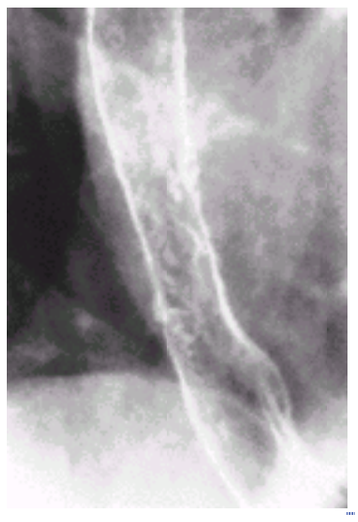

FIGURE 152-7. Reflux esophagitis with multiple areas of shallow ulceration seen en face and in profile in the distal esophagus. (From ref. [31].)

Barrett esophagus is a well-recognized complication of reflux esophagitis that is associated with a significantly increased risk for developing esophageal adenocarcinoma. Unfortunately, the classic radiologic features of Barrett esophagus (i.e., a high esophageal stricture or ulcer or a reticular mucosal pattern) occur in only a minority of patients. [33] However, data suggest that patients without reflux esophagitis or peptic strictures on double-contrast examinations rarely have Barrett esophagus at endoscopy. [34] Thus, double-contrast esophagography may be a useful screening study for Barrett esophagus to determine the relative need for endoscopy and biopsy in patients with reflux symptoms.
Infectious Esophagitis Esophagography has traditionally been considered an unreliable technique for diagnosing *Candida* esophagitis, with an overall sensitivity of less than 50%. [35] With double-contrast technique, however, esophagography has a sensitivity of about 90% in diagnosing *Candida* esophagitis. [36] The major advantage of this technique is its ability to demonstrate mucosal plaques that cannot easily be recognized on conventional single-contrast studies. These discrete, plaquelike lesions tend to be longitudinally oriented, appearing on double-contrast radiographs as linear or irregular filling defects with normal intervening mucosa (Fig. 152-8A).

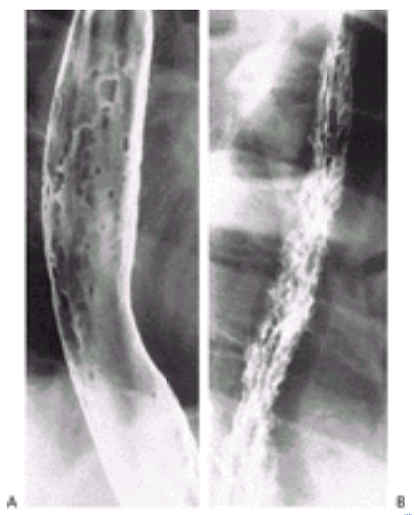

FIGURE 152-8. Candida esophagitis. **A:** Double-contrast esophagram shows discrete plaque-like defects with normal intervening mucosa. This appearance is characteristic of candidiasis. **B:** Severe Candida esophagitis in a patient with acquired immunodeficiency syndrome. Notice the shaggy contour of the esophagus, caused by multiple plaques, pseudomembranes, and ulcers. (**A,** from ref. [36].)

The AIDS epidemic has led to the development of a more fulminant form of *Candida* esophagitis, manifesting as a “shaggy” esophagus with a grossly irregular contour due to multiple plaques, pseudomembranes, and ulcers [37] (see Fig. 152-8B). Because this degree of esophagitis rarely occurs in other immunocompromised patients, the possibility of AIDS should be suspected when a shaggy esophagus is detected on barium studies, particularly in young homosexual men. Herpes and, less frequently, cytomegalovirus (CMV) esophagitis also occur in immunosuppressed patients with odynophagia, and these conditions should be suspected in the same clinical setting as *Candida* esophagitis. More than 50% of patients with herpes esophagitis have discrete, superficial ulcers on the esophageal mucosa that are readily detected on double-contrast radiographs [38] (Fig. 152-9). In contrast, CMV esophagitis, which occurs primarily in patients with AIDS, often manifests as one or more large, relatively flat ulcers in the esophagus. [37]

FIGURE 152-9. Herpes esophagitis with discrete superficial ulcers (*arrows*) on relatively normal background mucosa. Radiolucent halos of edematous mucosa surround the ulcers. (From ref. [37].)

HIV has also been associated with the development of giant esophageal ulcers in HIV-positive patients with odynophagia. The lesions typically appear radiographically as giant, flat ulcers indistinguishable from those caused by CMV. [39] Because HIV-related ulcers may respond dramatically to oral steroids, endoscopy is required to differentiate HIV from CMV infection in the esophagus before initiating treatment.

Esophageal Carcinoma Esophageal carcinoma is a deadly disease with an overall 5-year survival rate of only 5% to 10%. This dismal prognosis is primarily related to the advanced stage of the disease at the time of clinical presentation. Occasionally, esophageal cancer may be discovered at an early stage, and unlike advanced esophageal carcinoma, early esophageal cancer is a readily curable lesion, with reported 5-year survival rates approaching 90%. In Western countries, detection of these lesions is best accomplished by some form of radiologic or endoscopic surveillance of patients known to be at increased risk for developing esophageal cancer. Early esophageal cancers classically appear on double-contrast esophagrams as protruded lesions less than 3.5 cm in diameter. [40] They may be plaquelike lesions or small, sessile polyps with smooth or slightly lobulated contours. Other superficial spreading carcinomas may manifest radiographically as tiny coalescent nodules or plaques, causing localized nodularity or granularity of the mucosa. [40] In contrast, advanced esophageal carcinomas appear as polypoid, ulcerated, or infiltrating lesions with mass effect, ulceration, or irregular narrowing of the lumen. Some authors believe that endoscopy is warranted for all patients with dysphagia who have negative esophagrams because of the risk for missing esophageal cancer on barium studies. In a recent study, however, carcinoma of the esophagus or esophagogastric junction was diagnosed or suspected on double-contrast esophagography in 96% of patients with proven cancers. [41] In the same study, endoscopy was recommended to rule out malignant tumors of the esophagus or esophagogastric junction in only about 1% of all patients who had barium examinations. Thus, a high sensitivity can be achieved in the radiographic diagnosis of these tumors without exposing an inordinate number of patients to unnecessary endoscopy.
Erosive Gastritis Gastric erosions may be classified radiographically as complete or incomplete erosions. Most patients have complete or varioliform erosions in which a punctate or slitlike collection of barium is surrounded by a radiolucent halo of edematous mucosa [42] (Fig. 152-10A). Varioliform erosions are most commonly found in the gastric antrum and are often aligned on rugal folds. In contrast, incomplete or “flat” erosions appear as dots or streaks of barium without an edematous halo. Because the surrounding mucosa is normal, incomplete erosions have been extremely difficult to detect radiographically, accounting for less than 5% of all erosions seen on double-contrast studies.

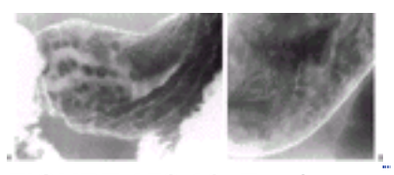

FIGURE 152-10. Erosive gastritis. **A:** Typical varioliform erosions in the gastric antrum. The erosions are aligned on the rugal folds. **B:** Linear and serpiginous erosions in the body of the stomach near the greater curvature are the result of recent ingestion of indomethacin.

Although erosions caused by aspirin or other nonsteroidal antiinflammatory drugs often are located in the gastric antrum, they sometimes occur in the gastric body, appearing as distinctive linear or serpiginous erosions that tend to be clustered together on or near the greater curvature [43] (see Fig. 152-10B). In such cases, it has been postulated that the erosions result from localized mucosal injury as the dissolving tablets collect by gravity in the most dependent portion of the stomach.
***Helicobacter pylori* Gastritis** *H pylori* gastritis can be diagnosed on barium studies by the presence of thickened folds or thickened, polypoid folds in the antrum, body, or, less commonly, fundus of the stomach. [44] It is important to recognize that fold thickening is a nonspecific radiographic finding. Nevertheless, *H pylori* gastritis should be a leading consideration in the differential diagnosis of thickened gastric folds in patients with dyspepsia, epigastric pain, or other upper gastrointestinal symptoms. Patients suspected of having peptic ulcer disease can be evaluated by a noninvasive *H pylori* test combined with a double-contrast upper gastrointestinal examination. If the barium study reveals a gastric or duodenal ulcer, a noninvasive *H pylori* test can be performed to determine whether or not antibiotic therapy should be initiated as well as conventional antiulcer therapy. Such an approach might avoid the need for endoscopy in many patients.
Gastric Ulcers In the past, some researchers advocated endoscopy and biopsy of all radiographically diagnosed gastric ulcers to rule out cancer in these patients. However, several studies have found that virtually all gastric ulcers with an unequivocally benign appearance on double-contrast upper gastrointestinal examinations are benign lesions. [45], [46] In those studies, about two thirds of all benign ulcers had a benign radiographic appearance. As a result, unnecessary endoscopy can be avoided in the initial evaluation of most gastric ulcers diagnosed on double-contrast examinations. Instead, typically, benign gastric ulcers could be followed radiographically to complete healing without need for endoscopic intervention. Because endoscopy is a considerably more expensive procedure than double-contrast radiography, the potential financial savings are enormous. Benign gastric ulcers classically appear en face as round or ovoid collections of barium, often associated with a smooth mound of edema or thin, straight folds that radiate directly to the edge of the ulcer crater. [46] When viewed in profile, benign ulcers project beyond the contour of the adjacent gastric wall and are often associated with an ulcer mound or collar. In contrast, malignant gastric ulcers classically appear en face as irregular ulcer craters within a discrete tumor mass, sometimes associated with nodularity or clubbing of adjacent folds owing to infiltration of the folds by tumor. When viewed in profile, malignant ulcers project inside the gastric lumen within a tumor mass that forms acute angles with the adjacent gastric wall rather than the obtuse, gently sloping angles expected for a benign mound of edema. Most gastric ulcers detected on double-contrast studies are smaller than 1 cm in diameter. [46] Although some benign ulcers are round and symmetric, others have a rod-shaped or linear appearance. Almost all benign ulcers occur in the antrum or body of the stomach, and most are located on the lesser curvature or posterior wall [46] (Fig. 152-11). Occasionally, benign gastric ulcers may be found on the greater curvature of the distal stomach. The latter ulcers are almost always caused by ingestion of aspirin. [46] As these aspirin-induced greater curvature ulcers enlarge, they have a tendency to penetrate inferiorly into the gastrocolic ligament, occasionally leading to the development of gastrocolic fistulas. [47]

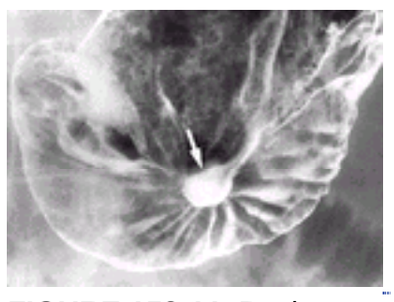

FIGURE 152-11. Benign gastric ulcer. Round, symmetric ulcer (*arrow*) is seen on the posterior gastric wall, with smooth folds radiating to the edge of the crater. This ulcer has the typical radiologic features of a benign gastric ulcer.

Ulcer healing may manifest radiographically as a decrease in the size of the ulcer and by a change in its shape. In most cases, ulcer healing produces a radiographically visible scar with a central pit or depression, radiating folds, or retraction of the adjacent gastric wall. [46]
Gastric Carcinoma Gastric carcinoma has a relatively bleak prognosis, with 5-year survival rates of only 10% to 30%. Advanced tumors may appear radiographically as polypoid or ulcerated lesions or, less frequently, as infiltrating lesions with diffuse narrowing of the stomach, producing a linitis plastica appearance. In contrast, early gastric cancer is a curable disease, with reported 5-year survival rates as high as 95%. The Japanese have developed an elaborate system for classifying these

tumors based on whether they are predominantly elevated, flat, or depressed lesions. Unfortunately, most patients in the United States with gastric carcinoma already have advanced lesions at the time of clinical presentation. As a result, early gastric cancer is unlikely to be detected on double-contrast studies or endoscopy as long as these examinations are performed predominantly on symptomatic patients. [48] The average sensitivity of single-contrast barium studies for the diagnosis of gastric carcinoma has only been about 75%. [49] Concern about missing gastric cancers on barium studies has therefore been used as a rationale for performing endoscopy as the initial diagnostic test in patients with upper gastrointestinal signs or symptoms. In a recent study, however, gastric carcinomas were diagnosed or suspected on double-contrast examinations in 96% of patients with proven lesions. [49] In a separate part of the study, only 3.5% of all patients who had double-contrast examinations during this period underwent endoscopy because of findings that were equivocal or suspicious for gastric carcinoma. Thus, a high sensitivity can be achieved in the radiographic diagnosis of gastric cancer while referring only a small percentage of symptomatic patients for endoscopy.

Gastric Lymphoma It is well recognized that chronic *H pylori* gastritis leads to the development of mucosa-associated lymphoid tissue (MALT) in the stomach. This lymphoid tissue is thought to be the precursor of low-grade B-cell gastric MALT lymphomas, which, if untreated, may undergo transformation to more high-grade lymphomas. [50] Gastric MALT lymphomas can sometimes be recognized on double-contrast upper gastrointestinal examinations by variably sized, rounded, often confluent nodules in the stomach [51] (Fig. 152-12). However, focal gastritis due to *H pylori* or other causes may produce similar findings, so that endoscopic biopsy specimens are required for a definitive diagnosis. In contrast, advanced gastric lymphoma may manifest on barium studies as thickened folds, multiple submucosal masses, centrally ulcerated bull's-eye lesions, or giant, cavitated lesions. [52]

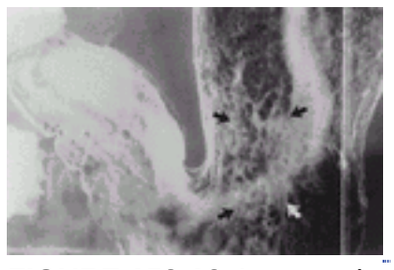

FIGURE 152-12. Low-grade gastric mucosa-associated lymphoid tissue (MALT) lymphoma. Multiple confluent nodules of varying sizes (*arrows*) are seen in gastric body. (From ref. [51].)

Other Gastric Tumors Leiomyomas are the most common benign submucosal tumors found in the stomach. These tumors usually appear on barium studies as smooth submucosal masses (with or without central ulceration) that form right angles or slightly obtuse angles with the adjacent gastric wall. Most leiomyomas are less than 3 cm in size. In contrast, malignant gastrointestinal stromal tumors usually appear as larger, more lobulated submucosal masses, often containing one or more ulcers or giant areas of cavitation. Ectopic pancreatic rests usually are located on the greater curvature of the distal antrum, appearing as small submucosal masses, sometimes with central umbilication or ulceration. Rarely, barium may reflux into rudimentary ductal structures. Gastric carcinoids may also manifest on barium studies as one or more small submucosal masses, occasionally containing central ulcers.

Duodenitis Duodenitis may manifest radiographically as thickened folds, mucosal nodules, erosions, or deformity of the bulb. [53] Duodenal erosions are detected less frequently than gastric erosions on double-contrast studies because of the difficulty in differentiating these lesions from normal mucosal pits. However, erosive duodenitis can be diagnosed when double-contrast radiographs reveal central barium collections surrounded by radiolucent halos of edematous mucosa.

Duodenal Ulcers Unlike gastric ulcers, which occur primarily on the lesser curvature or posterior wall of the stomach, as many as 50% of duodenal ulcers are located in the anterior wall. [31] Because most double-contrast radiographs are obtained with the patient in a supine or supine oblique position, the anterior wall of the duodenum is not optimally coated with barium, and anterior wall ulcers may be missed on the double-contrast portion of the study. For this reason, double-contrast views of the duodenum should be supplemented with prone compression views obtained with a low-density barium suspension to demonstrate ulcers on the anterior wall. Thus, the biphasic technique is particularly important for evaluating the duodenum.

SMALL BOWEL

The conventional small bowel follow-through examination usually consists of a series of overhead abdominal radiographs obtained at regular intervals after ingestion of barium. With this technique, the small bowel is evaluated fluoroscopically only if the overhead radiographs appear abnormal. Because this technique is extremely unreliable in detecting pathology in the small bowel, this form of examination should have no place in modern radiologic practice. Instead, adequate evaluation of the small bowel requires more detailed methods of examination, such as the small bowel meal (SBM) and enteroclysis. However, these techniques require time, effort, and interest by the radiologist. Barium studies of the small bowel should be requested only if there are good clinical indications of small bowel disease.

Techniques

Small Bowel Meal The "dedicated" or "fluoroscopic" SBM includes overhead films but uses fluoroscopy as the primary means of examining the small bowel. Unless contraindicated, metoclopramide (20 mg) is administered orally 20 minutes before the examination to accelerate transit of barium through the stomach and small bowel. The patient then ingests 500 to 600 mL of an appropriate 35% to 40% (weight/volume) suspension of barium sulfate. After a brief examination of the upper gastrointestinal tract, intermittent fluoroscopy is performed until all small bowel loops have been demonstrated. Periodic spot films are obtained to document the fluoroscopic findings.

Enteroclysis (Small Bowel Enema) A more detailed study of the entire small bowel is carried out by enteroclysis. [54] If not contraindicated, the patient swallows 20 mg of metoclopramide to accelerate transit. Surface anesthesia to the throat precedes intubation of the distal duodenum or proximal jejunum. Between 200 and 250 mL of a 75% to 80% suspension of barium is then injected, followed by infusion of 1 to 2 L of a 0.5% solution of methylcellulose in water. This biphasic examination first demonstrates the small bowel in single contrast and then in lumen-distended double contrast (Fig. 152-13). The radiologist must be present throughout the examination to assess individual bowel loops by graded compression and to document the fluoroscopic findings with periodic spot films. An overhead radiograph of the entire small bowel completes the examination.

FIGURE 152-13. Normal small bowel enema. **A:** Distal jejunum seen on a preliminary single-contrast examination. **B:** Same jejunal loops on double-contrast examination.

Application of Techniques

Small Bowel Meal The major advantage of the SBM is that it does not require intubation. Transit acceleration by oral metoclopramide is an important component of the examination because it decreases flocculation of barium and the time needed to perform the study. However, distention of the bowel lumen cannot be achieved by this technique. The SBM is an appropriate examination for evaluating established diseases of the small bowel, such as Crohn's disease. It is also adequate for investigating pathological conditions not associated with lumenal distention, such as radiation enteritis, ischemia, and hematomas. This technique can be used to demonstrate the level and degree of small bowel obstruction, although it is less successful in determining the cause.

Enteroclysis The major advantage of enteroclysis is that it combines transit acceleration with lumenal distention. Enteroclysis virtually prevents flocculation of barium. As a result, the double-contrast images permit assessment of mucosal surface detail, even through overlapping small bowel loops. The straightening of mucosal folds that occurs with lumenal distention permits detection of small, relatively subtle lesions. Normality becomes measurable in terms of wall thickness; fold thickness, shape, and height; and distance between folds. The major indications for enteroclysis include the following: *Small bowel obstruction, particularly intermittent obstruction*: enteroclysis often permits differentiation of the various causes of obstruction. [55]

Malabsorption states: enteroclysis can identify features of celiac disease, lymphangiectasia, Whipple disease, morphologic changes associated with bacterial overgrowth, and other conditions associated with malabsorption.

Crohn's disease: enteroclysis can delineate the full extent of disease, including skip lesions and fistulas, and can be used to distinguish fibrous strictures from stenotic

disease.
Small bowel tumors, particularly carcinoids, other primary and secondary malignancies, and lymphoma.
Meckel diverticulum: increased lumenal distention greatly improves its detection rate. [56]
Normality: enteroclysis is the most reliable radiologic examination for establishing morphologic normality of the small bowel.

Abnormalities

Small Bowel Obstruction Concern has been expressed regarding the possible inspissation of barium within obstructed small bowel. [57] Although animal studies and clinical experience have shown that such inspissation does not occur, [58] it may be advisable to replace barium-based techniques by CT or magnetic resonance imaging enteroclysis in patients who have high-grade or complete small bowel obstructions. [54] With lower grades of obstruction, barium enteroclysis remains the best method for delineating its site and cause, particularly in patients with intermittent obstruction. If a decompression tube has already been positioned beyond the duodenum, it should be used for the enteroclysis examination. A contrast study may also be needed when there is suspicion of small bowel perforation. In such cases, a water-soluble contrast agent is usually employed, although its high osmolality may cause an outpouring of fluid into the bowel lumen and dilution of its contrast density that degrades the quality of the examination.
Adhesions Adhesions account for almost 75% of small bowel obstructions. Enteroclysis can identify features that favor obstruction by a single band, multiple bands, or extensive adhesions. Single bands are more likely to produce high-grade obstruction. Closed-loop obstruction may be caused by prolapse of a bowel loop beneath an adhesive band. This type of obstruction is associated with twisting of bowel, with a high risk for ischemia and necrosis. Although barium studies may be helpful in the early stages of a closed loop obstruction, CT is essential for establishing the degree of vascular compromise in these patients. Multiple bands are almost always associated with adherence of the small bowel to anterior abdominal wall scars. Like extensive adhesions, they tend to produce lower-grade small bowel obstruction. Because of its ability to distend the lumen, enteroclysis draws attention to single bands as a cause of low-grade or intermittent obstruction, even when symptoms are minimal or absent.
Hernias Barium studies are not required for small bowel obstructions caused by clinically evident external hernias. However, enteroclysis is useful in detecting hernias of developmental or postsurgical origin, including peristomal, spigelian, or Richter hernias.
Malignancy In patients who have undergone laparotomy for abdominal malignancy, small bowel obstruction may be caused by adhesions, metastases, radiation, or residual tumor. These conditions can be differentiated by enteroclysis in more than 80% of patients. [54] This information can facilitate surgical management by providing a preoperative choice of resection of tumor, bypass of radiation-damaged bowel, or lysis of adhesions.
Malabsorption States Malabsorption is usually diagnosed by clinical and laboratory criteria. The purpose of barium studies is to determine the most likely cause of a clinically diagnosed malabsorption state or to document complications. In many conditions associated with malabsorption, abnormal accumulation of intralumenal fluid causes flocculation of barium on SBM. Because flocculated barium prevents accurate depiction of mucosal surface detail, enteroclysis is the preferred radiologic examination in these patients.
Celiac Disease The diagnosis of celiac disease must be firmly established to justify placing the patient on lifelong dietary restrictions. A confident diagnosis can be made in patients who have characteristic mucosal changes on duodenal biopsy and have shown a satisfactory response to gluten withdrawal. However, more than 50% of patients have atypical clinical presentations. As a result, the diagnosis may first be suggested by enteroclysis, which can demonstrate a measurably increased separation of folds in the distended proximal jejunum (Fig. 152-14). In one study, zero to three folds per inch of jejunum were found by enteroclysis in 73% of celiac patients but in only 2% of controls. [59] If coupled with the finding of “jejunization” of ileal folds, the enteroclysis recognition of celiac disease rises to 82%. Conversely, patients with five or more folds per inch of jejunum rarely had celiac disease.

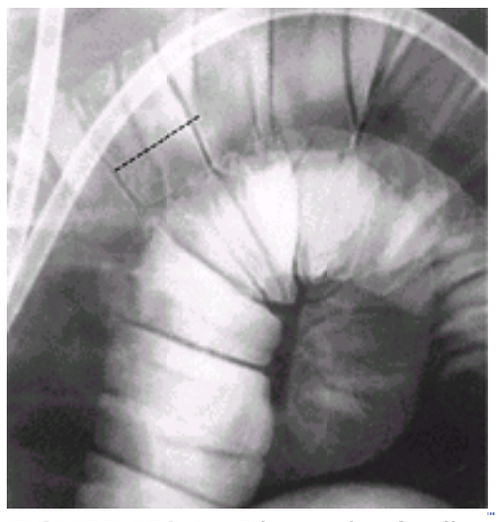

FIGURE 152-14. Diagnosis of celiac disease using a small bowel enema. The distended proximal jejunum shows an increased separation of folds, with only three folds per inch (*dotted line*).

Enteroclysis is especially important in celiac patients who relapse after an initial dietary response; enteroclysis can then distinguish between features due to dietary lapses and those of ulcerative jejunoileitis, T-cell lymphoma, and intestinal carcinoma.
Bacterial Overgrowth Syndrome Barium studies can accurately depict many structural abnormalities in the small bowel that cause stasis or contamination and lead to bacterial overgrowth. These abnormalities include strictures, blind pouch and blind loop syndromes, jejunoileal diverticulosis, and coloenteric fistulas. Other patients with bacterial overgrowth syndrome may have chronic intestinal pseudoobstruction due to scleroderma or other causes. Small bowel involvement by scleroderma may lead to intestinal dilation with crowded folds, producing the virtually pathognomonic “hide-bound” bowel sign. [60]
Intestinal Lymphangiectasia The primary and secondary forms of intestinal lymphangiectasia are manifested by nonspecific changes of fold thickening and fluid increase on conventional barium studies. With enteroclysis, it is possible to demonstrate 1- to 2-mm micronodules that represent villi distended by dilated lacteals. Whipple disease involving the small bowel may also manifest as tiny nodules due to villous distention by the enlarged lamina propria laden with foamy macrophages, bacilli, and periodic acid-Schiff–positive material. A similar nodular pattern may be demonstrated in patients with *Mycobacterium avium* complex enteritis, macroglobulinemia, immunoglobulin A deficiency, and other unusual conditions.
Crohn’s Disease Early radiologic findings of Crohn’s disease in the small bowel include a coarse villous pattern of the mucosa, thickened folds, and aphthous ulcers. The presence of linear ulcers along the mesenteric border of the bowel with pleating or sacculation of the uninvolved antimesenteric border is virtually diagnostic of Crohn’s disease (Fig. 152-15). With progression of disease, transaxial extension of linear ulcers and fissures produces a cobblestone appearance with narrowing of the lumen. Further progression of Crohn’s disease leads to complications such as fibrous strictures, fistulas, inflammatory masses, and abscesses.

FIGURE 152-15. Small bowel Crohn’s disease. Spot film from enteroclysis examination shows a long, linear ulcer (*large arrows*) on the mesenteric border of the bowel with multiple aphthous ulcers (*small arrows*) and thickened, interrupted folds. The linear mesenteric border ulcer is characteristic of Crohn’s disease.

Many features of Crohn's disease can be demonstrated as effectively by the SBM as by enteroclysis. Disease of the terminal ileum is particularly well shown by combining the SBM with a peroral pneumocolon (i.e., introducing barium by mouth and air by the rectum). [61] However, enteroclysis is the optimal radiologic examination for detecting early lesions, particularly the more proximal skip lesions. It is also a better examination for distinguishing Crohn's disease from other pathological conditions such as lymphoma, tuberculosis, ischemia, and metastatic disease.

Malignant Tumors

Adenocarcinoma Most primary adenocarcinomas of the small bowel are advanced tumors with regional lymph node involvement at the time of clinical presentation. In the absence of obstruction, these tumors can be missed on conventional small bowel follow-through examinations. Enteroclysis is the best radiologic technique for demonstrating these lesions at a less advanced stage (Fig. 152-16).

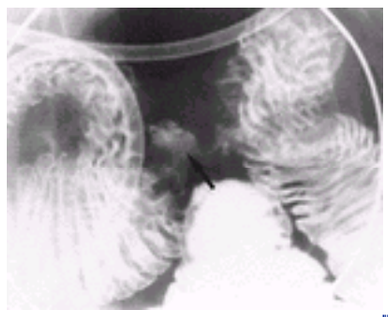

FIGURE 152-16. Annular adenocarcinoma of the proximal jejunum with a central ulceration (*arrow*).

Non-Hodgkin Lymphoma Primary small bowel lymphomas typically appear as cavitary lesions extending into the mesentery or as segmental infiltrating lesions. In other patients with disseminated lymphoma, barium studies may demonstrate submucosal nodules of various sizes. An enlarging mass of mesenteric nodal lymphoma can secondarily infiltrate a loop of small bowel. [54] CT can be used to delineate better the extent of mesenteric and lymph node involvement.

Other Malignancies

Small bowel carcinoids can be diagnosed by enteroclysis at the stage of incipient transmural extension of the primary tumor or tumors (Fig. 152-17). More advanced carcinoids are typically associated with distorted folds. Enlarging mesenteric metastases produce mass effect and secondary fibrotic alterations in adjacent bowel loops. Early carcinoids may appear as small, polypoid nodules, more often in the terminal ileum.

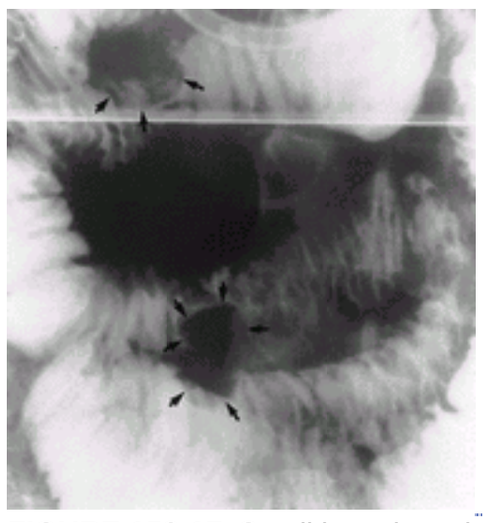

FIGURE 152-17. Small bowel carcinoids. Discrete submucosal masses (*arrows*) are seen in the mid small bowel. Also note the separation of small bowel loops caused by spread of tumor into the mesentery.

Both hematogenous and intraperitoneal-seeded metastases to the small bowel tend to occur as multiple lesions, often associated with signs of obstruction. Gastrointestinal stromal tumors may appear as excavated, exoenteric masses.

Meckel Diverticulum

Enteroclysis is the best radiologic technique for diagnosing Meckel diverticulum, with an overall detection rate comparable to that found at autopsy. [56] The diverticulum arises from the antimesenteric border of the distal ileum, forming a blind sac, with a characteristic mucosal fold pattern at its site of origin. Occasionally, it is possible to identify a defect in the diverticulum due to ectopic gastric mucosa. It is also possible to identify an invaginated Meckel diverticulum presenting with low-grade obstruction.

Obscure Blood Loss

In patients with unexplained gastrointestinal blood loss, enteroclysis is indicated when radiologic and endoscopic examinations of the upper gastrointestinal tract and colon fail to demonstrate a source of bleeding. Enteroclysis has a diagnostic yield of 21% in identifying the presumptive source of obscure gastrointestinal bleeding. [62] Most patients have tumors involving the small bowel; other diagnoses include ischemia, arteriovenous malformations, Meckel diverticulum, and celiac disease.

COLON

Since the 1920s, the barium enema has been used as the primary nonsurgical method for investigating the colon. Since the 1970s, colonoscopy has become an important diagnostic modality for evaluating the colonic mucosa and for removing polyps. Cross-sectional imaging techniques, particularly CT, have also become important for evaluating the extramucosal extent of disease. CT and ultrasound may also be used to assess bowel wall thickness. Because of its simplicity, low cost, safety, and accuracy, however, the barium enema remains a useful diagnostic technique for investigating the colon.

Single versus Double Contrast

Radiologic examination of the colon can be performed by a single- or double-contrast technique. In single-contrast studies, the entire colon is filled with a relatively low-density barium suspension. The examination is performed under fluoroscopic control, with extensive palpation and compression of the colon as it fills. A postevacuation radiograph is usually obtained to demonstrate additional mucosal detail. In double-contrast studies, a smaller volume of high-density barium is introduced into the colon, followed by insufflation of air. With this technique, the mucosal surface is coated by a thin layer of high-density barium, and the lumen is distended with air.

The double-contrast examination is considered to be the best radiologic technique for demonstrating fine mucosal lesions such as small polyps and the early changes of inflammatory bowel disease (IBD). [63], [64] It can also better demonstrate segments of the large bowel that are inaccessible to palpation, such as the rectum and the hepatic and splenic flexures. The single-contrast barium enema is the preferred technique when careful control of the flow of barium is required. A single-contrast

study should be performed in patients with suspected obstruction, diverticulitis, fistulas, or Hirschsprung disease. This technique is also frequently used in patients who are too old or debilitated to tolerate a double-contrast study.

Radiology versus Colonoscopy

There is ongoing controversy about the relative roles of radiology and endoscopy in investigating colonic disease. In general, the choice of technique depends on the clinical setting and the relative skill and experience of the examiners. Nevertheless, it should be recognized that colonoscopy is primarily of value for detecting mucosal lesions. It should not be used as the primary diagnostic modality when the patient's symptoms suggest an intramural or extrinsic lesion involving the bowel.
